MAOIs may be used for women with major depression who are not responsive to other medications and for women with panic disorder and bipolar disorder. Hypertensive crisis is the main reason that MAOIs are not prescribed more frequently than other psychotropic medications. The woman should be taught to watch for signs of hypertensive crisis—a throbbing occipital headache, stiff neck, chills, nausea, flushing, retroorbital pain, apprehension, pallor, sweating, chest pain, and palpitations. This crisis is brought on by the woman taking any of a large variety of over-the-counter medications or eating foods that contain tyramine, which normally is broken down by the enzyme *monoamine oxidase* (Hadley, Albanese, & Rochester, 2012).

MEDICATION ALERT

People taking MAOIs must be taught to totally avoid medications and foods that contain tyramine. Pseudoephedrine-containing medications, aged cheese, red wine, fava or Italian green beans, brewer’s yeast, smoked fish, chicken or beef livers, and preserved meats are examples of tyramine-containing substances (Hadley, Albanese, & Rochester, 2012).

The woman taking mood stabilizers (see Table 31-3) must be taught about the many side effects, and especially for those taking lithium, the need to have serum lithium levels determined every 6 months. Women with severe psychiatric syndromes such as schizophrenia, bipolar disorder, or psychotic depression will probably require antipsychotic medications (see Table 31-4). Most of these medications can cause sedation and orthostatic hypotension—both of which can interfere with the mother being able to care safely for her baby. They also can cause peripheral nervous system (PNS) effects such as constipation, dry mouth, blurred vision, tachycardia, urinary retention, weight gain, and agranulocytosis. CNS effects may include akathisia, dystonias, parkinsonian-like symptoms, tardive dyskinesia (irreversible), and neuroleptic malignant syndrome (potentially fatal). Medication education is especially important when caring for women who are taking antipsychotic medications. The nurse should use discretion in selecting the content to be shared because of the women’s altered thought processes and the large number of side/toxic effects. The nurse may choose to

do more extensive education with a close family member. The newer, atypical antipsychotic medications such as aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone are usually safer and have fewer side effects than the older, more traditional antipsychotics. Their safety in breastfeeding women, however, has not been established.

Psychotropic Medications and Lactation

Use of any psychotropic medication in a breastfeeding mother is done with consideration of risks and benefits. The risk of not treating the mother versus not breastfeeding the infant prompts providers to prescribe medications that reduce maternal symptoms without harming the infant. Concerns about many psychotropic drugs are related to the long-term use and potential effects on the infant (Lawrence & Lawrence, 2011).

Factors that affect the passage of a medication through breast milk include the size of the molecule, the solubility in lipids and water, the protein-binding capacity, the drug’s pH, and the rate of diffusion. Infant factors to consider relate to the gestational and chronologic age of the infant, weight, health, and frequency and amount of feeding (Lawrence & Lawrence, 2011). To minimize the infant’s exposure to maternal medication, the mother should avoid breastfeeding when the blood levels of the medication are peaking.

SSRIs are the most common treatment for PPD; they are also prescribed for anxiety disorders. Research has shown that the majority of the SSRIs taken by breastfeeding mothers pass through the milk to the infant in small amounts and have no untoward effects on the infant (Kendall-Tackett & Hale, 2010). Paroxetine (Paxil), sertraline (Zoloft), and nortriptyline (Pamelor) provide less infant exposure than fluoxetine (Prozac) and citalopram (Celexa). All breastfeeding mothers who take SSRIs should be taught to monitor their infants for signs of irritability, poor feeding, and alterations in sleep pattern (Hudak et al., 2012; Kendall-Tackett & Hale).

CLINICAL REASONING CASE STUDY

Postpartum Depression

Cara, 37, gave birth to a 7 lb, 6 oz boy 4 weeks ago. She has been diagnosed with postpartum depression, and an SSRI (paroxetine [Paxil]) medication has been prescribed. Cara is breastfeeding and has concerns about taking the medication.

1. Evidence—Is there sufficient evidence regarding the safety of psychotropic medications and lactation?
2. Assumptions—What assumptions can be made about the following?
 - a. Lactation risk categories of SSRI medications
 - b. Timing of feeding and medication administration
 - c. Risks of discontinuing medications while breastfeeding
3. What is the nursing priority in this situation?
4. Does the evidence objectively support your conclusion?

SSRI, Selective serotonin reuptake inhibitor.

Benzodiazepines, mood stabilizers, and antipsychotic medications are used frequently in the treatment of postpartum psychiatric disorders despite the lack of research in this population. No long-term effects have been reported in exclusively breastfed infants whose mothers were taking benzodiazepines on a regular basis. The shorter-acting agents (alprazolam [Xanax],

lorazepam [Ativan]) are favored over those with longer half-lives (clonazepam [Klonopin], diazepam [Valium]) (Lawrence & Lawrence, 2011).

Mood-stabilizing medications are present in the breast milk of women who take these drugs. Lithium has been the most extensively studied. Lithium has been linked to several serious adverse effects in breastfeeding infants, including hypotonia, hypothermia, cyanosis, and electrocardiogram abnormalities. Therefore, its use is not recommended in breastfeeding mothers. Valproic acid (Depakote) and carbamazepine (Tegretol) are considered reasonably safe while breastfeeding, although careful monitoring for infant hepatotoxicity is recommended. The benefits of breastfeeding and the potential risks must be carefully considered before using lithium or other mood stabilizers.

In summary, all psychotropic medications studied to date are excreted in breast milk. The best psychotropic medications for breastfeeding women are those with the greatest documentation of prior use, lower FDA risk category, few or no metabolites, and fewer side effects.

When breastfeeding women have emotional complications and need psychotropic medications, referral to a mental health care provider who specializes in postpartum disorders is preferred. The woman should be informed of the risks and benefits to her and her infant of the medications to be taken. Depressed women will need the nurse to reinforce the importance of taking antidepressants as ordered. Because antidepressants usually do not exert any significant effect for approximately 2 weeks and usually do not reach full effect for 4 to 6 weeks, many women discontinue taking the medication on their own. Client and family teaching should reinforce the need for taking medications until therapeutic effects are present and for as long as prescribed by the health care provider.

A complete guide to breastfeeding and drug compatibility can be found at the Drugs and Lactation Database (LactMed; <http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT>). This is a peer-reviewed and fully referenced database of drugs to which breastfeeding mothers may be exposed. Among the data included are maternal and infant levels of drugs, possible effects on breastfed infants and on lactation, and alternate drugs to consider.

Other Treatments for PPD

Other treatments for PPD include hormone therapy (often combined with antidepressant medication), complementary or alternative therapies, and ECT. Complementary and alternative medicine (CAM) therapies are increasingly being used by people with psychiatric disorders. Several commonly used CAM therapies (bright light therapy, exercise, massage, repetitive transcranial magnetic stimulation, and acupuncture) are considerations in the treatment of perinatal depression. A number of these treatments may be reasonable to consider for women during pregnancy or postpartum, but the safety and efficacy of these relative to standard treatments must still be systematically determined (Deligiannidis & Freeman, 2014; Manber, 2010).

ECT may be used for women with PPD who have not improved with antidepressant therapy. Psychotherapy in the form of group therapy or individual (interpersonal) therapy has been used with positive results alone and in conjunction with antidepressant therapy; however, more studies are needed to

determine what types of professional supports are most effective. Repetitive transcranial magnetic stimulation is a new therapy for PPD, but more studies need to be done to demonstrate the efficacy (Garcia, Flynn, Pierce, & Caudle, 2010). Alternative therapies may be used alone but often are used with other treatments for PPD. Safety and efficacy studies of these alternative therapies are needed to ensure that care and advice are based on evidence.

! NURSING ALERT

St. John's wort is often used to treat depression. It has not been proven safe for women who are breastfeeding.

PERINATAL SUBSTANCE ABUSE

Large numbers of women of childbearing age abuse potentially addictive and mood-altering drugs. Use of cocaine, marijuana, diazepam, opioids (including morphine, heroin, codeine, meperidine, methadone, and oxycodone), other prescription drugs, and approximately 150 other substances can lead to chemical dependency. Chemical dependency is a chronic, relapsing, and progressive disease. Without treatment or participation in recovery activities, it can progress and result in disability or premature death.

Pregnant women who abuse drugs can display warning signs such as receiving no prenatal care, late entry into care, or sporadic care, with multiple missed appointments. They may also show evidence of poor nutrition, have frequent encounters with law enforcement officials, or engage in marital and family disputes.

Dual diagnosis, which is very common, is the coexistence of **substance abuse** and another psychiatric disorder. Mood and anxiety disorders are the psychiatric disorders that are most commonly seen along with substance abuse in women. The psychiatric illness usually occurs before substance use begins (Wisner et al., 2012).

Drugs that affect the mother can also affect the fetus in multiple ways either directly or indirectly. Early in gestation drugs can cause significant teratogenic effects. During the fetal period, after major structural development is complete, drugs exert more subtle effects, including abnormal growth and maturation, alterations in neurotransmitters and their receptors, and brain organization. These are considered to be the direct effects of drugs (Behnke, Smith, Committee on Substance Abuse, & Committee on Fetus and Newborn, 2013). Drugs that exert a pharmacologic effect on the mother can indirectly affect the fetus. Indirect effects include altered delivery of nutrition to the fetus, either because of placental insufficiency or altered maternal health behaviors attributable to the mother's addiction.

Maternal factors such as decreased access/compliance with health care, increased exposure to violence, and increased risk of mental illness and infection can also indirectly place the fetus at risk (Behnke et al., 2013).

Prevalence

Because many pregnant women are reluctant to reveal their use of substances or the extent of their use, data on prevalence are highly variable. Approximately 15% of all pregnant women have

a substance-abuse problem (Gilbert, 2011). Blinded urine drug screens conducted at hospitals across the United States revealed that similar rates of substance use during pregnancy occurred in women of different ages, races, and social classes, although the specific substances used differed by race and social class. African-American and poor women were more likely to use illicit substances, particularly cocaine, whereas Caucasian and educated women were more likely to use alcohol, although polysubstance abuse was common (Wisner et al., 2012). National surveys have found that among pregnant women, those who are younger generally report more abuse of substances than their older counterparts. In one study pregnant women ages 15 to 17 had rates of illicit drug use (15.8%) that were similar to women of the same age who were not pregnant (13%) (National Institute of Drug Abuse [NIDA], 2011a).

Barriers to Treatment

Many pregnant women who are substance abusers do not receive treatment for their addictions. Social stigma, labeling, and guilt are significant barriers to receiving necessary care. Women often do not seek help because of the fear of losing custody of their child or children or criminal prosecution. Pregnant women who abuse substances commonly have little understanding of the ways in which these substances affect them, their pregnancies, and their babies. In many instances pregnant mothers who use psychoactive substances receive negative feedback from society and health care providers, who not only may condemn them for endangering the life of the fetus but may also even withhold support as a result. Barriers within the drug treatment system can also deter these women from receiving the help they need. Traditionally substance-abuse treatment programs have not addressed issues that affect pregnant women such as concurrent need for obstetric care and child care for other children. Long waiting lists and lack of health insurance present further barriers to treatment. Pregnant women with co-occurring substance abuse and psychiatric disorders face unique barriers because of the social stigma attached to both conditions and insufficient knowledge and training to manage coexisting disorders.

Legal Considerations

Practitioners should be aware that laws in some states consider in utero drug exposure to be a form of child abuse or neglect under civil child-welfare statutes. Health care providers may be required to report positive drug test results in pregnant women or their newborns to the state's child protection agency (AAP & ACOG, 2012). States vary in their requirements for the evidence of drug exposure to the fetus or newborn to report a case to the child welfare system. Legally mandated testing and reporting can potentially place the provider in an adversarial relationship with the client (AAP & ACOG).

Commonly Abused Drugs

Tobacco

Tobacco is a legal substance that can be addicting or harmful to the pregnant woman, fetus, and newborn. Fetal tobacco exposure is well known to be a risk factor for low birth weight and intrauterine growth restriction (IUGR). Decreasing birth weight is related to the number of cigarettes smoked. Multiple

studies have demonstrated a clear association between maternal smoking and perinatal morbidity and mortality. Maternal complications related to smoking include placenta previa, placental abruption, preterm premature rupture of membranes, and ectopic pregnancy. Fetal and neonatal risks related to maternal tobacco use include IUGR, low birth weight, perinatal mortality, and sudden infant death syndrome. Children born to mothers who smoke during pregnancy are at increased risk of asthma, infantile colic, and childhood obesity (AAP & ACOG, 2012).

Alcohol

Alcohol continues to be one of the most widely abused substances during pregnancy, and its effects on fetal development and infant outcomes have been well studied. Data from prenatal clinics and postnatal studies suggest that 20% to 30% of women drink at some time during pregnancy (National Institute on Alcohol Abuse and Alcoholism [NIAAA], 2010; Substance Abuse and Mental Health Services Administration [SAMSHA], 2012).

Alcohol is a known teratogen. It easily crosses the placenta to the fetus. A significant concentration of the drug can be identified in the amniotic fluid as well as in maternal and fetal blood (Behnke et al., 2013). Ethanol has direct teratogenic effects during the embryonic and fetal stages of development. It also causes altered neurotransmitter levels in the brain, altered brain morphology and neuronal development, and hypoxia (Behnke et al.).

Prenatal exposure to alcohol is probably the most common preventable cause of cognitive disability in the United States. Children exposed to binge drinking are 1.7 times more likely to be intellectually impaired and 2.5 times more likely to demonstrate delinquent behavior than children who were not exposed to alcohol (AAP & ACOG, 2012). Disorders associated with prenatal alcohol exposure include fetal alcohol syndrome (FAS), alcohol-related birth defects (ARBDs), and alcohol-related neurodevelopmental disorder. See Chapter 35 for information on newborn consequences of prenatal alcohol exposure.

Marijuana

Marijuana, a substance derived from the cannabis plant, is the most common illicit drug used in the United States. It is usually rolled into a cigarette and smoked but also may be mixed into food and eaten. Although the federal government considers marijuana a Schedule I substance (having no medicinal uses and high risk for abuse), two states have legalized marijuana for adult recreational use, and 23 states and the District of Columbia have passed laws allowing its use as a treatment for certain medical conditions (NIDA, 2014; ProCon.org, 2014).

Unlike other drugs, the placenta appears to limit fetal exposure to marijuana. The adverse effects of marijuana on the fetus are thought to be attributable to complex pharmacologic actions on developing systems, altered uterine blood flow, and altered maternal health behaviors (Behnke et al., 2013).

Cocaine

Cocaine is a powerfully addictive stimulant drug made from the leaves of the coca plant. It is one of the oldest known psychoactive substances. Cocaine is a Schedule II drug, which means that

it has high potential for abuse but can also be administered for legitimate medical purposes, such as local anesthesia for some eye, ear, and throat surgeries.

Cocaine is generally sold on the street as a fine, white crystalline powder and is also known as “coke,” “C,” “snow,” “flake,” or “blow.” It can be snorted, smoked, or injected. The term “crack,” which is the street name given to freebase cocaine, refers to the crackling sound heard when the mixture is smoked.

Pregnant cocaine users have an increased incidence of miscarriage, preterm labor, and placental abruption. They may give birth to infants who are small for gestational age. Intrauterine fetal demise (IUFD, stillborn) is also a risk. Because cocaine easily crosses both the placenta and the blood-brain barrier, it can cause significant teratogenic effects in the developing fetus (Behnke et al., 2013).

Methamphetamine

Methamphetamine is a relatively cheap and highly addictive stimulant that affects the CNS. It was developed early in the 20th century from its parent drug, amphetamine, and was used originally in nasal decongestants and bronchial inhalers (NIDA, 2013). Methamphetamine is classified by the U.S. Drug Enforcement Administration as a Schedule II stimulant, which makes it legally available only through a nonrefillable prescription. Medically it may be indicated for the treatment of attention deficit hyperactivity disorder (ADHD) and as a short-term component of weight-loss treatments.

Methamphetamine is a white, odorless, bitter-tasting crystalline powder that easily dissolves in water or alcohol. It is also called “meth,” “chalk,” “ice,” and “crystal” as well as many other terms.

Methamphetamine readily crosses the placenta and the blood-brain barrier and stimulates the CNS. Maternal risks associated with its use include preterm birth and placental abruption. Fetal effects include small size, lethargy, and heart and brain abnormalities (NIDA, 2013).

Opioids

Opioids are a class of natural, endogenous, and synthetic compounds. Morphine is one of many naturally occurring opioids. Codeine, heroin, hydromorphone (Dilaudid), fentanyl (Sublimaze), and methadone are examples of synthetic opioids (Hudak et al., 2012). Opioids act by attaching to specific proteins called opioid receptors, which are found in the brain, spinal cord, GI tract, and other organs in the body. When these drugs attach to their receptors, they reduce the perception of pain. In addition, opioids produce a euphoric response because these drugs also affect the brain regions involved in reward. Opioids rapidly cross the placenta, with drug equilibration between the mother and the fetus (Behnke et al., 2013).

Prescription Drug Abuse

Psychotherapeutic medications such as stimulants, sleeping pills, tranquilizers, and pain relievers are used by an estimated 2% of American women. Such medications can bring relief from undesirable conditions such as insomnia, anxiety, and pain. Because the medications have mind-altering capacity, misuse can produce psychologic and physical dependency in the same manner as illicit drugs. Prescription drug abuse is

the intentional use of a medication without a prescription; in a way other than as prescribed; or for the experience or feeling it causes. Prescription drug abuse remains a significant problem in the United States (NIDA, 2011b).

CARE MANAGEMENT

Screening

All pregnant women should be screened at their first prenatal visit regarding their past and present use of tobacco, alcohol, and other drugs, including the recreational use of prescription and over-the-counter medications as well as herbal remedies. Substance use information can be obtained by interview or use of a standardized screening tool. The overall approach and emotional tone of the clinician is more important than the specific wording or content used. Women are more likely to report substance use when asked in a nonjudgmental manner by an empathic interviewer and within the context of general health questions (AAP & ACOG, 2012).

Information about drug use should be obtained by first asking about the woman’s intake of over-the-counter and prescribed medications. Next her use of legal drugs such as caffeine, nicotine, and alcohol should be determined. Finally she should be questioned about her use of illicit drugs such as cocaine, heroin, and marijuana. The approximate frequency and amount should be documented for each drug used (Seidel, Ball, Dains, et al., 2011).

Use of validated screening questionnaires, along with the assurance of confidentiality, improves client-provider communication and can increase the truthfulness of client responses (AAP & ACOG, 2012). The *4Ps Plus* is a screening tool designed specifically to identify pregnant women who need in-depth assessment (Box 31-4). It consists of five questions and takes less than a minute to complete. Because women frequently deny or greatly underreport usage when asked about drug or alcohol consumption during pregnancy, asking about substance use before pregnancy is often an effective screening method (Wisner et al., 2012).

Toxicologic testing is often performed to screen for illicit drug use. Because positive test results have implications for clients beyond their health, informed consent should be obtained before testing is done. The legal implications of testing and the need for consent from the mother can vary among states; therefore, health care providers should be aware of local laws and legislative changes that can influence regional practice (AAP & ACOG, 2012).

BOX 31-4 Screening with the *4Ps Plus*

Parents: Did either of your parents ever have a problem with alcohol or drugs?

Partner: Does your partner have a problem with alcohol or drugs?

Past: Have you ever had any beer or wine or liquor?

Pregnancy: In the month before you knew you were pregnant, how many cigarettes did you smoke? In the month before you knew you were pregnant, how much beer, wine, or liquor did you drink?

From Chasnoff, I.J., Hung, W.C. (1999). *The 4Ps plus*. Chicago: NTI Publishing.

Several biologic specimens can be used to screen for drug exposure. The three specimens most commonly used to establish drug exposure during the prenatal and perinatal periods are urine, meconium, and hair; however, none is accepted as a gold standard. Other specimens such as umbilical cord tissue, cord blood, human milk, and amniotic fluid may also be used for testing (Behnke et al., 2013; Hudak et al., 2012).

Urine has been the most frequently tested biologic specimen because of its ease of collection. Both maternal and neonatal urine can be tested for the presence of several drugs. Urine testing identifies only recent drug use, because threshold levels of drug metabolites generally can be detected in urine only for several days. Therefore, false-negative urine test results can occur in the presence of significant intrauterine drug exposure. Urine is a good medium for detecting marijuana, nicotine, opiate, cocaine, and amphetamine exposure (Behnke et al., 2013; Hudak et al., 2012).

Drugs become trapped within the hair, so it can be analyzed to determine past drug use over a longer period. Hair is useful in detecting nicotine, opiate, cocaine, and amphetamine exposure. Both maternal and neonatal hair samples can be tested (Behnke et al., 2013; Hudak et al., 2012).

Umbilical cord tissue and meconium can also be analyzed to determine past drug use over a longer period of time. Both substances can be used to assess fetal exposure to amphetamines, opiates, cocaine, cannabinoids, and alcohol (Behnke et al., 2013; Hudak et al., 2012). Umbilical cord tissue has the additional benefit of availability at the time of birth. Therefore, results from umbilical cord tissue testing may be available more rapidly than those obtained from meconium testing, because meconium may not be passed by the neonate for several days after birth (Montgomery, Plate, Alder, et al., 2006; United States Drug Testing Laboratories, Inc. [USDTL], 2012b).

A 6-inch segment of the umbilical cord is required for testing (USDTL, 2012a). Collection instructions can be found at www.usdtl.com/cordstat.html.

Assessment

Because substance-abusing pregnant women are at risk for a variety of infections and medical conditions, a comprehensive medical history should be obtained, and a complete physical examination performed. Laboratory assessments likely include screening for syphilis, hepatitis B and C, and human immunodeficiency virus (HIV). A complete blood count and a skin test to screen for tuberculosis may also be ordered. In addition, the woman may be tested for other common sexually transmitted infections such as gonorrhea and chlamydia (Wisner et al., 2012). Initial and serial ultrasound studies are usually performed to determine gestational age because the woman may have had amenorrhea as a result of her drug use or have no idea when her last menstrual period occurred.

Interventions

Medical Management

The information gained by toxicologic testing should be used to assist the pregnant woman or new mother to receive the treatment she needs and not as a vehicle for punishment (AAP & ACOG, 2012). Intervention with the pregnant substance abuser begins with education about specific effects on pregnancy, the fetus, and the newborn for each drug used. Consequences of perinatal drug use should be clearly communicated, and abstinence recommended

as the safest course of action unless the woman is abusing opioids. Women are often more receptive to making lifestyle changes during pregnancy than at any other time in their lives. The casual, experimental, or recreational drug user is frequently able to achieve and maintain sobriety when she receives education, support, and continued monitoring throughout the remainder of the pregnancy. Periodic screening throughout pregnancy of women who have admitted to drug use may help them to continue abstinence.

It is difficult to estimate the full extent of the consequences of maternal drug abuse and to determine the specific hazard of a particular drug to the fetus. Multiple factors can have consequences and all interact to affect maternal, fetal, and child outcomes (NIDA, 2010). These factors include:

- The number and amount of all drugs abused, including nicotine
- The extent of prenatal care
- Possible neglect or abuse of the child
- Exposure to violence in the environment
- Socioeconomic conditions
- Maternal nutrition
- Other health conditions
- Exposure to sexually transmitted diseases

Treatment for substance abuse is individualized for each woman, depending on the type of drug used and the frequency and amount of use. Research has shown the value of evidence-based treatments in changing drug abuse and addiction behaviors in pregnant women. One recommended treatment is contingency management, in which participants are given incentives, such as small cash amounts, privileges, or prizes, for maintaining abstinence. Compared to a standard treatment condition, motivational incentive approaches appear to increase treatment retention and prolong abstinence in pregnant women with cocaine, opiate, and nicotine dependence (AAP & ACOG, 2012).

Women are more likely to attempt to stop smoking during pregnancy than at any other time in their lives. Quitting before conception is ideal, but even quitting before 16 weeks of gestation significantly decreases the adverse risks. Smoking-cessation programs during pregnancy are effective and should be offered to all pregnant smokers. These programs should continue throughout the postpartum period as well, because many women resume smoking after the birth (Gilbert, 2011; Wisner et al., 2012). The USPSTF (2009) found inadequate evidence to evaluate the safety or efficacy of pharmacotherapy (e.g., nicotine replacement therapy) during pregnancy.

The 5 A's Intervention was developed by the U.S. Public Health Service and is a best-practice guideline supported by the ACOG and the National Cancer Institute. The intervention is designed to take about 5 to 15 minutes and should be implemented with every client who is smoking or who has recently quit (see Box 4-12) (Agency for Healthcare Research and Quality [AHRQ], 2012). For more information on smoking cessation, visit the American Lung Association website at www.lungusa.org or the CDC website at www.cdc.gov/tobacco/data_statistics/fact_sheets/cessation/quitting/index.htm.

Detoxification, short-term inpatient or outpatient treatment, long-term residential treatment, aftercare services, and self-help support groups are all possible options for alcohol and drug abuse rehabilitation. Women for Sobriety may be a more helpful organization for women than Alcoholics Anonymous

or Narcotics Anonymous, which were originally developed for male substance abusers. In general long-term treatment of any sort is becoming increasingly difficult to obtain, particularly for women who lack insurance coverage. Although some programs allow a woman to keep her children with her at the treatment facility, far too few of them are available to meet the demand.

COMMUNITY ACTIVITY

Look in your local phone book's yellow pages or go online to find an "open" (one that welcomes visitors) twelve-step meeting in your community. Alcoholics Anonymous, Narcotics Anonymous, and Cocaine Anonymous are all examples of twelve-step recovery groups. Attend an open meeting held by one of these groups. Discuss your experience with your clinical group. Did pregnant women or new mothers attend the meeting? What was your impression of the meeting format and the discussion that occurred? Did you notice anything at the meeting that surprised you? Do you think that attending twelve-step meetings would be helpful for pregnant women or new mothers attempting to achieve and maintain sobriety? Give reasons to support your answer to the last question.

Women should be advised to remain abstinent from alcohol consumption during pregnancy because there is no known safe threshold for use. Health care providers should advise women that low-level consumption of alcohol in early pregnancy is not an indication for pregnancy termination. However, women who have already consumed alcohol during a current pregnancy should be advised to stop to minimize further risk (AAP & ACOG, 2012).

Pregnant women requiring withdrawal from alcohol should be admitted for inpatient management. Alcohol withdrawal treatment during pregnancy consists of the administration of benzodiazepines, commonly chlordiazepoxide (Librium), diazepam (Valium), lorazepam (Ativan), and oxazepam (Serax). Disulfiram (Antabuse) is teratogenic; therefore, its use in aversion therapy is contraindicated during pregnancy. Four medications are approved by the FDA for treating alcohol dependence, but their use during pregnancy has been limited. Acute management of alcohol withdrawal also includes thiamine replacement and maintenance of adequate hydration and electrolyte balance (Wisner et al., 2012).

Pregnant women who use cocaine should be advised to stop using immediately. These women need a great deal of assistance such as an alcohol and drug treatment program, individual or group counseling, and participation in self-help support groups to accomplish this major lifestyle change successfully.

Methamphetamines are stimulants with vasoconstrictive characteristics similar to those of cocaine and are used similarly. As is the case with cocaine users, methamphetamine users are urged to immediately stop all use during pregnancy. Because methamphetamine users are extremely psychologically addicted, the rate of relapse is very high.

The most effective treatments for methamphetamine addiction at this time are behavioral therapies, such as cognitive-behavioral and contingency-management interventions. There are currently no medications that counteract the specific effects of methamphetamine or that prolong abstinence from and reduce the abuse of methamphetamine (NIDA, 2013).

Research is under way to develop pharmacologic treatments for methamphetamine addiction. One approach targets the

activity of glial cells. A drug called AV411 (ibudilast) that suppresses the neuroinflammatory actions of glial cells has been shown to inhibit methamphetamine self-administration in rats and is now being fast-tracked in clinical trials to establish its safety and effectiveness in humans with methamphetamine addiction (NIDA, 2013).

Another treatment option is using the body's immune system to neutralize methamphetamine in the bloodstream before it reaches the brain. This approach includes injecting a user with antimethamphetamine antibodies or with vaccines that stimulate the body to produce its own such antibodies. Researchers have also begun a clinical trial to establish the safety of an anti-methamphetamine monoclonal antibody known as mAb7F9 in human methamphetamine users (NIDA, 2013).

Opioids are highly addictive and may require prolonged treatment. Maintenance programs with methadone can sustain opioid concentrations in the mother and fetus to minimize opioid craving and prevent fetal stress. Methadone maintenance treatment (MMT) has been used in opioid-dependent pregnant women for many years and is considered the standard of care for pregnant women who are dependent on heroin or other narcotics (Kraft & van der Anker, 2012; Wisner et al., 2012).

Opioid replacement therapy has been shown to decrease opioid and other drug abuse; reduce criminal activity; improve individual functioning; and decrease rates of infections such as hepatitis B and C, HIV, other sexually transmitted infections, and tuberculosis. In addition, opioid replacement therapy is associated with reduced fetal exposure to illicit drug use and improved neonatal outcomes. However, 30% to 80% of infants exposed to opioids, including methadone or buprenorphine, in utero require treatment for neonatal abstinence syndrome (NAS). Neither the incidence nor the severity of NAS correlates directly with the maternal medication dose at birth (see Chapter 35) (Wisner et al., 2012).

Buprenorphine, a synthetic opioid, has been found to be equally effective and as safe as methadone in the adult outpatient treatment of opioid dependence. Buprenorphine, either alone (Subutex) or in combination with naloxone (Suboxone), is used as both a first-line treatment of heroin addiction and a replacement drug for methadone (Hudak et al., 2012).

Nursing Interventions

Although substance abusers can be difficult to care for at any time, they are often particularly challenging during the intrapartum and postpartum periods because of manipulative and demanding behavior. Typically these women display poor control over their behavior and a low threshold for pain. Increased dependency needs and lack of involvement with infant care may also be apparent.

Nurses must understand that substance abuse is an illness and that these women deserve to be treated with patience, kindness, consistency, and firmness when necessary (Box 31-5). Even women who are actively abusing drugs experience pain during labor and after giving birth and may need both pharmacologic and nonpharmacologic interventions. Developing a standardized plan of care so clients have limited opportunities to play staff members against one another is helpful. Mother-infant attachment should be promoted by identifying the woman's strengths and reinforcing positive maternal feelings

BOX 31-5 Dealing with Pregnant Substance Abusers

Realize that the decision to become and remain sober can *only* be made by the substance abuser.

Understand that nurses do not have the power to cure anyone. They only serve as educators, supporters, and advocates.

Educate yourself about the effects of drug use in general and its effect on pregnancy and the newborn specifically.

Treat substance abusers with the same respect and consideration that you show other people.

Become familiar with your local treatment centers. Learn which of them accept pregnant women. Keep an up-to-date list of groups meeting in your community.

Remember that there are no "hopeless cases." It is *never* too late to quit!

Practice patience and persistence. It may take months or years to see the effects of your work.

and behaviors. Staffing should be sufficient to ensure strict surveillance of visitors and prevent unsupervised drug use.

Advice regarding breastfeeding must be individualized. Although all abused substances appear in breast milk, some in greater amounts than others, breastfeeding is definitely contraindicated in women who use amphetamines, alcohol, cocaine, heroin, or marijuana. However, methadone use is not a contraindication to breastfeeding. The baby's nutrition and safety

needs are of primary importance in this consideration. For some women a desire to breastfeed can provide strong motivation to achieve and maintain sobriety.

Smoking can interfere with the let-down reflex. Women who smoke and breastfeed should avoid smoking for 2 hours before a feeding to minimize the amount of nicotine in the milk and improve the milk-ejection reflex. All smokers should be discouraged from smoking in the same room with the infant because exposure to secondhand smoke can increase the likelihood that the infant will experience behavioral and respiratory health problems.

Follow-Up Care

Before a known substance abuser is discharged with her baby, the home situation must be assessed to determine that the environment is safe and that someone will be available to meet the infant's needs if the mother is unable to do so. The social services department of the birthing facility is usually involved in interviewing the mother before discharge to ensure that the infant's needs will be met. Family members or friends are sometimes asked to become actively involved with the mother and infant after discharge. A home care or public health nurse may be asked to make home visits to assess the mother's ability to care for the baby and provide guidance and support. If serious questions about the infant's well-being exist, the case is likely to be referred to the state child protective services agency for further action.

KEY POINTS

- Because pregnant women may have a history of mental disorder or substance abuse, careful assessment is extremely important at the first and each subsequent prenatal and postpartum visit.
- Mood disorders account for most mental health disorders in the postpartum period.
- Psychotherapy is the first-line treatment option for women with mild to moderate peripartum depression.
- Antidepressant medications are the usual treatment for PPD; however, specific precautions are needed for breastfeeding women.
- Treatment of peripartum onset of anxiety disorders requires a combination of medication, education, supportive measures, and psychotherapy.
- Treatment of both depression and anxiety is critical to improving mental health.
- Peripartum depression with suicidal or homicidal intent or plan as well as peripartum depression with psychotic features is a psychiatric emergency. Immediate evaluation by a mental health professional is warranted.
- Identification of women at greatest risk for substance abuse during pregnancy and depression in the postpartum period can be facilitated by use of various screening tools.
- Alcohol abuse during pregnancy is the leading cause of cognitive disability in the United States, and it is entirely preventable.
- Treatment programs must start with an understanding that substance abuse in women is a complex problem surrounded by multiple individual, familial, and social issues that require many levels of intervention and treatment.

Labor and Birth Complications

Deborah R. Bambini

<http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Differentiate between preterm birth and low birth weight.
- Describe the criteria for very preterm, early preterm, and late preterm and the implications of each.
- Discuss major risk factors associated with preterm labor.
- Analyze current interventions to prevent spontaneous preterm birth.
- Discuss the use of tocolytics and antenatal glucocorticoids for management of preterm labor.
- Design a nursing care plan for women with preterm premature rupture of membranes (preterm PROM).
- Explain the care of a woman with postterm pregnancy.
- Explain the challenge of caring for obese women during labor and birth.
- Summarize the nursing care for a trial of labor, the induction and augmentation of labor, forceps- and vacuum-assisted birth, cesarean birth, and vaginal birth after a cesarean birth (VBAC).
- Discuss obstetric emergencies and their appropriate management.

When complications arise during labor and birth, risk for perinatal morbidity and mortality increases. Some complications are anticipated, especially if the woman is identified to be at high risk during the antepartum period; other complications are unexpected or unforeseen. It is crucial for nurses to understand the normal birth process to prevent and detect deviations from normal labor and birth and to promptly implement nursing measures when complications arise. Optimal care of the laboring woman, fetus, and family experiencing complications is possible only when the nurse and other members of the obstetric team use their knowledge and skills in a concerted effort to provide competent and compassionate care. This chapter focuses on the problems of preterm labor and birth, dystocia, obesity, postterm pregnancy, and obstetric emergencies.

PRETERM LABOR AND BIRTH

Preterm labor is generally diagnosed clinically as regular contractions along with a change in cervical effacement or dilation or both or presentation with regular uterine contractions and cervical dilation of at least 2 cm. **Preterm birth** is any birth that occurs between 20 0/7 and 36 6/7 weeks of gestation (American College of Obstetricians and Gynecologists [ACOG], 2012). The preterm birth rate for all races in the United States has dropped each year since 2008, reaching 11.55% in 2012, the most recent year for which data are available (Martin, Hamilton, Osterman, et al., 2013a). This decline was largely the result of three major

practice changes: (1) improved fertility practices that reduced the risk for higher-order multiple gestations; (2) limiting scheduled births at less than 39 weeks of gestation to only those with valid indications; and (3) increased use of strategies to prevent recurrent preterm birth (Simhan, Iams, & Romero, 2012).

Preterm births are categorized as *very preterm* (<32 weeks of gestation), *moderately preterm* (32 to 34 weeks of gestation), and *late preterm* (34 to 36 weeks of gestation). The degree of risk for an infant born prematurely is directly related to the degree of prematurity. About 75% of all preterm births in the United States are categorized as late preterm. Late preterm infants are at increased risk for early death and long-term health problems when compared with infants who are born full term. Although late preterm babies do experience significant problems, the great majority of infant deaths and the most serious morbidity occur among the infants who are born before 32 weeks of gestation (very preterm birth) (Simhan, Berghella, & Iams, 2014). The very preterm birth rate in the United States was approximately 1.93% in 2012 (Martin et al., 2013a).

The World Health Organization estimates that 9.6% (almost 13 million) of all births worldwide in 2005 were preterm. The rate of preterm birth is highest in Africa and North America and lowest in Europe (Simhan et al., 2012). The incidence of preterm birth varies with race. In the United States, non-Hispanic black women have the highest rate, followed by Hispanic women. Non-Hispanic white women have the lowest rate of preterm birth. Although the rate of preterm birth for

non-Hispanic black women reached a record low of 16.53% in 2012, this rate is still far higher than for non-Hispanic white women (Martin et al., 2013a).

Preterm Birth Versus Low Birth Weight

Although they have distinctly different meanings, the terms *preterm birth* or *prematurity* and *low birth weight* were often interchanged in the past. Preterm birth describes length of gestation (i.e., less than 37 0/7 weeks regardless of the weight of the infant), whereas low birth weight describes only weight at the time of birth (i.e., 2500 g or less). Because birth weight was far easier to determine than gestational age, in many settings and publications low birth weight was used as a substitute term for preterm birth. Preterm birth, however, is a more dangerous health condition for an infant because less time in the uterus correlates with immaturity of body systems. Low-birth-weight babies can be, but are not necessarily, preterm; low birth weight can be caused by conditions other than preterm birth, such as **intrauterine growth restriction (IUGR)**, a condition of inadequate fetal growth not necessarily correlated with initiation of labor. Pregnant women who have various complications of pregnancy that interfere with uteroplacental perfusion, such as gestational hypertension or poor nutrition, may give birth to a baby at term who is low birth weight because of IUGR. However, infants born at a preterm gestation can weigh more than 2500 g at birth. Currently, thanks to advances in pregnancy dating, outcomes related to gestational age can increasingly be distinguished from outcomes related to birth weight. Therefore, use of birth weight as a substitute for gestational age in developed countries is no longer considered acceptable (Simhan et al., 2014).

Spontaneous Versus Indicated Preterm Birth

Preterm births are divided into two categories: spontaneous and indicated. Spontaneous preterm births occur following an early initiation of the labor process in the apparent absence of maternal or fetal illness and make up nearly 75% of all preterm births in developed countries. Conditions such as preterm labor with intact membranes and preterm PROM often result in preterm birth (Simhan et al., 2014). Box 32-1 lists risk factors for the development of spontaneous preterm labor.

Indicated preterm births occur as a means to resolve maternal or fetal risk related to continuing the pregnancy. About 25% of all preterm births in the United States are indicated because

of medical or obstetric conditions that affect the mother, the fetus, or both. An increase in the number of indicated preterm births between 34 and 36 weeks of gestation accounts for much of the rise in late preterm births (Simhan et al., 2012). Box 32-2 lists common causes of indicated preterm births. The remainder of this section deals with spontaneous preterm labor and birth.

Causes of Spontaneous Preterm Labor and Birth

Causes of preterm labor and birth are multifactorial (Flood & Malone, 2012). **Infection is the only factor shown to be definitely associated with preterm labor.** When bacterial cervical or urinary tract infections are present, the risk of preterm birth increases. Women in spontaneous preterm labor with intact membranes commonly have organisms that are normally found in the lower genital tract present in their amniotic fluid, placenta, and membranes (Simhan et al., 2014). Clinical and laboratory evidence of infection are more common when birth occurs earlier than 30 to 32 weeks of gestation rather than closer to term. Intraabdominal infections (e.g., appendicitis) also have been related to preterm birth (Simhan et al., 2012). Women with periodontal disease have been shown to have an increased risk for preterm birth. However, the risk is not reduced by periodontal care, suggesting that the link between periodontal disease and preterm birth is not a cause-and-effect relationship (Simhan et al., 2012).

Another proposed cause of preterm labor and birth is bleeding at the site of placental implantation in the uterus in the first or second trimester of pregnancy. The resulting uteroplacental ischemia or hemorrhage at the decidual layer of the placenta may somehow activate the preterm labor process. Intrauterine inflammation is associated with infection, uterine vascular compromise, and decidual hemorrhage and can contribute to preterm labor. Maternal and fetal stress, uterine overdistention,

BOX 32-2 Common Causes of Indicated Preterm Birth

- Preexisting or gestational diabetes
- Chronic hypertension
- Preeclampsia
- Obstetrical disorders or risk factors in the current or a previous pregnancy
- Previous cesarean birth via a classic uterine incision
- Placental disorders
- Medical disorders
- Seizures
- Thromboembolism
- Maternal HIV or active herpes infection
- Obesity
- Advanced maternal age
- Fetal disorders
- Chronic (IUGR) or acute (abnormal NST or BPP) fetal compromise
- Excessive or inadequate amount of amniotic fluid
- Congenital fetal abnormalities

BOX 32-1 Risk Factors for Spontaneous Preterm Labor

- History of previous spontaneous preterm birth
- Nonwhite race
- Genital tract colonization and infection
- Multifetal gestation
- Second-trimester bleeding
- Low prepregnancy weight

Data from Simhan, H.N., Berghella, V., & Iams, J.D. (2014). Preterm labor and birth. In R.K. Creasy, R. Resnik, J.D. Iams, et al. (Eds.), *Creasy and Resnik's maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders; Simhan, H., Iams, J., & Romero, R. (2012). Preterm birth. In S. Gabbe, J. Niebyl, & J. Simpson (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed.). Philadelphia: Saunders.

allergic reaction, and a decrease in progesterone are other factors that can play a part in initiating preterm labor. It is becoming increasingly clear that preterm labor is caused by multiple pathologic processes that eventually result in uterine contractions, cervical changes, and rupture of membranes (Buhimschi & Norman, 2014; Simhan et al., 2014).

Predicting Spontaneous Preterm Labor and Birth

Risk Factors

Predicting those at risk for preterm labor and birth includes identification of risk factors. In addition to the risk factors listed in Box 32-1, poverty; lack of education; living in a disadvantaged neighborhood, state, or region; and lack of access to prenatal care also have been identified as risk factors. The risk for preterm birth also appears to be genetically related. For example, women whose sisters gave birth prematurely are also more likely to do so, and the grandparents of women who give birth prematurely are more likely to have been born prematurely themselves than the grandparents of women who give birth at term (Simhan et al., 2014). Researchers have developed a variety of other risk scoring systems; however, no risk scoring system has thus far been successful in lowering the preterm birth rate (DeFranco, Lewis, & Odibo, 2013).

Cervical Length

One possible predictor of preterm labor is endocervical length. Changes in cervical length occur before uterine activity, so cervical measurement can identify women in whom the labor process has begun. However, because preterm cervical shortening occurs over a period of weeks, neither digital nor ultrasound cervical examination is very sensitive at predicting imminent preterm birth. Women whose cervical length is greater than 30 mm are unlikely to give birth prematurely even if they have symptoms of preterm labor (Simhan et al., 2012; Simhan et al., 2014).

Fetal Fibronectin Test

Fetal fibronectin (fFN) has been studied extensively and is marketed in the United States as a diagnostic test for preterm

labor. fFN is a glycoprotein “glue” found in plasma and produced during fetal life. It normally appears in cervical and vaginal secretions early in pregnancy and then again in late pregnancy. The test is performed by collecting fluid from the woman’s vagina using a swab during a speculum examination. The presence of fFN during the late second and early third trimesters of pregnancy may be related to placental inflammation, which is thought to be one cause of spontaneous preterm labor. The presence of fFN alone is not very sensitive as a predictor of preterm birth, however. Often the test is used to predict who will *not* go into preterm labor, because preterm labor is very unlikely to occur in women with a negative result (Simhan et al., 2014).

A combined approach to predicting preterm birth has been found to increase sensitivity and negative predictive value. Combining the evaluation of fFN levels and ultrasound measurement of cervical length was found to increase the ability to identify those at risk for preterm labor within the next 7 days as well as better identify those at low risk (DeFranco et al., 2013).

CARE MANAGEMENT

Assessment

DeFranco, Lewis, and Odibo (2013) reported that 30.2% of women who experienced preterm labor signs ultimately experienced preterm birth, whereas Simhan, Iams, and Romero (2012) state that at least 50% of all women who ultimately give birth prematurely have no identifiable risk factors. Therefore, it is important that all women be educated about preterm labor, not only in early pregnancy but also in the preconception period.

Nursing assessment for factors that contribute to this risk begins early in pregnancy and continues throughout the prenatal period. The onset of preterm labor is often insidious and can be easily mistaken for normal discomforts of pregnancy. Nursing diagnoses, expected outcomes of care, and evidence-based interventions are established for each woman based on her assessment findings (see the Nursing Care Plan).

NURSING CARE PLAN

Preterm Labor

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Deficient Knowledge related to recognition of preterm labor</i>	Woman and partner describe signs and symptoms of preterm labor.	<ul style="list-style-type: none"> Assess what woman and partner know about preterm labor and birth and how to recognize its presence. Discuss signs and symptoms that serve as warning signs of preterm labor so that woman or her partner has adequate information. Provide written supplemental materials that include a list of warning signs and instructions regarding what to do if any of listed signs occur. Discuss and demonstrate how to assess and time contractions. 	<ul style="list-style-type: none"> To identify areas of deficit To identify problems early Couple can reinforce and review learning and act swiftly and appropriately should a sign occur To provide needed skills to assess signs of labor

<i>Risk for Injury (maternal/fetal) related to recurrence of preterm labor</i>	Woman demonstrates ability to assess self for signs of recurring labor; maternal-fetal well-being is maintained.	<p>Teach woman and partner how to monitor uterine contraction activity daily.</p> <p>Instruct woman and partner to report rupture of membranes, vaginal bleeding, cramping, pelvic pressure, or low backache to appropriate health care resource immediately.</p> <p>Have woman monitor her weight, diet, fluid intake, and vital signs on a daily basis.</p> <p>Have woman limit activities to those recommended in restricted activity plan.</p> <p>Encourage woman to use side-lying position when reclining.</p> <p>Teach woman signs and symptoms of thrombophlebitis, and encourage gentle exercise of lower extremities.</p> <p>Counsel couple to abstain from sexual intercourse and nipple stimulation if symptoms of preterm labor occur.</p> <p>Encourage woman to practice relaxation techniques.</p> <p>Teach woman to take tocolytic or other medications per physician's orders.</p> <p>Teach woman and partner about and have them report any medication side effects immediately.</p> <p>Have family arrange for alternative strategies in carrying out woman's usual roles and functions.</p> <p>If small children are part of household, encourage family to make alternative arrangements for child care.</p>	<p>To provide immediate evidence of worsening condition</p> <p>Because such symptoms can be signs of labor</p> <p>To evaluate for potential problems</p> <p>To decrease likelihood of onset of labor</p> <p>To enhance placental perfusion</p> <p>Because pregnancy and limited activity increase risk for clot formation</p> <p>Because such activities may stimulate uterine contractions</p> <p>To decrease uterine tone and decrease anxiety and stress</p> <p>To inhibit uterine contractions</p> <p>To prevent medication-induced complications</p> <p>To decrease stress and limit temptations to increase activity</p>
<i>Anxiety related to preterm labor and potential birth of premature neonate</i>	Feeling and symptoms of anxiety are reduced.	<p>Provide calm, soothing atmosphere, and encourage family to provide emotional support.</p> <p>Encourage verbalization of fears.</p> <p>Involve woman and family in home management of her condition.</p> <p>Help woman identify and use appropriate coping strategies and support systems.</p> <p>Explore use of desensitization strategies such as progressive muscle relaxation, visual imagery, or thought stopping.</p> <p>Provide information about online support groups.</p>	<p>To enhance woman's adherence to her restricted activity protocol</p> <p>To facilitate coping</p> <p>To decrease intensity of emotional response</p> <p>To promote greater sense of control</p> <p>To reduce fear and anxiety</p> <p>To reduce fear-related emotions and related physical symptoms</p>
<i>Deficient Diversional Activity related to modified bed rest</i>	Woman will verbalize diminished feelings of boredom.	<p>Assist woman to creatively explore personally meaningful activities that can be pursued from the bed.</p> <p>Maintain emphasis on personal choices of woman.</p> <p>Evaluate support and system resources that are available in environment.</p> <p>Explore ways for woman to remain an active participant in home management and decision making.</p> <p>Engage support of family and friends in carrying out chosen activities and making necessary environmental alterations.</p> <p>Encourage woman to use Internet to communicate with other women on bed rest.</p> <p>Teach woman about stress management and relaxation techniques.</p>	<p>To reduce fear and anxiety</p> <p>To ensure activities that have meaning, purpose, and value to individual</p> <p>Because doing so promotes control and minimizes imposition of routines by others</p> <p>To assist in providing diversional activities</p> <p>To promote control</p> <p>To ensure success</p> <p>To obtain support and share feelings</p> <p>To help manage tension of confinement</p>

EVIDENCE-BASED PRACTICE

Magnesium Sulfate for Neuroprotection Against Cerebral Palsy**Ask the Question**

For women anticipating preterm birth, can any prenatal treatment protect the premature newborn from cerebral palsy?

Search for the Evidence

Search Strategies English language research-based publications since 2011 on magnesium sulfate, neuroprotection, preterm, premature were included.

Databases Used Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, UpToDate, and the professional websites for ACOG and AWHONN

Critical Appraisal of the Evidence

Among the many challenges for a premature baby is the risk of cerebral palsy, the most common motor disability in children. Alert clinicians noticed that newborns whose mothers had been given magnesium sulfate for tocolysis or preeclampsia were less likely to have cerebral palsy. Further research confirmed its benefit and safety.

- Magnesium sulfate facilitates vasodilation, reduces inflammation, and reduces calcium uptake into cells. It may delay cellular injury or death and increases blood flow to the brain (Merrill, 2013).
- Although magnesium sulfate is no longer recommended for stopping preterm labor, the American College of Obstetricians and Gynecologists (ACOG) and the Society for Maternal-Fetal Medicine (SMFM) (2013) still recommend magnesium sulfate for neuroprotection against cerebral palsy in women anticipating preterm birth at less than 32 weeks of gestation. In addition, they recommend the short-term use (up to 48 hours) from 24 to 34 weeks of gestation to allow for the administration of betamethasone for lung maturity.
- Study protocols are in place for ongoing research into the advisability of using neuroprotective magnesium sulfate for later gestational age, up to 34 weeks (Crowther, Middleton, Wilkinson, et al., 2013).
- Administering magnesium sulfate requires intravenous infusion and close monitoring for 24 hours, often in a hospital setting. A cost-effectiveness analysis reveals that giving neuroprotective magnesium sulfate to clients with threatened preterm birth saves \$1.5 million for every case of cerebral palsy that is averted (Bickford, Magee, Mitton, et al., 2013).

Apply the Evidence: Nursing Implications

- Magnesium sulfate should be given in settings where staff are familiar with its use, monitoring is available, and emergency resuscitation and ventilation equipment is available.
- Typical use in women in active preterm labor or with preterm premature rupture of membranes is a 4-g loading dose given over 30 to 60 minutes, followed by the maintenance dose of 1 g/hr, given until birth or for up to 24 hours, whichever comes first. Other tocolytics are discontinued.
- Prior to the loading dose, the nurse obtains baseline vital signs and patellar reflexes. These are repeated at 10 minutes after initiation and at the end of the loading dose. During the

maintenance dose, vitals are repeated hourly, reflexes every 2 hours, and continuous electronic fetal monitoring is recommended.

- Signs of magnesium toxicity include decrease in respirations of 4 breaths per minute from baseline rate or to less than 12 per minute; systolic blood pressure drop of 15 mm Hg from baseline; diminished reflexes; decreased urinary output; or fetal heart rate abnormalities. If these are noted, the nurse should stop the infusion and notify the health care provider. Calcium gluconate should be available nearby as an antidote.
- To improve safety, the infusion should be given via infusion device in prepackaged concentrations clearly labeled as loading and maintenance doses, and double-checked by another nurse.
- Neonatal hypermagnesemia, although rare, can present as apnea, respiratory depression, lethargy, poor feeding, and hyporeflexia. Neonatal resuscitation should be available.

Quality and Safety Competencies: Safety* Knowledge

Discuss effective strategies to reduce reliance on memory.

Clearly labeled standardized packaging of magnesium sulfate doses prevents medication errors.

Skills

Demonstrate effective use of technology and standardized practices that support safety and quality.

Standardized protocols and administering magnesium sulfate in facilities familiar with its use and equipped with adequate emergency equipment improve client safety.

Attitudes

Appreciate the cognitive and physical limits of human performance.

Having another nurse double-check bags and infusion timing prevents client injury.

Interventions**Prevention**

Primary prevention strategies that address risk factors associated with preterm labor and birth are less costly in human and financial terms than the high-tech and often lifelong care required by preterm infants and their families. Programs aimed

at health promotion and disease prevention that encourage healthy lifestyles for the population in general and women of childbearing age in particular should be developed. Preconception counseling and care for women, especially those with a history of preterm birth, can identify correctable risk factors and provide a means to encourage women to participate in

health-promoting activities. Smoking cessation, for example, has been shown to prevent preterm labor and birth.

Preterm birth can be prevented in some women by administering prophylactic progesterone supplementation. Daily vaginal suppositories or creams and weekly intramuscular injections of 17-alpha hydroxyprogesterone caproate have been shown to decrease the rate of preterm birth by about 40% in women with a history of prior preterm birth or with a short (less than 20-mm length) cervix before 25 weeks of gestation. Supplementation begins at 16 weeks and continues until 36 weeks of gestation. Progesterone supplementation does not affect the rate of preterm birth in women with multiple gestations. Exactly how progesterone works to prevent preterm birth is unclear (Simhan et al., 2012; Simhan et al., 2014).

Early Recognition and Diagnosis

Although preterm birth is often not preventable, early recognition of preterm labor is still essential to implement interventions that have been demonstrated to reduce neonatal morbidity and mortality. These interventions include (Simhan et al., 2012):

- Transferring the mother before birth to a hospital equipped to care for her preterm infant
- Giving antibiotics during labor to prevent neonatal group B streptococci infection
- Administering glucocorticoids to women in labor to prevent or reduce neonatal and infant morbidity and mortality from health problems including respiratory distress syndrome, intraventricular hemorrhage, and necrotizing enterocolitis
- Administering magnesium sulfate to women giving birth before 32 weeks of gestation to reduce the incidence of cerebral palsy in their infants

Although maternal transport helps ensure a better health outcome for the mother and the baby, it also has a downside. Women may be transported to tertiary centers far from home, making visits by family and friends difficult and increasing the anxiety levels of the woman and her family. Attention to the needs of the woman and her family before, during, and after the transport is essential to comprehensive nursing care (see Chapter 34).

BOX 32-3 Signs and Symptoms of Preterm Labor

Uterine Activity

- Uterine contractions occurring more frequently than every 10 minutes persisting for 1 hour or more
- Uterine contractions may be painful or painless

Discomfort

- Lower abdominal cramping similar to gas pains; may be accompanied by diarrhea
- Dull, intermittent low back pain (below the waist)
- Painful, menstrual-like cramps
- Suprapubic pain or pressure
- Pelvic pressure or heaviness; feeling that “baby is pushing down”
- Urinary frequency

Vaginal Discharge

- Change in character or amount of usual discharge: thicker (mucoid) or thinner (watery), bloody, brown or colorless, increased amount, odor
- Rupture of amniotic membranes

Because more than half of preterm births occur in women without obvious risk factors, it is essential that all pregnant women are taught the symptoms of preterm labor (Box 32-3). The nurse caring for women in a prenatal setting should educate them about how to recognize signs of preterm labor and then assess for these symptoms at each prenatal visit. Women also must be taught the significance of these symptoms of preterm labor and what to do should they occur (see Teaching for Self-Management: What to Do if Symptoms of Preterm Labor Occur).

TEACHING FOR SELF-MANAGEMENT

What to Do if Symptoms of Preterm Labor Occur

- Empty your bladder.
- Drink two to three glasses of water or juice.
- Lie down on your side for 1 hour.
- Palpate for contractions.
- If symptoms continue, call your health care provider or go to the birthing facility.
- If symptoms go away, resume light activity, but not what you were doing when the symptoms began.
- If symptoms return, call your health care provider or go to the birthing facility.
- If any of the following symptoms occur, call your health care provider or go to the birthing facility immediately:
 - Uterine contractions every 10 minutes or less for 1 hour or more
 - Vaginal bleeding
 - Smelly vaginal discharge
 - Fluid leaking from the vagina

In particular, client education regarding any symptoms of uterine contractions or cramping between 20 0/7 and 36 6/7 weeks of gestation must emphasize that these symptoms are not just normal discomforts of pregnancy but indications of possible preterm labor (Fig. 32-1). Waiting too long to see a health care provider could result in inevitable preterm birth without sufficient time to implement the interventions that have been shown to improve infant outcomes (see preceding discussion).

As mentioned, the diagnosis of preterm labor is based on three major diagnostic criteria:

- Gestational age between 20 0/7 and 36 6/7 weeks
- Uterine activity (e.g., regular contractions)
- Progressive cervical change (e.g., effacement of 80%, or cervical dilation of 2 cm or greater)

FIG 32-1 A nurse teaching a couple signs and symptoms of preterm labor. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

If the presence of fFN is used as another diagnostic criterion, a sample of cervical and vaginal secretions for testing should be obtained before an examination for cervical changes because the lubricant used to examine the cervix can reduce the accuracy of the test for fFN. The presence of vaginal bleeding or ruptured membranes or a history of intercourse within the past 24 hours also can reduce the accuracy of the test results.

The pregnant woman at 30 weeks of gestation with an irritable uterus but no documented cervical change is not in preterm labor, although she should be carefully evaluated during follow-up care to determine whether she has progressed to active preterm labor (e.g., effacement, dilation, or both). Misdiagnosis of preterm labor can lead to inappropriate use of pharmacologic agents that can be dangerous to the health of the woman, the fetus, or both (ACOG, 2012).

Lifestyle Modifications

Activity Restriction. Activity restriction, including bed rest and limited work, is commonly prescribed to prevent preterm birth. Bed rest, however, is not a benign intervention, and no evidence has been published in the literature to support its effectiveness in reducing preterm birth rates (Simhan et al., 2012; Simhan et al., 2014). Therefore, bed rest should not be routinely recommended (ACOG, 2012). Many health care providers recommend only modified bed rest.

COMMUNITY FOCUS

Identify a website intended for pregnant women who are on activity restriction for preterm labor. What criteria did you use to evaluate the website to determine the quality of the information provided? List at least three suggestions found on the website that would be helpful for women on activity restriction and their families.

Restriction of Sexual Activity. Restriction of sexual activity is frequently recommended for women at risk for preterm birth. This intervention has not been shown to be effective at preventing preterm birth. However, sexual abstinence has not been studied in women with specific risk factors for preterm birth, such as a short cervix. Therefore, more research is indicated (Simhan et al., 2014).

Home Care. Home care of the woman at risk for preterm birth is a challenge for the nurse, who must assist the woman and her family in dealing with the many difficulties faced by families in which one member is unable to fulfill usual role responsibilities.

The woman's environment can be modified for convenience by using tables and storage units around her bed or daytime resting place to keep essential items within reach (e.g., cell or smart phone, television, radio, MP3 player, CD player, computer with Internet access, snacks, books, magazines, newspapers, and items for hobbies) (Fig. 32-2). Ensuring that the bed or couch is near a window and the bathroom is also helpful. Covering the bed with an eggcrate mattress can relieve discomfort. Women often find that a daily schedule of smaller, more frequent meals, activities (e.g., paying bills, planning and helping with meal

FIG 32-2 Woman at home on restricted activity for preterm labor prevention. Note how she has arranged her daytime resting area so that needed items are close at hand. (Courtesy Amy Turner, Cary, NC.)

preparation, hobbies), limited naps, and hygiene and grooming (e.g., shower, dressing in street clothes, applying makeup) reduces boredom and helps them maintain control and normalcy. See *Teaching for Self-Management: Activities for Children of Women on Activity Restriction* for additional ideas and suggestions. Also see *Teaching for Self-Management: Coping with Activity Restriction* in Chapter 27 for more information. With modified bed rest, women are usually allowed bathroom privileges for toileting and showering and can be up to the table for meals.

TEACHING FOR SELF-MANAGEMENT

Activities for Children of Women on Activity Restriction

- Schedule brief play periods throughout the day.
- Keep a few favorite toys in a box or basket close to the bed or couch.
- Read to the children.
- Put puzzles together.
- Watch videos or play video games (remote control for television is ideal).
- Play card or board games.
- Color in coloring books.
- Cut out pictures from magazines and paste them on cardboard.
- Play bed basketball with a soft (sponge) ball or rolled up sock and a trash can or empty laundry basket.

Suppression of Uterine Activity

Tocolytics are medications given to arrest labor after uterine contractions and cervical change have occurred. No medications that have been approved for use as tocolytics by the U.S. Food and Drug Administration (FDA) are currently available in the United States. Ritodrine (Yutopar) was approved but has been withdrawn from the U.S. market. However, it is still used as a tocolytic in other countries. Drugs marketed for other purposes, such as treatment of asthma or hypertension or as

antiinflammatory or analgesic agents, are used on an “off-label” basis (i.e., drugs known to be effective for a specific purpose, although not specifically developed and tested for this purpose) to suppress preterm labor (Simhan et al., 2014). No tocolytic has been shown to reduce the rate of preterm birth. Rather, the rationale for giving these medications is to delay birth long enough to allow time for maternal transport and for corticosteroids to reach maximum benefit to reduce neonatal morbidity and mortality. Studies of individual drugs used for tocolysis rarely contain information about whether delaying birth improved infant outcomes (Simhan et al., 2012). Selecting the appropriate tocolytic medication requires consideration of each drug’s effectiveness, risks, and side effects. Important contraindications exist to the use of all tocolytics. Maternal and fetal contraindications to tocolytic therapy are listed in Box 32-4. Box 32-5 describes nursing care for women receiving tocolytic therapy.

Magnesium sulfate is the most commonly used tocolytic agent because maternal and fetal or neonatal adverse reactions are less common than with the beta-adrenergic agonists. Clinicians are familiar with its use as a treatment of preeclampsia and believe it is safer to use when compared with the beta-adrenergic

agonists. However, although magnesium sulfate is still frequently used, its effectiveness as a tocolytic is not supported by the literature (see the Medication Guide: Tocolytic Therapy for Preterm Labor) (Simhan et al., 2012; Simhan et al., 2014).

SAFETY ALERT

Because magnesium sulfate depresses the function of the central nervous system (CNS), it is essential that the nurse frequently assesses the woman’s respiratory status, deep tendon reflexes, and level of consciousness to identify signs that the serum level of magnesium sulfate is reaching toxic levels.

BOX 32-4 Contraindications to Tocolysis

Maternal

- Preeclampsia with severe features or eclampsia
- Bleeding with hemodynamic instability
- Contraindications to specific tocolytic medications

Fetal

- Intrauterine fetal demise
- Lethal fetal anomaly
- Nonreassuring fetal status
- Chorioamnionitis
- Preterm premature rupture of membranes (preterm PROM)

Data from American College of Obstetricians and Gynecologists. (ACOG). (2012). *Management of preterm labor*. ACOG practice bulletin no. 127. Washington, DC: ACOG.

BOX 32-5 Nursing Care for the Woman Receiving Tocolytic Therapy

- Explain the purpose and side effects of the tocolytic medication(s) to the woman and her family.
- Position the woman on her side to enhance placental perfusion and reduce pressure on the cervix.
- Monitor maternal vital signs including lung sounds and respiratory effort, fetal heart rate and pattern, and labor status according to hospital protocol and professional standards.
- Assess the mother and fetus for signs of adverse reactions related to the tocolytic medication(s) being administered (see the Medication Guide: Tocolytic Therapy for Preterm Labor).
- Determine maternal fluid balance by measuring the daily weight and intake and output.
- Limit fluid intake to 2500 to 3000 ml/day, especially if a beta-adrenergic agonist or magnesium sulfate is being administered.
- Provide psychosocial support and opportunities for the woman and family to express feelings and concerns.
- Offer comfort measures as needed.
- Encourage diversional activities and relaxation techniques.

Beta₂-adrenergic agonists (e.g., ritodrine and terbutaline [Brethine]) have been widely used as tocolytics. They have many maternal and fetal adverse reactions, however, including beta₁-stimulated cardiopulmonary (e.g., tachycardia) effects and beta₂-stimulated metabolic (e.g., hyperglycemia) effects. Therefore, beta₂-adrenergic agonists are increasingly being replaced by medications that are safer and have fewer adverse reactions. They should not be used in women with known or suspected heart disease, preeclampsia with severe features or eclampsia, pregestational or gestational diabetes, or hyperthyroidism (Simhan et al., 2012; Simhan et al., 2014). Use of beta₂-adrenergic agonists is also contraindicated in women with migraine headaches (Gilbert, 2011).

Terbutaline, the most commonly administered beta-adrenergic agonist used for tocolysis, relaxes uterine smooth muscle by stimulating beta₂-receptors in the uterine smooth muscle. Terbutaline is often given subcutaneously to facilitate maternal transfer to a tertiary center or to initiate tocolytic therapy while another agent with a slower onset of action is administered concurrently. Additionally, a subcutaneous injection of 0.25 mg may be given to suppress uterine tachysystole during labor induction or augmentation or to suppress contractions prior to cesarean birth. Long-term oral or subcutaneous administration (e.g., terbutaline pump) as maintenance therapy to suppress preterm labor has not been proven to be effective at reducing prematurity or neonatal morbidity so use of the drug for this purpose is not recommended (Gilbert, 2011; Simhan et al., 2012; Simhan et al., 2014) (see Medication Guide: Tocolytic Therapy for Preterm Labor).

Nifedipine (Adalat, Procardia), a calcium channel blocker, is a tocolytic agent that can suppress contractions. It works by preventing calcium from entering smooth muscle cells, thus reducing uterine contractions. Because of its ease of administration and low incidence of significant maternal and fetal side effects, nifedipine’s use is increasing (see Medication Guide: Tocolytic Therapy for Preterm Labor) (Simhan et al., 2012; Simhan et al., 2014).

MEDICATION ALERT

Administering nifedipine and magnesium sulfate simultaneously can cause skeletal muscle blockade. In addition, nifedipine should not be given along with or immediately following a beta₂-adrenergic agonist (e.g., terbutaline) because of effects on maternal heart rate and blood pressure (Simhan et al., 2012; Simhan et al., 2014).

SAFETY ALERT

Because using a calcium channel blocker can result in orthostatic hypotension and dizziness, it is essential to instruct women to slowly change position from supine to upright and then sit until any dizziness disappears before standing. In addition, it is important to maintain adequate fluid balance to reduce the drop in blood pressure that can occur with the drug-related vasodilation.

Indomethacin (Indocin), a nonsteroidal antiinflammatory drug (NSAID), has been shown in some trials to suppress preterm labor by blocking the production of prostaglandins. Serious maternal side effects are uncommon, and indomethacin is usually well tolerated. However, serious fetal or neonatal side effects have caused major concerns about its use as a tocolytic. Therefore, limiting the use of indomethacin to a period of 48 hours or less in women with preterm labor at less than 32 weeks of gestation is recommended (Simhan et al., 2012; Simhan et al., 2014) (see Medication Guide: Tocolytic Therapy for Preterm Labor).

MEDICATION GUIDE**Tocolytic Therapy for Preterm Labor**

MEDICATION AND ACTION	DOSAGE AND ROUTE*	ADVERSE EFFECTS	NURSING CONSIDERATIONS
Magnesium Sulfate			
CNS depressant; Relaxes smooth muscles, including uterus	IV fluid should contain 40 g in 1000 ml, piggyback to primary infusion, and administer using controller pump: Loading dose: 4-6 g over 20-30 minutes Maintenance dose: 1-4 g/hr Use for stabilization only Discontinue within 24-48 hours at the maintenance dose or if intolerable adverse effects occur	Maternal: <ul style="list-style-type: none"> Hot flushes, sweating, burning at the IV insertion site, nausea and vomiting, dry mouth, drowsiness, blurred vision, diplopia, headache, ileus, generalized muscle weakness, lethargy, dizziness Hypocalcemia Dyspnea Transient hypotension Some reactions may subside when loading dose is completed Intolerable: <ul style="list-style-type: none"> Respiratory rate fewer than 12 breaths/minute Pulmonary edema Absent DTRs Chest pain Severe hypotension Altered level of consciousness Extreme muscle weakness Urine output less than 25-30 ml/hour or less than 100 ml/4 hours Serum magnesium level of 10 mEq/L (9 mg/dl) or greater Fetal (uncommon): <ul style="list-style-type: none"> Decreased breathing movement Reduced FHR variability Nonreactive NST 	Assess woman and fetus to obtain baseline before beginning therapy and then before and after each incremental change; follow frequency of agency protocol. Drug is almost always given IV but can also be administered IM. Monitor serum magnesium levels with higher doses; therapeutic range is between 4 and 7.5 mEq/L or 5-8 mg/dl. Discontinue infusion and notify physician if intolerable adverse effects occur. Ensure that calcium gluconate or calcium chloride is available for emergency administration to reverse magnesium sulfate toxicity. Should not be given to women with myasthenia gravis. Total IV intake should be limited to 125 ml/hr.
Beta-Adrenergic Agonist (Beta-Mimetic)			
Terbutaline (Brethine) Relaxes smooth muscles, inhibiting uterine activity, and causing bronchodilation	Subcutaneous injection of 0.25 mg every 4 hours Treatment should last no longer than 24 hours Discontinue use if intolerable adverse effects occur	Maternal (most are mild and of limited duration): <ul style="list-style-type: none"> Tachycardia, chest discomfort, palpitations, arrhythmias Tremors, dizziness, nervousness Headache Nasal congestion Nausea and vomiting Hypokalemia Hyperglycemia Hypotension Intolerable: <ul style="list-style-type: none"> Tachycardia greater than 130 beats/minute BP less than 90/60 Chest pain Cardiac arrhythmias Myocardial infarction Pulmonary edema 	Should not be used in women with a history of cardiac disease, pregestational or gestational diabetes, severe gestational hypertension, preeclampsia with severe features or eclampsia, or hyperthyroidism, or with significant hemorrhage. Myocardial infarction leading to death has been reported after use.

MEDICATION GUIDE—cont'd

Tocolytic Therapy for Preterm Labor

MEDICATION AND ACTION	DOSAGE AND ROUTE*	ADVERSE EFFECTS	NURSING CONSIDERATIONS
Beta-Adrenergic Agonist (Beta-Mimetic)—cont'd		Fetal: <ul style="list-style-type: none"> • Tachycardia • Hyperinsulinemia • Hyperglycemia 	Assess woman and fetus according to agency protocol, being alert for adverse effects. Assess maternal glucose and potassium levels before treatment is initiated and periodically during treatment. Significant hyperglycemia (greater than 180 mg/dl) and hypokalemia (less than 2.5 mEq/L) may occur. Notify physician if the woman exhibits the following: Maternal heart rate greater than 130 beats/minute; arrhythmias, chest pain BP less than 90/60 mm Hg Signs of pulmonary edema (e.g., dyspnea, crackles, decreased SaO ₂). Fetal heart rate greater than 180 beats/minute. Hyperglycemia occurs more frequently in women who are being treated simultaneously with corticosteroids. Ensure that propranolol (Inderal) is available to reverse adverse effects related to cardiovascular function.
Prostaglandin Synthetase Inhibitors (NSAIDs)		Maternal (common): <ul style="list-style-type: none"> • Nausea and vomiting • Heartburn Less common, but more serious: <ul style="list-style-type: none"> • GI bleeding • Prolonged bleeding time • Thrombocytopenia • Asthma in aspirin-sensitive clients Fetal: <ul style="list-style-type: none"> • Constriction of ductus arteriosus • Oligohydramnios, caused by reduced fetal urine production • Neonatal pulmonary hypertension 	The long-acting formulations decrease the incidence of adverse effects. Used only if gestational age is less than 32 weeks. Administer for 48 hours or less. Do not use in women with renal or hepatic disease, active peptic ulcer disease, poorly controlled hypertension, asthma, or coagulation disorders. Can mask maternal fever. Assess woman and fetus according to agency policy, being alert for adverse effects. Determine amniotic fluid volume and function of fetal ductus arteriosus before initiating therapy and within 48 hours of discontinuing therapy; assessment is critical if therapy continues for more than 48 hours. Administer with food to decrease GI distress. Monitor for signs of postpartum hemorrhage.
Calcium Channel Blockers		Maternal (most effects are mild): <ul style="list-style-type: none"> • Hypotension • Headache • Flushing • Dizziness • Nausea Fetal: <ul style="list-style-type: none"> • Hypotension (questionable) 	Avoid concurrent use with magnesium sulfate because skeletal muscle blockade can result. Should not be given simultaneously with or immediately after terbutaline because of effects on heart rate and blood pressure. Assess woman and fetus according to agency protocol, being alert for adverse effects. Do not use sublingual route of administration.
Indomethacin (Indocin) Relaxes uterine smooth muscle by inhibiting prostaglandins	Loading dose: 50 mg orally, then 25-50 mg orally every 6 hours for 48 hours		
Nifedipine (Adalat, Procardia) Relaxes smooth muscles including the uterus by blocking calcium entry	Initial dose: 10-20 mg orally, every 3 to 6 hours until contractions are rare, followed by long-acting formulations of 30 or 60 mg every 8-12 hours for 48 hours while corticosteroids are being given (however, the ideal dose has not been established)		

NOTE: There are variations in recommended administration protocols; always consult agency protocol, which should be evidence based.

BP, Blood pressure; CNS, central nervous system; DTRs, deep tendon reflexes; FHR, fetal heart rate; GI, gastrointestinal; IM, intramuscular; IV, intravenous; NSAIDs, nonsteroidal antiinflammatory drugs; NST, nonstress test; SaO₂, arterial oxygen saturation; SOB, shortness of breath.

Resnik, J.D. Iams, et al. (Eds.), *Creasy and Resnik's maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders; Simhan, H., Iams, J., & Romero, R. (2012). Preterm birth. In S. Gabbe, J. Niebyl, & J. Simpson (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed.). Philadelphia: Saunders.

Promotion of Fetal Lung Maturity

Antenatal glucocorticoids, given as intramuscular (IM) injections to the mother to accelerate fetal lung maturity by stimulating fetal surfactant production, are now considered one of the most effective and cost-efficient interventions for preventing morbidity and mortality associated with preterm labor. Antenatal glucocorticoids have been shown to significantly reduce the incidence of respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis, and death in neonates, without increasing the risk of infection in either mothers or newborns (Mercer, 2014a). The National Institutes of Health (NIH) consensus panel recommended that all women between 24 and 34 weeks of gestation be given a single course of antenatal glucocorticoids when preterm birth is threatened, unless evidence indicates that glucocorticoids will have an adverse effect on the mother or birth is imminent. In general, women who

are candidates for tocolytic therapy are also candidates for antenatal glucocorticoids. The regimen for administration of antenatal glucocorticoids is given in the Medication Guide: Antenatal Glucocorticoid Therapy with Betamethasone or Dexamethasone.

The optimal timing and dosage of antenatal glucocorticoids is still being researched. Repetitive weekly doses may be beneficial but offer potential risks to fetal growth and development. Currently, a single repeat course of antenatal glucocorticoids may be considered if preterm birth threatens again after the initial course has been completed. This rescue course is given identically to the initial course if the initial course was administered more than 2 weeks previously, the gestational age remains less than 32 6/7 weeks, and imminent preterm birth is still considered likely (Mercer, 2014a; Simhan et al., 2014).

MEDICATION GUIDE

Antenatal Glucocorticoid Therapy with Betamethasone or Dexamethasone

Action

Stimulates fetal lung maturation by promoting release of enzymes that induce production or release of lung surfactant. **Note:** The U.S. Food and Drug Administration has not approved these medications for this use (i.e., this is an unlabeled use for obstetrics).

Indication

To prevent or reduce the severity of neonatal respiratory distress syndrome by accelerating lung maturity in fetuses between 24 and 34 weeks of gestation. Infants born to women who received antenatal glucocorticoids are also less likely to experience intraventricular hemorrhage, necrotizing enterocolitis, or neonatal death.

Dosage and Route

- **Betamethasone:** 12 mg intramuscular (IM) for two doses 24 hours apart
- **Dexamethasone:** 6 mg IM for four doses 12 hours apart

Maternal Effects

- Transient (lasting 72 hours) increase in white blood cell (WBC) count
- Hyperglycemia

Fetal Effects

Transient (lasting 72 hours) decrease in fetal breathing and body movements

Nursing Considerations

- Give deep IM in ventral gluteal or vastus lateralis muscle.
- Medication *must* be given by IM injection; oral administration is *not* an acceptable alternative.
- Injection is painful.
- Medication should *not* affect maternal blood pressure.
- Assess blood glucose levels. Women with diabetes whose blood sugars have previously been well controlled may require increased insulin doses for several days.

NURSING ALERT

All women between 24 and 34 weeks of gestation who are at risk for preterm birth within 7 days should receive treatment with a single course of antenatal glucocorticoids (Mercer, 2014a). Because optimal benefit to the fetus begins 24 hours after the first injection, timely administration is essential.

Management of Inevitable Preterm Birth

When preterm birth appears inevitable, magnesium sulfate may be administered to reduce or prevent neonatal neurologic morbidity (e.g., cerebral palsy). Current recommendations are that magnesium sulfate for neuroprotection is given to women who are at least 24 but less than 32 weeks of gestation at the time birth is expected to occur. How magnesium sulfate works to provide neuroprotection is not well understood. Although it is likely that the neuroprotective effects are the result of residual concentrations of the medication in the neonate's system, data are insufficient to determine the precise maternal dose necessary to achieve the benefit (Simhan et al., 2012; Simhan et al., 2014). Currently the dose of magnesium sulfate administered for neuroprotection is the same as that given for tocolysis (see Medication Guide: Tocolytic Therapy for Preterm Labor).

Labor that has progressed to a cervical dilation of 4 cm or more is likely to lead to inevitable preterm birth. If birth appears imminent, preparations to care for a small, immature neonate should be made. Women in preterm labor can rapidly progress to birth, and a very small fetus can be born through a partially dilated cervix. Also malpresentation (e.g., breech presentation) occurs much more frequently in preterm than in term fetuses. Therefore, nurses must be prepared to handle the emergency birth of a preterm infant, from either cephalic or breech presentation, without the woman's primary health care provider being present. Personnel skilled at neonatal resuscitation should be present at the time of birth. Equipment, supplies, and medications used for neonatal resuscitation should be gathered in advance and prepared for immediate use. If birth occurs in a hospital that is not prepared to provide continuing care for a preterm neonate, plans should be made for transfer of the baby to a higher level of care as soon as possible.

Fetal and Early Neonatal Loss

Preterm birth or the presence of congenital anomalies or genetic disorders incompatible with life are major reasons for intrauterine fetal demise (stillbirth) or early neonatal death. In many of these situations the parents will already have been told that the fetus has died or that the baby has a condition that is incompatible with life and will most likely die very soon after birth. Sometimes, however, the fetal death is unexpected, diagnosed only after the woman has been admitted to the labor and birth unit. Whatever the case, labor and birth nurses must be prepared to provide sensitive care to these women and their families (see Chapter 37).

If fetal or early neonatal death is expected, the parents and members of the health care team need to discuss the situation before the birth and decide on a management plan that is acceptable to everyone. Despite counseling about the likelihood of a poor outcome, some parents want “everything possible,” including cesarean birth for an abnormal fetal heart rate (FHR) tracing, to be done for the baby. If such intervention is not desired, usually the FHR is not monitored during labor.

Another major decision is whether to attempt neonatal resuscitation and to what lengths. Sometimes the feasibility of neonatal resuscitation cannot be determined until the baby’s size and physical appearance have been assessed. If the baby is too small, too immature, or too malformed for effective resuscitation, comfort care can be provided instead. The baby is kept warm and comfortable, either at the mother’s bedside or in the nursery, depending on the parents’ desires, until death occurs. Parents can choose to view and hold the baby as they wish.

After the birth the woman should be given the opportunity to decide if she wants to stay on the maternity unit or be moved to another hospital unit. She may prefer to be away from the sound of crying babies and exposure to other families who have had healthy infants. However, postpartum care and grief support may not be as good on another hospital unit, where the staff is not experienced in postpartum and bereavement care. Whether death occurs in utero or after birth, parents are faced with the same needs. See Chapter 37 for additional information on dealing with families experiencing a perinatal loss.

PREMATURE RUPTURE OF MEMBRANES

Premature rupture of membranes (PROM) is the spontaneous rupture of the amniotic sac and leakage of amniotic fluid beginning before the onset of labor at any gestational age. **Preterm premature rupture of membranes (preterm PROM)** (i.e., membrane rupture before 37 0/7 weeks of gestation) is associated with approximately 10% of all preterm births in the United States. Preterm PROM occurs twice as often in African-Americans as in other racial groups. The frequency of preterm PROM appears to have decreased since the 1990s (Mercer, 2012). Preterm PROM most likely results from pathologic weakening of the amniotic membranes caused by inflammation, stress from uterine contractions, or other factors that cause increased intrauterine pressure. Infection of the urogenital tract is a major risk factor associated with preterm PROM (Mercer, 2012, 2014b). Box 32-6 lists other risk factors. PROM or preterm PROM is diagnosed after the woman reports either a sudden gush of fluid or a slow leak of fluid from the vagina.

BOX 32-6 Risk Factors for Preterm Premature Rupture of Membranes (Preterm PROM)

- History of prior preterm birth, especially if associated with preterm PROM
- History of cervical conization or cerclage
- Urinary or genital tract infection
- Short cervical length in the second trimester
- Preterm labor in the current pregnancy
- Uterine overdistention
- Second- and third-trimester bleeding
- Pulmonary disease
- Connective tissue disorders
- Low socioeconomic status
- Low body mass index
- Nutritional deficiencies (copper and ascorbic acid)
- Cigarette smoking

Data from Mercer, B. (2012). Premature rupture of the membranes. In S. Gabbe, J. Niebyl, & J. Simpson (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed.). Philadelphia: Saunders.

Chorioamnionitis is the most common maternal complication of preterm PROM, making it a major complication of pregnancy (see later discussion). Other less common but serious maternal complications include placental abruption, sepsis, and death (Mercer, 2012, 2014b). Fetal complications from preterm PROM are primarily related to intrauterine infection, cord prolapse, umbilical cord compression associated with oligohydramnios, and placental abruption. Another possible fetal complication when preterm PROM occurs prior to 20 weeks of gestation is pulmonary hypoplasia (Mercer, 2012, 2014b).

CARE MANAGEMENT

Management of PROM is determined for each woman based on an assessment of the estimated risk of maternal, fetal, and neonatal complications if pregnancy is allowed to continue or immediate labor and birth are attempted. At term (at or after 37 0/7 weeks of gestation), because infection is the greatest maternal, fetal, and neonatal risk, birth is the best option. Labor will most likely be induced if it does not begin spontaneously soon after PROM occurs (Mercer, 2012, 2014b).

Active pursuit of labor and birth, rather than expectant management, is recommended for women who experience preterm PROM between 34 and 36 weeks of gestation. Although infants born at this gestational age have a higher risk for complications than babies born at or after 37 0/7 weeks, serious morbidity and mortality is uncommon. Because conservative management at this gestational age prolongs pregnancy by only a few days, significantly increases the risk of chorioamnionitis, and has not been shown to improve neonatal outcomes, immediate birth is considered to be the best management option. If pulmonary maturity can be documented, women with preterm PROM at 32 to 33 weeks gestation may also be offered immediate birth because they have an increased risk for complications with conservative management (Mercer, 2014b).

Preterm PROM before 32 weeks of gestation is usually managed expectantly or conservatively because the risks to the fetus and newborn associated with preterm birth are considered to be greater than the risks of infection. Women

will likely be hospitalized in an attempt to prolong the pregnancy and allow additional time for fetal maturation unless intrauterine infection, significant vaginal bleeding, placental abruption, preterm labor, or fetal compromise occurs (Mercer, 2012, 2014b). Nursing support of the woman and her family is critical at this time. They are often anxious about the health of the baby and the woman may fear that she was responsible in some way for the membrane rupture. Other nursing interventions include encouraging expression of feelings and concerns, providing information, and making referrals as needed.

Conservative management of preterm PROM includes fetal assessment by nonstress test (NST) and biophysical profile (BPP). The woman should also be taught how to assess her fetus using daily fetal movement counts (DFMCs) because a slowing of fetal movement is a warning sign of severe fetal compromise. (See Chapter 26 for further discussion of these tests.) In addition, the woman will be monitored for signs of labor, placental abruption, and the development of intrauterine infection. Antenatal glucocorticoids are administered to women who are less than 32 weeks of gestation because they decrease the risk of several neonatal complications. In addition, a 7-day course of broad-spectrum antibiotics (e.g., ampicillin, erythromycin) is administered. Antibiotic treatment has been shown to prolong the time between membrane rupture and birth, decrease maternal chorioamnionitis and postpartum endometritis, and prevent sepsis, pneumonia, and intraventricular hemorrhage in the neonate (Mercer, 2012).

Vigilance for signs of infection is a major part of the client education and nursing care after preterm PROM. The woman must be taught how to keep her genital area clean and that nothing should be introduced into her vagina. Signs of infection (e.g., fever, foul-smelling vaginal discharge, maternal and fetal tachycardia) should be reported immediately. If chorioamnionitis develops, labor is induced. If preterm labor occurs, tocolytic medications may be administered in an attempt to gain time for transporting the woman to a hospital capable of providing care to a preterm infant or for antenatal corticosteroids or antibiotics to reach effective levels (Gilbert, 2011).

CHORIOAMNIONITIS

Chorioamnionitis, bacterial infection of the amniotic cavity, is a major cause of complications for mothers and newborns at any gestational age. It occurs in approximately 1% to 5% of term births but in as many as 25% of preterm births (Duff, 2012). Other terms for this condition include *clinical chorioamnionitis*, *amnionitis*, *intrapartum infection*, *amniotic fluid infection*, and *intraamniotic infection*. Chorioamnionitis is usually diagnosed by the clinical findings of maternal fever, maternal and fetal tachycardia, uterine tenderness, and foul odor of amniotic fluid (Fishman & Gelber, 2012).

Chorioamnionitis most often occurs after membranes rupture or labor begins, as organisms that are part of the normal vaginal flora ascend into the amniotic cavity. Many of the risk factors for chorioamnionitis are associated with a long labor, such as prolonged membrane rupture, multiple vaginal examinations, and use of internal FHR and contraction monitoring modes (Duff, 2014). Other risk factors include young maternal

age, low socioeconomic status, nulliparity, and preexisting infections of the lower genital tract (Duff, 2012).

Women with chorioamnionitis can develop bacteremia. They are also more likely to have dysfunctional labor, which can result in the need for cesarean birth (see later discussion). If cesarean birth is necessary, wound infection or pelvic abscess can occur (Duff, 2012).

Neonatal risks include pneumonia, bacteremia, and sepsis. Death is more likely to occur in preterm than in term infants (Duff, 2012). There is increasing evidence that intrauterine infection is associated with increased risks of respiratory distress syndrome, periventricular leukomalacia, and cerebral palsy. It is thought that intrauterine infection leads to fetal infection that eventually produces a fetal inflammatory response syndrome with resulting pulmonary and central nervous system damage (Duff, 2014).

To prevent maternal and neonatal complications, prompt treatment with intravenous (IV) broad-spectrum antibiotics and birth of the fetus are necessary. Ampicillin or penicillin and gentamicin are most often used to treat chorioamnionitis during labor. After cesarean birth, an antibiotic that provides coverage for anaerobic organisms, such as clindamycin (Cleocin) or metronidazole (Flagyl) should be added. One additional dose of a combination of broad-spectrum antibiotics (e.g., ampicillin and gentamicin) given postpartum is usually sufficient treatment for women with chorioamnionitis (Duff, 2014).

The increased use of intrapartum antibiotic prophylaxis during labor in women who are group B streptococci (GBS) positive to prevent neonatal GBS infection has decreased the incidence of chorioamnionitis. Other measures that have proven to be effective in decreasing the frequency of chorioamnionitis are active management of labor (see later discussion), induction of labor rather than expectant management, following rupture of membranes at term, and use of prophylactic antibiotics in selected women with preterm PROM (Duff, 2014).

POSTTERM PREGNANCY, LABOR, AND BIRTH

A **postterm pregnancy** (also sometimes referred to as a *postdates* or *prolonged* pregnancy) is one that has 42 completed weeks of gestation (294 days) or more from the first day of the last menstrual period (LMP) (Cunningham, Leveno, Bloom, et al., 2014). Many pregnancies are misdiagnosed as postterm. The use of first-trimester ultrasound for pregnancy dating has confirmed that the first day of the LMP, traditionally used for pregnancy dating, is much less reliable as a predictor of true gestational age. Therefore, use of the LMP alone for pregnancy dating tends to greatly overestimate the number of postterm gestations (Rampersad & Macones, 2012).

The exact cause of true postterm pregnancy is still unknown. However, it is clear that the timing of labor is determined by complex interactions among the fetus, the placenta and membranes, the uterine myometrium, and the cervix. For example, congenital primary fetal adrenal hypoplasia and placental sulfatase deficiency cause low estrogen production. Low levels of estrogen can result in a decrease in prostaglandin precursors, thereby preventing normal cervical ripening, reducing the formation of oxytocin receptors in the myometrium, and delaying the onset of labor. Although postterm pregnancy is more

common in primiparous women, a woman who experiences one postterm pregnancy is more likely to experience it again in subsequent pregnancies (Rampersad & Macones, 2012).

Clinical manifestations of postterm pregnancy include maternal weight loss (more than 1.4 kg [approximately 3 lb]/wk) and decreased uterine size (related to decreased amniotic fluid), meconium in the amniotic fluid, and advanced bone maturation of the fetal skeleton with an exceptionally hard fetal skull (Gilbert, 2011).

Maternal and Fetal Risks

Maternal risks are often related to dysfunctional labor, such as increased risk for perineal injury related to fetal macrosomia. Risk for hemorrhage and infection is higher. Interventions such as induction of labor with prostaglandins or oxytocin, forceps- or vacuum-assisted birth, and cesarean birth are more likely to be necessary. Each of these interventions, of course, carries its own set of risks. The woman also may experience fatigue, physical discomfort, and psychologic reactions such as depression, frustration, and feelings of inadequacy as she passes her estimated date of birth. Relationships with close friends and family members may become strained and the woman's negative feelings about herself may be projected as feelings of resentment toward the fetus (Gilbert, 2011; Rampersad & Macones, 2012).

Another complication associated with postterm pregnancy is abnormal fetal growth. Although the risk of having a small for gestational age (SGA) infant is increased, only 10% to 20% of postterm fetuses are undernourished. Macrosomia (birth weight more than 4000 g) occurs far more often. Macrosomia occurs when the placenta continues to provide adequate nutrients to support fetal growth after 40 weeks of gestation. Macrosomic infants have an increased risk for operative birth and shoulder dystocia, leading to fetal injury (Rampersad & Macones, 2012).

Other fetal risks associated with postterm gestation are related to the intrauterine environment. After 43 to 44 weeks of gestation, the placenta begins to age. Enlarging areas of infarction and increased deposition of calcium and fibrin in its tissue decrease the placenta's reserve and can affect its ability to oxygenate the fetus. Decreased amniotic fluid (less than 400 ml), oligohydramnios, is the complication most frequently associated with postterm pregnancy. Because of the decreased amount of amniotic fluid, there is a potential for cord compression and resulting hypoxemia (Gilbert, 2011). Other potential complications include meconium-stained amniotic fluid and increased chance of meconium aspiration (Rampersad & Macones, 2012).

Postmaturity syndrome occurs in 10% to 20% of neonates born following postterm pregnancies. Postmaturity syndrome is characterized by dry, cracked, peeling skin; long nails; meconium staining of skin, nails, and umbilical cord; and perhaps loss of subcutaneous fat and muscle mass (Gilbert, 2011; Rampersad & Macones, 2012).

CARE MANAGEMENT

The management of postterm pregnancy is controversial. However, because perinatal morbidity and mortality increase greatly after 42 weeks of gestation, pregnancies are usually not allowed to continue after this time. In the United States, most physicians induce labor at 41 weeks of gestation. An alternative approach is to initiate twice-weekly fetal testing at 41 weeks of

gestation. The testing generally consists of either a BPP or NST along with an assessment of amniotic fluid volume (see Chapter 26 for discussion of these tests). Evidence is insufficient to determine which of the two management approaches is better (Rampersad & Macones, 2012).

During the postterm period the woman is encouraged to assess fetal activity daily, assess for signs of labor, and keep appointments with her primary health care provider (see Teaching for Self-Management: Postterm Pregnancy). The woman and her family should be encouraged to express their feelings (e.g., frustration, anger, impatience, fear) about the prolonged pregnancy and helped to realize that these feelings are normal. At times the emotional and physical strain of a postterm pregnancy can seem overwhelming. Referral to a support group or another supportive resource may be needed.

TEACHING FOR SELF-MANAGEMENT

Postterm Pregnancy

- Perform daily fetal movement counts.
- Assess for signs of labor.
- Call your primary health care provider if your membranes rupture or if you notice a decrease in or no fetal movement.
- Keep appointments for fetal assessment tests and cervical checks.
- Go to the birthing facility soon after labor begins.

During labor the fetus of a woman with a postterm pregnancy should be continuously monitored electronically for a more accurate assessment of the FHR and pattern. Inadequate fluid volume can lead to compression of the umbilical cord, which results in fetal hypoxia that is reflected in variable or prolonged deceleration patterns. If oligohydramnios is present, an amnioinfusion may be performed to restore amniotic fluid volume to maintain a cushioning of the cord. See Chapter 18 for additional information on amnioinfusion.

CLINICAL REASONING CASE STUDY

Postterm Pregnancy

Angela is a 31-year-old primigravida, presenting to the office for a routine prenatal visit. She is 40 weeks and 2 days of gestation and expresses her concern, stating, "My friends tell me that you'll try to talk me into inducing labor or a cesarean. I want to have my baby naturally! I don't want medications or surgery! This baby will know when he is ready." Angela has a birth plan that you have reviewed with her and plans to have both of her sisters and her husband be a part of the birth.

1. Evidence—Is there sufficient evidence to advise Angela about the best approach at this time?
2. Assumptions—Describe the underlying assumptions about each of the following:
 - a. Accuracy of last menstrual period (LMP)
 - b. Determination of postterm versus late-term gestation
 - c. Physiology underlying the onset of labor
 - d. Placental function after 40 weeks
 - e. Criteria for determining adequate placental function
 - f. Additional risks as gestational age increases
3. What are the implications and priorities for nursing care at this time?
4. Does the evidence objectively support your conclusion?

DYSFUNCTIONAL LABOR (DYSTOCIA)

Dysfunctional labor (dystocia) is defined as a long, difficult, or abnormal labor caused by various conditions associated with the five factors affecting labor. It is estimated that dysfunctional labor occurs in approximately 8% to 11% of all births and it is the most common indication for cesarean birth (Gilbert, 2011). A diagnosis of dysfunctional labor is ultimately responsible for approximately 60% of all cesarean births in the United States (Cunningham et al., 2014). It can be caused by any of the following factors:

- Ineffective uterine contractions or maternal bearing-down efforts (the powers)
- Alterations in the pelvic structure (the passage)
- Fetal causes, including abnormal presentation or position, anomalies, excessive size, and number of fetuses (the passenger)
- Maternal position during labor and birth
- Psychologic responses of the mother to labor related to past experiences, preparation, culture and heritage, and support system

These five factors are interdependent. In assessing the woman for an abnormal labor pattern, the nurse must consider the ways in which these factors interact and influence labor progress. Dysfunctional labor is suspected when there is an alteration in the characteristics of uterine contractions, a lack of progress in the rate of cervical dilation, or a lack of progress in fetal descent and expulsion.

Gilbert (2011) cited several factors that seem to increase a woman's risk for dysfunctional labor including the following:

- Overweight
- Short stature
- Advanced maternal age
- Infertility
- Prior version
- Masculine characteristics
- Uterine abnormalities (e.g., congenital malformations; overdistention, as with multiple gestation or polyhydramnios)
- Malpresentations and positions of the fetus
- Cephalopelvic disproportion (CPD) (or fetopelvic disproportion [FPD])
- Uterine overstimulation with oxytocin
- Maternal fatigue, dehydration and electrolyte imbalance, and fear
- Administration of an analgesic too early in labor or use of continuous epidural analgesia

Abnormal Uterine Activity

Abnormal uterine activity can be further described as being *hypertonic* or *hypotonic*.

Hypertonic Uterine Dysfunction

The woman experiencing hypertonic uterine dysfunction, or primary dysfunctional labor, often is an anxious nullipara who is having frequent and painful contractions that are ineffective in causing cervical dilation or effacement to progress. These contractions usually occur in the latent phase of first-stage labor (cervical dilation of less than 4 cm) and are usually uncoordinated. The force of the contractions may be in the midsection

of the uterus rather than in the fundus; therefore, the uterus is unable to apply downward pressure to push the presenting part against the cervix. The uterus may not relax completely between contractions.

Women with hypertonic uterine dysfunction may be exhausted and express concern about loss of control because of the intense pain they are experiencing and the lack of progress. Therapeutic rest, which is achieved with a warm bath or shower and the administration of an analgesic such as morphine to inhibit uterine contractions, reduce pain, and encourage sleep, is usually prescribed to manage hypertonic uterine dysfunction. In the absence of pain, zolpidem (Ambien) may be used to facilitate rest and sleep. After a 4- to 6-hour rest, these women are likely to awaken in active labor with a normal uterine contraction pattern (Gilbert, 2011; Wing & Farinelli, 2012).

Hypotonic Uterine Dysfunction

The second and more common type of uterine dysfunction is hypotonic uterine dysfunction, or secondary uterine inertia. The woman initially makes normal progress into the active phase of first-stage labor but then the contractions become weak and inefficient or stop altogether. The uterus is easily indented, even at the peak of contractions. Intrauterine pressure (IUP) during the contraction (usually less than 25 mm Hg) is insufficient for progress of cervical effacement and dilation. CPD and malposition are common causes of this type of uterine dysfunction.

A woman with hypotonic uterine dysfunction may become exhausted and be at increased risk for infection. Management usually consists of ruling out CPD and assessing the FHR and pattern, characteristics of amniotic fluid if membranes are ruptured, and maternal well-being. An intrauterine pressure catheter (IUPC) may be inserted to accurately evaluate uterine activity. If findings are normal, labor augmentation measures may be implemented (e.g., ambulation, hydrotherapy, rupture of membranes, nipple stimulation, oxytocin infusion).

Secondary Powers

Secondary powers, or bearing-down efforts, are compromised when large amounts of an analgesic are given. Anesthesia can also block the bearing-down reflex and, as a result, alter the effectiveness of voluntary bearing-down efforts. Exhaustion resulting from lack of sleep or long labor and fatigue resulting from inadequate hydration and food intake reduce the effectiveness of the woman's voluntary bearing-down efforts. Maternal position can work against the forces of gravity and decrease the strength and effectiveness of the contractions. Table 32-1 summarizes the characteristics of dysfunctional labor.

Abnormal Labor Patterns

Six abnormal labor patterns were identified and classified by Friedman (1989) in the 1950s according to the nature of cervical dilation and fetal descent. These patterns are (1) prolonged latent phase, (2) protracted active phase dilation, (3) secondary arrest: no change, (4) protracted descent, (5) arrest of descent, and (6) failure of descent. Table 32-2 further describes abnormal labor patterns. These patterns can result from a variety of causes, including ineffective uterine contractions, pelvic contractures, CPD, abnormal fetal presentation

TABLE 32-1 Dysfunctional Labor: Primary and Secondary Powers

PRIMARY POWERS (ABNORMAL UTERINE ACTIVITY)		SECONDARY POWERS
HYPERTONIC UTERINE DYSFUNCTION	HYPOTONIC UTERINE DYSFUNCTION	INADEQUATE VOLUNTARY EXPULSIVE FORCES
Description		
Usually occurs before 4-cm dilation; cause unknown, may be related to fear and tension	Cause is usually cephalopelvic disproportion or fetal malposition	Involves abdominal and levator ani muscles Occurs in second stage of labor; cause may be related to nerve block anesthetic, analgesia, exhaustion
Change in Pattern of Progress		
Pain out of proportion to intensity of contractions and to effectiveness of contractions in effacing and dilating the cervix Contractions increase in frequency and are uncoordinated Uterus is contracted between contractions, cannot be indented	Contractions decrease in frequency and intensity Uterus easily indented even at peak of contractions Uterus relaxed between contractions (normal)	No voluntary urge to push or bear down or inadequate or ineffective pushing
Potential Maternal Effects		
Loss of control related to intensity of pain and lack of progress Exhaustion Fear regarding unexpected nature of labor	Infection Exhaustion Stress regarding change in progress	Spontaneous vaginal birth prevented; assisted birth likely
Potential Fetal Effects		
Fetal asphyxia with meconium aspiration	Fetal infection Fetal and neonatal death	Fetal asphyxia
Care Management		
Initiate therapeutic rest measures Administer analgesic (e.g., morphine) if membranes are intact and pelvic adequacy is confirmed to relieve pain and permit woman to rest Assist with measures to enhance rest and relaxation (e.g., hydrotherapy, massage, music, distracting activities)	Rule out cephalopelvic disproportion Augment labor with oxytocin (Pitocin) Perform amniotomy Assist with measures to enhance the progress of labor (e.g., position changes, ambulation, hydrotherapy)	Coach woman in bearing down with contractions; assist with relaxation between contractions Position woman in favorable position for pushing Reduce epidural infusion rate Assist with forceps- or vacuum-assisted birth Prepare for cesarean birth if abnormal fetal status occurs

TABLE 32-2 Abnormal Labor Patterns

PATTERN	NULLIPARAS	MULTIPARAS
Prolonged latent phase	>20 hour	>14 hour
Protracted active phase dilation	<1.2 cm/hour	<1.5 cm/hr
Secondary arrest: no change	≥2 hour	≥2 hour
Protracted descent	<1 cm/hour	<2 cm/hour
Arrest of descent	≥1 hour	≥1/2 hour
Failure of descent	No change during deceleration phase and second stage	
Precipitous labor	>5 cm/hour	10 cm/hour

or position, early use of analgesics, nerve block analgesia or anesthesia, and anxiety and stress. Progress in either the first or the second stage of labor can be protracted (prolonged) or arrested (stopped). Abnormal progress can be identified by plotting cervical dilation and fetal descent on a labor graph (partogram) at various intervals after the onset of labor and comparing the resulting curve with the expected labor curve for a nulliparous or multiparous labor. If a woman exhibits an abnormal labor pattern, the primary health care provider should be notified.

Maternal morbidity and mortality from uterine rupture, infection, severe dehydration, and postpartum hemorrhage are higher for women experiencing dysfunctional labor. The fetus is at increased risk for hypoxia. A long and difficult labor also

can have an adverse psychologic effect on the mother, father or partner, and family.

Studies done since 2000 indicate that the pattern of labor progression is different from what Friedman observed in the 1950s. In general, modern labor progresses at a slower rate. The active labor phase now lasts twice as long as Friedman described. It is common for more than 2 hours to pass in the active phase of labor without cervical dilation. Maternal characteristics have changed considerably since Friedman's work was published. Women giving birth are older and heavier, and both of these factors are associated with longer labors. Clinical guidelines incorporating this new information must be developed to assist health care providers in managing contemporary labor and birth (Thorp & Laughon, 2014).

Precipitous Labor

Precipitous labor is defined as labor that lasts less than 3 hours from the onset of contractions to the time of birth. This abnormal labor pattern occurs in approximately 2% of all births in the United States. Precipitous birth alone is not usually associated with significant maternal or infant morbidity or mortality (Wing & Farinelli, 2012).

Precipitous labor can result from hypertonic uterine contractions that are tetanic in intensity. Conditions often associated with this type of uterine contraction include placental abruption, uterine tachysystole, and recent cocaine use (Wing & Farinelli, 2012).

Maternal complications can include uterine rupture, lacerations of the birth canal, amniotic fluid embolism (anaphylactoid syndrome of pregnancy), and postpartum hemorrhage. Fetal complications include shoulder dystocia (Wing & Farinelli), hypoxia caused by decreased periods of uterine relaxation between contractions, and, in rare instances, intracranial trauma related to rapid birth (Cunningham et al., 2014).

Women who have experienced precipitous labor often describe feelings of disbelief that their labor began so quickly, alarm that their labor progressed so rapidly, panic about the possibility they would not make it to the hospital in time to give birth, and finally, relief when they arrived at the hospital. In addition, women have expressed frustration when nurses did not believe them when they reported their readiness to push. Progress can be so rapid in some women that they may have difficulty remembering the details of their childbirth. They should be provided with an opportunity to discuss their labor and birth with caregivers.

Alterations in Pelvic Structure

Pelvic Dystocia

Pelvic dystocia can occur whenever there are contractures of the pelvic diameters that reduce the capacity of the bony pelvis, including the inlet, the midpelvis, outlet, or any combination of these planes. Pelvic contractures can be caused by congenital abnormalities, maternal malnutrition, neoplasms, or lower spinal disorders. An immature pelvic size predisposes some adolescent mothers to pelvic dystocia. Pelvic deformities also can be the result of vehicular or other accidents or trauma.

Soft-Tissue Dystocia

Soft-tissue dystocia results from obstruction of the birth passage by an anatomic abnormality other than that involving the bony pelvis. The obstruction can result from placenta previa (low-lying placenta) that partially or completely obstructs the internal cervical os. Other causes, such as leiomyomas (uterine fibroids) in the lower uterine segment, ovarian tumors, and a full bladder or rectum, can prevent the fetus from entering the pelvis. Occasionally cervical edema occurs during labor when the cervix is caught between the presenting part and the symphysis pubis or when the woman begins bearing-down efforts prematurely, thereby inhibiting complete dilation. Sexually transmitted infections (e.g., human papillomavirus) can alter cervical tissue integrity and thus interfere with adequate effacement and dilation.

Fetal Causes

Dystocia of fetal origin can be caused by anomalies, excessive fetal size (macrosomia), malpresentation, malposition, or multifetal pregnancy. Complications associated with dystocia of fetal origin include neonatal asphyxia, fetal injuries or fractures, and maternal vaginal lacerations. Although spontaneous vaginal birth is possible in these instances, a forceps-assisted, vacuum-assisted, or cesarean birth often is necessary.

Anomalies

Gross ascites, large tumors, open neural tube defects (e.g., myelomeningocele), and hydrocephalus are examples of fetal anomalies that can cause dystocia. The anomalies affect the

relationship of the fetal anatomy to the maternal pelvic capacity, with the result that the fetus is unable to descend through the pelvis and birth canal.

Cephalopelvic Disproportion

Cephalopelvic disproportion (CPD), also called fetopelvic disproportion (FPD), is disproportion between the size of the fetus and the size of the mother's pelvis. With CPD the fetus cannot fit through the maternal pelvis to be born vaginally. Although CPD is often related to excessive fetal size, or macrosomia (i.e., 4000 g or more), the problem in many cases is malposition of the fetal presenting part rather than true CPD (Wing & Farinelli, 2012). Fetal macrosomia is associated with maternal diabetes mellitus, obesity, multiparity, or the large size of one or both parents. If the maternal pelvis is too small, abnormally shaped, or deformed, CPD can be of maternal origin. In this case, the fetus can be of average size or even smaller. CPD cannot be accurately predicted (Wing & Farinelli).

Malposition

The most common fetal malposition is persistent occipitoposterior position (i.e., right occipitoposterior [ROP] or left occipitoposterior [LOP]; see Chapter 16), occurring in approximately 15% of all labors during the latent phase of the first stage of labor. About 5% of all fetuses are in this position at birth (Gilbert, 2011). Labor, especially the second stage, is prolonged. The woman typically complains of severe back pain from the pressure of the fetal head (occiput) pressing against her sacrum. See Box 19-8 for suggested positions to relieve back pain and encourage rotation of the fetal occiput to an anterior position, which will facilitate birth.

Evidence supports encouraging women whose fetus is in an occipitoposterior position to assume and maintain a Sims position on the same side as the fetal spine as much as possible during labor. There is limited evidence to support the commonly used hands-and-knees position (Desbriere, Blanc, Le Dú, et al., 2013).

Malpresentation

Malpresentation (the fetal presentation is something other than cephalic or head first) is another commonly reported complication of labor and birth. Breech presentation is the most common form of malpresentation, occurring in 3% to 4% of all labors (Lanni & Seeds, 2012). The three types of breech presentation are (Gilbert, 2011) (Fig. 32-3):

- Frank breech (hips flexed, knees extended)
- Complete breech (hips and knees flexed)
- Footling breech (when one foot [single footling] or both feet [double footling] present before the buttocks)

Breech presentations are associated with multifetal gestation, preterm birth, fetal and maternal anomalies, hydramnios, and oligohydramnios. High rates of breech presentation are also noted in fetuses with certain genetic disorders (e.g., trisomies 13, 18, and 21; Potter syndrome [renal agenesis]; and myotonic dystrophy). Fetuses with neuromuscular disorders have a high rate of breech presentation, perhaps because they are less capable of movement within the uterus (Thorp & Laughon, 2014). Diagnosis is made by abdominal palpation (e.g., Leopold

maneuvers) and vaginal examination and usually confirmed by ultrasound scan.

During labor the descent of the fetus in a breech presentation may be slow because the breech is not as effective a dilating wedge as is the fetal head. There is risk of prolapse of the cord

FIG 32-3 Breech presentation. **A**, Frank breech. **B**, Complete breech. **C**, Single footling breech. (From Gilbert, E. [2011]. *Manual of high risk pregnancy & delivery* [5th ed.]. St. Louis: Mosby.)

if the membranes rupture in early labor. The presence of meconium in amniotic fluid is not necessarily a sign of fetal distress because it results from pressure on the fetal abdominal wall as it travels through the birth canal. Assessment of FHR and pattern should be used to determine whether the passage of meconium is an expected finding associated with breech presentation or is an abnormal sign associated with fetal hypoxia. The heart tones of fetuses (FHTs) in a breech position are best heard at or above the umbilicus.

Vaginal birth is accomplished by mechanisms of labor that manipulate the buttocks and lower extremities as they emerge from the birth canal (Fig. 32-4). Risks associated with vaginal birth from a breech presentation include prolapse of the umbilical cord (especially in single or double footling breech presentations), trapping of the after-coming fetal head (especially with preterm infants), and trauma resulting from extension of the fetal head or nuchal position of the arms. Safe vaginal birth from a breech presentation is largely dependent on the experience, judgment, and skill of the health care provider who assists the birth. Criteria for attempting a vaginal birth from a breech presentation are (Thorp & Laughon, 2014):

- Frank or complete breech presentation
- Estimated fetal weight between 2000 and 3800 g
- Normal (gynecoid) maternal pelvis with adequate measurements
- Flexed fetal head

External cephalic version (ECV) (see later discussion) may be tried to turn the fetus to a vertex presentation. If the attempt at ECV is unsuccessful, the woman usually gives birth by cesarean (Gilbert, 2011).

Face and brow presentations are uncommon and are associated with fetal anomalies, pelvic contractures, and CPD. Spontaneous vaginal birth is possible if the fetus flexes to a vertex presentation, although forceps often are used. Cesarean birth is indicated if the presentation persists, if fetal distress occurs, or if

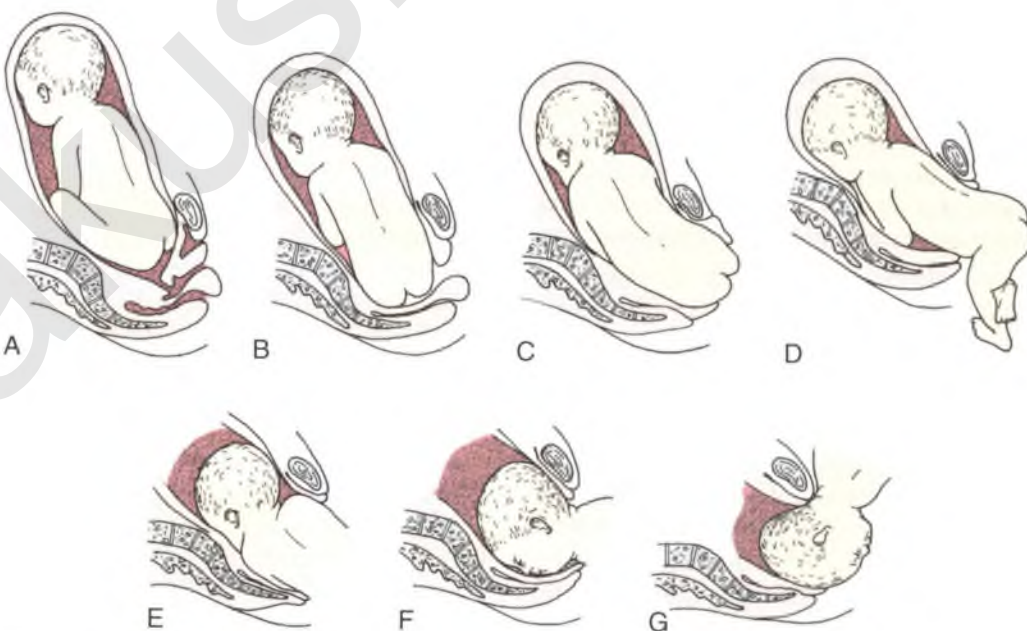

FIG 32-4 Mechanism of labor in breech presentation. **A**, Breech before onset of labor. **B**, Engagement and internal rotation. **C**, Lateral flexion. **D**, External rotation or restitution. **E**, Internal rotation of shoulders and head. **F**, Face rotates to sacrum when occiput is anterior. **G**, Head is born by gradual flexion during elevation of fetal body.

labor stops progressing. Cesarean birth is usually necessary for a fetus in a transverse lie (i.e., shoulder) presentation, although ECV may be attempted after 36 to 37 weeks of gestation (Thorpe & Laughon, 2014).

Multifetal Pregnancy

Multifetal pregnancy is the gestation of twins, triplets, quadruplets, or more infants. Twin gestations accounted for more than 3.3% of all live births in the United States in 2012. The rate of triplet or higher-order multiple births in 2012 was 124.4 per 100,000 births, the lowest rate in 18 years (Martin et al., 2013a). The number of multiple-gestation pregnancies rose dramatically in the 1980s and 1990s, most likely due to fertility-enhancing medications and procedures as well as more women older than age 35 continuing childbearing. When compared with younger women, those 35 years and older are naturally more likely to have a multifetal pregnancy. The rate of triplet and higher-order multiple pregnancies has been steadily declining since the all-time high rate of 193.5 per 100,000 births in 1998. This decrease has been attributed to refinements in the treatments used for infertility, particularly limiting the number of embryos transferred during in vitro fertilization (IVF) procedures (Malone & D'Alton, 2014; Newman & Unal, 2012).

Multiple births are associated with more complications (e.g., dysfunctional labor) than singleton births. The higher incidence of fetal and newborn complications and higher risk of perinatal mortality primarily stem from the birth of low-birth-weight infants resulting from preterm birth or IUGR (or both), in part related to placental dysfunction and twin-to-twin transfusion. Fetuses can experience distress and asphyxia during the birth process as a result of cord prolapse and the onset of placental separation with the birth of the first fetus. As a result the risk for long-term problems such as cerebral palsy is higher among infants who were part of a multiple birth.

In addition, fetal complications such as congenital anomalies and abnormal presentations can result in dysfunctional labor and an increased incidence of cesarean birth. For example, in only 40% to 45% of all twin pregnancies do both fetuses present in the vertex position, the most favorable for vaginal birth. In 35% to 40% of the pregnancies, one twin can present in the vertex position and the other in a breech or transverse lie presentation (Bowers, 2014).

The health status of the mother can be compromised by an increased risk for hypertension, anemia, and hemorrhage associated with uterine atony, placental abruption, and multiple or adherent placentas. Duration of the phases and stages of labor can vary from the duration experienced with singleton births.

Teamwork and planning are essential components of the management of labor and birth in multiple pregnancies, especially those of higher-order multiples. The nurse plays a key role in coordinating the activities of many highly skilled health care professionals. Early detection and management of the maternal, fetal, and newborn complications associated with multiple births are essential to achieve a positive outcome for mother and babies. Maternal positioning and active support are used to enhance labor progress and placental perfusion. Stimulation of labor with oxytocin, epidural anesthesia, internal or external version, and forceps and vacuum assistance may be used to accomplish the vaginal birth of twins. Cesarean birth

is almost always performed with higher-order multiple births. Each infant has its own team of health care providers present at the birth. Nurses provide important emotional support to women and their families to help reduce anxiety and stress. They explain events as they occur and offer updates on the status of the mother and infants.

Position of the Woman

The functional relationship among the uterine contractions, the fetus, and the mother's pelvis are altered by the maternal position. In addition, the position can provide a mechanical advantage or disadvantage to the mechanisms of labor by altering the effects of gravity and the body-part relationships that are important to the progress of labor. See Box 19-8 for suggested positions to enhance fetal descent.

Discouraging maternal movement or restricting labor to the recumbent or lithotomy position can compromise progress. The incidence of dysfunctional labor in women confined to these positions is increased, resulting in a greater need for augmentation of labor or forceps-assisted, vacuum-assisted, or cesarean birth.

Psychologic Responses

Hormones and neurotransmitters released in response to stress (e.g., catecholamines) can cause dysfunctional labor. Sources of stress vary for each woman, but pain and the absence of a support person are often related to dysfunctional labor. Confinement to bed and restriction of maternal movement can be a source of psychologic stress that compounds the physiologic stress caused by immobility in the unmedicated laboring woman. When anxiety is excessive it can inhibit cervical dilation and result in prolonged labor and increased pain perception. Anxiety also causes increased levels of stress-related hormones (e.g., beta-endorphin, adrenocorticotrophic hormone, cortisol, and epinephrine). These hormones act on the smooth muscles of the uterus. Increased levels can cause dysfunctional labor by reducing uterine contractility.

CARE MANAGEMENT

Risk assessment is a continual process in the laboring woman. By reviewing the woman's past labor or labors and observing her physical and psychologic responses to the current labor, any factors that might contribute to dysfunctional labor should be identified. The initial and ongoing physical assessments provide information about maternal well-being; status of labor in terms of the characteristics of uterine contractions and progress of cervical effacement and dilation; fetal well-being in terms of FHR and pattern, presentation, station, and position; and status of the amniotic membranes. Nursing diagnoses that might be identified in women experiencing dystocia include the following:

- *Risk for Injury* to mother or fetus related to
 - interventions implemented for dystocia
- *Powerlessness* related to
 - loss of control
- *Ineffective Coping* related to
 - inadequate support system
 - exhaustion secondary to a prolonged labor process
 - pain

- *Risk for Impaired Parenting* related to
 - separation from infant associated with emergency cesarean birth
 - emotional responses to a traumatic childbirth experience

Nursing diagnoses, expected outcomes of care, and interventions are established for each woman based on assessment findings. Many interventions for dysfunctional labor (e.g., ECV, cervical ripening, induction or augmentation of labor, and operative procedures [forceps- or vacuum-assisted birth, cesarean birth]) are implemented collaboratively with other members of the health care team. Commonly performed interventions are discussed in detail in the *Obstetric Procedures* section. Nursing interventions are identified with each procedure.

When providing care for a woman who is experiencing labor or birth complications, all members of the health care team are responsible for complying with professional standards of care. This promotes client safety and helps improve outcomes.

OBESITY

Excessive weight is an increasingly serious problem for children, adolescents, and adults living in affluent nations, including the United States, and pregnant women are no exception. The body mass index (BMI) is used to define obesity. People with a BMI of 25 or greater are categorized as overweight, whereas those with a BMI of 30 or greater are considered obese. Individuals with a BMI of 40 or greater are classified as severely obese (Picklesimer & Dorman, 2013).

Obese women are likely to begin pregnancy with preexisting medical conditions such as chronic hypertension and type 2 diabetes. While pregnant, they can develop pregnancy-associated hypertensive disorders, or gestational diabetes may be diagnosed. Obese women also have an increased incidence of a postterm pregnancy. All of these factors can increase the likelihood that labor will be induced. In addition to an increased risk for cesarean birth in general, obese women are also more likely to require emergency cesarean birth. During the postpartum period they are at risk for thromboembolism and wound disruption and infection after cesarean birth (Picklesimer & Dorman, 2013). As the woman's BMI increases, so does the risk for developing these complications (Halloran, Cheng, Wall, et al., 2012).

CARE MANAGEMENT

Nursing care of obese women during labor and birth is challenging for a number of reasons. Sometimes standard furniture such as beds, chairs, and operating tables is simply not large enough to accommodate the woman's size. Extra-large furniture may not fit through a standard doorway, so room renovation can be necessary. Some hospitals have created rooms specifically designed to accommodate obese clients (Fig. 32-5). Continuous external FHR and contraction monitoring can be extremely difficult if not impossible to perform. Special equipment, such as extra-large blood pressure cuffs, is necessary to properly assess the woman's condition.

Even routine procedures require more time and effort to accomplish when a woman is obese. This can slow essential

FIG 32-5 Room specifically designed to accommodate obese pregnant clients. Note lift attached to ceiling for use in transferring women from the bed to chairs or stretchers. (Courtesy Dee Lowdermilk, Chapel Hill, NC).

interventions and increase risks to the mother and fetus, such as when an emergency cesarean birth is needed. Establishing IV access, for example, can require multiple attempts, sometimes by multiple people. Mobility is often a problem. Moving the woman from a labor room to the operating room and transferring her from a bed to the operating table can require the assistance of additional personnel or special equipment, especially if regional anesthesia is already in effect. If it is not, surgery can be further delayed by anesthetic complications, such as difficulty establishing an epidural or spinal block or accomplishing endotracheal intubation.

Postoperatively, obese women are at increased risk for thromboembolic complications. In the immediate recovery period, use of thromboembolic stockings (TED hose) and sequential compression device (SCD) boots helps to decrease the risk of thrombus formation. Some women also may be given heparin prophylactically for clot prevention (Simpson & O'Brien-Abel, 2014). In the postpartum period women should also be encouraged to get out of bed and begin ambulating as soon as possible.

Keeping the incision clean and dry to prevent wound infection and promote healing is another postoperative challenge. Many obese women have a pannus (large roll of abdominal fat) that overlies a lower abdominal transverse skin incision made just above the pubic area. The pannus causes the area to remain moist, which encourages infection. Women should be taught to wash the incision with soap and water several times a day, drying the area well afterward. Using a handheld hair dryer on a low setting works well. Sutures or staples used to close the skin incision are generally left in place longer than usual to avoid possible wound disruption when they are removed. Sometimes the skin and subcutaneous layers of the incision are left open to heal by secondary intention to avoid possible dehiscence. If this course of action is chosen, the woman and other family members are taught to perform dressing changes and wound care.

OBSTETRIC PROCEDURES

Version

Version is the turning of the fetus from one presentation to another. It may be performed externally or internally by the health care provider.

External Cephalic Version

External cephalic version (ECV) is used in an attempt to turn the fetus from a breech or shoulder presentation to a vertex presentation for birth. It may be attempted in a labor and birth setting late in gestation. ECV is attempted by the exertion of gentle, constant pressure on the abdomen (Fig. 32-6). Before ECV is attempted, ultrasound scanning is done to:

- Determine the fetal position
- Locate the umbilical cord
- Rule out placenta previa
- Evaluate the adequacy of the maternal pelvis
- Assess the amount of amniotic fluid, the gestational age, and the presence of any anomalies

An NST is performed to confirm fetal well-being, or the FHR and pattern are monitored for a period of time (i.e., 10 to 20 minutes). Informed consent is obtained. A tocolytic agent such as terbutaline often is given to relax the uterus and facilitate the maneuver. **Contraindications to ECV include** (Thorp & Laughon, 2014):

- Uterine anomalies
- Third-trimester bleeding
- Multiple gestation
- Oligohydramnios
- Evidence of uteroplacental insufficiency
- A nuchal cord (identified by ultrasound)
- Previous cesarean birth or other significant uterine surgery
- Obvious CPD

ECV is most successful in a multiparous woman who has a normal amount of amniotic fluid and whose fetus is not yet engaged in the pelvis (Rosman, Guijt, Vlemmix, et al., 2013). The procedure should be performed in a hospital equipped to provide emergency surgery because 1% to 2% of women who have ECV develop placental abruption or umbilical cord compression requiring immediate cesarean birth (Thorp & Laughon, 2014).

During an attempted ECV the nurse continuously monitors the FHR and pattern, especially for bradycardia and variable decelerations; checks the maternal vital signs; and assesses the woman's level of comfort because the procedure can be painful. After the procedure is completed, the nurse continues to monitor maternal vital signs and uterine activity and assess for vaginal bleeding until the woman's condition is determined to be stable. FHR and pattern monitoring should continue for at least 1 hour. Women who are Rh negative should receive Rh immune globulin because the manipulation can cause fetomaternal bleeding (Thorp & Laughon).

Internal Version

With internal version the fetus is turned by the health care provider, who inserts a hand into the uterus and changes the presentation to cephalic (head) or podalic (foot). Internal version is only rarely used, most often in twin gestations to deliver the

FIG 32-6 External version of fetus from breech to vertex presentation. This must be achieved without force. **A**, Breech is pushed up out of pelvic inlet while head is pulled toward inlet. **B**, Head is pushed toward inlet while breech is pulled upward.

second fetus. The safety of this procedure has not been documented; maternal and fetal injury is possible. Cesarean birth is the usual method for managing malpresentation in multifetal pregnancies. The nurse's role is to monitor the status of the fetus and to provide support to the woman.

Induction of Labor

Induction of labor is the chemical or mechanical initiation of uterine contractions before their spontaneous onset for the purpose of bringing about birth. Labor may be induced either electively or for indicated reasons. Induction of labor is one of the most commonly performed obstetric procedures in the United States. Approximately 24% of term births (infants born between 37 and 41 weeks of gestation) result from labors that were induced (Hill & Harvey, 2013). It is likely that the rate of elective inductions is increasing more rapidly than the rate of indicated inductions. Additionally, there is concern that elective inductions may increase the risk of cesarean birth, especially among primigravid women and particularly those older than age 35 (Martin, Hamilton, Sutton, et al., 2012; Thorp & Laughon, 2014; Wing & Farinelli, 2012).

Induction of labor is indicated if continuing the pregnancy could be dangerous for either the woman or the fetus, and if no contraindications exist to artificial rupture of the membranes (amniotomy) or augmenting uterine contractions with oxytocin. Prior to labor induction, gestational age should be determined and any potential risks to the maternal-fetal unit evaluated. Women must be fully counseled regarding risks, benefits, and alternatives of labor stimulation methods as part of the process for informed consent (ACOG, 2013a; Thorp & Laughon, 2014). Box 32-7 lists indications and contraindications for labor induction.

Elective Induction of Labor

An elective induction is one in which labor is initiated without a medical indication. Methods to ripen the cervix (e.g., application of prostaglandins or intracervical insertion of a balloon catheter) enhance the likelihood of successful induction. Many elective inductions are purely for the convenience of the woman or her primary health care provider. At times, however, labor may be electively induced to allay maternal fears and anxieties associated with prior perinatal losses or to ensure that experienced multispecialty personnel are available to handle anticipated maternal or neonatal complications immediately

BOX 32-7 Indications and Contraindications for Labor Induction

Maternal Indications

- Hypertensive complications of pregnancy: gestational hypertension, preeclampsia, eclampsia
- Fetal death
- Chorioamnionitis

Fetal Indications

Any condition in which a variety of fetal tests demonstrate significant fetal jeopardy in any of the following situations:

- Diabetes
- Postterm pregnancy, especially when oligohydramnios is present
- Hypertensive complications of pregnancy
- Intrauterine growth restriction
- Isoimmunization
- Chorioamnionitis
- Premature rupture of membranes with established fetal maturity

Contraindications

- Acute, severe fetal distress
- Shoulder presentation (transverse lie)
- Floating fetal presenting part
- Uncontrolled hemorrhage
- Placenta previa
- Previous uterine incision that prohibits a trial of labor

Relative Contraindications

- Grand multiparity (five or more pregnancies that ended after 20 weeks of gestation)
- Multiple gestation
- Suspected cephalopelvic disproportion (CPD)
- Breech presentations
- Inability to adequately monitor the FHR throughout labor

Data from Thorp, J.M., & Laughon, S.K. (2014). Clinical aspects of normal and abnormal labor. In R.K. Creasy, R. Resnik, J.D. Iams, et al. (Eds.), *Creasy and Resnik's maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders.

following birth (Wing & Farinelli, 2012; Yount & Lassiter, 2013).

The major risks associated with elective labor induction at term are increased rates of cesarean birth, neonatal morbidity, and cost (Wing & Farinelli, 2012). To prevent iatrogenic prematurity, elective induction of labor should not be initiated until the woman reaches 39 completed weeks of gestation (ACOG, 2013a; Swamy, 2012). The American College of Obstetricians and Gynecologists (ACOG) and the American Academy of Pediatrics (AAP) have for many years recommended that elective induction of labor not be initiated until the woman reaches 39 weeks or more of gestation. The National Quality Forum and The Joint Commission have developed perinatal quality measures to monitor appropriate gestational age for elective birth (Simpson, 2011). The March of Dimes and the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) have created informational campaigns to educate pregnant women and their families about the dangers of early-term births (visit their websites at www.gothefull40.com and www.marchofdimes.com/pregnancy/getready_atleast39weeks.html) (Craighead, 2012). Birth data from the United States

TABLE 32-3 Bishop Score

	SCORE			
	0	1	2	3
Dilation (cm)	0	1-2	3-4	≥5
Effacement (%)	0-30	40-50	60-70	≥80
Station (cm)	-3	-2	-1, 0	+1, +2
Cervical consistency	Firm	Medium	Soft	Soft
Cervical position	Posterior	Midposition	Anterior	Anterior

Modified from Bishop, E.H. (1964). Pelvic scoring for elective induction. *Obstetrics and Gynecology*, 24(2), 266-268.

for 2011, the most recent data available, indicate that births at 37 to 38 weeks of gestation have declined, whereas births at 39 weeks of gestation or more are increasing (Martin et al., 2013b).

Chemical, mechanical, physical, and alternative methods are used to ripen the cervix and induce labor. IV oxytocin (Pitocin) and amniotomy are the most common methods used in the United States. Success rates for induction of labor are higher when the condition of the cervix is favorable, or inducible. Cervical ripeness is the most important predictor of successful induction. A rating system such as the **Bishop score** (Table 32-3) can be used to evaluate inducibility. For example, a score of 8 or more on this 13-point scale indicates that the cervix is soft, anterior, 50% or more effaced, and dilated 2 cm or more and that the presenting part is engaged. When the Bishop score totals 8 or more, induction of labor is usually successful (ACOG, 2013a; Gilbert, 2011; Swamy, 2012). The Bishop score should be documented prior to the use of methods to ripen the cervix or induce labor.

Cervical Ripening Methods

Chemical Agents. Preparations of prostaglandins E₁ (PGE₁) and E₂ (PGE₂) have been shown to be effective when used before induction to “ripen” (soften and thin) the cervix (see Medication Guides: Prostaglandin E₁ [PGE₁]: Misoprostol [Cytotec] and Prostaglandin E₂ [PGE₂]: Dinoprostone [Cervidil Insert; Prepidil Gel]) (Hill & Harvey, 2013). In some cases, women spontaneously begin laboring after the administration of prostaglandin, thereby eliminating the need to administer oxytocin to induce labor. Additional advantages of prostaglandin use for cervical ripening include decreased oxytocin induction time and a decrease in the amount of oxytocin required for successful induction (Gilbert, 2011). PGE₁, although much less expensive and more effective than PGE₂ for inducing labor and birth, is associated with a higher risk for uterine tachysystole with abnormal fetal heart rate and pattern changes and passage of meconium into the amniotic fluid. Most of these adverse outcomes are associated with higher dose protocols (ACOG, 2013a; Wing & Farinelli, 2012). Although the drug's manufacturer has acknowledged for several years that PGE₁ is effective for cervical ripening and labor induction, it has not yet been approved by the FDA for these uses (Thorp & Laughon, 2014; Yount & Lassiter, 2013). PGE₂ in the form of a vaginal insert (dinoprostone [Cervidil]), although more expensive than PGE₁, has the major advantage of easy removal should adverse reactions, including uterine tachysystole, occur (Yount & Lassiter).

MEDICATION GUIDE

Prostaglandin E₁ (PGE₁): Misoprostol (Cytotec)

Action

PGE₁ ripens the cervix, making it softer and causing it to begin to dilate and efface; it stimulates uterine contractions.

Indications

- PGE₁ is used for preinduction cervical ripening (ripen cervix before oxytocin induction of labor when the Bishop score is 4 or less) and to induce labor or abortion (abortifacient agent); it has not yet been approved by the FDA for cervical ripening or labor induction (i.e., this is an unlabeled use for obstetrics).
- It should not be used if the woman has a history of previous cesarean birth or other major uterine surgery.

Dosage and Administration

- Misoprostol is available either as a 100- or a 200-mcg tablet. Therefore, tablets must be broken to prepare the correct dose. This preparation should take place in the pharmacy to ensure accurate doses.
- Recommended initial dose is 25 mcg. Insert intravaginally into the posterior vaginal fornix using the tips of index and middle fingers without the use of a lubricant. Repeat every 4 hours or until an effective contraction pattern is established (three or more uterine contractions in 10 minutes), the cervix ripens (Bishop score of 8 or greater), or significant adverse effects occur.

Adverse Effects

Higher doses (e.g., 50 mcg every 6 hours) are more likely to result in adverse reactions such as nausea and vomiting, diarrhea, fever, uterine tachysystole with or without an abnormal FHR and pattern, or fetal passage of meconium. The risk for adverse reactions

is reduced with lower dosages and longer intervals between doses.

Nursing Considerations

- Explain the procedure to the woman and her family; ensure that an informed consent has been obtained as per agency policy.
- Assess the woman and fetus before each insertion and during treatment following agency protocol for frequency. Assess maternal vital signs and health status, FHR and pattern, and status of pregnancy, including indications for cervical ripening or induction of labor, signs of labor or impending labor, and the Bishop score. Recognize that an abnormal FHR and pattern; maternal fever, infection, vaginal bleeding, or hypersensitivity; and regular, progressive uterine contractions contraindicate the use of misoprostol.
- Avoid giving aluminum hydroxide and magnesium-containing antacids along with misoprostol.
- Use with caution in women with renal failure because the medication is eliminated through the kidneys.
- Have the woman void before insertion.
- Assist the woman to maintain a supine position with a lateral tilt or a side-lying position for 30 to 40 minutes after insertion.
- Prepare to (1) swab the vagina to remove unabsorbed medication using a saline-soaked gauze wrapped around fingers or (2) administer terbutaline 0.25 mg subcutaneously if significant adverse effects occur.
- Initiate oxytocin for induction of labor no sooner than 4 hours after the last dose of misoprostol was administered, following agency protocol, if ripening has occurred and labor has not begun.
- Document all assessment findings and administration procedures.

FDA, U.S. Food and Drug Administration; FHR, fetal heart rate.

Data from Hill, W., & Harvey, C. (2013). Induction of labor. In N. Troiano, C. Harvey, & B. Chez (Eds.), *AWHONN's high risk and critical care obstetrics* (3rd ed.). Philadelphia: Wolters Kluwer/Lippincott Williams & Wilkins; Moleti, C. (2009). Trends and controversies in labor induction, *MCN: The American Journal of Maternal/Child Nursing*, 34(1), 40-47; Thorp, J.M., & Laughon, S.K. (2014). Clinical aspects of normal and abnormal labor. In R.K. Creasy, R. Resnik, J.D. Lams, et al. (Eds.), *Creasy and Resnik's maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders.

Mechanical and Physical Methods. Mechanical dilators ripen the cervix by stimulating the release of endogenous prostaglandins. Balloon catheters (e.g., Foley catheter) can be inserted through the intracervical canal to ripen and dilate the cervix. The catheter balloon is inflated above the internal cervical os with 30 to 50 ml of sterile water. This process results in pressure and stretching of the lower uterine segment and the cervix, as well as the release of endogenous prostaglandins. It is especially helpful for women who cannot receive exogenous prostaglandins for cervical ripening. The balloon usually falls out within 8 to 12 hours, when cervical dilation reaches approximately 3 cm. Evidence supports the insertion of a balloon catheter as a cervical ripening method because of its low cost compared with prostaglandins, stability at room temperature, and reduced risk for uterine tachysystole with or without fetal heart rate changes (ACOG, 2013a; Hill & Harvey, 2013; Yount & Lassiter, 2013).

Hydroscopic dilators (substances that absorb fluid from surrounding tissues and then enlarge) also can be used for cervical ripening. Laminaria tents (natural cervical dilators made from desiccated seaweed) and synthetic dilators containing magnesium sulfate (Lamicel) are inserted into the endocervix without rupturing the membranes. As they absorb fluid, they expand and cause cervical dilation and the release of endogenous

prostaglandins. These dilators are left in place for 6 to 12 hours before being removed to assess cervical dilation. Fresh dilators are inserted if further cervical dilation is necessary. Synthetic dilators swell faster than natural dilators and become larger with less discomfort. When compared with prostaglandins, these mechanical methods achieved a lower rate of birth within 24 hours, but caused no change in the cesarean birth rate. Additionally, they were less likely to cause uterine tachysystole with or without changes in the fetal heart rate (ACOG, 2013a; Thorp & Laughon, 2014).

Hydroscopic dilators compare favorably with prostaglandins in their effectiveness in ripening the cervix but are associated with increased discomfort at insertion and during expansion and a higher incidence of postpartum maternal and newborn infections. They are a reliable alternative when prostaglandins are contraindicated or are unavailable.

Nursing responsibilities for women who have dilators inserted include (Gilbert, 2011):

- Documenting the number of dilators and sponges inserted during the procedure, as well as the number removed
- Assessing for urinary retention, rupture of membranes, uterine tenderness or pain, contractions, vaginal bleeding, infection, and fetal distress

MEDICATION GUIDE

Prostaglandin E₂ (PGE₂): Dinoprostone (Cervidil Insert; Prepidil Gel)

Action

PGE₂ ripens the cervix, making it softer and causing it to dilate and efface; it stimulates uterine contractions. Dinoprostone is the only FDA-approved medication for cervical ripening or labor induction.

Indications

- PGE₂ is used for preinduction cervical ripening (ripen the cervix before oxytocin induction of labor when the Bishop score is 4 or less) and for induction of labor or abortion (abortifacient agent).
- It is not recommended for use if the woman has a history of previous cesarean birth or other major uterine surgery.

Dosage and Route

Cervidil Insert

Dosage is 10 mg of dinoprostone designed to be gradually released (approximately 0.3 mg/hr) over 12 hours. Insert is placed transvaginally into the posterior fornix of the vagina. The insert is removed after 12 hours or at the onset of active labor or earlier if tachysystole or abnormal FHR and patterns occur.

Prepidil Gel

Dosage is 0.5 mg of dinoprostone in a 2.5-ml syringe. Gel is administered through a catheter attached to the syringe into the cervical canal just below the internal cervical os. Dose may be repeated every 6 hours as needed for cervical ripening up to a maximum cumulative dose of 1.5 mg (3 doses) in a 24-hour period.

Adverse Effects

Potential adverse effects include headache, nausea and vomiting, diarrhea, fever, hypotension, uterine tachysystole with or without an abnormal FHR and pattern, or fetal passage of meconium.

Nursing Considerations

- Explain the procedure to the woman and her family. Ensure that an informed consent has been obtained as per agency policy.

- Assess the woman and fetus before each insertion and during treatment following agency protocol for frequency. Assess maternal vital signs and health status, FHR and pattern, and status of pregnancy, including indications for cervical ripening or induction of labor, signs of labor or impending labor, and the Bishop score. Recognize that an abnormal FHR and pattern; maternal fever, infection, vaginal bleeding, or hypersensitivity; and regular, progressive uterine contractions contraindicate the use of dinoprostone.
- Avoid use in women with asthma, glaucoma, and hypotension or hypertension.
- Use with caution if the woman has cardiac, renal, or hepatic disease; anemia; jaundice; diabetes; epilepsy; or genitourinary (GU) infections.
- Bring the gel to room temperature just before administration. Do not force the warming process by using a warm-water bath or other source of external heat such as microwave because heat may cause inactivation.
- Keep the insert frozen until just before insertion. No warming is needed.
- Have the woman void before insertion.
- Assist the woman to maintain a supine position with a lateral tilt or a side-lying position for at least 30 minutes after insertion of the gel or for 2 hours after placement of the insert.
- Allow the woman to ambulate after the recommended period of bed rest and observation.
- Prepare to pull the string to remove the insert and to administer terbutaline 0.25 mg subcutaneously if significant adverse effects occur. There is no effective way to remove the gel from the vagina if uterine tachysystole or abnormal FHR and patterns occur.
- Delay the initiation of oxytocin for induction of labor for 6 to 12 hours after the last instillation of the gel or for 30 to 60 minutes after removal of the insert, or follow agency protocol for induction if ripening has occurred but labor has not begun.
- Document all assessment findings and administration procedures.

FDA, U.S. Food and Drug Administration; FHR, fetal heart rate.

Data from Hill, W., & Harvey, C. (2013). Induction of labor. In N. Troiano, C. Harvey, & B. Chez (Eds.), *AWHONN's high risk and critical care obstetrics* (3rd ed.). Philadelphia: Wolters Kluwer/Lippincott Williams & Wilkins; Moleti, C. (2009). Trends and controversies in labor induction, *MCN: The American Journal of Maternal/Child Nursing*, 34(1), 40-47.

Amniotic membrane stripping or sweeping is a method of inducing labor through the release of prostaglandins and oxytocin. The procedure involves separation of the membrane from the wall of the cervix and lower uterine segment by inserting a finger into the internal cervical os and rotating it 360 degrees. Membrane stripping seems to work best when the woman is a primigravida at term with an unripe cervix and with the vertex well applied to the cervix. In some studies it has been associated with shorter pregnancies and a decreased likelihood of progressing past 42 weeks of gestation. The procedure is uncomfortable and increases the risk for infection, rupture of membranes, bleeding, and precipitous labor and birth (Wing & Farinelli, 2012).

Routine membrane stripping is not recommended because there is no evidence that this practice improves maternal or fetal outcome. However, weekly membrane stripping at term shortens the time interval to the onset of spontaneous labor and may decrease the need for labor induction using chemical

or mechanical methods. Therefore, membrane stripping may be offered after 39 weeks of gestation to women who wish to hasten the onset of spontaneous labor (Wing & Farinelli, 2012).

Physical methods such as sexual intercourse (prostaglandins in the semen and stimulation of contractions with orgasm), nipple stimulation (release of endogenous oxytocin from the pituitary gland), and walking (gravity applies pressure to the cervix, which stimulates the secretion of endogenous oxytocin) may be used by women to “self-induce” labor in an effort to “get it over with.” Breast (nipple) stimulation has been shown to increase the number of women who go into labor within 72 hours, but safety issues associated with this method have not been fully evaluated. Although orgasm does stimulate uterine contractions, there is inadequate evidence to support the belief that sexual intercourse enhances cervical ripening (Thorp & Laughon, 2014). Ambulation is an effective measure to augment labor (Yount & Lassiter, 2013).

Alternative Methods. Various alternative methods have been used by women to stimulate cervical ripening and the onset of labor. For example, blue cohosh and castor oil can be used for their labor stimulation effects, and black cohosh and evening primrose oil can ripen the cervix. Nurses must be knowledgeable about these preparations and ask about their use when assessing women during prenatal visits and on admission during labor. Women may accidentally take too much of the preparation or use it incorrectly. Also these preparations may potentiate the effect of pharmacologic methods to stimulate cervical ripening and uterine contractions, thereby increasing the potential for tachysystole and precipitous labor and birth (Gilbert, 2011; Yount & Lassiter, 2013).

Acupuncture has been used effectively to induce labor and has been found, in several studies, to reduce the duration of labor, the use of oxytocin, and the rate of cesarean birth. Specific points have been identified to stimulate uterine contractions or to facilitate cervical dilation. More than one treatment may be required to establish labor (Gilbert, 2011).

Amniotomy. Amniotomy (i.e., artificial rupture of membranes [AROM]) can be used to induce labor when the condition of the cervix is favorable (ripe) or to augment labor if progress begins to slow. Labor usually begins within 12 hours of AROM. Amniotomy can decrease the duration of labor by up to 2 hours, even without oxytocin administration. However, if amniotomy does not stimulate labor, the resulting prolonged rupture may lead to chorioamnionitis. Variable FHR deceleration patterns can occur as a result of cord compression associated with umbilical cord prolapse or a decreased amount of amniotic fluid. Once an amniotomy is performed, the woman is committed to labor with an unknown outcome for how and when she will give birth. For this reason amniotomy often is used in combination with oxytocin induction.

Before the procedure the woman should be told what to expect. She also should be assured that the actual rupture of the membranes is painless for her and the fetus, although she may experience some discomfort when the Amnihook or other sharp instrument is inserted through the vagina and cervix (Box 32-8). The presenting part of the fetus should be engaged and well applied to the cervix prior to the procedure to prevent cord prolapse (Wing & Farinelli, 2012). The woman should also be free of active infection of the genital tract (e.g., herpes) and should be human immunodeficiency virus (HIV) negative. After rupture the amniotic fluid is allowed to drain slowly. The color, odor, and consistency of the fluid are assessed (i.e., for the presence or absence of meconium or blood). The time of rupture is recorded.

⚡ SAFETY ALERT

The FHR is assessed before and immediately after the amniotomy to detect any changes. Transient tachycardia is common. Bradycardia and variable decelerations can indicate cord compression or prolapse.

The woman's temperature should be checked at least every 2 hours after rupture of membranes, more frequently if signs or symptoms of infection are noted. If her temperature is 38°

BOX 32-8 Procedure: Assisting with Amniotomy

Procedure

- Explain to the woman what will be done.
- Assess the fetal heart rate (FHR) and pattern before the procedure begins to obtain a baseline reading.
- Place several underpads under the woman's buttocks to absorb the fluid.
- Position the woman on a padded bedpan, fracture pan, or rolled-up towel to elevate her hips.
- Assist the health care provider who is performing the procedure by providing sterile gloves and lubricant for the vaginal examination.
- Unwrap the sterile package containing an Amnihook or Allis clamp and pass the instrument to the primary health care provider, who inserts it alongside the fingers and then hooks and tears the membranes.
- Reassess the FHR and pattern.
- Assess the color, consistency, and odor of the fluid.
- Assess the woman's temperature every 2 hours or per protocol.
- Evaluate the woman for signs and symptoms of infection.

Documentation

Record the following:

- FHR and pattern before and after the procedure
- Time of rupture
- Color, odor, and consistency of the fluid
- Maternal status (how well procedure was tolerated)

C (100.4° F) or higher, the nurse notifies the primary health care provider. The nurse assesses for other signs and symptoms of infection, such as maternal chills, uterine tenderness on palpation, foul-smelling vaginal drainage, and fetal tachycardia. Comfort measures, such as frequently changing the woman's underpads and perineal cleansing, are implemented.

LEGAL TIP: Performing Amniotomy

Performing amniotomy is outside the scope of practice of nurses. In some locations, however, nurses have been asked to perform this procedure. A policy that is consistent with professional standards of care and clearly explains the nurse's role in amniotomy should be in place in all labor and birth areas.

Oxytocin

Oxytocin is a hormone normally produced by the posterior pituitary gland. It stimulates uterine contractions and aids in milk let-down. Synthetic oxytocin (Pitocin) may be used either to induce labor or to augment labor that is progressing slowly because of inadequate uterine contractions. Oxytocin is used in the majority of all births in the United States. It is also the drug most commonly associated with adverse events during labor and birth. The most common errors involving oxytocin administration during labor are dose related.

⚡ SAFETY ALERT

Oxytocin is included on the list of high-alert medications designated by the Institute for Safe Medication Practices because it has the potential to cause significant harm when used inappropriately (Institute for Safe Medication Practices [ISMP], 2012).

Oxytocin can present hazards to the mother and fetus. Maternal hazards include placental abruption, uterine rupture, unnecessary cesarean birth due to abnormal FHR and patterns, postpartum hemorrhage, and infection. When placental perfusion is diminished by contractions that are too frequent or prolonged, the fetus can experience hypoxemia and acidemia, which eventually result in late decelerations and minimal or absent baseline variability. The goal of oxytocin use is to produce contractions of normal intensity, duration, and frequency using the lowest dose possible (Simpson, 2011).

The primary health care provider writes the order for the induction or augmentation of labor with oxytocin. The nurse implements the order by initiating the primary IV infusion and administering the oxytocin solution through a secondary line. The nurse's actions related to the assessment and care of a woman whose labor is being induced are guided by hospital protocol and professional standards (Fig. 32-7 and the Medication Guide: Oxytocin [Pitocin]).

The recommended protocol for administering oxytocin is to begin with a starting dose of 1 milliunit/min and to increase by 1 to 2 milliunits/min no more frequently than every 30

MEDICATION GUIDE

Oxytocin (Pitocin)

Action

Oxytocin is a hormone produced in the posterior pituitary gland that stimulates uterine contractions and aids in milk let-down. Pitocin is a synthetic form of this hormone.

Indications

Oxytocin is used primarily for labor induction and augmentation; it is also used to control postpartum bleeding.

Dosage

- The IV solution containing oxytocin should be mixed in a standard concentration. Concentrations often used are 10 units in 1000 ml of fluid, 20 units in 1000 ml of fluid, or 30 units in 500 ml of fluid.
- Oxytocin is administered intravenously through a secondary line connected to the main line at the proximal port (connection closest to the IV insertion site). Oxytocin is always administered by infusion pump.
- Begin oxytocin administration at 1 milliunit/minute. Increase the rate by 1 to 2 milliunits/minute, no more frequently than every 30 to 60 minutes based on the response of the woman and fetus and the progress of labor.
- The goal of oxytocin administration is to produce acceptable uterine contractions as evidenced by:
 - Consistent achievement of 200 to 220 MVUs or
 - A consistent pattern of one contraction every 2 to 3 minutes, lasting 80 to 90 seconds, and strong to palpation

Adverse Effects

- Possible maternal adverse effects include uterine tachysystole, placental abruption, uterine rupture, unplanned cesarean birth caused by abnormal FHR and patterns, postpartum hemorrhage, infection, and death from water intoxication (e.g., severe hyponatremia).
- Possible fetal adverse effects include hypoxemia and acidosis, eventually resulting in abnormal FHR and patterns.

Nursing Considerations

- Client and partner teaching and support:
 - Reasons for use of oxytocin (e.g., start or improve labor)
 - Reactions to expect concerning the nature of contractions: the intensity of the contraction increases more rapidly, holds

the peak longer, and ends more quickly; contractions come regularly and more often

- Monitoring to anticipate
- Continue to keep woman and her partner informed regarding progress.
- Remember that women vary greatly in their response to oxytocin; some require only very small amounts of medication to produce adequate contractions, whereas others need larger doses.
- Assessment:
 - Assess fetal status using electronic fetal monitoring; evaluate tracing every 15 minutes and with every change in dose during the first stage of labor and every 5 minutes during the active pushing phase of the second stage of labor.
 - Monitor the contraction pattern and uterine resting tone every 15 minutes and with every change in dose during the first stage of labor and every 5 minutes during the second stage of labor.
 - Monitor blood pressure, pulse, and respirations every 30 to 60 minutes and with every change in dose.
 - Assess intake and output; limit IV intake to 1000 ml in 8 hours; urine output should be 120 ml or more every 4 hours.
 - Perform a vaginal examination as indicated.
 - Monitor for side effects, including nausea, vomiting, headache, and hypotension.
 - Observe emotional responses of the woman and her partner.
- Use a standard definition for uterine tachysystole that does not include an abnormal FHR and pattern or the woman's perception of pain (see Emergency: Uterine Tachysystole with Oxytocin).
- The rate of oxytocin infusion should be continually titrated to the lowest dose that achieves acceptable labor progress. Usually the oxytocin dose can be decreased or discontinued after rupture of membranes and in the active phase of first-stage labor.
- Documentation:
 - The time the oxytocin infusion is begun, and each time the infusion is increased, decreased, or discontinued
 - Assessment data as described above
 - Interventions for uterine tachysystole and abnormal FHR and patterns and the response to the interventions
 - Notification of the primary health care provider and that person's response

minutes (Simpson, 2011). This recommendation is based on research findings related to the pharmacokinetics of oxytocin. The uterus responds to oxytocin within 3 to 5 minutes of IV administration. The half-life of oxytocin (the time required to metabolize and eliminate half the dose) is approximately 10 to 12 minutes. Approximately 40 minutes is required to reach a steady state of oxytocin (the point in time when the rate of oxytocin administered intravenously equals the rate of oxytocin elimination) and for the full effect of a dosage increment to be reflected in more intense, frequent, and longer contractions (Hill & Harvey, 2013; Simpson) (see Medication Guide: Oxytocin [Pitocin] and Fig. 32-7). Low-dose (physiologic) protocols such as the one described result in decreased risk for oxytocin-induced tachysystole and unnecessary cesarean birth because of abnormal FHR or patterns (Simpson). High-dose protocols, in which the initial dose of oxytocin is larger and the dosage is increased more rapidly, have been found to result in shorter labors, fewer forceps-assisted births, and fewer cesarean births because of dystocia. However, high-dose protocols have been associated with an increased incidence of uterine tachysystole and more cesarean births related to fetal distress (Kunz, Loftus, & Nichols, 2013; Wing & Farinelli, 2012). Some practitioners administer oxytocin in 10-minute pulsed infusions rather than as a continuous infusion. This method, which is more like endogenous secretion of oxytocin than the other approaches, is reported to be effective for labor induction but requires significantly less oxytocin use (Simpson; Wing & Farinelli).

Nursing Interventions. An evidence-based protocol for preparing and administering oxytocin should be established by the obstetric department (physicians, nurses) in each institution. Other safety measures recommended for use of this high-alert drug are using a standard concentration of oxytocin and a standard definition of uterine tachysystole that does not include an abnormal FHR or pattern or the woman's perception of pain. Additionally, standardized treatment of oxytocin-induced uterine tachysystole is recommended (Kunz et al., 2013; Simpson, 2011; Swamy, 2012) (see Emergency box: Uterine Tachysystole with Oxytocin [Pitocin] Infusion).

EMERGENCY

Uterine Tachysystole with Oxytocin (Pitocin) Infusion

Signs

- More than five contractions in 10 minutes *or*
- A series of single contractions lasting >2 minutes *or*
- Contractions of normal duration occurring within 1 minute of each other

Interventions (with Normal [Category I] FHR Tracing)

- Reposition or maintain woman in side-lying position (either side).
- Administer IV fluid bolus with 500 ml lactated Ringer's solution.
- If uterine activity has not returned to normal after 10 minutes, decrease the oxytocin dose by at least half. If uterine activity has not returned to normal after another 10 minutes, discontinue the oxytocin infusion until fewer than five contractions occur in 10 minutes.

Interventions (with Indeterminate [Category II] or Abnormal [Category III] FHR Tracing)

- Discontinue oxytocin infusion immediately.
- Reposition or maintain woman in side-lying position (either side).
- Administer IV fluid bolus with 500 ml lactated Ringer's solution.
- Consider giving oxygen at 10 L/minute if the above interventions do not resolve the indeterminate or abnormal (category II or category III) FHR tracing.
- If no response, consider giving 0.25 mg terbutaline subcutaneously according to unit protocol or standing orders.
- Notify primary health care provider of actions taken and maternal and fetal response.

Resumption of Oxytocin After Resolution of Tachysystole

- If the oxytocin infusion has been discontinued for less than 20 to 30 minutes, resume at no more than one half the rate that caused the tachysystole.
- If the oxytocin infusion has been discontinued for more than 30 to 40 minutes, resume at the initial starting dose.

FHR, Fetal heart rate; IV, intravenous.

Data from Simpson, K. (2011). Clinicians' guide to the use of oxytocin for labor induction and augmentation. *Journal of Midwifery & Women's Health*, 56(3), 214-221.

The definition of excessive uterine contractions needs to be standardized. The Eunice Kennedy Shriver National Institute of Child Health and Human Development, along with the ACOG and the Society for Maternal-Fetal Medicine, sponsored a workshop in April 2008 to review definitions, interpretation, and research recommendations for intrapartum fetal monitoring. Workshop participants also recommended standardizing definitions regarding uterine contractions for use in clinical practice. This group defined **uterine tachysystole** as more than five contractions in 10 minutes, averaged over a 30-minute window. The term tachysystole applies to both spontaneous and stimulated labor. Participants also recommended that use of the terms *hyperstimulation* and *hyperactivity* be abandoned because they are not defined (Macones, Hankins, Spong, et al., 2008).

Augmentation of Labor

Augmentation of labor is the stimulation of uterine contractions after labor has started spontaneously and progress is

unsatisfactory. Augmentation is usually implemented to manage hypotonic uterine dysfunction, resulting in a slowing of the labor process (protracted active phase). Common augmentation methods include oxytocin infusion and amniotomy. Non-invasive methods such as emptying the bladder, ambulation and position changes, relaxation measures, nourishment and hydration, and hydrotherapy should be attempted before initiating invasive interventions. The administration procedure and nursing assessment and care measures for augmenting labor with oxytocin are similar to those used for induction of labor with oxytocin (see Medication Guide: Oxytocin [Pitocin]).

Some physicians advocate active management of labor, that is, augmentation of labor to establish efficient labor with the aggressive use of oxytocin so that the woman gives birth within 12 hours of admission to the labor unit. Advocates of active management believe that intervening early (as soon as a nulliparous woman is not dilating her cervix at least 1 cm/hr) with use of higher (pharmacologic) oxytocin doses administered at frequent increment intervals (e.g., a starting dose of 6 milliunits/min with increases of 6 milliunits/min every 15 minutes) shortens labor (Gilbert, 2011).

Additional components of the active management of labor include (1) strict criteria to diagnose that the woman is indeed in active labor with 100% cervical effacement, (2) amniotomy within 1 hour of admission of a woman in labor if spontaneous rupture of the membranes has not occurred, and (3) continuous presence of a personal nurse who provides one-on-one care for the woman while she is in labor. Many U.S. obstetricians emphasize using high-dose oxytocin protocols but do not implement all the other components of active management. At least one review of published studies on the effectiveness of active management of labor protocols concluded that the presence of a personal nurse who provides constant emotional and physical support is the only component associated with shorter labors and lower rates of cesarean birth (Gilbert, 2011).

Operative Vaginal Birth

Operative vaginal births are performed using either forceps or a vacuum extractor. The use of both devices continues to decline. In 2012, less than 4% of all births were accomplished using forceps or vacuum assistance (Martin et al., 2013a). Indications and prerequisites for the use of both instruments are similar. The decision to use forceps or vacuum is based on the experience and personal preference of the physician performing the procedure. There are several types of operative vaginal births (AAP & ACOG, 2012).

Forceps-Assisted Birth

A **forceps-assisted birth** is one in which an instrument with two curved blades is used to assist in the birth of the fetal head. The cephalic-like curve of the forceps commonly used is similar to the shape of the fetal head, with a pelvic curve to the blades conforming to the curve of the pelvic axis. The blades are joined by a pin, screw, or groove arrangement. These locks prevent the forceps from compressing the fetal skull (Fig. 32-8). There are several types of forceps-assisted births, defined primarily by the station and position of the fetal head in relationship to the maternal pelvis (Table 32-4) (AAP & ACOG, 2012).

FIG 32-8 Types of forceps. Piper forceps are used to assist delivery of the head in a breech birth.

TABLE 32-4 Definitions for Forceps- and Vacuum-Assisted Births

Outlet	Fetal scalp is visible on the perineum without manually separating the labia
Low	Fetal head is at least at the +2 station
Midpelvis	Fetal head is engaged (no higher than 0 station) but above the +2 station

Data from American Academy of Pediatrics (AAP) and American College of Obstetricians and Gynecologists (ACOG) (2012). *Guidelines for perinatal care* (7th ed.). Washington, DC: ACOG.

Maternal indications for forceps-assisted birth include a prolonged second stage of labor and the need to shorten the second stage of labor for maternal reasons (e.g., maternal exhaustion or maternal cardiopulmonary or cerebrovascular disease) (Nielsen & Galan, 2012). Fetal indications include birth of a fetus in distress or in certain abnormal presentations; arrest of rotation; or extraction of the head in a breech presentation. The use of forceps during birth has been decreasing, replaced by vacuum extraction or cesarean birth (Nielsen & Galan; Thorp & Laughon, 2014).

Certain conditions are required for a forceps-assisted birth to be successful. The woman's cervix must be fully dilated to prevent lacerations and hemorrhage. The bladder should be empty. The presenting part must be engaged—vertex presentation is desired. Membranes must be ruptured so that the position of the fetal head can be precisely determined and

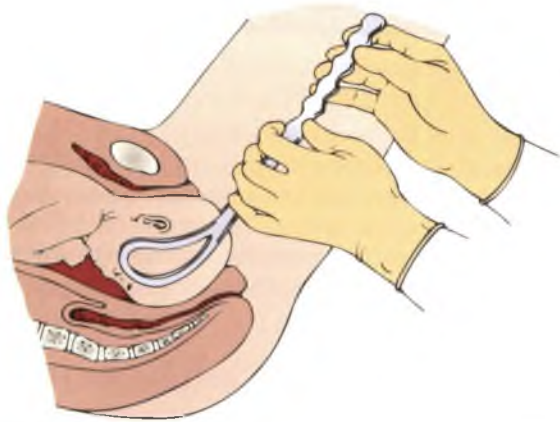

FIG 32-9 Outlet forceps-assisted extraction of the head.

the forceps can firmly grasp the head during birth (Fig. 32-9). In addition, the size of the maternal pelvis must be assessed as adequate for the estimated fetal head circumference and weight.

Medical Management. Both blades are positioned by the physician, and the handles are locked. Traction is usually applied during contractions. The mother may or may not be instructed to push during contractions, depending on physician preference. If a decrease in the fetal heart rate occurs, the forceps are removed and reapplied.

⚡ SAFETY ALERT

Because compression of the cord between the fetal head and the forceps will cause a decrease in FHR, the FHR is assessed, reported, and recorded before and after application of the forceps.

Nursing Interventions. When a forceps-assisted birth is deemed necessary, the nurse obtains the type of forceps requested by the physician. The nurse can explain to the mother that the forceps blades fit the same way two tablespoons fit around an egg, with the blades placed in front of the baby's ears.

After birth the mother should be assessed for vaginal or cervical lacerations, urinary retention, and hematoma formation in the pelvic soft tissues, which can result from blood vessel damage. The infant should be assessed for bruising or abrasions at the site of the blade applications, facial palsy resulting from pressure of the blades on the facial nerve, and subdural hematoma. Newborn and postpartum caregivers should be told that a forceps-assisted birth was performed.

Vacuum-Assisted Birth

Vacuum-assisted birth, or vacuum extraction, is a birth method involving the attachment of a vacuum cup to the fetal head, using negative pressure to assist in the birth of the head (Fig. 32-10, A). It is generally not used to assist birth before 34 weeks of gestation. Indications for its use are the same as those for outlet forceps. Prerequisites for use include a completely dilated cervix, ruptured membranes, engaged head, vertex presentation, and no suspicion of CPD (Cunningham et al., 2014). The types of vacuum-assisted births are defined the same as for forceps-assisted births—by the station and position of the fetal

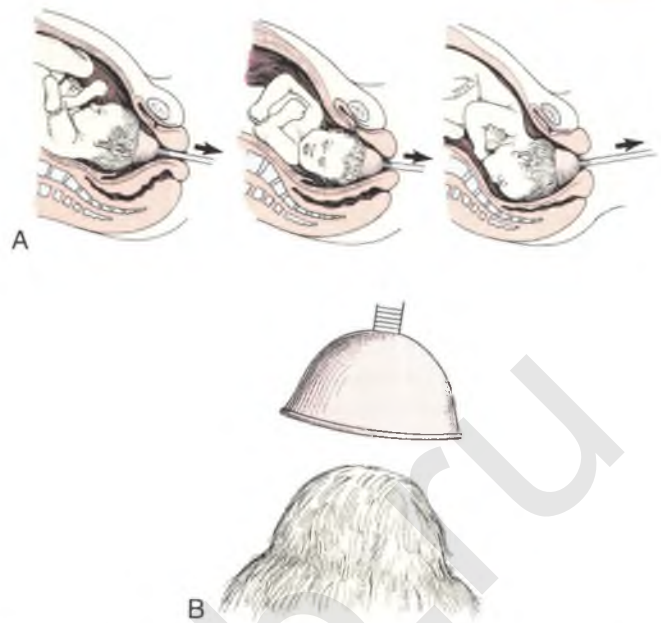

FIG 32-10 Use of vacuum extraction to rotate fetal head and assist with descent. A, Arrow indicates direction of traction on the vacuum cup. B, Caput succedaneum formed by the vacuum cup.

head in relation to the maternal pelvis (see Table 32-4) (AAP & ACOG, 2012). Advantages of vacuum-assisted compared with forceps-assisted birth are the ease with which the vacuum can be placed and the need for less anesthesia. Also it is far easier to teach and to learn the skills necessary to safely use the vacuum than to gain a similar level of skill with forceps (Thorp & Laughon, 2014).

Medical Management. The vacuum cup is applied to the fetal head by the physician. There are basically two types of vacuum devices. One is a self-contained unit, which allows the physician to both position the cup on the baby's head and generate the desired amount of negative pressure to create a vacuum. When the other type of vacuum device is used, the physician applies the cup to the baby's head, after which the nurse connects the suction tubing attached to the cup to wall suction or a separate hand pump and generates the amount of pressure requested by the physician. With both devices, a caput develops inside the cup as the pressure is initiated (see Fig. 32-10, B). The woman is encouraged to push as traction is applied by the physician. The vacuum cup is released and removed after birth of the head. If vacuum extraction is not successful, a forceps-assisted or cesarean birth is usually performed.

Risks to the newborn include cephalhematoma, scalp lacerations, and subdural hematoma. These complications can be reduced by strict adherence to the manufacturer's recommendations for method of application, amount of pressure to be generated, and duration of application. Maternal risks include perineal, vaginal, or cervical lacerations and soft-tissue hematomas.

Nursing Interventions. The nurse provides education and support for the woman who has a vacuum-assisted birth. The nurse can prepare the woman for birth and encourage her to remain active in the birth process by pushing during contractions. The FHR should be assessed frequently during the procedure. Documentation of the procedure in the medical

BOX 32-9 Assisting with Birth by Vacuum Extraction

- Assess the fetal heart rate frequently during the procedure.
- Encourage the woman to push during contractions.
- If responsible for generating pressure for the vacuum, do not exceed the “green zone” indicated on the pump. Verify with the physician the amount of pressure to be generated.
- Document the number of pulls attempted, the maximum pressure used, and any pop-offs that occur.

record is important and is often the nurse’s responsibility (Box 32-9). Neonatal caregivers should be told that the birth was vacuum assisted. After birth the newborn is observed for signs of trauma and infection at the application site and for cerebral irritation (e.g., poor sucking or listlessness). The newborn can be at risk for hyperbilirubinemia and neonatal jaundice as bruising resolves. The parents need to be reassured that the caput succedaneum usually disappears in 3 to 5 days (see Fig. 32-10, B) (Gilbert, 2011).

Cesarean Birth

Cesarean birth is the birth of a fetus through a transabdominal incision of the uterus. Whether cesarean birth is planned (scheduled) or unplanned, the loss of experiencing a vaginal birth can have a negative effect on a woman’s self-concept. An effort is therefore made to maintain the focus on the birth of the baby rather than on the operative procedure.

The purpose of cesarean birth is to preserve the well-being of the mother and her fetus. It may be the best choice for birth when evidence exists of maternal or fetal complications. Since the advent of modern surgical methods and care and the use of antibiotics, maternal and fetal morbidity and mortality have decreased. In addition, incisions are usually made into the lower uterine segment rather than in the muscular body of the uterus, thus promoting more effective healing. However, despite these advances, cesarean birth still poses threats to the health of the mother and infant.

In 2010, the cesarean birth rate in the United States was 32.8%, down from an all-time high of 32.9% in 2009. This was the first decrease in the overall cesarean birth rate since 1996. The cesarean birth rate has remained unchanged at 32.8% in both 2011 and 2012 (Martin et al., 2013a). Despite this recent small decrease, the cesarean birth rate in the United States remains very high. Part of the reason is that a number of common risk factors for cesarean birth are increasing in frequency, especially in developed countries. These factors include fetal macrosomia, advanced maternal age, obesity, gestational diabetes, multifetal pregnancy, and dystocia in nulliparous women (Thorp & Laughon, 2014). In addition, there has been a decline in the number of VBACs and trial of labor after cesarean (TOLACs). Eden and colleagues found that the number of women who were allowed a TOLAC decreased dramatically after 1996, when information about the increased risk for uterine rupture with VBAC was published (Eden, Denman, Emeis, et al., 2012). Limited use of a TOLAC, due in part to concerns about safety and medicolegal considerations, is another reason for the high cesarean birth rate (Martin et al., 2013b).

BOX 32-10 Indications for Cesarean Birth

Maternal

- Specific cardiac disease (e.g., Marfan syndrome, unstable coronary artery disease)
- Specific respiratory disease (e.g., Guillain-Barré syndrome)
- Conditions associated with increased intracranial pressure
- Mechanical obstruction of the lower uterine segment (tumors, fibroids)
- Mechanical vulvar obstruction (e.g., extensive condylomata)
- History of previous cesarean birth

Fetal

- Abnormal fetal heart rate (FHR) or pattern
- Malpresentation (e.g., breech or transverse lie)
- Active maternal herpes lesions
- Maternal human immunodeficiency virus (HIV) with a viral load of more than 1000 copies/ml
- Congenital anomalies

Maternal-Fetal

- Dysfunctional labor (e.g., cephalopelvic disproportion, “failure to progress” in labor)
- Placental abruption
- Placenta previa
- Elective cesarean birth (cesarean on maternal request)

Data from Berghella, V., & Landon, M. (2012). Cesarean delivery. In S. Gabbe, J. Niebyl, & J. Simpson (Eds.), *Obstetrics: Normal and problem pregnancies* (6th ed.). Philadelphia: Saunders; Duff, P. (2014). Maternal and fetal infections. In R.K. Creasy, R. Resnik, J.D. Iams, et al. (Eds.), *Creasy and Resnik’s maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders; Thorp, J.M., & Laughon, S.K. (2014). Clinical aspects of normal and abnormal labor. In R.K. Creasy, R. Resnik, J.D. Iams, et al. (Eds.), *Creasy and Resnik’s maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders.

Indications

Few absolute indications exist for cesarean birth. Currently most are performed for conditions that might pose a threat to both the mother and the fetus if vaginal birth occurred, such as placenta previa or placental abruption (Campbell, 2011). Box 32-10 lists common indications for cesarean birth.

Elective Cesarean Birth

Elective cesarean birth, sometimes referred to as *cesarean on request* or *cesarean on demand*, refers to a primary cesarean birth without medical or obstetric indication. Reasons given for elective cesarean birth include fear of pain during labor and birth and the mistaken belief that the surgery will prevent future problems with pelvic support, bladder and bowel incontinence, or sexual dysfunction (Ecker, 2013). At this time evidence is insufficient to recommend elective cesarean birth to prevent urinary or fecal incontinence later in life (ACOG, 2013b; Thorp & Laughon, 2014). Although some nulliparous women may fear the pain of labor because of no firsthand experience, multiparous women may request a cesarean birth after a previous traumatic vaginal birth. Other women desire an elective cesarean birth because of the convenience of planning a date, or having control and choice about when to give birth (Ecker).

Only limited data are available comparing cesarean births on request with planned vaginal births (ACOG, 2013b). In a committee opinion (2013b), the ACOG lists potential risks of

cesarean birth on request that include a longer hospital stay for the woman, an increased risk of respiratory problems for the baby, and greater complications in subsequent pregnancies, including uterine rupture and placental implantation problems. The ACOG recommends that cesarean birth on request not be performed unless a gestational age of 39 weeks has been accurately determined. Cesarean birth on request is not recommended for women who desire several additional children, because the risks for placenta previa, placenta accreta, and cesarean hysterectomy increase with each cesarean birth (Berghella & Landon, 2012).

Scheduled Cesarean Birth

Cesarean birth is scheduled or planned if:

- Labor and vaginal birth are contraindicated (e.g., complete placenta previa, active genital herpes, positive HIV status with a high viral load)
- Birth is necessary but labor is not inducible (e.g., hypertensive states that cause a poor intrauterine environment that threatens the fetus)
- This course of action has been chosen by the primary health care provider and the woman (e.g., a repeat cesarean birth)

Women who are scheduled for a cesarean birth usually have time to prepare for it psychologically. However, the psychologic responses of these women may differ. Those having a repeat cesarean birth may have disturbing memories of the conditions preceding the initial (primary) cesarean birth and of their experiences in the postoperative recovery period. They may be concerned about the added burdens of caring for the infant and perhaps other children while recovering from surgery. Others may feel glad that they have been relieved of the uncertainty about the date and time of the birth and are free of the pain of labor.

Unplanned Cesarean Birth

The psychosocial outcomes of unplanned or emergency cesarean birth are usually more pronounced and negative when compared with the outcomes associated with a scheduled or planned cesarean birth. Women and their families experience abrupt changes in their expectations for birth, postpartum care, and care of the new baby at home. This can be an extremely traumatic experience for all.

The woman may approach the procedure tired and discouraged after an ineffective and difficult labor. Fear predominates as she worries about her own safety and well-being and that of her fetus. She may be dehydrated, with low glycogen reserves. Because preoperative procedures must be done rapidly, there is often little time for explanation of the procedures and the operation itself. Because maternal and family anxiety levels are high at this time, much of what is said can be forgotten or misunderstood. The woman can experience feelings of anger or guilt in the postpartum period. Fatigue is often noticeable in these women, and they need much supportive care.

Forced Cesarean Birth

A woman's refusal to undergo cesarean birth when indicated for fetal reasons is often described as a *maternal-fetal conflict*. Health care providers are ethically obliged to protect the

well-being of mother as well as fetus; a decision for one affects the other. If a woman refuses a cesarean birth that is recommended because of fetal jeopardy, health care providers must make every effort to find out why she is refusing and provide information that may persuade her to change her mind. If the woman continues to refuse surgery, then health care providers must decide if it is ethical to get a court order for the surgery. Every effort, however, should be made to avoid this legal step.

Surgical Techniques

The skin incision will either be vertical, extending from near the umbilicus to the mons pubis or transverse (Pfannenstiel) in the lower abdomen (Fig. 32-11). The transverse incision, sometimes referred to as the “bikini” incision, is performed more often. The type of skin incision is generally determined by the urgency of the surgery and the presence of any prior skin incisions (Berghella & Landon, 2012). The type of skin incision does *not* necessarily indicate the type of uterine incision.

The two main types of uterine incisions are the low transverse (Fig. 32-12, A) or vertical incision, which may be either low or classic (see Fig. 32-12, B and C). Ideally the vertical incision is contained entirely within the lower uterine segment,

FIG 32-11 Skin incisions for cesarean birth. A, Vertical. B, Horizontal (Pfannenstiel).

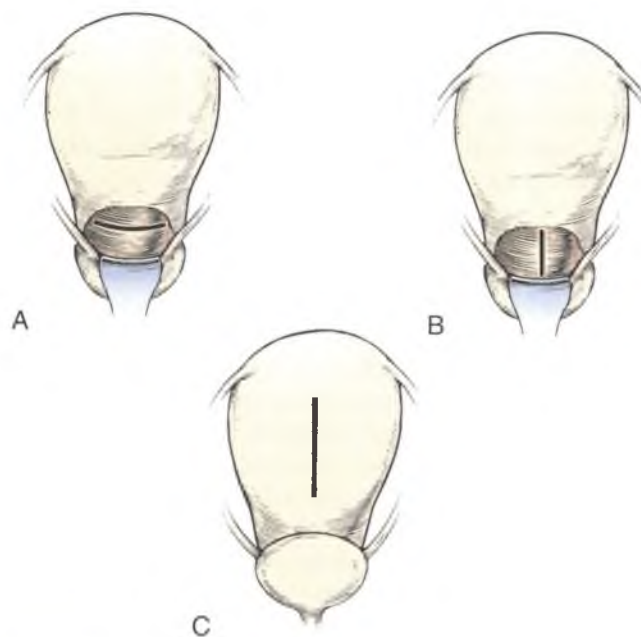

FIG 32-12 Uterine incisions for cesarean birth. A, Low transverse incision. B, Low vertical incision. C, Classic incision. (From Gabbe, S.G., Niebyl, J., Simpson, J., et al. [2012]. *Obstetrics: Normal and problem pregnancies* [6th ed.]. Philadelphia: Saunders.)

but extension into the contractile portion of the uterus (e.g., a classic incision) is common. Indications for a vertical incision include an underdeveloped lower uterine segment, a transverse lie or preterm breech presentation, certain fetal anomalies such as massive hydrocephalus, and an anterior placenta previa (Berghella & Landon, 2012). Because it is associated with a higher incidence of uterine rupture in subsequent pregnancies than is lower-segment cesarean birth, vaginal birth after a classic uterine incision is contraindicated.

The low transverse uterine incision is performed in more than 90% of cesarean births (see Fig. 32-12, A). Compared with the vertical incision, the transverse incision is preferred because it does not compromise the upper uterine segment, is easier to perform and repair, and is associated with less blood loss. It also provides for the option of TOLAC and VBAC in subsequent pregnancies (Berghella & Landon, 2012).

Complications and Risks

Possible maternal complications related to cesarean birth include anesthesia events (problems with intubation, drug reactions, aspiration pneumonia), hemorrhage, bowel or bladder injury, amniotic fluid embolism, and air embolism. Possible postpartum complications include atelectasis; endometritis; urinary tract infection; abdominal wound hematoma formation, dehiscence, infection, or necrotizing fasciitis; thromboembolic disease; and bowel dysfunction (Thorp & Laughon, 2014). In addition to these risks, the woman is also at economic risk because the cost of cesarean birth is higher than that of vaginal birth, and a longer recovery period may require additional expenditures.

Cesarean birth is associated with uncommon but significant dangers to the infant. The fetus may be born prematurely if the gestational age has not been accurately determined (iatrogenic prematurity). Fetal asphyxia can occur if the uterus and placenta are poorly perfused as a result of maternal hypotension caused by regional anesthesia (epidural or spinal) or maternal positioning. Fetal injuries (e.g., injuries caused by scalpel lacerations) can also occur during the surgery. The newborn is more likely to require resuscitation efforts and develop respiratory complications (Campbell, 2011; Thorp & Laughon, 2014).

Anesthesia

Spinal, epidural, and general anesthetics are used for cesarean births. Epidural blocks are popular because women want to be awake for and aware of the birth experience. However, the choice of anesthetic depends on several factors. The mother's medical history or present condition, such as a spinal injury, hemorrhage, or coagulopathy, may rule out the use of regional anesthesia. Time is another factor, especially if there is an emergency and the life of the mother or infant is at stake. In an emergency general anesthesia will most likely be used unless the woman already has an epidural block in effect. The woman herself is a factor. Either she may not know all the options or may have fears about having "a needle in her back" or about being awake and feeling pain. She needs to be fully informed about the risks and benefits of the different types of anesthesia so that she can participate in the decision whenever there is a choice.

CARE MANAGEMENT

Prenatal Preparation

A discussion of cesarean birth should be included in all child-birth preparation classes. No woman can be guaranteed a vaginal birth, even if she is in good health and no indication of danger to the fetus exists before the onset of labor. Therefore, every woman needs to be aware of and prepared for the possibility of having a cesarean birth.

Childbirth educators should emphasize the similarities and differences between a cesarean and a vaginal birth. In support of the philosophy of family-centered birth, many hospitals have instituted policies that permit fathers or partners and family members to share in these births as they do in vaginal births. Women who have undergone cesarean birth agree that the continued presence and support of their partners helped them respond more positively to the entire experience. In addition to preparing women for the possibility of cesarean birth, childbirth educators should empower them to believe in their ability to give birth vaginally and to seek care measures during labor that will enhance the progress of their labors and reduce their risk for cesarean birth.

Preoperative Care

Family-centered care is the goal for the woman who is to undergo cesarean birth and for her family. Preparing a woman for cesarean birth is the same as that for other elective or emergency surgery. The primary health care provider discusses, with the woman and her family, the need for the cesarean birth and the prognosis for the mother and infant. A member of the anesthesia care team assesses the woman's cardiopulmonary status and describes the options for anesthesia. Women who are scheduled for an elective cesarean are often told not to eat or drink (remain NPO [nothing by mouth]) for at least 8 hours prior to the surgery. Informed consent is obtained for the procedure.

Blood tests are usually done a day or two before a planned cesarean birth or on admission to the labor and birth unit. Laboratory tests commonly ordered include a complete blood cell count and blood type and Rh status. Maternal vital signs and FHR and pattern are assessed according to hospital protocol until the operation begins. IV fluids are started to maintain hydration and to provide an open line for administering blood or medications if needed. Other preoperative preparations include making sure that an informed consent form has been signed, inserting a retention (Foley) catheter to keep the bladder empty, and administering prescribed preoperative medications. In addition to medications given to prevent aspiration pneumonia, women may also receive prophylactic antibiotics to prevent postoperative infection. In the rare instance that an abdominal-mons shave or a clipping of pubic hair is ordered by the primary health care provider, it is performed in the operating room just prior to making the incision because shaving can result in injury to the skin, thereby increasing the risk for infection. Often, TED hose or SCD boots are placed on the woman's legs to prevent blood clot formation. Removal of contact lenses, dentures, nail polish, and jewelry may be optional, depending on hospital policies and the type of anesthesia used. If the woman wears glasses and is going to be awake, the nurse should make sure her glasses accompany her to the operating room so she can see her infant.

During the preoperative preparation, the support person is encouraged to remain with the woman as much as possible to provide continuing emotional support (if this action is culturally acceptable to the woman and support person). The nurse provides essential information about the preoperative procedures during this time. Although the nursing actions may be carried out quickly if a cesarean birth is unplanned, verbal communication, particularly explanations, is important. Silence can be frightening to the woman and her support person. The nurse's use of touch (if culturally appropriate) can communicate feelings of care and concern for the woman. The nurse can assess the woman's and her partner's perceptions about cesarean birth. As the woman expresses her feelings, the nurse may identify a potential for a disturbance in self-concept during the postpartum period that would need to be addressed. If there is time before the birth, the nurse can teach the woman about postoperative expectations and about pain relief, position changes, leg exercises, coughing, and deep-breathing measures.

Intraoperative Care

Cesarean births occur in operating rooms in the surgical suite or in the labor and birth unit. Staff members from the labor and birth unit may scrub and circulate during the surgery or these functions may be assumed by members of the hospital's surgery staff (Fig. 32-13). If possible, the partner or other support person, who is dressed appropriately for the operating room, accompanies the mother to the operating room and remains close to her for continued comfort and support. In unplanned cesarean birth, the nurse who cared for the woman during labor should be part of the nursing care team in the operating room if possible.

The nurse who is circulating may assist with positioning the woman on the birth (operating) table. It is important to position her so that the uterus is displaced laterally to prevent compression of the inferior vena cava, which causes decreased placental perfusion. This is usually accomplished by placing a wedge under the hip or tilting the table to one side. A retention (Foley) catheter is inserted into the bladder at this time if one is not already in place. The woman's legs should be strapped to the table to ensure proper positioning during the surgery.

As is done in other surgical procedures, a "time out" should be conducted just before the operation begins. This is an opportunity for all members of the surgical team to participate in confirming the woman's identity and the planned procedure(s) to be performed. The circulating nurse is usually responsible for ensuring that the operative consent form has been signed and witnessed and is in the woman's chart. Members of the surgical team confirm that ordered preoperative medications have been given and that blood products, if ordered, are available. Information about drug or other allergies is also shared.

If the partner is not allowed or chooses not to be present, the nurse can stay in communication with him or her and give progress reports whenever possible. If the woman is awake during the birth, the nurse, anesthesia care provider, or both can tell her what is happening and provide support. She may be anxious about the sensations she is experiencing, such as the coldness of solutions used to cleanse the abdomen and pressure or pulling during the actual birth of the infant. She also may

FIG 32-13 Cesarean birth. **A**, "Bikini" incision has been made, the muscle layer is separated, the abdomen is entered, and the uterus has been exposed and incised; suctioning of amniotic fluid continues as head is brought up through the incision. Note small amount of bleeding. **B**, The neonate's birth through the uterine incision is nearly complete. **C**, A quick assessment is performed; note extreme molding of head resulting from cephalopelvic disproportion. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

be apprehensive because of the bright lights or the presence of unfamiliar equipment and masked and gowned personnel in the room. Explanations can help to decrease her anxiety.

A nurse from the labor and birth unit is usually present to provide care for the infant. In addition, a pediatrician or a nurse team skilled in neonatal resuscitation may also be present for the surgery because these infants are considered to be at risk until evidence of physiologic stability after the birth is observed. A radiant warmer bed with resuscitation equipment is readied before surgery. Personnel who are responsible for care are expert not only in resuscitative techniques but also in their ability to detect normal and abnormal infant responses (AAP & American Heart Association [AHA], 2011). After birth, if the infant's condition permits and the mother is awake, the baby

FIG 32-14 **A**, Parents and their newborn. The physician manually removes the placenta, suctions the remaining amniotic fluid and blood from the uterine cavity, and repairs the uterine incision, peritoneum, muscle layer, fatty tissue, and finally the skin, while the new family shares some time together. **B**, Parents become better acquainted with their newborn while mother rests after surgery. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

may be placed skin-to-skin on the mother or may be given to the woman's partner to hold (Fig. 32-14). The infant whose condition is compromised is transported after initial stabilization to the newborn nursery or neonatal intensive care unit (NICU) for observation and the implementation of appropriate interventions. In some institutions the partner may accompany the infant; if not, personnel keep the family informed of the infant's progress and parent-infant contacts are initiated as soon as possible.

If family members cannot accompany the woman during surgery, they are directed to the surgical or obstetric waiting room. The physician then reports on the condition of the mother and infant to the family members after the birth is completed. Family members may be allowed to accompany the infant as she or he is transferred to the nursery, giving them an opportunity to see and admire the new baby.

LEGAL TIP: Disclosure of Client Information

Some mothers or fathers want the privilege of informing family and friends about the sex of the infant (if it was not known before birth) or other information about the birth. Before responding to requests for such information from people waiting outside the birthing area, the nurse should check to see if the mother has given consent for such information to be released and to whom.

Immediate Postoperative Care

Once surgery is completed, the mother is transferred to a postanesthesia recovery area. After a cesarean birth, women have postoperative and postpartum needs that must be addressed. They are surgical clients as well as new mothers. Nursing assessments in this immediate postpartum period follow agency protocol and include degree of recovery from the effects of anesthesia, postoperative and postbirth status, and degree of pain. A patent airway is maintained, and the woman is positioned to prevent possible aspiration. Blood pressure and pulse are assessed at least every 15 minutes for 2 hours. Temperature should be assessed every 4 hours for the first 8 hours after birth and then at least every 8 hours (AAP & ACOG, 2012). The condition of the incisional dressing and the fundus and the amount of lochia are assessed, as well as the IV intake and the urine output through the retention (Foley) catheter. Oxytocin usually is added to at least the first liter of the IV infusion to ensure that the fundus remains firmly contracted, thereby reducing blood loss. The woman is assisted to cough, deep-breathe, turn, and perform leg exercises. She will likely have SCD boots on her legs. Medications for pain relief should be administered before postoperative pain becomes severe.

If the baby is present, the mother and her partner are given some time alone with him or her to facilitate bonding and attachment. The mother may hold her newborn skin-to-skin and initiate breastfeeding. The woman is ready for discharge from the postanesthesia recovery area once her condition is stable and the effects of anesthesia have worn off (i.e., she is alert and oriented and able to feel and move her extremities).

Postoperative Postpartum Care

The attitude of the nurse and other health care team members can influence the woman's perception of herself after a cesarean birth. The caregivers should stress that the woman is a new mother first and a surgical client second. This attitude helps the woman perceive herself as having the same problems and needs as other new mothers, while requiring supportive postoperative care.

The woman's physiologic concerns can be dominated by pain at the incision site and discomfort resulting from intestinal gas. For the first 24 hours following surgery, pain relief may be provided by epidural opioids, patient-controlled analgesia (PCA), or IV or intramuscular injections. The most commonly used analgesics include opioids (e.g., hydromorphone [Dilaudid], morphine sulfate, nalbuphine [Nubain]) and NSAIDs (e.g., ketorolac [Toradol]). If opioids are used, an antiemetic (e.g., metoclopramide [Reglan]) is often administered either as needed by the woman or around the clock as long as the opioid is used. Palpation of the fundus with the possibility of massage should be performed after an analgesic is given to decrease pain. By 24 hours after surgery, women are usually taking oral analgesics. Other comfort measures such as position changes, splinting of the incision with pillows, and relaxation and breathing techniques (e.g., those learned in childbirth classes) may be implemented (see Teaching for Self-Management: Nonpharmacologic Postpartum Pain Relief After Cesarean Birth).

TEACHING FOR SELF-MANAGEMENT**Nonpharmacologic Postpartum Pain Relief After Cesarean Birth****Incisional**

- Splint the incision with a pillow when moving or coughing.
- Use relaxation techniques such as music, breathing, and dim lights.

Intestinal Gas

- Walk as often as you can.
- Do not eat or drink gas-forming foods, carbonated beverages, whole milk, or ice.
- Do not use straws for drinking fluids.
- Take antifatulence medication if prescribed.
- Lie on your left side to expel gas.
- Rock in a rocking chair.

Women are often the best judges of what their bodies need and can tolerate, including the postoperative ingestion of foods and fluids. Some health care providers keep women NPO or allow only “sips and chips” (sips of clear fluids and teaspoons of crushed ice) until bowel sounds return. The diet is then advanced to full liquids. After women are passing flatus they can resume a regular diet (Gilbert, 2011). Because most women have an epidural or spinal anesthetic for surgery, many health care providers allow the early introduction of solid food if desired and tolerated. IV fluids are usually continued until the woman is tolerating fluids orally. Ambulation and rocking in a rocking chair may relieve gas pains. Avoiding gas-forming foods, ice chips, carbonated beverages, and using a straw to drink beverages can help limit gas formation, thereby minimizing the severity of gas pains (see Teaching for Self-Management: Nonpharmacologic Postpartum Pain Relief After Cesarean Birth).

Nursing Interventions

Nurses must be alert to a woman’s physiologic needs, managing care to ensure adequate rest and pain relief. Mother-baby care (couplet care) for a cesarean birth mother may have to be modified according to her physical limitations as a surgical client.

Daily care includes perineal care, breast care, and routine hygienic care. The woman may shower after the original incisional dressing is removed, usually on the first postoperative day (if showering is acceptable according to the woman’s cultural beliefs and practices). The indwelling (Foley) catheter usually is also removed on the first postpartum day. The woman is encouraged to be out of bed and ambulating several times each day as soon as the urinary catheter is removed. Use of TED hose or SCD boots should continue as long as the woman remains in bed. They may be removed when she begins ambulating. The nurse assesses the woman’s vital signs, incision, fundus, and lochia according to hospital policies, procedures, or protocols. Breath sounds, bowel sounds, circulatory status of lower extremities, and urinary and bowel elimination patterns also are assessed. It is important to observe maternal emotional status and progress of attachment to her baby.

SAFETY ALERT

The woman should be taught to seek assistance initially when getting out of bed, especially when an IV line and catheter are still in place. Thereafter, when rising from a supine position, she should sit on the side of the bed first to determine if dizziness will occur, then stand at the bedside, and finally ambulate.

During the postpartum period the nurse provides care that meets the psychologic and teaching needs of women who have had cesarean births. This includes explaining postpartum procedures to help the woman participate in her recovery from surgery. The nurse can also help the woman plan care and visits from family and friends that will allow for adequate rest periods. Providing information on and assistance with infant care can facilitate adjustment to her role as a mother. With adequate support these women can benefit from mother-baby care to facilitate attachment and enhance involvement in newborn care. The woman is supported as she breastfeeds her baby by receiving individualized assistance to comfortably hold and position the baby at her breast. Using the side-lying or football (under the arm or clutch hold) position and supporting the newborn with pillows can enhance comfort and facilitate successful breastfeeding. The partner and other family members can be included in infant teaching sessions and in explanations about the woman’s recovery.

SAFETY ALERT

When holding her baby or breastfeeding, a woman may become drowsy and even fall asleep because of the sedation that occurs with the use of analgesics. It is important that someone be with her during these times.

The couple also should be encouraged to express their feelings about the birth experience. Some parents are angry, frustrated, or disappointed that a vaginal birth was not possible. Some women express feelings of low self-esteem or a negative self-image. Others express relief and gratitude that the baby is healthy and safely born. It may be helpful for them to have the nurse who was present during the birth visit and help fill in “gaps” about the experience.

Discharge after cesarean birth is usually by the third postoperative day. The time is often determined by criteria established by the woman’s insurance carrier or the federal government (e.g., diagnosis-related groups [DRGs]). The Newborns’ and Mothers’ Health Protection Act of 1996 provides for a length of stay of up to 96 hours for cesarean births. These criteria may not coincide with the woman’s physical or psychosocial readiness for discharge. Some states have added home care provisions for mothers who meet appropriate criteria for discharge and choose to leave sooner than the allowed length of stay. This policy recognizes that home care is less costly than hospital care and in most cases is more beneficial for recovery.

The nurse provides discharge teaching to prepare the woman for self-care and newborn care while trying to ensure that she is comfortable and able to rest. The nurse assesses the woman’s information needs and coordinates the health care team’s efforts to meet them. Discharge teaching and planning

should include information about nutrition; measures to relieve pain and discomfort; exercise and specific activity restrictions; time management that includes periods of uninterrupted rest and sleep; hygiene, breast, and incision care; timing for resumption of sexual activity and contraception; signs of complications (see Teaching for Self-Management: Signs of Postoperative Complications After Discharge Following Cesarean Birth and Teaching for Self-Management: Signs of Postpartum Blues, Depression, and Psychosis in Chapter 31); and infant care. The nurse assesses the woman's need for continued support or counseling to facilitate her emotional recovery from the birth. The woman's family and friends should be educated regarding her needs during the recovery process, and their assistance should be coordinated before discharge. Referral to support groups (e.g., www.birthrites.org) or to community agencies may be indicated to further promote the recovery process. A postdischarge program of telephone follow-up and home visits can facilitate the woman's full recovery after cesarean birth.

TEACHING FOR SELF-MANAGEMENT

Signs of Postoperative Complications After Discharge Following Cesarean Birth

Report the following signs to your health care provider:

- Temperature exceeding 38° C (100.4° F)
- Urination: painful urination, urgency, cloudy urine
- Lochia: heavier than a normal menstrual period, clots, odor
- Cesarean incision: redness, swelling, bruising, foul-smelling discharge or bleeding, wound separation
- Severe, increasing abdominal pain

Trial of Labor

A **trial of labor (TOL)** is the observance of a woman and her fetus for a reasonable period (e.g., 4 to 6 hours) of spontaneous active labor to assess the safety of vaginal birth for the mother and infant. It may be initiated if the mother's pelvis is of questionable size or shape or if the fetus is in an abnormal presentation or position. By far the most common reason for a TOL is if the woman wishes to have a vaginal birth after a previous cesarean birth. A woman who has had a previous cesarean birth with a low transverse uterine incision may be a candidate for a TOL. Fetal sonography, maternal pelvimetry, or both may be done before a TOL to rule out CPD. During a TOL the woman is evaluated for active labor, including adequate contractions, engagement and descent of the presenting part, and effacement and dilation of the cervix.

The nurse assesses maternal vital signs and FHR and pattern and is alert for signs of potential complications. If complications develop, the nurse is responsible for initiating appropriate actions, including notifying the primary health care provider, and for evaluating and documenting the maternal and fetal responses to the interventions. Nurses must recognize that the woman and her partner are often anxious about maternal and fetal well-being. Supporting and encouraging the woman and her partner and providing information regarding progress can reduce stress and enhance the labor process and facilitate a successful outcome.

Vaginal Birth After Cesarean

Indications for primary cesarean birth, such as dysfunctional labor, breech presentation, or abnormal FHR or patterns, often are nonrecurring. Therefore, a woman who has had a cesarean birth with a low transverse incision may subsequently become pregnant, experience no contraindications to labor and vaginal birth during the pregnancy, and choose to attempt a **vaginal birth after cesarean (VBAC)**. Box 32-11 lists selection criteria suggested by the ACOG for identifying candidates for VBAC.

The overall success rate of VBAC is approximately 60% to 80% (Signore, 2012). The strongest predictors for a successful VBAC are a prior vaginal birth and spontaneous (rather than induced or augmented) labor (ACOG, 2010). Women whose first cesarean birth was performed because of a nonrecurring indication (e.g., breech presentation) also are likely to have a successful VBAC (Berghella & Landon, 2012). Women with the following characteristics are less likely to have a successful VBAC (ACOG, 2010; Eden et al., 2013):

- Recurrent indication (e.g., labor dystocia) for initial cesarean birth
- Increased maternal age
- Non-Caucasian race or ethnicity
- Gestational age >40 weeks
- Maternal obesity (BMI >30)
- Preeclampsia
- Short interpregnancy interval
- Estimated fetal weight >4000 g
- Giving birth at a rural or private hospital

Women who succeed in having a VBAC and thus avoid major abdominal surgery have less hemorrhage, fewer infections, and a shorter recovery period than do women who give birth by repeat cesarean (ACOG, 2010). The major risk associated with VBAC is uterine rupture (see later discussion) (Berghella & Landon, 2012). Other maternal risks include operative injury, blood transfusion, hysterectomy, endometritis, and death (ACOG).

Women are most often the primary decision makers with regard to choice of birth method. During the prenatal period the woman should be given information about VBAC and encouraged to choose it as an alternative to repeat cesarean birth, as long as no contraindications exist. VBAC support groups (e.g., www.vbac.com) and prenatal classes can help prepare the woman psychologically for labor and vaginal birth. Women need to believe not only that their efforts during a TOL will be successful but also that they are fully capable of doing what is necessary to give birth vaginally. They must be given the opportunity to discuss their previous labor experience, including feelings of failure and loss of control, and to express concern they

BOX 32-11 Selection Criteria for Vaginal Birth After Cesarean

- One or two previous low-transverse cesarean births
- Clinically adequate pelvis
- No other uterine scars or history of previous rupture
- Physicians immediately available throughout active labor capable of monitoring labor and performing an emergency cesarean birth if necessary

Data from American College of Obstetricians and Gynecologists (ACOG). (2010). *Vaginal birth after previous cesarean delivery*. ACOG practice bulletin no. 115. Washington, DC: ACOG

may have about how they will manage during their upcoming labor and birth. Not everyone is enthusiastic about TOL and VBAC. After being fully informed about the benefits and risks, more than 25% of potential candidates choose to have a repeat cesarean birth instead (Thorp & Laughon, 2014).

If a woman chooses TOL, the nurse is attentive to her psychology as well as physical needs during the TOL. Anxiety increases the release of catecholamines and can inhibit the release of oxytocin, thus delaying the progress of labor and possibly leading to a repeat cesarean birth. To alleviate such anxiety the nurse can encourage the woman to use breathing and relaxation techniques and to change positions to promote labor progress. The woman's partner can be encouraged to provide comfort measures and emotional support. Collaboration among the woman in labor, her partner, the nurse, and other health care providers often results in a successful VBAC. If a TOL does not result in vaginal birth, the woman will need support and encouragement to express her feelings about having another cesarean birth. It is very important that this outcome not be labeled a failed VBAC.

Since 1996 VBAC rates have been decreasing, with the current rate being less than 10%. Both medical and nonmedical factors have contributed to this decline. In March 2010 the Eunice Kennedy Shriver National Institute of Child Health and Human Development and the National Institutes of Health (NIH) convened a consensus development conference to examine issues related to VBAC. The statement produced by the panel of experts affirmed that TOL is a reasonable option for many women who have had a previous cesarean birth. The experts found, however, that many women who are appropriate candidates for TOL and VBAC do not have access to providers and health care facilities that are able and willing to offer this option (Berghella & Landon, 2012). ACOG continues to recommend that TOL and VBAC be offered only in facilities that have staff immediately available to provide emergency care. Because resources for immediate cesarean birth may not be available in all birthing facilities, the best alternative in some situations may be to refer interested women to other facilities that have the obstetric, anesthetic, pediatric, and surgical staff necessary to offer TOL and VBAC (Berghella & Landon).

OBSTETRIC EMERGENCIES

Meconium-Stained Amniotic Fluid

Meconium-stained amniotic fluid indicates that the fetus has passed meconium (first stool) before birth. Meconium-stained amniotic fluid is green. The consistency of the meconium fluid is often described as either thin (light) or thick (heavy), depending on the amount of meconium present. Three possible reasons for the passage of meconium are (1) it is a normal physiologic function that occurs with maturity (meconium passage being infrequent before weeks 23 or 24, with an increased incidence after 38 weeks) or with a breech presentation; (2) it is the result of hypoxia-induced peristalsis and sphincter relaxation; or (3) it can be a sequel to umbilical cord compression–induced vagal stimulation in mature fetuses.

The major risk associated with meconium-stained amniotic fluid is the development of meconium aspiration syndrome (MAS) in the newborn. MAS causes a severe form of aspiration pneumonia that occurs most often in term or postterm infants

who have passed meconium in utero. MAS most likely results from a long-standing intrauterine process, rather than from aspiration immediately following birth as respirations are initiated (see Chapter 34) (Rozance & Rosenberg, 2012).

CARE MANAGEMENT

The presence of a team skilled in neonatal resuscitation is required at the birth of any infant with meconium-stained amniotic fluid. When meconium-stained amniotic fluid is present, the AAP and the American Heart Association's (AHA) Neonatal Resuscitation Program no longer recommends routine suctioning of the newborn's mouth and nose on the perineum (after the head is out but before the rest of the baby is born) followed by endotracheal suctioning after birth. Instead, management of a newborn with meconium-stained amniotic fluid is based only on assessment of the baby's condition at birth. No clinical studies warrant basing tracheal suctioning guidelines simply on meconium consistency (AAP & AHA, 2011). See *Emergency: Immediate Management of the Newborn with Meconium-Stained Amniotic Fluid* for specific interventions.

+ EMERGENCY

Immediate Management of the Newborn with Meconium-Stained Amniotic Fluid

Before Birth

- Assess the amniotic fluid for the presence of meconium after rupture of membranes.
- If the amniotic fluid is meconium stained, gather equipment and supplies that might be necessary for neonatal resuscitation.
- Have at least one person capable of performing endotracheal intubation on the baby present at the birth.

Immediately After Birth

- Assess the baby's respiratory efforts, heart rate, and muscle tone.
- Suction only the baby's mouth and nose, using either a bulb syringe or a large-bore suction catheter if the baby has:
 - Strong respiratory efforts
 - Good muscle tone
 - Heart rate >100 beats/minute
- Suction the trachea using an endotracheal tube connected to a meconium aspiration device and suction source to remove any meconium present before many spontaneous respirations have occurred or assisted ventilation has been initiated if the baby has:
 - Depressed respirations
 - Decreased muscle tone
 - Heart rate <100 beats/minute

Data from American Academy of Pediatrics (AAP) & American Heart Association (AHA). (2011). *Textbook of neonatal resuscitation* (6th ed.). Dallas: AHA.

⚡ SAFETY ALERT

Every birth should be attended by at least one person whose only responsibility is the baby and who is capable of initiating resuscitation. Either that person or someone else who is immediately available should have the skills required to perform a complete resuscitation, including endotracheal suctioning to remove meconium, if necessary.

Shoulder Dystocia

Shoulder dystocia is an uncommon obstetric emergency that increases the risk for fetal and maternal morbidity and mortality during the attempt to accomplish birth vaginally. Shoulder dystocia is a condition in which the head is born, but the anterior shoulder cannot pass under the pubic arch. It is estimated that 0.34% of all vaginal births are complicated by shoulder dystocia (Leung, Stuart, Suen, et al., 2011). The incidence of shoulder dystocia has increased in recent years, perhaps because of larger birth weights or simply because more attention is now paid to documenting the condition.

Fetopelvic disproportion (FPD) related to excessive fetal size (more than 4000 g) or maternal pelvic abnormalities can cause shoulder dystocia, although up to half of all cases of shoulder dystocia occur with smaller fetuses (Simpson & O'Brien-Abel, 2014; Thorp & Laughon, 2014). Other risk factors for shoulder dystocia include maternal diabetes (risk for macrosomia), a history of shoulder dystocia with a previous birth, and a prolonged second stage of labor. In half of all cases of shoulder dystocia, however, no risk factors are identified (Thorp & Laughon). Shoulder dystocia cannot be accurately predicted or prevented (Simpson & O'Brien-Abel).

Signs that indicate the presence of shoulder dystocia include slowing of the progress of the second stage of labor and formation of a caput succedaneum that increases in size. The nurse should observe for retraction of the fetal head against the perineum immediately following its emergence (turtle sign), an early sign of shoulder dystocia. External rotation does not occur (Simpson & O'Brien-Abel, 2014; Thorp & Laughon, 2014).

Fetal injuries are usually caused either by asphyxia related to the delay in completing the birth or by trauma from the maneuvers used to accomplish the birth. Complications related to trauma include brachial plexus and phrenic nerve injuries and fracture of the humerus or clavicle. The most serious complication is brachial plexus injury (Erb palsy), which occurs in 10% to 20% of infants born following shoulder dystocia. Evidence now exists that brachial plexus injuries can result from intrauterine forces during the second stage of labor rather than from the maneuvers used to accomplish birth (Lanni & Seeds, 2012). If brachial plexus injuries are recognized early and treated properly, 80% to 90% heal completely. Therefore, permanent neurologic injury is rare, occurring in only 1 or 2 of every 10,000 births. The major maternal complications associated with shoulder dystocia are postpartum hemorrhage and rectal injuries (Thorp & Laughon, 2014).

CARE MANAGEMENT

Many maneuvers such as suprapubic pressure and maternal position changes have been suggested and tried to free the anterior shoulder, although no particular maneuver has been found to be most effective. The specific method used is less important than is being prepared at every vaginal birth to deal with shoulder dystocia using a planned sequence of interventions if the need arises (Lanni & Seeds, 2012).

In the McRoberts maneuver (Fig. 32-15), the woman's legs are flexed apart, with her knees on her abdomen (Ansell, McAra-Couper, & Smythe, 2012; Lanni & Seeds, 2012). This maneuver causes the sacrum to straighten, and the symphysis pubis to

FIG 32-15 McRoberts maneuver. (From Gabbe, S., Niebyl, J., & Simpson, J. [2012]. *Obstetrics: Normal and problem pregnancies* [6th ed.]. Philadelphia: Saunders.)

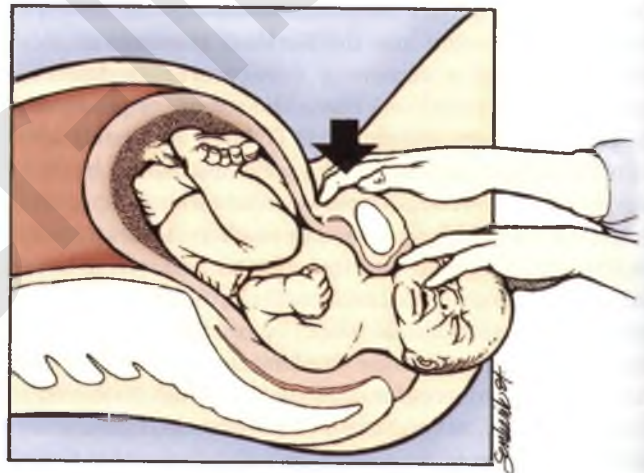

FIG 32-16 Application of suprapubic pressure. (From Gabbe, S., Niebyl, J., & Simpson, J. [2007]. *Obstetrics: Normal and problem pregnancies* [5th ed.]. Philadelphia: Churchill Livingstone.)

rotate toward the mother's head. The angle of pelvic inclination is decreased, which frees the shoulder. Suprapubic pressure can then be applied to the anterior shoulder (Fig. 32-16) in an attempt to push the shoulder under the symphysis pubis (Rozance & Rosenberg, 2012). The McRoberts maneuver is the preferred method when a woman is receiving epidural anesthesia.

Having the woman move to a hands-and-knees position (the Gaskin maneuver), a squatting position, or lateral recumbent position also has been used to resolve cases of shoulder dystocia. However, the Gaskin maneuver requires that the woman be mobile, with no significant loss of motor function caused by regional anesthesia (Ansell et al., 2012).

Fundal pressure as a method of relieving shoulder dystocia should be avoided. Its use has been associated with neurologic complications (Gilbert, 2011).

When shoulder dystocia is diagnosed, the nurse should stay calm and immediately call for additional assistance (i.e., extra nurses, anesthesia care provider, and neonatal resuscitation

FIG 32-17 Prolapse of umbilical cord. Note pressure of presenting part on umbilical cord, which endangers fetal circulation. **A**, Occult (hidden) prolapse of cord. **B**, Complete prolapse of cord. Note that membranes are intact. **C**, Cord presenting in front of the fetal head may be seen in vagina. **D**, Frank breech presentation with prolapsed cord.

team). The nurse then helps the woman assume the position or positions that may facilitate birth of the shoulders, assists the primary health care provider with these maneuvers and techniques during birth, and documents the maneuvers, including the total amount of time required to resolve the shoulder dystocia. The nurse also provides encouragement and support to reduce anxiety. Newborn assessment should include examination for fracture of the clavicle or humerus as well as brachial plexus injuries and asphyxia (Thorp & Laughon, 2014). Maternal assessment should focus on early detection of hemorrhage and trauma to the vagina, perineum, and rectum.

Prolapsed Umbilical Cord

Prolapse of the umbilical cord occurs when the cord lies below the presenting part of the fetus. Umbilical cord prolapse may be occult (hidden, rather than visible) at any time during labor whether or not the membranes are ruptured (Fig. 32-17, *A* and *B*). It is most common to see frank (visible) prolapse directly after rupture of membranes, when gravity washes the cord in front of the presenting part (see Fig. 32-17, *C* and *D*). Contributing factors include a long cord (longer than 100 cm), malpresentation (breech or transverse lie), or an unengaged presenting part.

If the presenting part does not fit snugly into the lower uterine segment (e.g., as in polyhydramnios), when the membranes rupture, a sudden gush of amniotic fluid may cause the cord to be displaced downward. Similarly the cord may prolapse during amniotomy if the presenting part is high. A small fetus may not fit snugly into the lower uterine segment; as a result, cord prolapse is more likely to occur.

CARE MANAGEMENT

Prompt recognition of a prolapsed umbilical cord is important because fetal hypoxia resulting from prolonged cord compression (i.e., occlusion of blood flow to and from the fetus for more than 5 minutes) usually results in CNS damage or death of the fetus. Pressure on the cord may be relieved by the examiner putting a sterile gloved hand into the vagina and holding the presenting part off the umbilical cord (Fig. 32-18, *A* and *B*). The woman may also be assisted into a position such as a modified

FIG 32-18 Arrows indicate direction of pressure against presenting part to relieve compression of prolapsed umbilical cord. Pressure exerted by examiner's fingers in **A**, vertex presentation, and **B**, breech presentation. **C**, Gravity relieves pressure when woman is in modified Sims position with hips elevated as high as possible with pillows. **D**, Knee-chest position.

Sims (see Fig. 32-18, *C*), Trendelenburg, or knee-chest (see Fig. 32-18, *D*) position, in which gravity keeps the pressure of the presenting part off the cord. If the cervix is fully dilated, a forceps- or vacuum-assisted birth can be performed for the fetus in a cephalic presentation; otherwise, a cesarean birth is likely to be performed. Abnormal FHR and pattern (e.g., bradycardia, absent or minimal variability, and variable or prolonged decelerations), inadequate uterine relaxation, and bleeding also can occur as a result of a prolapsed umbilical cord. (Indications for immediate interventions are presented in Emergency: Prolapsed Umbilical Cord.) Ongoing assessment of the woman and her fetus is critical to determine the effectiveness of each action

taken. The woman and her family are often aware of the seriousness of the situation; therefore, the nurse must provide support by giving explanations for the interventions being implemented and their effect on the status of the fetus.

+ EMERGENCY

Prolapsed Umbilical Cord

Signs

- Variable or prolonged deceleration during uterine contractions
- Woman reports feeling the cord after membranes rupture
- Cord is seen or felt in or protruding from the vagina

Interventions

- Call for assistance. Do not leave the woman alone.
- Have someone notify the primary health care provider immediately.
- Glove the examining hand quickly and insert two fingers into the vagina to the cervix. With one finger on either side of the cord or both fingers to one side, exert upward pressure against the presenting part to relieve compression of the cord (see Fig. 32-18, *A* and *B*). Do *not* move your hand! Another person may place a rolled towel under the woman's right or left hip.
- Place woman into the extreme Trendelenburg or a modified Sims position (see Fig. 32-18, *C*) or a knee-chest position (see Fig. 32-18, *D*).
- If cord is protruding from vagina, wrap loosely in a sterile towel saturated with warm sterile normal saline solution. Do not attempt to replace cord into cervix.
- Administer oxygen to the woman by nonrebreather mask at 8 to 10 L/minute until birth is accomplished.
- Start intravenous (IV) fluids or increase existing drip rate.
- Continue to monitor fetal heart rate (FHR) continuously, by internal fetal scalp electrode, if possible.
- Explain to woman and support person what is happening and the way it is being managed.
- Prepare for immediate vaginal birth if cervix is fully dilated or cesarean birth if it is not.

Rupture of the Uterus

Uterine rupture, in which there is complete nonsurgical disruption of all uterine layers, is a rare but life-threatening obstetric injury that occurs in 1 of 8000 to 1 in 15,000 births when there is no history of previous uterine scarring (Nikolaou, Kourea, Antonopoulos, et al., 2013). In women with a history of uterine injury, the risk increases to 0.5% if labor occurs spontaneously and 1.5% if it is induced (Kok, Wiersma, Opmeer, et al., 2013). During labor and birth the major risk factor for uterine rupture is a scarred uterus as a result of previous cesarean birth or other uterine surgery. Rupture usually occurs during a TOL for VBAC; symptomatic rupture is rarely observed in planned, repeat cesarean births. The likelihood of uterine rupture depends on the type and location of the previous uterine scar. Uterine rupture occurs most often with a previous classic incision. Other factors that increase the risk for uterine rupture include multiple prior cesarean births, no previous vaginal births, induced or augmented labor, term gestation, multifetal gestation, fetal macrosomia, postcesarean birth infection, and short interpregnancy interval (Berghella & Landon, 2012; Bernstein, Matalon-Grazi, & Rosenn, 2012; Francois & Foley, 2012).

Uterine dehiscence, sometimes called incomplete uterine rupture, is separation of a prior scar. It may go unnoticed unless the woman undergoes a subsequent cesarean birth or other uterine surgery. The potential for maternal or fetal complications as a result of uterine dehiscence is negligible because separation of a prior scar does not result in hemorrhage (Berghella & Landon, 2012).

Signs and symptoms vary with the extent of the uterine rupture. The most common finding is an abnormal FHR tracing, particularly variable or prolonged decelerations or bradycardia. A loss of fetal station also can occur. The woman can experience constant abdominal pain, uterine tenderness, a change in uterine shape, and cessation of contractions (Berghella & Landon, 2012; Francois & Foley, 2012; Holmgren, Scott, Porter, et al., 2012). She may also exhibit signs of hypovolemic shock caused by hemorrhage (i.e., hypotension, tachypnea, pallor, and cool, clammy skin). If the placenta separates, the FHR will be absent. Fetal parts may be palpable through the abdomen.

CARE MANAGEMENT

Prevention is the best treatment. Women who have had a cesarean birth with a classic uterine incision are advised not to labor or attempt vaginal birth in subsequent pregnancies. Those at risk for uterine rupture are assessed closely during labor. Women whose labor is induced with oxytocin or prostaglandin (especially if their previous birth was cesarean) are monitored for signs of uterine tachysystole because this can precipitate uterine rupture. If tachysystole occurs, the oxytocin infusion is discontinued or decreased, and a tocolytic medication may be given to decrease the intensity of the uterine contractions (see Emergency: Uterine Tachysystole with Oxytocin [Pitocin] Infusion). After giving birth, the woman is assessed for excessive bleeding, especially if the fundus is firm and signs of hemorrhagic shock are present.

If rupture occurs, management depends on the severity. A small rupture may be managed with a laparotomy and birth of the infant, repair of the laceration, and blood transfusions, if needed. Hysterectomy may be necessary if the rupture is large and difficult to repair or if the woman is hemodynamically unstable (Francois & Foley, 2012).

The nurse's role can include starting IV fluids, transfusing blood products, administering oxygen, and assisting with preparations for immediate surgery. Supporting the woman's family and providing information about the treatment are important during this emergency. The associated fetal mortality rate is high (approximately 50% to 75%), particularly if the fetus is ejected from the uterus into the abdominal cavity. Maternal morbidity and mortality also can be substantial (Cunningham et al., 2014). Providing information about spiritual support services or suggesting that the family contact their own support system may be warranted.

Amniotic Fluid Embolus

Amniotic fluid embolus (AFE), also known as **anaphylactoid syndrome of pregnancy**, is a rare but devastating complication of pregnancy characterized by the sudden, acute onset of hypoxia, hypotension, cardiovascular collapse, and coagulopathy. The incidence of AFE in the United States is estimated at

1 in 8000 to 1 in 30,000 births. The true incidence is unknown because of the difficulty in confirming the diagnosis and inconsistent reporting of nonfatal cases (Jones & Clark, 2013).

AFE occurs during labor, during birth, or within 30 minutes after birth. This combination of sudden respiratory and cardiovascular collapse, along with coagulopathy, is similar to that observed in clients with anaphylactic or septic shock. In both conditions a foreign substance is introduced into the circulation, resulting in disseminated intravascular coagulation (DIC), hypotension, and hypoxia (Robbins, Martin, & Wilson, 2014).

In AFE the foreign substance that initiates the condition is presumed to be present in amniotic fluid that is introduced into the maternal circulation. However, the exact factor that initiates AFE has not been identified. In the past, particles of fetal debris (e.g., vernix, hair, skin cells, or meconium) found in amniotic fluid were thought to be responsible for initiating the syndrome; however, fetal debris can be found in the pulmonary circulation of most healthy laboring women. Also fetal debris is identified in only 78% of women diagnosed with AFE. Therefore, AFE is diagnosed clinically (Jones & Clark, 2013; Robbins et al., 2014; Simpson & O'Brien-Abel, 2014). The most recent population-based studies suggest that the U.S. mortality rate has dropped from a reported rate of 61% to a current rate of 22% (Robbins et al.). Neonatal outcome in cases of AFE is poor. If the event occurs before birth, the neonatal survival rate is approximately 80%. However, only half of these fetuses survive neurologically intact (Jones & Clark).

Maternal risk factors for AFE include advanced age; placenta previa or abruption; preeclampsia, eclampsia, and other hypertensive disorders; diabetes; labor induction and forceps-assisted or cesarean birth; and cervical laceration or uterine rupture (Kramer, Rouleau, Liu, et al., 2012). Previously it was thought that the hypertonic uterine contractions that often accompany AFE actually caused the event. Instead, it appears that the physiologic response to AFE produces the hypertonic contractions (Jones & Clark, 2013).

CARE MANAGEMENT

The immediate interventions for AFE are summarized in Emergency: Amniotic Fluid Embolus (Anaphylactoid Syndrome of Pregnancy). Care must be instituted immediately. Cardiopulmonary resuscitation is often necessary. If cardiopulmonary arrest occurs, a perimortem cesarean birth should be considered after 4 minutes of unsuccessful resuscitative efforts, both to improve the chances for optimal fetal survival and to facilitate maternal resuscitation (Robbins et al., 2014). The nurse's immediate responsibility is to assist with the resuscitation efforts.

KEY POINTS

- Preterm birth is any birth that occurs between 20 0/7 and 36 6/7 weeks of gestation.
- Preterm labor is generally diagnosed clinically as regular contractions along with a change in cervical effacement or dilation or both or presentation with regular uterine contractions and cervical dilation of at least 2 cm.

EMERGENCY

Amniotic Fluid Embolus (Anaphylactoid Syndrome of Pregnancy)

Signs

- Respiratory distress
 - Restlessness
 - Dyspnea
 - Cyanosis
 - Pulmonary edema
 - Respiratory arrest
- Circulatory collapse
 - Hypotension
 - Tachycardia
 - Shock
 - Cardiac arrest
- Hemorrhage
 - Coagulation failure: bleeding from incisions, venipuncture sites, trauma (lacerations); petechiae, ecchymoses, purpura
 - Uterine atony

Interventions

- Oxygenate.
 - Administer oxygen by nonrebreather face mask (8 to 10 L/minute) or resuscitation bag delivering 100% oxygen.
 - Prepare for intubation and mechanical ventilation.
 - Initiate or assist with cardiopulmonary resuscitation. Tilt pregnant woman 30 degrees to her side to displace uterus.
- Maintain cardiac output and replace fluid losses.
 - Position woman onto her side.
 - Administer intravenous (IV) fluids.
 - Administer blood products: packed cells, fresh-frozen plasma.
 - Insert indwelling catheter, and measure hourly urine output.
- Correct coagulation failure.
- Monitor fetal and maternal status.
- Prepare for emergency birth once woman's condition is stabilized.
- Provide emotional support to woman, her partner, and family.

If the woman survives she is usually moved to a critical care unit. Additional interventions include replacing blood and clotting factors and maintaining adequate hydration and blood pressure. The woman is usually placed on mechanical ventilation with continuous hemodynamic monitoring (Robbins et al., 2014).

Support of the woman's partner and family is needed; they will be anxious and distressed. Brief explanations of what is happening are important during the emergency and can be reinforced after the immediate crisis is over. If the woman dies, emotional support and involvement of the perinatal loss support team or other resources for grief counseling are needed. Referral to grief and loss support groups also is appropriate (see Chapter 37). The nursing staff also may need help in coping with feelings and emotions that result from a maternal death.

- The incidence of preterm birth varies considerably by race. In the United States, non-Hispanic black women have the highest rate of preterm birth.
- The cause of preterm labor is unknown and is assumed to be multifactorial; therefore, it is not possible to predict with certainty which women will experience preterm labor and birth.

KEY POINTS—cont'd

- Because the onset of preterm labor is often insidious and can be mistaken for normal discomforts of pregnancy, nurses should teach all pregnant women how to detect the early symptoms of preterm labor and to call their primary health care provider when symptoms occur.
- The best reason to use tocolytic therapy is to achieve sufficient time to administer glucocorticoids in an effort to accelerate fetal lung maturity. Additionally, time is allowed for transport of the woman prior to birth to a center equipped to care for preterm infants.
- If fetal or early neonatal death is expected, the parents and members of the health care team need to discuss the situation before the birth and decide on a management plan that is acceptable to everyone.
- Vigilance for signs of infection is an essential component of the care management for women with preterm PROM.
- Dysfunctional labor results from differences in the normal relationships among any of the five factors affecting labor and is characterized by differences in the pattern of progress in labor.
- Obese women are at risk for several pregnancy complications, including cesarean birth. Even routine procedures require more time and effort to accomplish when the client is obese.
- Uterine contractility is increased by the effects of oxytocin and prostaglandin and is decreased by tocolytic agents.
- Labor should not be induced electively until the woman has reached at least 39 weeks of gestation.
- Cervical ripening using chemical or mechanical measures can increase the success of labor induction.
- Expectant parents benefit from learning about operative obstetrics (e.g., forceps-assisted, vacuum-assisted, or cesarean birth) during the prenatal period.
- The basic purpose of cesarean birth is to preserve the well-being of the mother and her fetus.
- Unless contraindicated, vaginal birth is possible after a previous cesarean birth.
- Obstetric emergencies (e.g., meconium-stained amniotic fluid, shoulder dystocia, prolapsed cord, rupture of the uterus, and amniotic fluid embolism) occur rarely but require immediate intervention to preserve the health or life of the mother and fetus or newborn.

Postpartum Complications

Rhonda K. Lanning

 <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Identify the causes, signs and symptoms, and medical and nursing management of postpartum hemorrhage.
- Describe hemorrhagic shock as a complication of postpartum hemorrhage, including management and hazards of therapy.
- Differentiate the causes of postpartum infection.
- Summarize assessment and care of women with postpartum infection.
- Describe thromboembolic disorders, including incidence, etiology, signs and symptoms, and medical and nursing management.

The postpartum period is a time of change and transition for mothers and newborns. Mothers experience incredible physiologic shifts and emotional adjustments in the hours and days following birth. Perinatal nurses provide education, care, and support for mothers and newborns during this important time. In addition, nurses have the responsibility to pay careful attention to signs and symptoms of complications. The nurse works collaboratively with the health care team to provide safe and effective care to women experiencing postpartum physiologic complications. The nurse's rapid response to complications such as hemorrhage and infection are critical to the well-being of the new mother. This chapter focuses on these two important postpartum complications.

POSTPARTUM HEMORRHAGE

Definition and Incidence

Postpartum hemorrhage (PPH) continues to be a leading cause of maternal morbidity and mortality in the United States and throughout the world (World Health Organization [WHO], 2012). Postpartum hemorrhage is a life-threatening event that can occur with little warning and is often not recognized until the mother has profound symptoms.

PPH is defined as the loss of 500 ml or more of blood after vaginal birth and 1000 ml or more after cesarean birth. Either a 10% change in hematocrit between admission for labor and postpartum or the need for erythrocyte transfusion is also used to define PPH (Francois & Foley, 2012). However, defining PPH clinically can be ambiguous. Diagnosis is often based on subjective observations, with blood loss often being underestimated by as much as 50% (Cunningham, Leveno, Bloom, et al., 2014).

In 2010 The Joint Commission (TJC) issued the *Sentinel Event Alert: Preventing Maternal Death*. It identified the most preventable errors as the following:

- Failure to adequately control blood pressure in hypertensive women
- Failure to adequately diagnose and treat pulmonary edema in women with preeclampsia
- Failure to pay attention to vital signs following cesarean birth
- Hemorrhage following cesarean birth (TJC, 2010)

Postpartum hemorrhage is classified as early or late with respect to the birth. Early, acute, or primary PPH occurs within 24 hours of the birth. Late or secondary PPH occurs more than 24 hours but less than 6 weeks after the birth (Francois & Foley, 2012). Today's health care environment encourages shortened hospital stays after birth, which increases the potential for acute episodes of PPH to occur outside the traditional hospital or birth center setting.

Etiology and Risk Factors

When excessive bleeding is observed, it is important to note the color and consistency of the blood as well as the stage of labor. From birth of the infant until separation of the placenta, the character and quantity of blood passed can suggest excessive bleeding. For example, dark red blood is likely of venous origin, perhaps from varices or superficial lacerations of the birth canal. Bright blood is arterial and can indicate deep lacerations of the cervix. spurts of blood with clots can indicate partial placental separation. Failure of blood to clot or remain clotted indicates a pathologic condition or coagulopathy such as disseminated intravascular coagulation (DIC) (see Chapter 28).

Excessive bleeding can occur during the period from the separation of the placenta to its expulsion or removal. Commonly

such excessive bleeding is the result of incomplete placental separation, undue manipulation of the fundus, or excessive traction on the cord. After the placenta has been expelled or removed, persistent or excessive blood loss usually is the result of uterine atony or prolapse of the uterus into the vagina. Late PPH can be the result of subinvolution of the uterus, endometritis, or retained placental fragments (Francois & Foley, 2012). Predisposing factors for PPH are listed in Box 33-1.

Uterine Atony

The greatest risk for early postpartum hemorrhage is during the first hour after birth. During this time, large venous areas are exposed after the placenta separates from the uterine wall. The corpus or body of the uterus is essentially a basket-weave of strong, interlacing smooth muscle bundles through which many large maternal blood vessels pass (see Fig. 4-3). Bleeding is controlled by the contraction of smooth muscle in the uterus. If the uterus is flaccid after detachment of all or part of the placenta, brisk venous bleeding occurs, and normal coagulation of the open vasculature is impaired and continues until the uterine muscle is contracted. This marked hypotonia of the uterus is called **uterine atony**.

Uterine atony is the leading cause of early PPH. It is associated with high parity, polyhydramnios, fetal macrosomia, and multiple gestations. In such conditions the uterus is “overstretched” and contracts poorly after birth. Other causes of atony include traumatic birth, use of halogenated anesthetic (e.g., halothane), magnesium sulfate, rapid or prolonged labor, chorioamnionitis, use of oxytocin for labor induction or augmentation, and uterine atony in a previous pregnancy (Francois & Foley, 2012).

CLINICAL REASONING CASE STUDY

Postpartum Hemorrhage

You are the mother-baby nurse assigned to Ms. Avery. She is a G6 P5 who gave birth to a 9-lb (4082 kg) baby boy this morning. Ms. Avery had an uncomplicated but precipitous vaginal birth. Perineum is intact. She is breastfeeding. All labs are normal. She is now 5 hours postpartum. A family member calls out from the client’s room for assistance. When you walk into the room Ms. Avery is standing up on her way to the bathroom with a large pool of blood on the floor. She states, “I don’t know what happened; it all just came when I stood up. I am so dizzy and lightheaded.” What do you, as the nurse, do next?

1. Evidence—Is there sufficient evidence to draw conclusions about what the nurse should do?
2. Assumptions—Describe underlying assumptions about each of the following:
 - a. Identify risk factors for early postpartum hemorrhage (PPH) and specifically those described for Ms. Avery.
 - b. Need for frequent assessments in the early postpartum period
 - c. Use of oxytocics for prevention and management of PPH
3. What implications and priorities for nursing care can be made at this time?
4. Does the evidence objectively support your conclusion?

Retained Placenta

When the placenta has not been delivered within 30 minutes after birth despite gentle traction on the umbilical cord and

BOX 33-1 Risk Factors and Causes of Postpartum Hemorrhage

Uterine atony

- Overdistended uterus
 - Large fetus
 - Multiple fetuses
 - Hydramnios
 - Distention with clots
- Anesthesia and analgesia
 - Conduction anesthesia
- Previous history of uterine atony
- High parity
- Prolonged labor, oxytocin-induced labor
- Trauma during labor and birth
 - Forceps-assisted birth
 - Vacuum-assisted birth
 - Cesarean birth

Unrepaired lacerations of the birth canal

Retained placental fragments

Ruptured uterus

Inversion of the uterus

Placenta accreta, increta, percreta

Coagulation disorders

Placental abruption

Placenta previa

Manual removal of a retained placenta

Magnesium sulfate administration during labor or the postpartum period

Chorioamnionitis

Uterine subinvolution

uterine massage, it is described as “retained.” Initial management of a retained placenta consists of manual separation and removal by the physician or nurse-midwife (Fig. 33-1). This involves the provider reaching into the uterus and gently separating the placenta from the uterine wall and removing it manually. When the mother has regional anesthesia for labor, supplementary anesthesia is usually not needed. For other women, administration of light nitrous oxide and oxygen inhalation anesthesia or intravenous (IV) pain medications should be considered. A tocolytic medication such as nitroglycerin IV may be given to promote uterine relaxation (Francois & Foley, 2012). After removal of a retained placenta, the woman is at continued risk for PPH and infection.

Fragments of the placenta can remain in the uterus after spontaneous separation of the placenta during the third stage of labor. In this case the woman will have excessive bleeding and the uterus feels boggy (soft) due to uterine atony. Ultrasonography can be used to detect placental fragments. The physician or nurse-midwife may attempt manual exploration to remove the fragments; uterine curettage (removal of uterine contents using a curette or vacuum suction) may be necessary.

In rare instances there is abnormal adherence of the placenta to the myometrium. It is unknown why this occurs, but it is thought to result from zygote implantation in an area of defective endometrium so that no zone of separation exists between the placenta and the decidua. Attempts to remove the placenta in the usual manner are unsuccessful, and laceration or perforation of the uterine wall can result, putting the woman at great risk for severe PPH and infection (Francois & Foley, 2012).

FIG 33-1 Manual uterine exploration. (From Francois, K.E., & Foley, M.R. [2012]. *Antepartum and postpartum hemorrhage*. In S.G. Gabbe, J.R. Niebyl, J.L. Simpson, et al. [Eds.], *Obstetrics: Normal and problem pregnancies* [6th ed.]. Philadelphia: Saunders.)

Unusual placental adherence can be partial or complete. The following degrees of attachment are recognized:

Placenta accreta—Slight penetration of myometrium

Placenta increta—Deep penetration of myometrium

Placenta percreta—Perforation of uterus

Placenta accreta is most common, with its incidence increasing in association with the rise in cesarean birth rates (Cunningham et al., 2014). Other risk factors include placenta previa, prior uterine surgery, endometrial defects, submucosal fibroids, parity, and maternal age (Francois & Foley, 2012). Placenta accreta can be diagnosed before birth using ultrasound and magnetic resonance imaging (MRI), but often it is not recognized until there is excessive bleeding after birth. Bleeding with complete or total placenta accreta may not occur unless manual removal of the placenta is attempted. With more extensive involvement, bleeding becomes profuse when delivery of the placenta is attempted. Less blood is lost if the diagnosis is made antenatally and no attempt is made to manually remove the placenta. Treatment includes blood component replacement therapy. Hysterectomy can be indicated for all three types of placental adherence if bleeding is uncontrolled (Cunningham et al.).

Lacerations of the Genital Tract

Lacerations of the cervix, vagina, and perineum also are causes of PPH. Hemorrhage related to lacerations should be suspected if bleeding continues despite a firm, contracted uterine fundus. This bleeding can be a slow trickle, an oozing, or frank hemorrhage. Factors that influence the causes and incidence of obstetric lacerations of the lower genital tract include operative birth, precipitous or rapid birth, congenital abnormalities of

the maternal soft tissue, and contracted pelvis. Other possible causes of lacerations are size, abnormal presentation and position of the fetus; relative size of the presenting part and the birth canal; previous scarring from infection, injury, or operation; and vulvar, perineal, and vaginal varicosities.

Lacerations of the perineum are the most common of all injuries in the lower portion of the genital tract. These are classified as first, second, third, and fourth degree (see Chapter 19). An episiotomy can extend to become either a third- or fourth-degree laceration.

Prolonged pressure of the fetal head on the vaginal mucosa ultimately interferes with the circulation and may produce ischemic or pressure necrosis. The state of the tissues in combination with the type of birth can result in deep vaginal lacerations, with consequent predisposition to vaginal hematomas.

Cervical lacerations usually occur at the lateral angles of the external os. Most are shallow, and bleeding is minimal. More extensive lacerations may extend into the vaginal vault or into the lower uterine segment.

Lacerations are usually identified and sutured immediately after birth. After the bleeding has been controlled, the care of the woman with lacerations of the perineum is similar to that for women with episiotomies (i.e., analgesia as needed for pain and hot or cold applications as necessary). The need for increased fiber in the diet and increased intake of fluids is emphasized to reduce the risk of constipation. Stool softeners may be used to assist the woman in reestablishing bowel habits without straining and putting stress on the suture lines.

Hematomas

Pelvic hematomas (i.e., a collection of blood in the connective tissue) can be vulvar, vaginal, or retroperitoneal in origin. Vulvar hematomas are the most common. Pain is the most common symptom, and most vulvar hematomas are visible. Vaginal hematomas occur more commonly in association with a forceps-assisted birth, an episiotomy, or primigravidity (Francois & Foley, 2012).

Retroperitoneal hematomas are the least common but life threatening. They are caused by laceration of one of the vessels attached to the hypogastric artery, usually associated with rupture of a cesarean scar during labor. During the postpartum period, if the woman reports persistent perineal or rectal pain or a feeling of pressure in the vagina, a careful examination is made. However, a retroperitoneal hematoma can cause minimal pain and the initial symptoms can be signs of shock (Francois & Foley, 2012).

Hematomas are usually surgically evacuated. Once the bleeding has been controlled, usual postpartum care is provided with careful attention to pain relief, monitoring the amount of bleeding, replacing fluids, and reviewing laboratory results (hemoglobin and hematocrit).

Inversion of the Uterus

Inversion of the uterus (turning inside out) after birth is a rare but potentially life-threatening complication. The incidence of uterine inversion varies from 1 in 2000 to 1 in 20,000 births and differs depending on whether the birth was vaginal or cesarean (Cunningham et al., 2014) and can recur with a subsequent birth. Uterine inversion can be incomplete, complete,

or prolapsed. Incomplete inversion cannot be seen; a smooth mass can be palpated through the dilated cervix. In complete inversion, the lining of the fundus crosses through the cervical os and forms a mass in the vagina. Prolapsed inversion of the uterus is obvious—a large, red, rounded mass (perhaps with the placenta attached) protrudes 20 to 30 cm outside the introitus.

Contributing factors to uterine inversion include fundal implantation of the placenta, vigorous fundal pressure, excessive traction applied to the cord, fetal macrosomia, short umbilical cord, tocolysis, prolonged labor, uterine atony, nulliparity, and abnormally adherent placental tissue (Francois & Foley, 2012). The primary presenting signs of uterine inversion are sudden and include hemorrhage, shock, and pain. The uterus is not palpable abdominally. The uterus must be replaced into its proper position by the physician or nurse-midwife.

Prevention—always the easiest, least expensive, and most effective therapy—is especially appropriate for uterine inversion. The umbilical cord should not be pulled unless there are clear signs of placental separation.

Uterine inversion is an emergency situation requiring immediate interventions that include maternal fluid resuscitation, replacement of the uterus within the pelvic cavity, and correction of associated clinical conditions. Tocolytics or halogenated anesthetics may be given to relax the uterus before attempting replacement (Francois & Foley, 2012). Oxytocic agents are administered after the uterus is repositioned; broad-spectrum antibiotics are initiated. The woman's response to treatment is monitored closely to prevent shock or fluid overload. If the uterus has been repositioned manually, care must be taken to avoid aggressive fundal massage.

Subinvolution of the Uterus

Late postpartum bleeding can result from **subinvolution** of the uterus (delayed return of the enlarged uterus to normal size and function). Recognized causes of subinvolution include retained placental fragments and pelvic infection. Signs and symptoms include prolonged lochial discharge, irregular or excessive bleeding, and sometimes hemorrhage. A pelvic examination usually reveals a larger-than-normal uterus that can be boggy.

Treatment of subinvolution depends on the cause. Ergonovine (Ergotrate) or methylergonovine (Methergine), 0.2 mg every 3 to 4 hours for 24 to 48 hours, is often used. Dilation and curettage (D&C) may be performed to remove retained placental fragments or to debride the placental site. If the cause of subinvolution is infection, antibiotic therapy is needed (Cunningham et al., 2014).

CARE MANAGEMENT

Assessment

Early recognition and treatment of PPH are critical to care management (Fig. 33-2). The first step is to evaluate the contractility of the uterus. If the uterus is hypotonic or boggy, management is directed toward increasing contractility and minimizing blood loss.

If the uterus is firmly contracted and bleeding continues, the source of bleeding still must be identified and treated. Assessment may include visual or manual inspection of the perineum, the vagina, the uterus, the cervix, or the rectum, as well as

laboratory studies (e.g., hemoglobin, hematocrit, coagulation studies, platelet count). Treatment depends on the source of the bleeding.

Medical Management

The initial intervention in management of excessive postpartum bleeding due to uterine atony is firm massage of the uterine fundus (see Fig. 21-4). Expression of any clots in the uterus, elimination of bladder distention, and continuous IV infusion of 10 to 40 units of oxytocin added to 1000 ml of lactated Ringer's or normal saline solution also are primary interventions. If the uterus fails to respond to oxytocin, other uterotonic medications are administered. Misoprostol (Cytotec), a synthetic prostaglandin E₁ analog, is often used. An advantage is that it can be given rectally, sublingually, or orally. Methylergonovine may be given intramuscularly to produce sustained uterine contractions. A derivative of prostaglandin F₂α (carboprost tromethamine [Carboprost; Hemabate]) may be given intramuscularly. It can also be given intramyometrially at cesarean birth or intraabdominally after vaginal birth. Prostaglandin E₂ (Dinoprostone) vaginal or rectal suppository can be used for postpartum hemorrhage. (See Medication Guide: Uterotonic Drugs to Manage Postpartum Hemorrhage for a comparison of uterotonic drugs and common dosages used to manage PPH). In addition to the medications used to contract the uterus, rapid administration of crystalloid solutions or blood or blood products or both will be needed to restore the woman's intravascular volume (Francois & Foley, 2012).

MEDICATION ALERT

Use of ergonovine or methylergonovine is contraindicated in the presence of hypertension or cardiovascular disease. Prostaglandin F₂α should not be given to women with a history of asthma as it can cause bronchoconstriction (Francois & Foley, 2012).

Oxygen can be given by nonrebreather face mask to enhance oxygen delivery to the cells. An indwelling urinary catheter is usually inserted to monitor urine output as a measure of intravascular volume. Laboratory studies usually include a complete blood count with platelet count, fibrinogen, fibrin split products, prothrombin time, and partial thromboplastin time. Blood type and antibody screen are done if not previously performed (Cunningham et al., 2014).

If bleeding persists, bimanual compression (Fig. 33-3) may be performed by the obstetrician or nurse-midwife. This procedure involves inserting a fist into the vagina and pressing the knuckles against the anterior side of the uterus, and then placing the other hand on the abdomen and massaging the posterior uterus with it. If the uterus still does not become firm, the health care provider performs manual exploration of the uterine cavity for retained placental fragments.

Surgical Management

If the preceding procedures are ineffective, surgical management is needed. Surgical management options include uterine tamponade (uterine packing or an intrauterine tamponade balloon) (Fig. 33-4), bilateral uterine artery ligation, ligation of utero-ovarian arteries and infundibulopelvic vessels, and

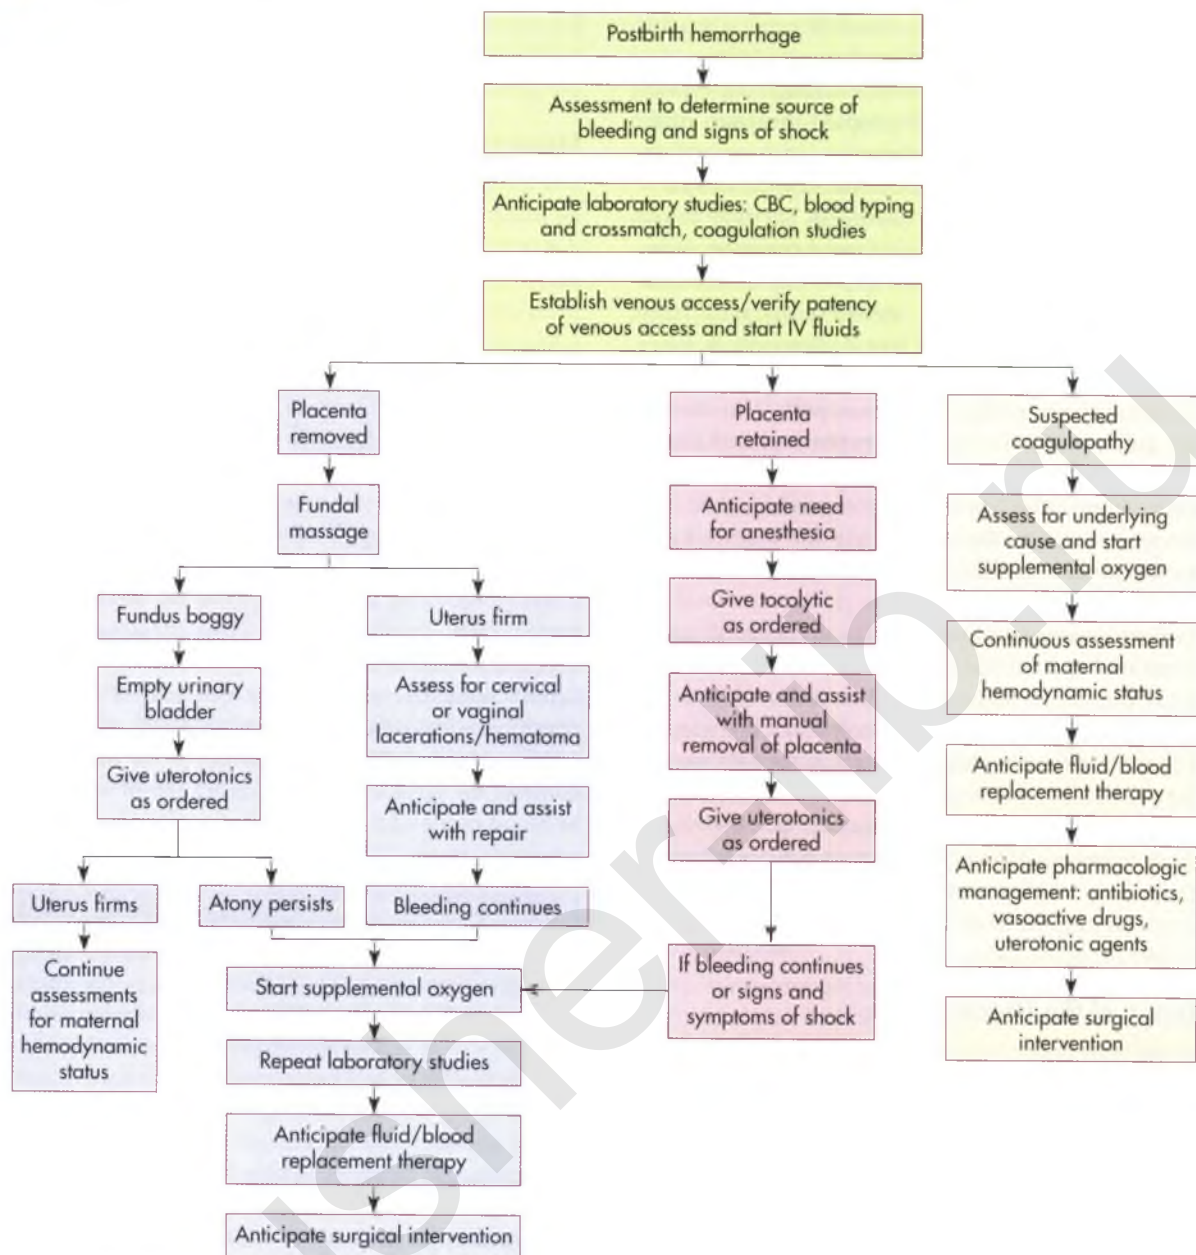

FIG 33-2 Nursing assessments for postpartum bleeding. (Uterotonics are medications to contract the uterus; tocolytics are medications to relax the uterus.) *CBC*, Complete blood count; *IV*, intravenous.

selective arterial embolization. Uterine compression suturing (e.g., B-Lynch or Hayman vertical sutures) may be performed and is sometimes combined with a tamponade balloon (see Fig. 33-4). If other treatment measures are ineffective, hysterectomy likely is needed (Cunningham et al., 2014; Francois & Foley, 2012).

Nursing Interventions

The nurse must be alert to the symptoms of hemorrhage and be prepared to act quickly to minimize blood loss (see Fig. 33-2). Astute assessment of circulatory status can be done with non-invasive monitoring (Box 33-2). Nursing diagnoses, expected outcomes of care, and interventions are based on the cause of PPH as previously discussed (see Nursing Care Plan).

The woman and her family will be anxious about her condition. The nurse can intervene by calmly providing explanations

about interventions being performed and the need to act quickly.

Once the woman's condition is stabilized and she has begun the recovery process, preparations for discharge are made. Discharge instructions for the woman who experienced PPH are similar to those for any postpartum woman. In addition, the woman should be told that she will probably feel fatigue, even exhaustion, and will need to limit her physical activities to conserve her strength. She may need instructions about increasing her dietary iron and protein intake and iron supplementation to rebuild lost red blood cell (RBC) volume. She may need assistance with infant care and household activities until she has regained strength. The nurse should assess the mother's anticipated level of support from family and friends and help the mother plan how to ask for help when returning home. Some mothers experiencing a PPH have problems with delayed lactogenesis, insufficient

MEDICATION GUIDE

Uterotonic Drugs to Manage Postpartum Hemorrhage

DRUG	ACTION	SIDE EFFECTS	CONTRAINDICATIONS	DOSAGE AND ROUTE	NURSING CONSIDERATIONS
Oxytocin (Pitocin)	Contraction of uterus; decreases bleeding	Infrequent: water intoxication, nausea and vomiting	None for PPH	10 to 20 units/L up to 80 units/L diluted in lactated Ringer's solution or normal saline at 125 to 200 milliunits/min IV; or 10 to 20 units IM	Continue to monitor vaginal bleeding and uterine tone.
Misoprostol (Cytotec)	Contraction of uterus	Headache, nausea, vomiting, diarrhea, fever, chills	None	600 to 1000 mcg rectally once or 400 mcg sublingually or PO once	Continue to monitor vaginal bleeding and uterine tone.
Methylergonovine (Methergine)	Contraction of uterus	Hypertension, hypotension, nausea, vomiting, headache	Hypertension, pre-eclampsia, cardiac disease	0.2 mg IM q2-4h up to five doses; may also be given intrauterine or orally	Check blood pressure before giving, and do not give if >140/90 mm Hg; continue monitoring vaginal bleeding and uterine tone.
15-Methylprostaglandin F _{2α} (Prostin/15 m; Carboprost, Hemabate)	Contraction of uterus	Headache, nausea and vomiting, fever, chills, tachycardia, hypertension, diarrhea	Avoid with asthma or hypertension	250 mcg IM or intrauterine injection every q15-90 min up to eight doses	Continue to monitor vaginal bleeding and uterine tone.
Dinoprostone (Prostin E ₂)	Contraction of uterus	Headache, nausea and vomiting, fever, chills, diarrhea	Use with caution with history of asthma, hypertension, or hypotension	20 mg vaginal or rectal suppository q2h	Continue to monitor vaginal bleeding and uterine tone.

IM, Intramuscular; IV, intravenous; PO, by mouth; PPH, postpartum hemorrhage.

milk production, or postpartum depression (PPD). Referrals for home care follow-up or to community resources may be needed, including lactation support or a postpartum doula service.

HEMORRHAGIC (HYPOVOLEMIC) SHOCK

Hemorrhage can result in **hemorrhagic (hypovolemic) shock**. Shock is an emergency situation in which the perfusion of body organs can become severely compromised and death can occur. Physiologic compensatory mechanisms are activated in response to hemorrhage. The adrenal glands release catecholamines, causing arterioles and venules in the skin, lungs, gastrointestinal tract, liver, and kidneys to constrict. The available blood flow is diverted to the brain and heart and away from other organs, including the uterus. If shock is prolonged, the continued reduction in cellular oxygenation results in an accumulation of lactic acid and acidosis (from anaerobic glucose metabolism). Acidosis (lowered serum pH) causes arteriolar vasodilation; venule vasoconstriction persists. A circular pattern is established (i.e., decreased perfusion, increased tissue anoxia and acidosis, edema formation, and pooling of blood further decrease the perfusion). Cellular death occurs. See *Emergency: Hemorrhagic Shock* for assessments and interventions for hemorrhagic shock.

Observation

- Presence or absence of anxiety, apprehension, restlessness, disorientation

Measurement

- Blood pressure
- Pulse oximetry
- Urinary output

best practice approaches that can be adopted by other institutions (Lyndon, Lagrew, Shields, et al., 2010). The use of obstetric rapid response teams and massive transfusion protocols is vital to promoting safe, effective care and improving outcomes.

LEGAL TIP: Standard of Care for Bleeding Emergencies

The standard of care for obstetric emergency situations such as PPH or hypovolemic shock is that provision should be made for the nurse to implement nursing actions independently. Policies, procedures, standing orders or protocols, and clinical guidelines should be established by each health care facility in which births occur and should be agreed on by health care providers involved in the care of obstetric clients.

Medical Management

Vigorous treatment is necessary to prevent adverse outcomes. Management of hypovolemic shock involves restoring circulating blood volume and eliminating the cause of the hemorrhage (e.g., lacerations, uterine atony, or inversion). Critical to successful management of the woman with a hemorrhagic complication is establishment of venous access, preferably with a large-bore IV catheter. Establishing two IV lines facilitates fluid resuscitation. Fluid resuscitation includes administering crystalloids (lactated Ringer's, normal saline solution), colloids (albumin), blood, and blood components. To restore circulating blood volume, a rapid IV infusion of crystalloid solution is given at a rate of 3 ml infused for every 1 ml of estimated blood loss (e.g., 3000 ml infused for 1000 ml of blood loss). Packed red blood cells (RBCs) are usually infused if the woman is still actively bleeding and no improvement in her condition is noted after the initial

CARE MANAGEMENT

In order for staff to be best prepared for obstetric hemorrhage, institutions must develop standardized management protocols and regularly conduct emergency drills. The California Maternal Quality Care Collaborative (www.cmqcc.org) has developed

crystalloid infusion. Infusion of fresh frozen plasma may be needed if clotting factors and platelet counts are below normal values (Cunningham et al., 2014; Francois & Foley, 2012).

Nursing Interventions

Hemorrhagic shock can occur rapidly, but the classic signs of shock may not appear until the postpartum woman has lost 30% to 40% of blood volume. The nurse must continue to reassess the woman's condition as evidenced by the degree of measurable and anticipated blood loss while also mobilizing appropriate resources.

Most interventions are instituted to improve or monitor tissue perfusion. Fluid resuscitation must be monitored carefully because fluid overload can occur. Intravascular fluid overload occurs most often with colloid therapy.

Transfusion reactions can follow administration of blood or blood components, including cryoprecipitates. Even in an emergency, each unit of blood or blood products should be carefully checked per hospital protocol. Complications of fluid or blood replacement therapy include hemolytic reactions, febrile reactions, allergic reactions, circulatory overload, and air embolism.

The nurse continues to monitor the woman's pulse and blood

frequently and provides additional indications of blood volume and oxygen saturation (Gilbert, 2011). In early stages of decreased blood flow the woman may report "seeing stars" or feeling dizzy or nauseated. She can become restless and orthopedic. As cerebral hypoxia increases, she can become confused and react slowly to stimuli or not at all. Some women complain of headaches.

Continuous electrocardiographic monitoring may be indicated for the woman who is hypotensive or tachycardic, continues to bleed profusely, or is in shock. A Foley catheter is inserted and a urometer is attached to allow hourly assessment of urine output. The most objective and least invasive assessment of adequate organ perfusion and oxygenation is a urine output of at least 30 ml/hr (Cunningham et al., 2014). Hemoglobin and hematocrit levels, platelet count, and coagulation studies are closely monitored.

COAGULOPATHIES

When bleeding is continuous and there is no identifiable source, a coagulopathy can be the cause. The woman's coagulation status must be assessed quickly and continuously. Abnormal results depend on the cause and can include increased prothrombin time, increased partial thromboplastin time, decreased platelets, decreased fibrinogen level, increased fibrin degradation products, and prolonged bleeding time. Causes of coagulopathies can include pregnancy complications such as idiopathic or immune thrombocytopenic purpura, von Willebrand disease, or DIC.

Idiopathic Thrombocytopenic Purpura

Idiopathic or immune thrombocytopenic purpura (ITP) is an autoimmune disorder in which antiplatelet antibodies decrease the life span of the platelets. Thrombocytopenia, capillary fragility, and increased bleeding time are diagnostic findings. ITP can cause severe hemorrhage after cesarean birth or cervical or vaginal lacerations. The incidence of postpartum uterine bleeding and vaginal hematomas is also increased. Neonatal thrombocytopenia can result, but serious bleeding is unusual (Rozance & Rosenberg, 2012).

Medical management focuses on control of platelet stability. If ITP was diagnosed during pregnancy, the woman likely was treated with corticosteroids or IV immunoglobulin. Platelet transfusions are usually given when there is significant bleeding. A splenectomy may be needed if the ITP does not respond to medical management (Cunningham et al., 2014).

von Willebrand Disease

von Willebrand disease (vWD), a type of hemophilia, is probably the most common of all hereditary bleeding disorders. Although vWD is rare, it is among the most common congenital clotting defects in U.S. women of childbearing age. It results from a deficiency or defect in a blood clotting protein called *von Willebrand factor (vWF)*. There are as many as 20 variations of vWD, most of which are inherited as autosomal dominant traits—types I and II are the most common. Symptoms include recurrent bleeding episodes such as nosebleeds or after tooth extraction, bruising easily, prolonged bleeding time (the most important test), factor VIII deficiency (mild to moderate),

EMERGENCY

Hemorrhagic Shock

ASSESSMENTS

- Respirations
- Pulse
- Blood pressure
- Skin
- Urinary output
- Level of consciousness
- Mental status
- Central venous pressure

CHARACTERISTICS

- Rapid and shallow
- Rapid, weak, irregular
- Decreasing (late sign)
- Cool, pale, clammy
- Decreasing
- Lethargy → coma
- Anxiety → coma
- Decreased

INTERVENTIONS

- Summon assistance and equipment.
- Start intravenous infusion per standing orders.
- Ensure patent airway; administer oxygen.
- Continue to monitor status.

pressure. If invasive hemodynamic monitoring is ordered, the nurse may assist with placement of a central venous pressure (CVP) or pulmonary artery (Swan-Ganz) catheter. Subsequently, the nurse monitors CVP, pulmonary artery pressure, or pulmonary artery wedge pressure as ordered (Gilbert, 2011).

Additional assessments include evaluating skin temperature, color, and turgor and mucous membranes. Breath sounds should be auscultated before fluid volume replacement to provide a baseline for future assessment. The nurse inspects for signs of DIC such as oozing at the sites of incisions or injections and assessment for the presence of petechiae or ecchymosis in areas not associated with surgery or trauma are critical in evaluating for DIC (see Chapter 28).

Oxygen is administered, preferably by a nonrebreather face mask, at 10 to 12 L/min to maintain oxygen saturation. Oxygen saturation should be monitored with a pulse oximeter, although measurements are not always accurate in a client with hypovolemia or decreased perfusion. Level of consciousness is assessed

 **NURSING CARE PLAN**
Postpartum Hemorrhage

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Deficient Fluid Volume related to postpartum hemorrhage</i>	Woman will demonstrate fluid balance as evidenced by stable vital signs, prompt capillary refill time, and balanced intake and output.	Monitor vital signs, oxygen saturation, urine specific gravity, and capillary refill.	To provide baseline data
		Measure and record amount and type of bleeding by weighing and counting saturated pads; if woman is at home, teach her to count pads and save any clots or tissue; if woman is admitted to the hospital, save clots and tissue for further examination.	To estimate type and amount of blood loss for fluid replacement
		Provide quiet environment.	To promote rest and decrease metabolic demands
		Give explanation of all procedures.	To reduce anxiety
		Begin intravenous (IV) access with 18-gauge or larger catheter for infusion of isotonic solution as ordered.	To provide fluid or blood replacement
		Administer medications as ordered, such as oxytocin, misoprostol, methylergonovine, or prostaglandin F ₂ α.	To increase contractility of uterus
		Insert indwelling urinary catheter.	To provide most accurate assessment of renal function and hypovolemia
		Prepare for surgical intervention as needed.	To stop source of bleeding
		Monitor vital signs, oxygen saturation, arterial blood gases, and hematocrit and hemoglobin.	To assess for hypovolemic shock and decreased tissue perfusion
		Assess capillary refill, mucous membranes, and skin temperature.	To note indicators of vasoconstriction
<i>Ineffective Tissue Perfusion related to hypovolemia</i>	Woman will have stable vital signs, oxygen saturation, and arterial blood gases and adequate hematocrit and hemoglobin.	Give supplementary oxygen as ordered.	To provide additional oxygenation to tissues
		Suction as needed, and insert oral airway.	To maintain clear, open airway for oxygenation
		Monitor arterial blood gases.	To provide information about acidosis or hypoxia
		Administer sodium bicarbonate if ordered.	To reverse metabolic acidosis
		Use therapeutic communication, evaluate woman's understanding of events.	To provide clarification of any misconceptions
		Provide calm, competent attitude and environment	To aid in decreasing anxiety
		Explain all procedures.	To decrease anxiety about unknown
		Allow woman to verbalize feelings.	To permit clarification of information and promote trust
		Continue to assess vital signs or other clinical indicators of hypovolemic shock.	To evaluate if psychologic response of anxiety intensifies physiologic indicators
		<i>Risk for Infection related to blood loss and invasive procedures as result of postpartum hemorrhage</i>	Woman will verbalize understanding of risk factors. Woman will demonstrate no signs of infection.
Teach woman to maintain proper hand hygiene (particularly before handling her newborn) and to maintain scrupulous perineal care with frequent change and careful disposal of perineal pads.	To avoid spread of microorganisms		
Monitor vital signs.	To detect signs of systemic infection		
Monitor level of fatigue and lethargy, evidence of chills, loss of appetite, nausea and vomiting, and abdominal pain.	To indicate extent of infection and serve as indicators of status of infection		
Monitor lochia for foul smell.	To indicate status of infection		
Assist with collection of intrauterine cultures or other specimens for laboratory analysis.	To identify specific causative organism		
Monitor laboratory values (i.e., white blood cell [WBC] count, cultures).	For indicators of type and status of infection		
Ensure adequate fluid and nutritional intake.	To promote healthy recovery		
Administer and monitor broad-spectrum antibiotics as ordered.	To prevent or treat infection		
Administer antipyretics as ordered and necessary.	To reduce elevated temperature		
<i>Anxiety related to sudden change in health status</i>	Woman will verbalize that anxious feelings are diminished.	Administer sodium bicarbonate if ordered.	To reverse metabolic acidosis
		Use therapeutic communication, evaluate woman's understanding of events.	To provide clarification of any misconceptions
		Provide calm, competent attitude and environment	To aid in decreasing anxiety
		Explain all procedures.	To decrease anxiety about unknown
		Allow woman to verbalize feelings.	To permit clarification of information and promote trust
		Continue to assess vital signs or other clinical indicators of hypovolemic shock.	To evaluate if psychologic response of anxiety intensifies physiologic indicators
		Maintain Standard Precautions and use proper hand hygiene technique when providing care.	To prevent introduction of or spread of infection
		Teach woman to maintain proper hand hygiene (particularly before handling her newborn) and to maintain scrupulous perineal care with frequent change and careful disposal of perineal pads.	To avoid spread of microorganisms
		Monitor vital signs.	To detect signs of systemic infection
		Monitor level of fatigue and lethargy, evidence of chills, loss of appetite, nausea and vomiting, and abdominal pain.	To indicate extent of infection and serve as indicators of status of infection

and bleeding from mucous membranes. Although factor VIII increases during pregnancy, a risk for PPH still exists as levels of vWF begin to decrease (Cunningham et al., 2014). The woman can be at risk for bleeding for up to 4 weeks after birth.

The treatment of choice is administration of desmopressin, which promotes the release of vWF and factor VIII. It can be given nasally, intravenously, or orally. Transfusion therapy with plasma products that have been treated for viruses and contain factor VIII and vWF also may be used. Concentrates of anti-hemophilic factor (Humate-P or Alphanate) can be administered (Cunningham et al., 2014).

VENOUS THROMBOEMBOLIC DISORDERS

Venous thromboembolism (VTE) results from the formation of a blood clot or clots inside a blood vessel and is caused by inflammation (**thrombophlebitis**) or partial obstruction of the vessel (Fig. 33-5). Three thromboembolic conditions are of concern in the postpartum period:

Superficial venous thrombosis—Involvement of the superficial saphenous venous system

Deep venous thrombosis (DVT)—Occurs most often in the lower extremities; involvement varies but can extend from the foot to the iliofemoral region

Pulmonary embolism (PE)—Complication of DVT occurring when part of a blood clot dislodges and is carried to the pulmonary artery, where it occludes the vessel and obstructs blood flow to the lungs

Incidence and Etiology

The incidence of venous thromboembolism (VTE) is approximately 1 in 1000 pregnancies (Cunningham et al., 2014; Pettker & Lockwood, 2012). VTE can occur in any trimester of pregnancy and in the postpartum period. DVT occurs most often during pregnancy, and PE is more common in the postpartum period. The incidence of VTE in the postpartum period has declined since early ambulation after childbirth has become standard practice. However, PE is a major cause of maternal death (Pettker & Lockwood). The primary causes of thromboembolic disease are venous stasis and hypercoagulation, both of which are present in pregnancy and continue into the postpartum period. Cesarean birth nearly doubles the risk for VTE; therefore, routine preoperative placement of pneumatic compression devices is recommended. Other risk factors include operative vaginal birth; history of venous thrombosis, pulmonary embolism, or varicosities; obesity; maternal age greater than 35; multiparity; and smoking (Pettker & Lockwood).

Clinical Manifestations

Superficial venous thrombosis is the most common form of postpartum thrombophlebitis. It is characterized by pain and tenderness in the lower extremity. Physical examination may reveal warmth; redness; and an enlarged, hardened vein over the site of the thrombosis.

Deep vein thrombosis is more common during pregnancy than in the postpartum period and is characterized by unilateral leg pain, calf tenderness, and swelling. Physical examination may reveal redness and warmth, but women can have a large clot with few symptoms. A positive Homans sign may

FIG 33-5 Deep venous thrombophlebitis.

be present, but it is usually not performed because more objective tests are needed for diagnosis (Parker & Lockwood, 2012).

Acute pulmonary embolism usually results from dislodged deep vein thrombi. Presenting symptoms are dyspnea and tachypnea (more than 20 breaths/minute). Other signs and symptoms frequently seen include tachycardia (more than 100 beats/minute), apprehension, pleuritic chest pain, cough, hemoptysis, elevated temperature, and syncope (Cunningham et al., 2014; Pettker & Lockwood, 2012).

Physical examination is not a sensitive diagnostic indicator for thrombosis. Venous ultrasonography with or without color Doppler is the most commonly used diagnostic test. MRI and D-dimer assays also may be used (Pettker & Lockwood, 2012). With PE, echocardiographic abnormalities may be seen in right ventricular size or function. Pregnancy limits the usefulness of arterial blood gases and oxygen saturation in diagnosis. A ventilation-perfusion scan, spiral computed tomography scan, magnetic resonance angiography, and pulmonary arteriogram may be used for diagnosis (Pettker & Lockwood).

Medical Management

Superficial venous thrombosis is treated with analgesia (non-steroidal antiinflammatory agents), rest with elevation of the affected leg, and elastic compression stockings (Cunningham et al., 2014). Heat may also be applied locally.

DVT is initially treated with anticoagulant therapy (usually continuous IV heparin), bed rest with the affected leg elevated, and analgesia. After the symptoms have decreased, the woman may be fitted with elastic compression stockings to wear when she is allowed to ambulate. She is taught how to put on the stockings before getting out of bed. IV heparin therapy continues for 3 to 5 days or until symptoms resolve. Oral anticoagulant therapy (warfarin [Coumadin]) is started during this time and will be continued for about 3 months. In long-term therapy the prothrombin

time should be monitored at least monthly in an infant and vitamin K given if necessary (Lawrence & Lawrence, 2011).

Acute PE is an emergent situation that requires prompt treatment. Massive pulmonary emboli can lead to pulmonary hypertension and right ventricular dysfunction; if right ventricular dysfunction is present, mortality can be as high as 25% (Cunningham et al., 2014). Immediate treatment of PE is anticoagulant therapy. Continuous IV heparin therapy is used for PE until symptoms have resolved. Intermittent subcutaneous heparin or oral anticoagulant therapy is often continued for up to 6 months (Pettker & Lockwood, 2012).

Nursing Interventions

In the birthing facility, nursing care of the woman with a thrombosis consists of ongoing assessments: inspecting and palpating the affected area; palpating the peripheral pulses; checking Homans sign; and measuring and comparing leg circumferences. Signs of PE, including chest pain, coughing, dyspnea, and tachypnea, and respiratory status for presence of crackles are also assessed. Laboratory reports are monitored for prothrombin or partial thromboplastin times. The nurse assesses for unusual bleeding. Increased lochia, generalized petechiae, hematuria, or oozing from venipuncture sites should be reported to the provider immediately (James, 2013). In addition, the mother and her family are assessed for their level of understanding about the diagnosis and their ability to cope during the unexpected extended period of recovery.

Interventions include explanations and education about diagnosis and treatment. The woman will need assistance with personal care as long as she is on bed rest; the family should be encouraged to participate in the care if that is what she and they wish. While the woman is on bed rest she should be encouraged to change positions frequently but to avoid placing her knees in a sharply flexed position that could cause pooling of blood in the lower extremities. She also should be cautioned to avoid rubbing the affected area because this action could cause the clot to dislodge. Heparin and warfarin are administered as ordered, and the physician is notified if clotting times are outside the therapeutic level. If the woman is breastfeeding, she is informed that neither heparin nor warfarin is excreted in significant quantities in breast milk (Lawrence & Lawrence, 2011). If the infant has been discharged, the family is encouraged to bring the infant for feedings as permitted by hospital policy; the mother also can express milk to be sent home.

Pain can be managed with a variety of measures. Changing positions, elevating the leg, and applying moist heat may decrease discomfort. It may be necessary to administer analgesics and antiinflammatory medications.

The woman is usually discharged home on oral anticoagulants and will need an explanation of the treatment schedule and possible side effects. If subcutaneous injections are to be given, the woman and family are taught how to administer the medication and about site rotation. They should also be given information about safe care practices to prevent bleeding and injury while she is on anticoagulant therapy (e.g., using a soft toothbrush and an electric razor). She will need information about follow-up with her health care provider to monitor

clotting times and regulate the correct dosage of anticoagulant therapy. The woman should also use a reliable form of contraception if taking warfarin because this medication is considered teratogenic (Gilbert, 2011). Oral contraceptives are contraindicated because of the increased risk for thrombosis (Cunningham et al., 2014).

MEDICATION ALERT

Medications containing aspirin are not given to women on anticoagulant therapy because aspirin inhibits synthesis of clotting factors and can lead to prolonged clotting time and increased risk for bleeding.

POSTPARTUM INFECTIONS

Postpartum infection, or *puerperal infection*, is any clinical infection of the genital tract that occurs within 28 days after miscarriage, induced abortion, or birth. The definition used in the United States continues to be the presence of a fever of 38°C (100.4° F) or more on 2 successive days of the first 10 postpartum days (not counting the first 24 hours after birth). In the United States it occurs after approximately 2% of vaginal births and 10% to 15% of cesarean births (Katz, 2012). Other common postpartum infections include wound infections, urinary tract infections (UTIs), and respiratory tract infections. Mastitis, or breast infection, should also be considered as a possible diagnosis among breastfeeding mothers, with symptoms such as fever, malaise, flulike symptoms, and a sore area in a breast (Lawrence & Lawrence, 2011) (Fig. 33-6). (See Chapter 25 for further discussion of mastitis.)

The most common infecting organisms are the numerous streptococcal and anaerobic organisms. *Staphylococcus aureus*, gonococci, coliform bacteria, and clostridia are less common but serious pathogenic organisms that can cause puerperal infection. Postpartum infections are more common in women who have concurrent medical or immunosuppressive conditions or who had a cesarean or other operative birth. Intrapartal factors such as prolonged rupture of membranes, prolonged labor, and intrauterine monitoring of uterine contractions or fetal heart rate and pattern increase the risk for infection (Cunningham

FIG 33-6 Mastitis, right breast, upper quadrant. (In R. K. Creasy, R. Resnik, J. D. Iams, et al. (Eds.), *Creasy and Resnik's maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders.)

et al., 2014). Factors that predispose the woman to postpartum infection are listed in Box 33-3.

Endometritis

Endometritis (infection of the lining of the uterus) is the most common postpartum infection. It usually begins as a localized infection at the placental site (Fig. 33-7) but can spread to the entire endometrium. Incidence is higher after cesarean birth. Signs of endometritis include fever (usually greater than 38° C [100.4° F]), increased pulse, chills, anorexia, nausea, fatigue and lethargy, pelvic pain, uterine tenderness, and foul-smelling, profuse lochia. Leukocytosis and a markedly increased RBC sedimentation rate are typical laboratory findings of postpartum infections. Anemia can also be present. Blood cultures or intracervical or intrauterine bacterial cultures (aerobic and anaerobic) should reveal the offending pathogens within 36 to 48 hours (Cunningham et al., 2014).

Management

Management of endometritis consists of IV broad-spectrum antibiotic therapy (cephalosporins, penicillins, or clindamycin and gentamicin) and supportive care, including hydration, rest, and pain relief. Antibiotic therapy is usually discontinued 24 hours after the woman is asymptomatic. Assessments of lochia, vital signs, and changes in the woman's condition continue during treatment. Comfort measures depend on the symptoms and may include cool compresses, warm blankets, perineal care, and sitz baths. Teaching should include side effects of therapy, prevention of spread of infection, signs and symptoms of worsening condition, adherence to the treatment plan, and the need for follow-up care. Women may need to be encouraged or assisted to maintain mother-infant interactions and breastfeeding.

BOX 33-3 Predisposing Factors for Postpartum Infection

Preconception or Antepartal Factors

- History of previous venous thrombosis, urinary tract infection, mastitis, pneumonia
- Diabetes mellitus
- Alcoholism
- Drug abuse
- Immunosuppression
- Anemia
- Malnutrition

Intrapartal Factors

- Cesarean birth
- Operative vaginal birth
- Prolonged rupture of membranes
- Chorioamnionitis
- Prolonged labor
- Bladder catheterization
- Internal fetal/uterine pressure monitoring
- Multiple vaginal examinations after rupture of membranes
- Epidural analgesia/anesthesia
- Retained placental fragments
- Postpartum hemorrhage
- Episiotomy or lacerations
- Hematomas

Wound Infections

Wound infections are common postpartum infections that often develop after mothers are discharged home. Sites of infection include the cesarean incision and repaired laceration or episiotomy site. Predisposing factors are similar to those for endometritis (see Box 33-3). Signs of wound infection include fever, erythema, edema, warmth, tenderness, pain, seropurulent drainage, and wound separation.

Management

Treatment of wound infections may combine antibiotic therapy with wound debridement. Wounds can be opened and drained. Nursing care includes frequent assessments of the wound and vital signs and wound care. Comfort measures include analgesics, sitz baths, warm compresses, and perineal care. Teaching includes good hygiene techniques (e.g., changing perineal pads front to back, hand hygiene before and after perineal care), self-care measures, and signs of worsening conditions to report to the primary health care provider. The mother is usually discharged to home for self-care or home nursing care after treatment is initiated in the inpatient setting.

Urinary Tract Infections

Urinary tract infections (UTIs) occur in 2% to 4% of postpartum women. Risk factors include urinary catheterization, frequent pelvic examinations, regional (epidural or spinal) anesthesia, genital tract injury, history of UTI, and cesarean birth. Signs and symptoms include dysuria, frequency and urgency, low-grade fever, urinary retention, hematuria, and pyuria. Costovertebral angle tenderness or flank pain can indicate upper UTI. The most common infecting organism is *Escherichia coli*, although other gram-negative aerobic bacilli can cause UTIs.

Management

Medical management for UTIs consists of antibiotic therapy, analgesia, and hydration. Postpartum women are usually treated on an outpatient basis; therefore, teaching should include instructions on how to monitor temperature, bladder function, and appearance of urine. The woman should also be taught about signs of potential complications and the

FIG 33-7 Postpartum infection—endometritis.

importance of taking all antibiotics as prescribed. Other suggestions for prevention of UTIs include proper perineal care, wiping from front to back after urinating or having a bowel movement, and increasing fluid intake. Although cranberries and cranberry juice have been widely used for the prevention and treatment of UTIs, the authors of a meta-analysis of 24 studies concluded that the evidence of benefit for drinking cranberry juice to prevent UTIs is small and thus do not recommend it for prevention. Further studies are needed (Jepson, Williams, & Craig, 2012).

CARE MANAGEMENT

Assessment and Nursing Diagnoses

Women who are predisposed to postpartum infection (see Box 33-3) should be assessed carefully. Signs and symptoms associated with postpartum infection were discussed with each infection. Elevation of temperature, redness, and swelling are common signs. The mother may also complain of chills, fever, localized tenderness, or pain. Depending on the type of infection, laboratory tests usually include a complete blood count, venous blood cultures, urine cultures, and uterine tissue cultures. Assessment includes a review of the woman's history, and the laboratory results should be included in the assessment. Nursing diagnoses for women experiencing postpartum infection are listed in Box 33-4.

Interventions

The most effective and least expensive treatment of postpartum infection is prevention. Preventive measures include good prenatal nutrition to reduce risk of anemia and intrapartum hemorrhage. Proper maternal perineal hygiene with thorough hand hygiene is emphasized. Strict adherence to aseptic techniques by all health care personnel caring for women during labor, birth, and the postpartum period is very important. Specific medical, surgical and nursing interventions were discussed with each infection.

Postpartum women are usually discharged to home by 48 hours after birth. This is often before signs of infection are evident. Nurses in birth centers and hospital settings must be able to identify women at risk for postpartum infection and

BOX 33-4 Nursing Diagnoses for Women Experiencing Postpartum Infection

Deficient Knowledge *related to:*

provide anticipatory teaching and counseling before discharge. This teaching should include the signs of infection and when to notify the health care provider. After discharge, telephone follow-up, hotlines, support groups, lactation counselors, home visits by nurses, and teaching materials (videos, written materials) can be used to decrease the risk for postpartum infections. Home care nurses must be able to recognize the signs and symptoms of postpartum infection and then contact the mother's primary health care provider or have her make the contact. Home care nurses must also be able to provide the appropriate nursing care for women who need follow-up care at home.

COMMUNITY ACTIVITY

After giving birth many women are discharged home before an infection can develop. Prepare a "Fact Sheet About Postpartum Infection" that could be distributed to postpartum women on discharge from the hospitals or birth centers in your community. The fact sheet should include a brief summary of the types of common infections, signs and symptoms, ways to help prevent infection, and when to call the health care provider. If your community has a large population of women who do not speak English, consider a fact sheet in Spanish or other language as appropriate.

KEY POINTS

- Postpartum hemorrhage is a major cause of obstetric morbidity and mortality throughout the world and is the leading reason for obstetric intensive care unit admissions.
- Hemorrhagic (hypovolemic) shock is an emergency situation in which the perfusion of body organs can become severely compromised and death can ensue.
- The potential side effects of therapeutic interventions can further compromise the woman with a hemorrhagic disorder.
- Clotting disorders are associated with many obstetric complications.
- Postpartum infection is a major cause of maternal morbidity and mortality throughout the world.
- Postpartum UTIs are common because of trauma experienced during labor.
- Prevention is the most effective and least expensive treatment of postpartum infection.

Nursing Care of the High Risk Newborn

Debbie Fraser

<http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Compare characteristics of preterm, late preterm, early term, and postterm neonates.
- Discuss respiratory distress syndrome and the approach to treatment.
- Compare methods of oxygen therapy.
- Analyze appropriate nursing interventions for nutritional care of the preterm infant.
- Discuss the pathophysiology of retinopathy of prematurity, bronchopulmonary dysplasia, patent ductus arteriosus, necrotizing enterocolitis, and intraventricular hemorrhage and the risk factors that predispose preterm infants to these problems.
- Discuss pain assessment and management in the preterm infant.
- Describe the signs and symptoms of perinatal asphyxia.
- Analyze the pathophysiology of meconium aspiration syndrome and its clinical signs.
- Plan developmentally appropriate care for high risk infants.
- Discuss the needs of parents of high risk infants.
- Describe nursing care for late preterm infants and list specific discharge teaching needs for parents of late preterm infants.
- Analyze common problems experienced by small- and large for gestational age infants.
- Evaluate a neonatal transport plan.
- Discuss nursing interventions for families of preterm and high risk infants experiencing anticipatory loss and grief.

Modern technology and expert nursing care have made important contributions to improving the health and overall survival of high risk infants. However, infants who are born considerably before term and survive are particularly susceptible to developing problems related to their preterm birth. These problems can also occur in term and late preterm infants, although not as frequently, and include necrotizing enterocolitis (NEC), bronchopulmonary dysplasia (BPD), intraventricular and periventricular hemorrhage, and retinopathy of prematurity (ROP).

High risk infants are most often classified according to birth weight, gestational age, and predominant pathophysiologic problems (Box 34-1). Intrauterine growth rates differ among infants; factors such as heredity, placental insufficiency, and maternal disease influence intrauterine growth and birth weight. For the high risk infant, an accurate assessment of gestational age (see Chapter 24) is critical in helping the nurse anticipate problems. The response of the preterm, late preterm, or postterm infant to extrauterine life differs from that of the term infant. By understanding the physiologic basis of these differences, the nurse can assess these infants with a keen awareness of the potential problems they are most likely to encounter.

Preterm Infants

The vast majority of high risk infants are those born at less than 37 weeks of gestation: preterm and late preterm infants. The preterm birth rate in the United States showed a fairly steady increase from the early 1980s to 2006. Then, in 2006, the rate began to steadily decline to 11.55% in 2012. The greatest decline (11%) was among late preterm births, which constitute the largest percentage of all preterm births (Martin, Hamilton, Osterman, et al., 2013). This drop may be related to practice-based efforts to reduce elective births prior to 39 weeks of gestation unless there is a medical indication.

At times the nurse is able to anticipate problems, such as when a woman is admitted in preterm labor. At other times the birth of a high risk infant is unanticipated. In either case the personnel and equipment necessary for immediate care of the infant must be available.

Preterm infants are at risk because their organ systems are immature and they lack adequate nutrient reserves. The potential problems and care needs of the preterm infant weighing 2000 g (4.4 lb) differ from those of the term or postterm infant of equal weight. If these infants have physiologic disorders and anomalies as well, they affect the infant's response to treatment. In general, the closer infants are to term in relation to gestational

BOX 34-1 Classification of High Risk Infants**Classification According to Size**

Low-birth-weight (LBW) infant: an infant whose birth weight is less than 2500 g (5.5 lb), regardless of gestational age

Very low-birth-weight (VLBW) infant: an infant whose birth weight is less than 1500 g (3.3 lb)

Extremely low-birth-weight (ELBW) infant: an infant whose birth weight is less than 1000 g (2.2 lb)

Appropriate for gestational age (AGA) infant: an infant whose birth weight falls between the 10th and 90th percentiles on intrauterine growth curves

Small for date (SFD) or small for gestational age (SGA) infant: an infant whose rate of intrauterine growth was restricted and whose birth weight falls below the 10th percentile on intrauterine growth curves

Large for gestational age (LGA) infant: an infant whose birth weight falls above the 90th percentile on intrauterine growth curves

Intrauterine growth restriction (IUGR): found in infants whose intrauterine growth is restricted (sometimes used as a more descriptive term for the SGA infant)

Symmetric IUGR: growth restriction in which the weight, length, and head circumference are all affected

Asymmetric IUGR: growth restriction in which the head circumference remains within normal parameters while the birth weight falls below the 10th percentile

Classification According to Gestational Age

- **Preterm (premature):** an infant born before completion of 37 weeks of gestation
- **Late preterm:** an infant born from 34 0/7 through 36 6/7 weeks of gestation
- **Early term:** an infant born from 37 0/7 through 38 6/7 weeks of gestation
- **Full term:** an infant born from 39 0/7 weeks through 40 6/7 weeks of gestation
- **Late term:** an infant born from 41 0/7 through 41 6/7 weeks of gestation
- **Postterm (postmature):** an infant born after 42 weeks of gestation,

Data from American Academy of Pediatrics (AAP) & American College of Obstetricians and Gynecologists (ACOG). (2012). *Guidelines for perinatal care* (7th ed.). Elk Grove Village, IL: Author; American College of Obstetricians and Gynecologists (ACOG). 2013. Committee opinion no. 579: Definition of term pregnancy. *Obstetrics and Gynecology*, 122(5), 1139-1140.

age and birth weight, the easier their adjustment to the external environment.

Preterm, low-birth-weight (LBW), and extremely low-birth-weight (ELBW) infants often require hospitalization beyond the typical 48 hours after birth. Their physiologic immaturity and associated problems can require extensive use of technologic and pharmacologic interventions. The cost of the care of preterm and LBW infants is estimated to be billions of dollars each year and continues to rise as the use of technology increases.

Varying opinions exist about the practical and ethical dimensions of resuscitation of **extremely low-birth-weight (ELBW)** infants (those infants whose birth weight is 1000 g [2.2 lb] or less). Ethical issues associated with resuscitation of such infants include:

- Should resuscitation be attempted and to what extent should it be continued?
- Who should decide?

- Is the cost of resuscitation justified?
- Do the benefits of technology outweigh the burdens in relation to the quality of life?

Everyone involved (health care providers, nurses, parents, ethicists, clergy, attorneys, etc.) should participate in discussions addressing these controversial questions. Although there are no clear answers, such discussions help clarify the issues and promote family-centered approaches to care. That care can involve sustaining life or providing care and support for a peaceful death. Nurses are key to the care of these infants and their families.

Physiologic Functions

Respiratory Function. The preterm infant is likely to have difficulty making the pulmonary transition from intrauterine to extrauterine life. Numerous problems can affect the respiratory systems of preterm infants:

- Decreased number of functional alveoli
- Deficient surfactant levels
- Smaller lumen in the respiratory system
- Greater collapsibility or obstruction of respiratory passages
- Insufficient calcification of the bony thorax
- Weak or absent gag reflex
- Immature and friable capillaries in the lungs
- Greater distance between functional alveoli and the capillary bed

In combination, these deficits have the potential to severely hinder the preterm infant's respiratory efforts and can produce respiratory distress or apnea. Nurses must be alert to signs of respiratory distress or apnea and ready to intervene to promote adequate oxygenation.

Respiratory difficulty often follows a progressive pattern. Infants normally breathe between 30 and 60 breaths/minute, relying significantly on their abdominal muscles to accomplish this. However, the respiratory rate can increase without a change in rhythm. Early signs of respiratory distress include flaring of the nares and an expiratory grunt. Depending on the cause, retractions can begin as subcostal, suprasternal, or intercostal. If the infant shows increasing respiratory effort (e.g., seesaw breathing patterns, retractions, flaring of the nares, expiratory grunting, and/or apneic spells), this indicates deepening distress. A compromised infant's color progresses from pink to **circumoral cyanosis** and then to generalized cyanosis.

around mouth

! NURSING ALERT

Acrocyanosis is a normal finding in the neonate, but central cyanosis indicates an underlying problem that requires immediate evaluation.

Periodic breathing is a respiratory pattern commonly seen in preterm infants. Such infants exhibit 5- to 10-second respiratory pauses followed by 10 to 15 seconds of compensatory rapid respirations. Such periodic breathing should not be confused with **apnea**, which is a 20-second or greater cessation of respiration, or a shorter pause accompanied by bradycardia, cyanosis, or hypotonia (Alvaro, 2012).

Cardiovascular Function. Evaluation of heart rate and rhythm, skin color, blood pressure, perfusion, pulses, oxygen

saturation, and acid-base status provides information on cardiovascular status. The nurse must be prepared to intervene if symptoms of hypovolemia, shock, or both are found. These symptoms include hypotension, slow capillary refill (>3 seconds), and continued respiratory distress despite the provision of oxygen and ventilation.

An accurate and timely blood pressure (BP) reading can assist in making an early diagnosis of cardiorespiratory disease and in monitoring the effects of fluid therapy. BP is monitored routinely in the sick neonate by internal or external means. Direct recording with arterial catheters is often used but carries the risks inherent in any procedure in which a catheter is introduced into an artery. An umbilical venous catheter can also be used to monitor the neonate's central venous pressure. Oscillometry (Dinamap) is a noninvasive, effective means for detecting alterations in systemic BP (hypotension or hypertension) and for identifying the need to implement appropriate therapy to maintain cardiovascular function.

Maintaining Body Temperature. Preterm infants are susceptible to temperature instability as a result of numerous factors. Because of their large body surface in relation to their weight, preterm infants are at high risk for heat loss. Other factors that place preterm infants at risk for temperature instability include:

- Minimal insulating subcutaneous fat
- Limited stores of brown fat (an internal source for the generation of heat present in normal term infants)
- Fragile capillaries
- Decreased or absent reflex control of skin capillaries (shiver response)
- Inadequate muscle mass activity (rendering the preterm infant unable to produce his or her own heat)
- Poor muscle tone, resulting in more body surface area being exposed to the cooling effects of the environment
- An immature temperature regulation center in the brain

The goal of thermoregulation is to create a *neutral thermal environment* (NTE), which is the environmental temperature at which oxygen consumption is minimal but adequate to maintain body temperature (Blackburn, 2013). With the knowledge of the four mechanisms of heat transfer (convection, conduction, radiation, and evaporation), the nurse can create an environment for the preterm infant that prevents temperature instability (see Chapter 24). The infant is kept in a radiant warmer bed or in an incubator with control settings to maintain an NTE. Because the preterm infant has few reserves in terms of calories and fat stores, cold sensitivity is a problem. This infant can easily lose heat and develop hypothermia. Physiologically the infant tries to conserve heat and burns more calories, causing the metabolic system to go into overdrive, further stressing the already compromised neonate. This is known as *cold stress*.

A critical nursing role is to prevent or minimize hypothermia and cold stress (see Fig. 23-2) by recognizing the risk factors and using intervention strategies to prevent and treat such stress. Signs of hypothermia and cold stress are listed in Box 34-2.

The nurse should attempt to prevent hyperthermia. Given that overheating produces an increase in oxygen and calorie consumption, the infant is also jeopardized if he or she

BOX 34-2 Signs of Hypothermia and Hyperthermia

Hypothermia (Cold Stress)

Apnea
Bradycardia
Central cyanosis
Coagulation defects (i.e., pulmonary hemorrhage)
Hypoglycemia
Hypotonia
Hypoxia
Feeding intolerance (abdominal distention, emesis, increased residuals)
Increased metabolic rate
Irritability
Lethargy
Metabolic acidosis
Peripheral vasoconstriction (persistent pulmonary hypertension of the newborn)
Poor weight gain (chronic hypothermia)
Shivering (mature infants in presence of severe hypothermia)
Weak cry or suck

Hyperthermia

Apnea
Central nervous system depression
Dehydration (increased insensible water loss)
Flushed/red skin
Hypernatremia
Irritability
Lethargy
Poor feeding
Seizures
Sweating
Tachycardia
Tachypnea
Warm to touch
Weak or absent cry

Data from Blackburn, S. (2013). *Maternal, fetal, and neonatal physiology: A clinical perspective* (4th ed.). Maryland Heights, MO: Saunders; Brown, V.D., & Landers, S. (2011). Heat balance. In S.L. Gardner, B.S. Carter, M. Enzman-Hines, & J.A. Hernandez (Eds.), *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis: Mosby.

becomes hyperthermic. The preterm infant is not able to sweat and thus dissipate heat. Overheating can lead to apnea, tachycardia, and eventually bradycardia, as well as consumption of calories that the preterm infant cannot afford to expend (see Box 34-2).

Central Nervous System Function. The preterm infant's central nervous system (CNS) is susceptible to injury as a result of:

- Birth trauma with damage to immature structures
- Bleeding from fragile capillaries
- An impaired coagulation process, including prolonged prothrombin time
- Recurrent hypoxic and hyperoxic episodes
- Predisposition to hypoglycemia
- Fluctuating systemic BP with concomitant variation in cerebral blood flow and pressure

In the preterm neonate, neurologic function is dependent on gestational age, associated illness factors, and predisposing factors such as intrauterine asphyxia that can cause neurologic

damage. Clinical signs of neurologic dysfunction can be subtle, nonspecific, or specific. Five categories of clinical manifestations should be thoroughly evaluated in the preterm infant: seizure activity, hyperirritability, CNS depression, increased intracranial pressure (ICP), and abnormal movements such as decorticate posturing. Primary and tendon reflexes are generally present in preterm infants by 28 weeks of gestation; evaluation of these reflexes should be part of the neurologic examination (see Table 23-4).

The developing nervous system has the ability to reorganize neural connection after injury, meaning that some injuries that would be permanent in adults are not so in infants. Certain neurologic signs appear to be predictive of later abnormalities. These signs include hypotonia, decreased level of activity, weak cry for more than 24 hours, and inability to coordinate suck and swallow. Ongoing assessment and documentation of these neurologic signs are needed for the purpose of discharge teaching and making follow-up recommendations, as well as for their predictive value.

Maintaining Adequate Nutrition. The goal of neonatal nutrition is to promote normal growth and development. However, maintaining adequate nutrition in the preterm infant is complicated by problems with intake and metabolism. Based on the gestational age, the preterm infant often has the following disadvantages with regard to intake: weak or absent suck, swallow, and gag reflexes; difficulty coordinating sucking, swallowing, and breathing; small stomach capacity; and weak abdominal muscles. The preterm infant's metabolic functions are compromised by a limited store of nutrients, a decreased ability to digest proteins or absorb nutrients, and immature enzyme systems.

The nurse must continually assess the infant's ability to consume and digest nutrients. Some preterm infants require gavage or intravenous (IV) feedings instead of oral feedings. An area of research that holds promise for preterm infants is use of **minimal enteral nutrition (MEN)** that can provide only 1 ml/hr (Anderson, Wood, Keller, & Hay, 2011; de Curtis & Rigo, 2012). These feedings stimulate the gastrointestinal (GI) system with minute amounts of breast milk or formula, usually given via gavage, so that when enteral feedings of greater volume can begin, the GI system is primed for nutrient absorption. They also may help to protect LBW infants from sepsis (Ors, 2013).

Maintaining Renal Function. The preterm infant's immature renal system is unable to adequately excrete metabolites and drugs, concentrate urine, or maintain acid-base, fluid, or electrolyte balance. Therefore, intake and output, as well as specific gravity, must be assessed. Laboratory tests are done to determine acid-base and electrolyte balance. Medication levels are monitored in preterm infants because certain medications can overwhelm the immature system's ability to excrete them.

Maintaining Hematologic Status. The preterm infant is predisposed to hematologic problems because of:

- Increased capillary fragility
- Increased tendency to bleed (prolonged prothrombin time and partial thromboplastin time)
- Slowed production of red blood cells resulting from rapid decrease in erythropoiesis after birth

BOX 34-3 Signs and Symptoms of Infection

- Temperature instability
 - Hypothermia
 - Hyperthermia
- Central nervous system changes
 - Lethargy
 - Irritability
- Changes in color
 - Cyanosis, pallor
 - Jaundice
- Cardiovascular instability
 - Poor perfusion
 - Hypotension
 - Bradycardia/tachycardia
- Respiratory distress
 - Tachypnea
 - Apnea
 - Retractions, nasal flaring, grunting
- Gastrointestinal problems
 - Feeding intolerance
 - Vomiting
 - Diarrhea
 - Glucose instability
- Metabolic acidosis

Data from Bodin, M.B. (2014). Immune system. In C. Kenner, & J.W. Lott (Eds.), *Comprehensive neonatal care* (5th ed.). New York: Springer; Edwards, M.S. (2011). Postnatal bacterial infections. In R.J. Martin, A.A. Fanaroff, & M.C. Walsh (Eds.), *Fanaroff & Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* (9th ed.). St. Louis: Mosby.

- Loss of blood due to frequent blood sampling for laboratory tests
- Decreased red blood cell survival related to the relatively larger size of the red blood cell and its increased permeability to sodium and potassium

The nurse assesses such infants for any evidence of bleeding from puncture sites and the GI tract. Infants are examined for signs of anemia (decreased hemoglobin and hematocrit levels, pale skin, increased apnea, lethargy, tachycardia, and poor weight gain). The amount of blood drawn for laboratory testing is closely monitored and recorded.

Resisting Infection. Preterm infants are at increased risk for infection because they have a shortage of stored maternal immunoglobulins, an impaired ability to make antibodies, and a compromised integumentary system (thin skin and fragile capillaries). Preterm infants exhibit various nonspecific signs and symptoms of infection (Box 34-3). Early identification and treatment of sepsis are essential (see Chapter 35). As with all aspects of care, strict attention to hand hygiene is the single most important measure to prevent health care-acquired infections.

Growth and Development Potential. Although it is impossible to predict with complete accuracy the growth and development potential of each preterm infant, some findings support an anticipated favorable outcome in the absence of ongoing medical problems that can affect growth, such as BPD, NEC, and CNS problems. The lower the birth weight, the greater the likelihood the infant will experience negative outcomes.

The age of a preterm newborn is corrected by adding the gestational age and the postnatal age. For example, an infant born 4 weeks ago at 32 weeks of gestation would now be considered

36 weeks of age. The infant's **corrected age** at 6 months after the birth date is then 4 months, and the infant's responses are accordingly evaluated against the norm expected for a 4-month-old. The growth and development milestones (e.g., motor milestones, vocalization, growth) are corrected for gestational age until the child is approximately 2½ years old.

Certain measurable factors predict normal growth and development. The preterm infant experiences catch-up body growth during the first 2 years of life; this is most likely to occur when the infant has a normal birth length (Kliegman, 2011). The head is the first to experience catch-up growth, followed by a gain in weight and height. At the infant's discharge from the hospital, which usually occurs between 36 and 40 weeks of postconception age, the infant should exhibit:

- An ability to raise the head when prone and to hold the head parallel with the body when tested for the head-lag response
- An ability to cry vigorously when hungry
- An appropriate amount and pattern of weight gain according to growth curves
- Neurologic responses appropriate for corrected age

At 39 to 40 weeks of corrected age, the infant should be able to focus on the examiner's or parent's face and to follow with his or her eyes.

Very low-birth-weight (VLBW) (<1500 g [3.3 lb]) survivors are at high risk for neurologic and cognitive disabilities in varying degrees of severity; these include cerebral palsy, borderline intelligence, and learning disabilities (Daily, Carter, & Carter, 2011). Ongoing research focuses on examining other factors

including environmental ones that can cause adverse cognitive and neurodevelopmental outcomes for VLBW and ELBW babies as they grow and develop.

CARE MANAGEMENT

The goal of care for the preterm infant is to promote normal growth and development by providing an extrauterine environment that approximates the healthy intrauterine environment. A multidisciplinary team of physicians, nurses, nurse practitioners, infant developmental specialists, and respiratory therapists collaborates to provide the intensive care needed.

The admission of a preterm newborn to the intensive care nursery is usually an emergent situation. A rapid initial evaluation determines the infant's need for lifesaving treatment. Resuscitation is started in the birthing unit, and the newborn's needs for warmth and oxygen are provided for during transfer to the nursery.

Nursing care is focused on the continual assessment and analysis of the infant's physiologic status. Nursing diagnoses and expected outcomes of care such as those in the Nursing Care Plan for the High Risk Infant are identified (see Nursing Care Plan and Clinical Reasoning Case Study). Nurses fulfill many roles in providing the intensive and extended care that these infants require. In addition, they are the support persons and teachers during the first phase of the parents' adjustment to the birth of their preterm infant. Interventions for specific aspects of care including nursing actions are discussed in the following sections.

NURSING CARE PLAN

The High Risk Preterm Newborn

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Ineffective Breathing Pattern related to pulmonary and neuromuscular immaturity, decreased energy, fatigue</i>	Infant exhibits adequate oxygenation (i.e., arterial blood gases [ABGs] and acid-base within normal limits [WNL]; oxygen saturation 92% or greater; respiratory rate and pattern WNL; breath sounds clear; absence of grunting and nasal flaring, minimal retractions, skin color WNL).	Position neonate prone or supine, avoiding neck hyperextension. Avoid Trendelenburg position. Suction nasopharynx, trachea, and endotracheal tube as indicated. Avoid oversuctioning. Administer oxygen and monitor neonatal response. Maintain a neutral thermal environment. Monitor arterial blood gases, acid-base balance, oxygen saturation, respiratory rate and pattern, breath sounds, and airway patency; observe for grunting, nasal flaring, retractions, and cyanosis.	To promote optimum air exchange. Use a side-lying position after feeding or in cases of excessive mucus production to avoid aspiration. Can cause increased intracranial pressure and reduce lung capacity To remove mucus Can cause bronchospasm, bradycardia, and hypoxia and predispose neonate to intraventricular hemorrhage To maintain oxygen saturation To conserve oxygen use To detect signs of respiratory distress

 **NURSING CARE PLAN—cont'd**
The High Risk Preterm Newborn

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Ineffective Thermo-regulation related to immature temperature regulation and minimal subcutaneous fat stores</i>	Infant maintains stable body temperature within normal range for postconceptional age (36.5° to 37.2° C [97.7° to 99° F).	Place neonate in a prewarmed radiant warmer. Place temperature probe on neonatal abdomen. Take axillary temperature periodically. Avoid infant exposure to cool air and drafts, cold scales, cold stethoscopes, cold examination tables, and prolonged bathing. Monitor probe frequently.	To maintain stable temperature To control heat levels in radiant warmer To monitor temperature and cross-check functioning of warmer unit To prevent heat loss
<i>Risk for Infection related to immature immune system</i>	Infant exhibits no evidence of health-care acquired infection.	Transfer infant to a servo-controlled open warmer bed or incubator. Institute scrupulous hand hygiene techniques before and after handling neonate, ensure all supplies and/or equipment are clean before use, and ensure strict aseptic technique with invasive procedures. Prevent contact with individuals who have communicable infections, and instruct parents in infection-control procedures. Administer prescribed antibiotics. Continually monitor vital signs for stability.	Detachment can cause overheating or warmer-induced hyperthermia. When temperature has stabilized To minimize exposure to infective organisms To minimize infection risk To provide coverage for infection during sepsis workup Instability, hypothermia, or prolonged temperature elevations serve as indicators for infection.
<i>Risk for Imbalanced Nutrition: Less Than Body Requirements related to inability to ingest nutrients secondary to immaturity</i>	Infant receives adequate amount of nutrients with sufficient caloric intake to maintain positive nitrogen balance; demonstrates steady weight gain.	Administer parenteral fluid/total parenteral nutrition (TPN) as prescribed. Monitor for signs of intolerance to TPN. Periodically assess readiness for oral feeding (i.e., strong suck, swallow, and gag reflexes). Advance volume and concentration of formula when orally feeding per unit protocol. If mother desires to breastfeed, demonstrate how to express milk.	To provide adequate nutrition and fluid intake Can interfere with effective replenishment of nutrients To provide appropriate transition from TPN to oral feeding as soon as neonate is ready To avoid overfeeding and feeding intolerance To establish and maintain lactation until infant can breastfeed
<i>Risk for Deficient Fluid Volume/Excess Fluid Volume related to immature physiology</i>	Infant exhibits evidence of fluid homeostasis.	Administer parenteral fluids as prescribed and regulate carefully. Avoid hypertonic fluids such as undiluted medications, and concentrated glucose. Implement strategies (e.g., use of plastic covers and increase of ambient humidity). Monitor hydration status (i.e., skin turgor, blood pressure, edema, weight, mucous membranes, fontanelles, urine specific gravity, electrolytes) and intake and output.	To maintain fluid balance To prevent excess solute load on immature kidneys To minimize insensible water loss To evaluate for evidence of dehydration or overhydration

Continued

 **NURSING CARE PLAN—cont'd**
The High Risk Preterm Newborn

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Risk for Impaired Skin Integrity related to immature skin structure, immobility, or invasive procedures</i>	Infant's skin remains intact, with no evidence of irritation or injury.	Cleanse skin as needed with plain warm water and apply moisturizing agents to skin. When performing procedures, minimize use of tape and apply a skin barrier between tape and skin; use transparent elastic film for securing central and peripheral lines; use limb electrodes for monitoring or attach with hydrogel and rotate electrodes frequently; remove adhesives with soap and water rather than alcohol or acetone-based adhesive removers. Monitor use of thermal devices such as warmers or heating pads carefully. Monitor skin closely for evidence of redness, rash, irritation, bruising, breakdown, ischemia, and infiltration.	To maintain the skin's acid mantle To minimize skin damage To prevent burns To detect and treat potential complications early
<i>Risk for Injury related to increased intracranial pressure (ICP) and intraventricular hemorrhage secondary to immature central nervous system</i>	Infant will exhibit normal ICP with no evidence of intraventricular hemorrhage.	Institute minimum stimulation protocol (i.e., minimal handling, clustering care techniques, avoidance of sudden head movements to one side, undisturbed sleep periods, light variations to simulate day and night, limiting personnel and equipment noise in environment). Institute ordered pharmacologic and nonpharmacologic pain control methods. Avoid hypertonic solutions and medications. Elevate head of bed 15 to 20 degrees. Monitor vital signs. Recognize signs of overstimulation (i.e., flaccidity, yawning, irritability, crying, staring, active averting).	To decrease stress responses, which can increase ICP To manage pain and reduce physical stress To increase cerebral blood flow To decrease ICP To assess for evidence of ICP To stop stimulation to allow rest
<i>Impaired Parenting related to separation and interruption of parent/infant attachment secondary to premature birth</i>	Parents establish contact with neonate; demonstrate competent parenting skills and willingness to care for neonate.	Before parents' first visit to the NICU, prepare them by explaining the neonate's appearance, and the surrounding equipment and its function. Keep parents informed about infant's condition (improvements and setbacks) and important aspects of infant's care; encourage and answer parental questions; actively listen to parents' concerns. Encourage parents to visit the NICU often; to name infant (if that is culturally appropriate); to touch, hold, or caress infant as physical condition permits; to be actively involved in infant's care; and to bring personal items (i.e., clothing, stuffed animals, or pictures of family). Reinforce parents' involvement and praise care endeavors. Encourage parents to bring other siblings to visit; explain to siblings what they are seeing; encourage siblings to draw pictures or write letters for infant and place in or near infant's crib. Refer parents to social services as needed.	To diminish fear and decrease sense of shock To establish trust, open communication, and caring atmosphere to aid in coping To allow for formation of emotional bond To increase self-confidence in their contribution To promote family involvement, help ease sibling fears, and let them contribute to infant's care To ensure comprehensive care
<i>Grieving related to perceived loss of premature infant</i>	Parents express feelings about the potential loss and seek support from staff, family, clergy, and other support systems.	Encourage parents to express feelings about perceived loss of infant. Encourage parents to use family, friends, clergy, and other support people. Plan time on each shift to sit and listen to parents. Inform parents about support groups in the facility and the community.	To reinforce reality and help alleviate guilt To enhance coping ability To demonstrate concern, empathy, and support To encourage parents to use available resources

CLINICAL REASONING CASE STUDY

The Preterm Infant

A 1400-g (3-lb) female infant is born at an estimated gestational age of 33 weeks. The parents are very excited about this birth because they have been trying to become pregnant for 6 years. They name the baby Anna. After a brief visit with her parents, Anna is taken to the special care nursery for observation. She is placed on an open-bed warmer to maintain her temperature and is placed on a pulse oximeter and a cardiorespiratory monitor. Anna's oxygen levels are good in room air and she does not require any respiratory support.

1. Evidence—What kinds of initial complications might be expected in an infant born at 33 weeks of gestation?
2. Assumptions—What assumptions can be made about the following?
 - a. Anna's expected progress
 - b. The possibility of Anna being able to be held by her parents and breastfed
 - c. The length of time Anna might be hospitalized
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

The nurse uses many technologic support systems to monitor the body responses and maintain the body functions of the infant. Technical skill must be combined with a gentle touch and concern about the traumatic effects of harsh lighting and loud machinery noise. Provision of individualized behavioral and environmental care has been shown to reduce infant stress, conserve energy, and promote better neurobehavioral outcomes (Gardner & Goldson, 2011).

Physical Care

The environmental support measures for the preterm infant typically consist of the following equipment and procedures:

- An incubator or radiant warmer to control body temperature
- Oxygen administration, depending on the infant's cardiopulmonary and circulatory status
- Electronic monitors as needed for the ongoing assessment of respiratory and cardiac functions
- Assistive devices for positioning the infant in neutral flexion and with boundaries
- Clustering of care and minimization of stimulation according to infant cues

Various metabolic support measures that can be instituted consist of the following:

- Parenteral fluids to help support nutrition and maintain normal arterial blood gas (ABG) levels and acid-base balance
- IV access to facilitate the administration of antibiotic therapy if sepsis is a concern
- Blood work to monitor ABG levels, pH, blood glucose levels, electrolytes, and the status of blood cultures

Maintaining Body Temperature

The high risk infant is susceptible to heat loss and its complications. In addition, LBW infants can be unable to increase their metabolic rate because of impaired gas exchange, caloric intake restrictions, or poor thermoregulation. Transepidermal water loss is greater because of skin immaturity in very preterm

FIG 34-1 Preterm infant in polyethylene bag to protect against heat loss. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

infants (those at less than 28 weeks of gestation) and can contribute to temperature instability.

The preterm infant should be transferred from the birthing room in a prewarmed incubator; ELBW infants can be placed in a polyethylene bag to decrease heat and water loss (Fig. 34-1). Skin-to-skin contact (kangaroo care) between the stable preterm infant and parent is a viable option for interaction because of the maintenance of appropriate body temperature by the infant (see later in this chapter for further discussion of kangaroo care).

High risk infants are cared for in the thermoneutral environment created by use of an external heat source. A probe to an external heat source supplied by a radiant warmer or a servo-controlled incubator is attached to the infant. The infant acts as a thermostat to regulate the amount of heat supplied by the external source. This idealized environment maintains an infant's normal body temperature between 36.5° and 37.2° C (97.9° F and 99° F). Maintaining a thermoneutral condition in the youngest, most immature infants decreases the need for them to generate additional heat, increasing physiologic stability and decreasing oxygen consumption (Blackburn, 2013; Brown & Landers, 2011).

Care of the Hypothermic Infant. The hypothermic infant can appear pale and mottled; the skin is cool to touch, especially the extremities. Acrocyanosis and respiratory distress can occur as oxygen consumption increases in an effort to generate heat. As hypothermia worsens, the infant can have apnea, bradycardia, and central cyanosis.

When an infant becomes hypothermic, rewarming should begin immediately by providing external heat. However, rapid changes in body temperature can cause apnea and acidosis. For the infant with mild hypothermia, slow rewarming is recommended. External heat sources should be slightly warmer than skin temperature and increased gradually until the infant's temperature is within the range of NTE. For the severely hypothermic infant (body temperature less than 35° C [95° F]), more rapid rewarming is needed. Use of radiant heaters or heated water mattresses helps prevent prolonged metabolic acidosis and hypoglycemia and reduces mortality (Brown & Landers, 2011).

Respiratory Care

Oxygen Therapy. Clinical criteria that indicate the need for oxygen administration include increased respiratory effort, respiratory distress with apnea, tachycardia, bradycardia, and

central cyanosis with or without hypotonia. The need for oxygen should be substantiated by biochemical data (arterial oxygen pressure [PaO₂] of less than 60 mm Hg or an oxygen saturation of less than 92%).

Oxygen administered to an infant is warmed and humidified to prevent cold stress and drying of the respiratory mucosa. During the administration of oxygen, the concentration, volume, temperature, and humidity of the gas are carefully controlled. Delivery of oxygen for more than a few minutes requires the use of special equipment (hood, nasal cannula, positive-pressure mask, or endotracheal tube) because the concentration of free-flow oxygen cannot be monitored accurately. Free-flow oxygen into an incubator should not be used because the concentration fluctuates dramatically each time the doors or portholes are opened. The indiscriminate use of oxygen can be hazardous. Possible complications of oxygen therapy include ROP and BPD.

Infants who need oxygen should have their respiratory status assessed at least hourly. This includes a continuous pulse oximetry reading and at least one blood gas measurement. There should also be hourly documentation of pulse oximetry readings as well as the amount of oxygen being administered and the mode of delivery (Gardner, Enzman-Hines, & Dickey, 2011b). Necessary interventions are then determined on the basis of the clinical assessment findings. The interventions ordered are those that can directly manage the underlying disease process and range from hood oxygen administration to ventilator therapy.

Neonatal Resuscitation. In 2010 the American Heart Association (AHA) published neonatal resuscitation guidelines (AHA, 2010). A rapid assessment of infants can identify those who do not require resuscitation: those born at term gestation, with no evidence of meconium or infection in the amniotic fluid; those who are breathing or crying; and those with good muscle tone. If any of these characteristics is absent, the infant should receive the following actions in sequence: (1) initial steps in stabilization: provide warmth by placing the baby under a radiant warmer, position the head to open the airway, clear the airway with a bulb syringe or suction catheter, dry the baby, stimulate breathing, and reposition the baby; (2) ventilation; (3) chest compressions; and (4) administration of epinephrine or volume expansion or both. The decision to move from one category of action to the next is based on the assessment of respirations, heart rate, and color. Rapid decision making is imperative; 30 seconds are allotted for each step. The condition of the infant is reevaluated and the decision made whether to progress to the next step (see Fig. 24-1).

Resuscitation of asphyxiated newborns with 21% oxygen (room air) rather than 100% oxygen is recommended (AHA, 2010). Proponents for room air resuscitation suggest that fewer complications are associated with oxidative stress and hyperoxemia when room air is administered. The 2010 AHA resuscitation standards for neonatal resuscitation indicate that if the infant's condition does not improve within 90 seconds, supplemental oxygen should be provided. The amount of oxygen to use should be determined by the infant's oxygen saturation level and age in minutes. The stated goal is to minimize oxygen free radicals by preventing hyperoxia using supplemental oxygen at levels less than 100% (AHA). A review of several studies indicates that neonatal mortality is reduced by 4% to 5% when room air instead of 100% oxygen is used for neonatal resuscitation (Harach, 2013). Fluctuations in oxygen saturation are also deemed harmful.

Experts recommend that oxygen saturations for ELBW infants are maintained between 88% and 93% but definitely not exceeding 95% (Botet, Figueras-Aloy, Miracle-Echegoyen, et al., 2012).

Hood Therapy. A hood can be used to administer oxygen to infants who do not require mechanical pressure support. The hood is a clear plastic cover sized to fit over the head and neck of the infant (Fig. 34-2, A). Inside the hood the infant receives a controlled amount of oxygen. The nurse checks the oxygen level at least every hour because the concentration must be adjusted in response to the infant's condition. If the hood is removed for holding, feeding, or suctioning, an alternative source of oxygen must be provided (Gardner et al., 2011b).

Nasal Cannula. Infants requiring low-flow amounts of oxygen can benefit from the use of a nasal cannula (see Fig. 34-2, B). These work well for older infants who are recuperating but still require supplemental oxygen. They are the preferred method for home oxygen administration. Nasal cannulas permit the infant to receive an adequate, continuous flow of oxygen while allowing optimal vision, positioning, and parental holding. Infants can breastfeed or bottle feed while receiving oxygen by this method. Nasal cannulas come in various sizes; proper fit is important. The nasal prongs must be inspected and cleaned frequently to make sure they are not partially obstructed by milk or secretions.

Continuous Positive Airway Pressure Therapy. Infants who are unable to maintain an adequate PaO₂ despite the administration

FIG 34-2 A, Infant under oxygen hood. B, Infant with nasal cannula. (A, Courtesy Lauren and Brian LiVecchi, Raleigh, NC; B, courtesy Cheryl Briggs, RNC, Annapolis, MD.)

FIG 34-3 Infant receiving ventilatory assistance with nasal continuous positive airway pressure (CPAP). (Courtesy Randi and Jacob Wills, Clayton, NC.)

FIG 34-4 Infant intubated and on ventilator. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

of oxygen by hood or nasal cannula may require **continuous positive airway pressure (CPAP)**. CPAP infuses oxygen or air under a preset pressure by means of nasal prongs or a face mask (Fig. 34-3). It is often achieved by sending the oxygen bubbling through water to the infant; this is referred to as bubble CPAP. Researchers are investigating whether the work of neonatal breathing is improved with bubble CPAP versus variable-flow devices (Rebello, Yagui, Vale, et al., 2011). In either case, an orogastric tube should be in place for decompression of the stomach during use of nasal prongs. CPAP increases the functional residual capacity, improves the diffusion time of pulmonary gases, including oxygen, and can decrease pulmonary shunting. If implemented early enough, CPAP can preclude the need for mechanical ventilation (Gardner et al., 2011b). CPAP can cause vascular shunting in the pulmonary beds, which can lead to the complications of persistent pulmonary hypertension and severe respiratory distress.

Mechanical Ventilation. Mechanical ventilation must be implemented if other methods of therapy cannot correct abnormalities in oxygenation (Fig. 34-4). Its use is indicated whenever blood gas values demonstrate severe hypoxemia or severe hypercapnia. Intubation and ventilation can be needed for infants who have apnea with bradycardia, ineffective respiratory effort, shock, asphyxia, infection, meconium aspiration syndrome, respiratory distress syndrome (RDS), or congenital defects that affect ventilation (Gardner et al., 2011b). Ventilator settings are determined by the infant's individual needs. The ventilator is set to provide a predetermined amount of oxygen during spontaneous respirations and during mechanical ventilation in the absence of spontaneous respirations. Newer technologies in ventilation allow oxygen to be delivered at lower pressures and in assist modes, thereby preventing the overriding of the infant's spontaneous breathing and providing distending pressures within a physiologic range. Barotrauma and associated complications such as *pneumothorax* (accumulation of air in the pleural space) and *pulmonary interstitial emphysema* (PIE) (free air that accumulates in interstitial tissue) are decreased. See Table 34-1 for a description of the types of mechanical ventilation used in newborns.

TABLE 34-1 Common Methods for Assisted Ventilation in Neonatal Respiratory Distress

METHOD	DESCRIPTION	HOW PROVIDED
Continuous distending pressure—continuous positive airway pressure (CPAP)	Provides constant distending pressure to airway in spontaneously breathing infant	Nasal prongs or nasopharyngeal tubes Face mask Bubble CPAP uses water resistance
Intermittent mandatory ventilation (IMV)	Allows infant to breathe spontaneously at own rate but provides mechanical cycled respirations and pressure at regular preset intervals; infant can maintain asynchronous ventilation efforts, which diminishes effective gas exchange; uses positive end-expiratory pressure (PEEP)	Endotracheal intubation
Synchronized intermittent mandatory ventilation (SIMV)	Mechanically delivered breaths are synchronized to the onset of spontaneous infant breaths; assist or control (A/C) mode facilitates full inspiratory synchrony; involves signal detection of onset of spontaneous respiration from abdominal movement, thoracic impedance, and airway pressure or flow changes; pressure support ventilation provides an inspiratory pressure assist when spontaneous breathing is detected to decrease infant's work of breathing	Patient-triggered infant ventilator with signal detector and A/C mode; endotracheal tube; SIMV, A/C, and pressure support are also referred to as patient-triggered ventilation
Volume guarantee ventilation	Delivers a predetermined volume of gas using an inspiratory pressure that varies according to the infant's lung compliance (often used in conjunction with SIMV)	Volume guarantee ventilator with flow sensor; endotracheal tube
High-frequency oscillation (HFO)	Application of high-frequency, low-volume, sine-wave flow oscillations to airway at rates between 480 and 1200 breaths/minute	Variable-speed piston pump (or loudspeaker, fluidic oscillator); endotracheal tube
High-frequency jet ventilation (HFJV)	Uses a separate, parallel, low-compliant circuit and injector port to deliver small pulses or jets of fresh gas deep into airway at rates between 250 and 900 breaths/minute	May be used alone or with low-rate IMV; endotracheal tube

High-Frequency Ventilation. High-frequency ventilation (HFV) is accomplished through the use of jet ventilators, oscillators, or high-frequency flow interrupters (Gardner et al., 2011b). These methods provide smaller volumes of oxygen at a significantly more rapid rate (more than 300 breaths/minute) than traditional mechanical ventilators. As a result the intrathoracic pressure is decreased and the risk of barotrauma is reduced. HFV is beneficial in treating infants with air leaks, pulmonary hypoplasia, diaphragmatic hernia, and meconium aspiration (Fraser, 2012a).

SAFETY ALERT

Rates of retinopathy of prematurity and bronchopulmonary dysplasia are reduced when arterial oxygen saturation (SaO_2) is kept between 93% and 95%.

Surfactant Administration. Surfactant is a surface-active phospholipid secreted by the alveolar epithelium. Acting much the same as a detergent, this substance reduces the surface tension of fluids that line the alveoli and respiratory passages, resulting in uniform expansion and maintenance of lung expansion at low intraalveolar pressure. Before 34 weeks of gestation, most infants do not produce enough surfactant to survive extrauterine life. As a result, lung compliance is decreased, and inadequate gas exchange occurs as the lungs become atelectatic and require greater pressures to expand.

Surfactant can be administered as an adjunct to oxygen and ventilation therapy. With administration of artificial surfactant, respiratory compliance is improved until the infant can generate sufficient surfactant. Exogenous surfactant is either artificial or natural and is given in several doses through an endotracheal tube. The American Academy of Pediatrics (AAP) recommends the use of surfactant in infants with RDS as soon as possible after birth, especially for ELBW infants and those not exposed to maternal antenatal steroids (Polin, Carlo, & Committee on Fetus and Newborn, 2014). The administration of antenatal steroids to the mother and surfactant replacement has decreased the incidence of RDS and concomitant morbidities. Use of artificial surfactant has been associated with a significantly reduced length of time on ventilators and oxygen therapy, and an increased survival rate in preterm infants (Polin, Carlo, & Committee on Fetus and Newborn). As with any drug therapy, the infant must be monitored for potential side effects such as a patent ductus arteriosus (PDA) and pulmonary hemorrhage (see Medication Guide: Surfactant Replacement).

Additional Therapies

Nitric Oxide Therapy. Inhaled nitric oxide (INO), delivered as a gas, causes potent and sustained pulmonary vasodilation in the pulmonary circulation. Nitric oxide is a colorless, highly diffusible gas that can be administered through the ventilator circuit blended with oxygen. It binds with hemoglobin in red blood cells and is inactivated after metabolism. INO is used to decrease or reverse pulmonary hypertension, pulmonary vasoconstriction, acidosis, and hypoxemia in term and late preterm infants with conditions such as persistent pulmonary hypertension, meconium aspiration syndrome, pneumonia, sepsis, and congenital diaphragmatic hernia. INO therapy can be used in conjunction with surfactant replacement therapy,

MEDICATION GUIDE

Surfactant Replacement

Drug/Source

- Beractant* (Survanta)—Exogenous surfactant from bovine lung extract
- Poractant alpha* (Curosurf)—Modified porcine-derived minced lung extract
- Calfactant* (Infrasurf)—Natural surfactant extracted from calf lung lavage
- Lucinactant (Surfaxin): Synthetic surfactant
- Colfosceril (Exosurf): Synthetic surfactant

Action

These medications provide exogenous surfactant to promote lung maturity.

Indications

Surfactants are used to prevent and treat respiratory distress syndrome (RDS) in preterm infants. The drug should be administered prophylactically to infants less than 30 weeks of gestation with RDS as soon as possible after intubation and initial stabilization. It should be given prophylactically to extremely preterm infants at high risk for RDS, especially if there was no exposure to antenatal steroids. Early rescue surfactant treatment may be given to infants less than 2 hours of age with signs of RDS. Late rescue surfactant treatment may be administered to infants at 4 to 6 hours of age who require mechanical ventilation. Rescue surfactant may be given to infants with hypoxic respiratory failure that results from secondary surfactant deficiency; this includes meconium aspiration syndrome, sepsis or pneumonia, and pulmonary hemorrhage (Polin, Carlo, & Committee on Fetus and Newborn, 2014).

Dosage and Route

Dosage depends on the drug used. Administer via endotracheal tube as a bolus or in smaller amounts, or via infusion into the endotracheal tube through an adaptor port (Polin, Carlo, & Committee on Fetus and Newborn, 2014).

- Beractant* (Survanta)—4 ml/kg
- Poractant alpha* (Curosurf)—2.5 ml/kg
- Calfactant* (Infrasurf)—3 ml/kg
- Lucinactant (Surfaxin)—5.8 ml/kg

Adverse Reactions

Adverse events are most often related to the administration procedure and include oxygen desaturation, transient bradycardia, alterations in blood pressure, and drug reflux.

Nursing Considerations

The nurse observes the infant for changes. Diuresis can occur with improvement. Ventilator settings may need changing as the infant's ability to oxygenate increases.

*Bovine and porcine products can be objectionable to parents because of religious or cultural beliefs (Jewish, Islamic, or Hindu); prior to administering surfactant to infant, informed consent from parents is essential (Gardner et al., 2011b).

Data from Gardner, S., Enzman-Hines, M., & Dickey, L. (2011b). Respiratory diseases. In S. Gardner, B. Carter, M. Enzman-Hines, & J. Hernandez (Eds.), *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis: Mosby; Polin, R.A., Carlo, W.A., & Committee on Fetus and Newborn. (2014). Surfactant replacement therapy for preterm and term neonates with respiratory distress. *Pediatrics*, 133(1), 156-163.

high-frequency ventilation, or extracorporeal membrane oxygenation (ECMO). In the few studies conducted with human infants, positive results were seen: oxygen saturation improved, and no toxic effects from methemoglobin or increased levels of nitrogen oxide were documented. INO shows much promise in reducing adverse respiratory sequelae of prematurity. Its use has reduced the need for invasive technologies such as ECMO (Gardner et al., 2011b).

Extracorporeal Membrane Oxygenation. ECMO is a very complex and costly treatment that is sometimes used to support life and allow treatment of intractable hypoxemia due to severe cardiac or respiratory failure. This therapy involves a modified heart-lung machine, although in ECMO the heart is not stopped, and blood does not entirely bypass the lungs. Blood is shunted from a catheter in the right atrium or right internal jugular vein by gravity to a servo-regulated roller pump, pumped through a membrane lung, where it is oxygenated, and through a small heat exchanger, where it is warmed, and then returned to the systemic circulation via a major artery such as the carotid artery to the aortic arch. ECMO provides oxygen to the circulation, allowing the lungs to “rest,” and decreases pulmonary hypertension and hypoxemia in such conditions as persistent pulmonary hypertension of the newborn, congenital diaphragmatic hernia, sepsis, meconium aspiration, and severe pneumonia. ECMO is contraindicated for preterm infants younger than 34 weeks of gestation because of the anticoagulant therapy required in the pump and circuits, which can increase the potential for intraventricular hemorrhage (Gardner et al., 2011b).

Partial Liquid Ventilation. For infants with severe RDS, the use of partial liquid ventilation (PLV) can improve outcomes. Perfluorocarbon liquid is instilled into the lungs during gaseous (mechanical) ventilation. PLV is beneficial to the surfactant-deficient or immature lung because it reduces or eliminates surface tension, improves oxygenation through the re-creation of a fetal lung environment, and helps reexpand atelectatic areas. The safety and efficacy of PLV are being evaluated in the United States (Gardner et al., 2011b).

Weaning from Respiratory Assistance. The goal of weaning is the withdrawal of all oxygen support. Respiratory assistance is weaned slowly as the infant’s status improves. The infant is ready to be weaned from respiratory assistance once the ABG and oxygen saturation levels are maintained within normal limits. A spontaneous, adequate respiratory effort must be present, and the infant must show improved muscle tone during increased activity. Weaning is done in a stepwise and gradual manner. This can consist of the infant being extubated, placed on CPAP, and then weaned to oxygen by means of a hood or nasal cannula. Throughout the weaning process, the infant’s oxygen levels are monitored by pulse oximetry, transcutaneous oxygen (TcPO₂) monitoring, and blood gas levels. The infant is assessed for signs and symptoms indicating poor tolerance of the process. These include an increased pulse, respiratory distress, or cyanosis, or a combination of these. If these occur, the amount of oxygen being delivered is increased and weaning proceeds more slowly as assessments continue. Underlying causes of intolerance of weaning can be BPD, a PDA, or CNS damage.

Some infants do not tolerate weaning from oxygen therapy before discharge from the hospital. They can require supplementary oxygen at home for weeks or months.

Nutritional Care

It is not always possible to provide enteral (by the GI route) nourishment to a high risk infant. Such infants are often too ill or weak to breastfeed or bottle feed because of respiratory distress or sepsis. Early enteral feeding of the asphyxiated neonate with a low Apgar score also is avoided to prevent bowel necrosis. In such cases, nutrition is provided parenterally. Infants who require parenteral nutrition are likely to have one or more of the following problems:

- Lack of a coordinated suck-and-swallow reflex
- Inability to suck because of a congenital anomaly
- Respiratory distress requiring aggressive ventilator support
- Asphyxiation with a potential for NEC

Type of Nourishment. The type, mode, volume, and schedule of feedings are based on:

- Initially, the birth weight, and then the current weight of the preterm infant
- Pattern of weight gain or loss (infants weighing less than 1500 g (3.3 lb) require more energy for growth and thermoregulation and can gain weight poorly with either breast- or bottle feedings)
- Presence or absence of suck-and-swallow reflex in all infants at less than 35 weeks of gestation
- Behavioral readiness to take oral feedings
- Physical condition, including presence or absence of bowel sounds, abdominal distention, or bloody stools, as well as presence and degree of respiratory distress or apneic episodes
- Residual from previous feeding, if being gavage fed
- Malformations (especially GI defects such as gastroschisis, omphalocele, or esophageal atresia), including the need for a gastrostomy feeding tube
- Renal function, including urinary output and laboratory values (nitrogen balance, electrolyte balance, glucose level); preterm infants are especially susceptible to altered renal function

Human milk is the best source of nutrition for term and preterm infants (AAP Section on Breastfeeding, 2012). Even small preterm infants (32 to 36 weeks) are able to breastfeed if they have adequate sucking and swallowing reflexes and no other contraindications, such as respiratory complications or concurrent illness. Preterm infants who are breastfed rather than bottle fed demonstrate fewer oxygen desaturations, absence of bradycardia, warmer than normal skin temperature, and improved coordination of sucking, swallowing, and breathing (Gardner & Lawrence, 2011). Mothers who wish to breastfeed their preterm infants are encouraged to express their milk using a hospital-grade electric pump until their infants are sufficiently stable to tolerate feeding at the breast, and to continue pumping after feedings until the infant is able to exclusively breastfeed, usually after discharge from the hospital (Meier, Patel, Bigger, et al., 2013). Appropriate guidelines for the storage of expressed mother’s milk should be used to decrease the risk of milk contamination and destruction of its beneficial properties (Jones, 2011).

Commercially available preterm formulas are cow’s milk based and whey predominant and have a higher concentration of protein, calcium and phosphorus than term formulas to meet the unique needs of the preterm infant (de Curtis & Rigo, 2012). Most preterm formulas are either 22 or 24 cal/oz.

Human milk with fortifier (protein, phosphorus, and calcium) is recommended for LBW preterm infants because it increases weight gain and improves bone mineralization better than nonfortified human milk (Gardner & Lawrence, 2011). Supplementation with iron, vitamin D, and multivitamins may be considered in exclusively breastfed LBW infants.

Weight and Fluid Loss or Gain. The caloric, nutrient, and fluid requirements of high risk infants are greater than those of the healthy term newborn. Premature or dysmature (malnourished) newborns often have limited stores of nutrients and fluids. In addition, symptomatic or asymptomatic hypoglycemia, electrolyte imbalances, or other metabolic disturbances can develop in an infant whose nutritional intake is poor. Such hypoglycemia can cause serious damage to carbohydrate-dependent brain cells.

The infant's weight is measured and recorded daily, and the rate of weight loss or gain is calculated. Further depletion of weight and metabolic stores can occur as a result of one or a combination of the following factors:

- Birth asphyxia
- Increased respirations or respiratory effort
- Patent ductus arteriosus (PDA)
- Hypothermic environment
- Insensible fluid loss caused by evaporation (with radiant heat or phototherapy)
- Vomiting, diarrhea, and dysfunctional absorption from the GI tract
- Growth demands (a preterm infant's growth rate approximates that of fetal growth during the last trimester and is at least two times faster than a term infant's growth rate after birth)
- Inability of the renal system to concentrate urine and maintain an adequate rate of urea excretion, as well as infant's inadequate response to antidiuretic hormone

The high risk newborn is predisposed to weight and fluid losses because of the greater amount of fluid needed to meet the demands of the increased cellular metabolic processes (resulting from stress, repair, or growth). The body weight of preterm infants has higher water content than that of their full-term counterparts (Blackburn, 2013). Most of this water is in the extracellular fluid compartment. Even with the early institution of fluid and nutritional intake, the preterm infant's weight and fluid losses seem exaggerated. Inadequate fluid intake, resulting from either delayed administration or insufficient volume, can further cause weight and fluid losses in the preterm infant.

Insensible water loss (IWL) is an evaporative loss that occurs largely through the skin (70%) and through the respiratory tract (30%). The basal IWL in a term infant is approximately 20 ml/kg/day. It is significantly increased in preterm infants, and especially in ELBW infants with thin, gelatinous skin (Blackburn, 2013). The effects of radiant warmers, incubators, phototherapy, and other factors can increase the IWL. Humidifying the respiratory gases administered can prevent some of this loss.

During the first week of extrauterine life the preterm infant can lose up to 15% of his or her birth weight. In contrast, a weight loss up to 10% is acceptable in a term, appropriate for gestational age (AGA) infant. After the initial week, a preterm infant's loss or gain during each 24-hour period should not

BOX 34-4 Calculation of a Weight Loss or Gain

Example 1

Day 1	1750 g (birth weight)	$\frac{70}{1750} = \frac{X}{100}$
Day 3	1680 g 70-g loss	$1750X = 7000$ $\frac{7000}{1750} = 4.0$
		$1750 \overline{) 7000.0}$ $X = 4\%$ weight loss

Example 2

Day 3	1680 g	$\frac{40}{1680} = \frac{X}{100}$
Day 4	1720 g 40-g gain	$1680X = 4000$ $\frac{4000}{1680} = 2.38$
		$1680 \overline{) 4,000.00}$ $X = 2.4\%$ weight gain

exceed 2% of the previous day's weight. (To calculate a weight loss or gain, see Box 34-4.)

Increased stooling or voiding, increased evaporative losses, inadequate volume or incorrect fluid administration, and problems with malabsorption can cause weight loss. Implementation of interventions and frequent assessment of the infant and the environment are necessary to correct the problems. Common interventions include adjusting the incubator temperature; "swamping" or providing high levels of humidity under a cover over the radiant warmer; monitoring and adjusting the volume and type of fluid being administered; assessing the urinary output, including the specific gravity; and assessing the blood glucose levels. Hyperglycemia results in urinary loss of glucose that can cause osmotic diuresis, which increases the risk of dehydration (Yoo, Ahn, Lee, et al., 2013).

If the infant is gaining more than the expected amount of weight, this can be due to overfeeding or fluid retention. The nurse reports and records the findings and continues to assess the infant's fluid status, urinary output, and blood glucose levels. Interventions are determined by the infant's specific disorder and nutritional needs.

Elimination Patterns. The infant's elimination patterns are assessed and documented. This includes the frequency of urination, as well as the amount and color of the urine. The assessment of the infant's bowel movements includes the frequency of stooling and the character of the stool, as well as whether there is constipation, diarrhea, or loss of fats (steatorrhea). The nurse may request guaiac tests to assess for blood in the stool, tests to detect stool-reducing substances, and a pH determination to assess for malabsorption. Infants with unexplained abdominal distention are assessed carefully to rule out the presence of hypomotility obstructions of the GI tract or NEC.

Oral Feeding. Nourishment by the oral route is preferred for the infant who has adequate strength and GI function. The best milk for an infant is from the mother. Breast milk can be fed by breast, bottle, cup, or spoon. Throughout the feeding the nurse assesses the newborn's tolerance of the procedure. Preterm infants can be put to breast for nonnutritive suckling and practice feeds as soon as medically stable. The nurse or lactation consultant assists the mother by providing support and help as necessary when the infant breastfeeds.

The needs of the high risk infant must be considered when determining the type and frequency of the feedings. Many high risk infants cannot suck well enough to breastfeed or bottle feed until they have recovered from their initial illness or matured physically (corrected age more than 32 weeks of gestation). Mothers of high risk infants are encouraged to continue expressing breast milk with a hospital-grade electric pump, especially if theirs is a very premature infant who will not breastfeed for many weeks. Because of the significant breastfeeding attrition rates among these mothers, they need ongoing support and encouragement to continue pumping while their infant is not yet able to nurse. If no breast milk is available (from the mother or a milk bank), commercial formula is used. The calories, protein, and mineral content of commercial formulas vary. The type of nipple selected (“preemie,” regular, orthodontic) depends on the infant’s ability to suck from the specific type of nipple. The nurse also considers the energy the infant needs to expend in the process. However, the practice of delaying breastfeeding until the baby is able to effectively bottle feed is not evidence-based because studies continue to confirm that breastfeeding is less stressful than bottle feeding (Gardner & Lawrence, 2011).

Overfeeding of the preterm infant should be avoided because this can lead to abdominal distention, with apnea, vomiting, and possibly aspiration of the feeding. The nurse monitors the infant’s abdominal girth when distention is obvious.

Gavage Feeding. Gavage feeding is a method of providing nourishment to the infant who is compromised by respiratory distress, the infant who is too immature to have a coordinated suck-and-swallow reflex, or the infant who is easily fatigued by sucking. In gavage feeding, breast milk or commercial infant formula is given to the infant through a nasogastric or orogastric tube (Fig. 34-5). This spares the infant the work of sucking.

Gavage feeding can be done with an intermittently placed tube providing a bolus feeding or continuously through an indwelling catheter. Infants who cannot tolerate large bolus feedings are given continuous feedings. Minimal enteral nutrition can be used to stimulate or prime the GI tract to achieve better absorption of nutrients when bolus or regular intermittent gavage feedings can be given (Blackburn, 2013).

Breast milk or formula can be supplied intermittently via gavage by using a syringe with gravity-controlled flow, or it can be given continuously by using an infusion pump. The type of fluid instilled is recorded with every syringe change. The volume of the continuous feedings is recorded hourly, and the residual gastric aspirate is measured every 2 to 4 hours. Aspirates of less than a 1-hour volume can be re-fed to the infant. For intermittent feedings, residuals of less than 50% of the previous feeding can be re-fed to the infant to prevent the loss of gastric electrolytes. Feeding is usually stopped if the residual is greater than 50% of the feeding or if residuals are increasing and is not resumed until the infant can be assessed for a possible feeding intolerance (Anderson et al., 2011).

The orogastric route for gavage feedings is preferred because most infants are preferential nose breathers. In addition, when indwelling nasogastric tubes are used, there is a risk for necrosis of the nares. However, some infants do not

FIG 34-5 Gavage feeding. **A**, Measurement of gavage feeding tube from tip of nose to earlobe and to midpoint between end of xiphoid process and umbilicus. Tape may be used to mark correct length on tube. For accurate measure the infant should be facing up. **B**, Insertion of gavage tube using orogastric route. **C**, Indwelling gavage tube, nasogastric route. After feeding by orogastric or nasogastric tube, infant is propped on right side or placed prone (preterm infant) for 1 hour to facilitate emptying of stomach into small intestine. (A and B, Courtesy Cheryl Briggs, RNC, Annapolis, MD; C, Courtesy Randi and Jacob Wills, Clayton, NC.)

BOX 34-5 Procedure for Inserting a Gavage Feeding Tube

Equipment

- Infant feeding tube
 - For infants less than 1 kg (2.2 lb), size 4 Fr
 - For infants more than 1 kg (2.2 lb), size 5 Fr to 6 Fr
 - Stethoscope
 - Sterile water (lubricant)
 - Syringe: 5 to 10 ml
 - Tape, optional transparent dressing
 - Gloves
1. Measure the length of the gavage tube from the tip of the nose to the earlobe to the midpoint between the xiphoid process and the umbilicus (see Fig. 34-5, A). Mark the tube with indelible ink or a piece of tape.
 2. Lubricate the tip of the tube with sterile water and insert gently through the nose or mouth (see Fig. 34-5, B) until the predetermined mark is reached. Placement of the tube in the trachea will cause the infant to gag, cough, or become cyanotic.
 3. Check correct placement of the tube by:
 - a. Pulling back on the plunger to aspirate stomach contents. Lack of stomach aspirate or fluid is not necessarily evidence of improper placement. Aspiration of respiratory secretions can be mistaken for stomach contents; however, the pH of the stomach contents is much lower (more acidic) than the pH of respiratory secretions.
 - b. Injecting a small amount of air (1-3 ml) into the tube while listening for gurgling by using a stethoscope placed over the stomach. Ensure that the tube is inserted to the mark; air entering the stomach can be heard even if the tube is positioned above the gastroesophageal (cardiac) sphincter.
 - c. Abdominal or chest radiography. This is the only definitive way to verify tube placement.
 4. Using tape or a transparent dressing, secure the tube in place and tape it to the cheek to prevent accidental dislodgment and incorrect positioning (see Fig. 34-5, C).
 - a. Assess the infant's skin integrity before taping the tube.
 - b. Edematous or very preterm infants should have a pectin barrier placed under the tape to prevent abrasions, or a hydrocolloid adhesive should be used to prevent epidermal stripping.
 5. Tube placement *must* be assessed before each feeding.

tolerate oral tube placement. A small nasogastric feeding tube can be placed in older infants who would otherwise gag or vomit or in ones who are learning to suck. To insert the tube and give the feeding, the nurse should follow the sequence given in Box 34-5.

Gastrostomy Feedings. Gastrostomy feedings are used for infants with neurologic problems or certain congenital malformations that require long-term tube feedings. This involves the surgical placement of a tube through the skin of the abdomen into the stomach. The tube is then taped in an upright position to prevent trauma to the incision site. After the site heals the nurse initiates small bolus feedings per the physician's orders. Feedings by gravity are done slowly over 20- to 30-minute periods. Special care must be taken to prevent rapid bolusing of the fluid because this can lead to abdominal distention, GI reflux into the esophagus, or respiratory compromise. Meticulous skin care at the tube insertion site is necessary to prevent skin breakdown

or infection. In addition, intake and output are closely monitored because these infants are prone to diarrhea until regular feedings are established.

Parenteral Nutrition. Supplemental parenteral fluids are indicated for infants who are unable to obtain sufficient fluids or calories by enteral feeding. Some of these infants are dependent on total parenteral nutrition (TPN) for extensive periods. The nurse assesses and documents the following in infants receiving parenteral fluids or TPN:

- Type and infusion rate of the solution
- Functional status of the infusion equipment, including the tubing and infusion pump
- Infusion site for possible complications (phlebitis, infiltration, dislodgment)
- Caloric intake
- Infant's responses to therapy

The physician or nurse practitioner orders TPN per the hospital protocol. These orders must specify the electrolytes and nutrients desired, as well as the volume and rate of infusion. The composition of calories, protein, and fats is calculated on an individual basis.

While caring for the infant receiving parenteral fluids or TPN, the nurse secures and protects the insertion site. Scrupulous hand hygiene is used before handling the TPN tubing or IV sites. Strict sterile technique is implemented for dressing changes (Kilbride, Leick-Rude, Olsen, & Stiens, 2011). The nurse must observe the principles of neonatal skin care. The nurse carefully inspects the infusion site for signs of infiltration and repositions the infant frequently to maintain body alignment and protect the site. Parents need explanations about TPN and the ways in which the IV equipment and solutions affect their infant.

Advancing Infant Feedings. Feedings are advanced as assessment data and the infant's ability to tolerate the feedings warrant. Documentation of a preterm infant's sucking patterns also can be used to determine readiness to nipple feed. Feedings are advanced from passive (parenteral and gavage) to active (bottle- and breastfeeding). At each step the nurse must carefully assess the infant's response to prevent stress to the infant.

The infant receiving nutrition parenterally is gradually weaned off this type of nutrition. To do this the nourishment given by continuous or intermittent gavage feedings is increased and the parenteral fluids are decreased. Even the smallest infant is sometimes given MEN to stimulate the GI system to mature and to enhance caloric intake (Blackburn, 2013).

Feedings are advanced slowly and cautiously because if advanced too rapidly, the infant can develop vomiting (with an attendant risk of aspiration), diarrhea, abdominal distention, and apneic episodes. Rapid advancements in the volume of feeds have been implicated as a risk factor for NEC (Christensen, Lambert, Baer, & Gordon, 2013). Rapid advancement also can cause fluid retention with cardiac compromise or a pronounced diuresis with hyponatremia.

If the infant needs additional calories, a commercial human milk fortifier can be added to the gavaged breast milk, or the number of calories per 30 ml of commercial formula can be increased. Soy and elemental formulas are used only for infants with very special dietary needs, such as allergies to cow's milk or chronic malabsorption. Calories in breast milk can be lost if the

cream separates and adheres to the tubing during continuous infusion. This problem is decreased if microbore tubing is used for both continuous and intermittent gavage feedings.

The infant receiving gavage feedings progresses to bottle feeding or breast milk feedings. To do this the gavage feedings are decreased as the infant's ability to suckle breast milk or formula improves. Often during this transition the infant is fed by both bottle or breast and gavage feeding to ensure the intake of both the prescribed volume of food and nutrients. However, when there is an indwelling tube, during breast or bottle feedings, some infants experience increased respiratory effort, so nurses must watch for this. The parents need support during this transition because many families measure their parenting competence by how well they can feed their infant. For breastfed infants, it is important to weigh the infant before and after breastfeeding to determine the infant's intake (Gardner & Lawrence, 2011).

As the time of discharge nears, the appropriate method of feeding and the assessments pertaining to the method (e.g., tolerance of feedings, status of gavage tube placement) are reviewed with the parents. The parents should be encouraged to interact with the infant by talking and making eye contact with the infant during the feeding. This stimulates the psychosocial development of the infant and facilitates bonding and attachment.

Nonnutritive Sucking. If the infant is receiving only parenteral nutrition or gavage feeds, **nonnutritive sucking** should be encouraged for several reasons (Fig. 34-6). Allowing the infant to suck on a pacifier during gavage or between oral feedings can improve oxygenation. In addition, such nonnutritive sucking can lead to decreased energy expenditure with less restlessness. It also promotes positive weight gain and better sucking skills (Gardner & Lawrence, 2011).

Mothers of preterm infants should be encouraged to allow their infants to start sucking at the breast during kangaroo care (skin-to-skin). In some infants, the suck-and-swallow reflexes are coordinated as early as 32 weeks of gestation. If the neonate is unable to suck, the mother can place the infant near the nipple to encourage nuzzling or licking.

Infants with intrauterine growth restriction (IUGR) can have an age-appropriate sucking reflex but require thermoregulatory support, making it difficult to breastfeed. These infants also may benefit from nonnutritive sucking or nuzzling at the breast for short periods.

Skin Care

The skin of preterm infants is characteristically immature compared with that of full-term infants. Because of its increased sensitivity and fragility, the use of alkaline-based soap that might destroy the acid mantle of the skin is avoided. Vernix caseosa has benefits for the preterm infant's skin. Vernix acts as an epidermal barrier, decreases bacterial contamination of the skin through its antimicrobial peptides and proteins, and decreases transepidermal water loss (Blackburn, 2013). Experts recommend that a validated skin assessment tool such as the Neonatal Skin Condition Score (NSCS) be used once daily to evaluate the high risk infant's skin condition so as to implement interventions aimed at minimizing skin breakdown (Lund & Durand, 2011).

FIG 34-7 Although necessary, neonatal intensive care unit equipment can contribute to significant environmental stimulation. Note bed, wall oxygen attachments, monitor, ventilator, incubator, and pumps, all of which have alarm systems. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

Environmental Concerns

Infants in neonatal intensive care units (NICUs) are exposed to high levels of auditory input from the various machine alarms, and this can have adverse effects (Fig. 34-7). In addition, continual noise levels of 45 to 85 decibels (db) are common in NICUs. An incubator alone produces a constant noise level of 60 to 80 db, and each new piece of life-support equipment used adds another 20 db to the background noise. The infant's hearing can be damaged if it is exposed to a constant decibel level of 90 db or frequent decibel swings higher than 110 db. Cochlear damage has been recognized as a side effect of the NICU environment. Hearing losses have been identified in NICU graduates; these losses lead to long-term speech and language deficits. Over time more emphasis has been placed on noise in the NICU and the adverse or long-term effects on neonates (Wachman & Lahav, 2011).

Respiratory equipment or a phototherapy mask can alter the infant's vision, making it difficult to interact with parents and caregivers. The infant may be unable to establish diurnal and nocturnal rhythms because of the continuous exposure to

overhead lighting. In addition, sedation or pain medications affect the way in which the infant perceives the environment.

An additional concern in the care of infants is that some drugs used for infant therapy can potentiate environmental hazards. Drugs such as aminoglycosides can potentiate noise-induced hearing loss (Zimmerman & Lahav, 2013). Routine hearing screening should be performed in all infants before discharge, with universal screening completed by no later than the third month of life (AAP Joint Committee on Infant Hearing, 2007).

Research is ongoing to determine the long-term effects of light and noise on the preterm infant (Aita, Johnston, Goulet, et al., 2013). Cycling of light and covering of incubators to reduce direct light hitting the retina are two areas of research. The retina of the immature infant has little protection from the nearly translucent eyelid, thus allowing light to almost constantly penetrate the retina unless it is artificially protected by dimming the lights or using incubator covers. Cycled lighting has been shown to have a positive effect on growth (Morag & Ohlsson, 2011). Light and sound can be adverse stimuli for the preterm infant who is already stressed. Signs of stress include increased metabolic rate, increased oxygen and caloric use, and depression of the immune system. The nurse must monitor the macroenvironment and the microenvironment (unit and immediate environments) for sources of overstimulation. Providing a developmentally supportive environment can lead to decreased complications and length of stay. There are national recommendations for sound and light levels in the NICU.

Nurses can modify the environment to provide a developmentally supportive milieu. In that way the infant's neurobehavioral and physiologic needs can be better met, the infant's developing organization can be supported, and growth and development can be fostered (Legendre, Burtner, Martinez, & Crowe, 2011).

Developmental Care

The goal of developmental care is to support each infant's efforts to become as well organized, competent, and stable as possible. Developmental care includes all care procedures and the physical and social aspects of care in the NICU (Legendre et al., 2011). The caregiver uses the infant's own behavior and physiologic functioning as the basis for planning care and providing interventions. Through caregiver observation, the infant's strengths, thresholds for disorganization, and vulnerable areas can be identified. The family is included in developmental care. Working together, the family and other caregivers provide opportunities to enhance the strengths of the family and the infant and to reduce the stress that is associated with the birth and care of high risk infants.

Reducing light and noise levels by instituting "quiet hours" at regularly scheduled times and positioning are just two ways in which nurses can support infants in their development. Sleep interruptions are minimized, and positioning and bundling the infant help promote self-regulation and prevent disorganization (Allen, 2012; Byrne & Garber, 2013).

Positioning. The motor development of preterm infants permits less flexion than in term infants. Caregivers can provide a variety of positions for infants; side-lying and prone are preferred to supine (but only in the nursery). Body containment

FIG 34-8 Developmental care: positioning of preterm infant using containment while undergoing phototherapy. (Courtesy Randi and Jacob Wills, Clayton, NC.)

with use of blanket rolls, swaddling, holding the infant's arms in a crossed position, and secure holding provide boundaries (Fig. 34-8). Use of facilitated tucking promotes self-regulation during feeding, procedures, and other stressful interventions. The prone position encourages flexion of the extremities; a sling or hip roll assists in maintaining flexion. Keeping the extremities close to the body helps calm the infant and decreases stimulation. Proper body alignment is necessary to prevent developmental problems that can affect the ability to walk as the child matures (Altimier & Phillips, 2013).

Reducing Inappropriate Stimuli. Staff can reduce unnecessary noise by closing doors or portholes on incubators quietly, placing only necessary objects gently on top of incubators, keeping radios at low volume, speaking quietly, and handling equipment noiselessly. Another source is internal noise created by mechanical sources such as CPAP. These noise sources must be considered when thinking about long-term effects on hearing. Earmuffs can be used during scans (Arthurs, Edwards, Austin, et al., 2012).

Infants can be protected from light by dimming the lights during the night, placing a blanket over the incubator, or covering the infant's eyes with a mask. Sleep-wake cycles can be induced with such measures. Infants need periods in which there are no disruptions and sleep can occur. Clustering of care can promote longer uninterrupted periods of sleep (Legendre et al., 2011).

Infant Communication. Infants communicate their needs and ability to tolerate sensory stimulation through physiologic responses. The nurses and parents of high risk infants must therefore be alert to such cues. Although term infants can thrive on stimulation, this same stimulation in high risk infants can provoke physical symptoms of stress and anxiety (Gardner & Goldson, 2011).

Problems with noxious stimuli and barriers to normal contact can cause anxiety and tension. Clues to overstimulation include averting the gaze, hiccupping, gagging, or regurgitating food. Term infants exhibit a startle reflex, and preterm infants move all of their limbs in an uncoordinated fashion in response to noxious stimuli. An irregular respiratory rate or an increased

heart rate can develop in severely distressed infants, and they can be unable to regain a calm state.

A relaxed infant state is indicated by stabilization of vital signs, closed eyes, and a relaxed posture. Nonintubated infants may make soothing verbal sounds when they are relaxed. Infants requiring artificial ventilation cannot cry audibly and often show their distress through posturing; they relax once their needs are met. As high risk infants heal and mature, they increasingly respond to stimuli in a self-regulated manner rather than with a dissociated response. Infants who do not show increased self-regulation should be evaluated for a neurologic problem.

Infant Stimulation. The Newborn Individualized Developmental Care and Assessment Program (NIDCAP, 2008) (www.nidcap.com) routinely integrates aspects of neurodevelopmental theory with caregivers' observations, environmental interventions, and parental support. Routine reassessment is built into the program's design. Developmental stimuli may consist of such simple measures as kangaroo care or placing a waterbed mattress on the top of the infant's mattress. The simplest calming technique is for the caregiver to use both hands to contain the infant's extremities close to the body. The care of the infant is organized to allow extended periods of undisturbed rest and sleep. Pain medications or sedatives should be administered consistently per the unit's protocol.

Infants acquire a sense of trust as they learn the feel, sound, and smell of their parents. High risk infants also must learn to trust their caregivers to obtain comfort. However, caregivers in the nursery also can inflict pain as part of the care they must give. For this reason it is important for parents and caregivers to use comforting interventions such as removing painful stimuli, stopping hunger, and changing wet or soiled clothing to foster trust. They can offer nonnutritive sucking or use oral sucrose for pain relief and topical creams before procedures to avoid pain. All these techniques are part of developmental, supportive care (Altimier & Phillips, 2013).

When the infant is ready for stimulation, the nurse has many options. Most infants can tolerate being held, even if only for short periods. Additional ways for the nurse or parents to stimulate infants include cuddling, rocking, singing, talking to the infant, and using music therapy. These activities are beneficial and promote growth and weight gain as well as shorten the length of hospital stay. Stroking the infant's skin during medical therapy can provide tactile stimulation. The caregiver responds to the infant's cues by offering reassurance, providing nonnutritive sucking, stroking the infant's back, and talking to the infant. Infant massage is gaining evidence as a way to promote weight gain (Gardner & Goldson, 2011).

Mobiles and decals that can be changed frequently may be placed within the infant's visual range to stimulate the infant visually. Wind-up musical toys provide rhythmic distractions as long as they are not too loud. If the infant is receiving phototherapy, the protective eyepatches are removed periodically (e.g., during feeding) to allow parent-infant or caregiver-infant interaction.

Kangaroo Care. Although it must be individually adjusted, kangaroo care and short periods of gentle massage can help reduce stress in preterm infants (Fig. 34-9). The parent is bare-chested or may wear a loose-fitting, open-front top that

FIG 34-9 Father holding infant in kangaroo care. (Courtesy Randi and Jacob Wills, Clayton, NC.)

has a modified marsupial-like pocket carrier for the infant. The undressed (except for diaper) infant is placed in a vertical position on the parent's bare chest, which permits direct eye contact, skin-to-skin sensations, and close proximity. Skin-to-skin contact can have a positive healing effect for the mother who had a high risk pregnancy. Additional benefits include early contact with mechanically ventilated infants, maintenance of neonatal thermal stability and oxygen saturation, increased feeding vigor and enhanced breastfeeding, maintenance of organized state, decreased pain perception during painful heelsticks, and minimal untoward effects of being held (Cong, Cusson, Walsh, et al., 2012; Flacking, Ewald, & Wallin, 2011; Jefferies & Canadian Paediatric Society Fetus and Newborn Committee, 2012).

Parental Adaptation to a Preterm Infant

Parents of premature infants often have difficulty in bonding and relating to their babies. The need to be empowered to recognize their competence and achieve competence is the basis of the Creating Opportunities for Parent Empowerment (COPE) program. This early educational-behavioral intervention model promotes more positive parent-infant interactions and enhanced ability to read and respond to infant cues (Gooding, Cooper, Blaine, et al., 2011; Siegel, Gardner, & Dickey, 2011).

Parental Tasks. Parents of preterm infants must accomplish numerous psychologic tasks before effective relationships and parenting patterns can evolve. These tasks include the following:

- Experiencing **anticipatory grief** over the potential loss of an infant. The parent grieves in preparation for the infant's

possible death, although the parent clings to the hope that the infant will survive. This process begins during labor and lasts until the infant dies or shows evidence of surviving. Anticipatory grief occurs when families have knowledge of an impending loss, such as when a baby is admitted to a NICU with problems or when a diagnosis of an anencephalic fetus is made with ultrasonography. The baby is still alive, but the prognosis is poor. Being able to anticipate the loss gives families an opportunity to plan, feel more in control of their situation, and say goodbye in a special way. However, some individuals or family members distance or detach themselves from the experience or from their loved ones as a way of protecting themselves from the pain of loss and grief. How a parent responds to this situation depends on religious, spiritual, and cultural beliefs. These must be considered when planning care. The nurse's role is to advocate for the family so that other health professionals realize that the family is grieving. Being fully present for these families and practicing active listening are important (see Chapter 37).

- The mother's acceptance of her failure to give birth to a healthy full-term infant. Grief and depression typify this phase, which persists until the infant is out of danger and is expected to survive.
- Resuming the process of relating to the infant. As the baby's condition begins to improve and the baby gains weight, is able to breastfeed or bottle feed, and is weaned from the incubator or radiant warmer, the parent can begin the process of developing an attachment to the infant that was interrupted by the infant's critical condition at birth.
- Learning about the ways in which this baby differs in terms of his or her special needs and growth patterns, caregiving needs, and growth and development expectations
- Adjusting the home environment to accommodate the needs of the new infant. Parents are encouraged to limit the number of visitors to minimize exposure of the infant to pathogens. The environmental temperature may have to be altered to optimize conditions for the infant.

Parental Responses. Physical contact with the infant is important to establish early bonding and attachment. If it

is not possible for parents to hold the infant, they can touch and stroke the baby as they speak softly (Fig. 34-10). As the infant's condition improves, parents can hold the neonate and provide kangaroo care (see Fig. 34-10). They gradually begin to participate in infant activities, such as feeding, bathing, and changing. Parents go through numerous phases of adjustment as they learn to parent their infant. Nurses facilitate the transition to parenthood through their teaching and support of parental efforts.

Parental Support. The nurse as caregiver, support person, and educator is responsible for shaping the environment and responding with sensitivity to the needs of the parents and infant. Nurses are instrumental in helping parents learn who their infant is and to recognize behavioral cues in his or her development and to use these cues in the care they provide (Gardner & Goldson, 2011).

When a high risk birth is anticipated, the family can be given a tour of the NICU or shown a video to prepare them for the sights and activities of the unit. After an unanticipated preterm birth, the parents can be given a booklet, view a video, or have someone describe what they will see when they go to the unit to see their infant.

As soon as possible, the parents should see and touch their infant so that they can begin to acknowledge the reality of the birth and the infant's true appearance and condition. The premature or sick baby's appearance can be stressful to the parents. They will need encouragement as they begin to accomplish the psychologic tasks imposed by the high risk birth. For the following reasons, a nurse or physician should be present during the parents' first visit:

- To help them "see" the infant rather than focus on the equipment. The importance and purpose of the equipment that surrounds their infant should be explained to them.
- To explain the characteristics normal for an infant of their baby's gestational age; in this way parents do not compare their child with a term, healthy infant
- To encourage the parents to express their feelings about the pregnancy, labor, and birth and the experience of having a high risk infant

FIG 34-10 A, Mother and father touch preterm infant. B, Mother caresses preterm infant. (Courtesy Randi and Jacob Wills, Clayton, NC.)

- To assess the parents' perceptions of the infant to determine the appropriate time for them to become actively involved in care

When the parents cannot be present physically to visit with the infant, staff members devise appropriate methods to keep them informed and to help them feel connected to the newborn. Examples are daily phone calls, notes written as if by the infant, and photographs of the infant.

The birth of a preterm or high risk infant affects the entire family. Nurses need to consider responses and reactions of grandparents and siblings as they provide family-centered care for the infant and family. Grandparents often experience grief and sadness as they watch their own children experiencing the difficulties and challenges of having a preterm or high risk infant. They worry about the well-being of their grandchild. Siblings also react to the birth of the preterm or high risk infant. If they are old enough to realize that the mother was supposed to be bringing home a new baby, they can be very confused when the baby must remain in the hospital. When possible it can be helpful to allow siblings to visit the new baby in the NICU environment so that they can see the infant (Fig. 34-11). Once the infant is brought home, some children are bewildered and angry at the seemingly disproportionate amount of

parental time spent on the newborn. Nurses can facilitate visits by grandparents and siblings while the infant is hospitalized and can help parents anticipate possible reactions of siblings once the baby is discharged.

Some hospitals have support groups for the parents of infants in NICUs. These groups help parents experiencing anxiety and grief by encouraging them to share their feelings. Hospitals may arrange to have an experienced NICU parent make contact with a new group member to provide additional support. The volunteer parents provide support by making hospital visits, phone calls, and home visits. Mothers in particular are prone to post-traumatic stress that can hinder their ability to interact with or care for their infant (Forcada-Guex, Borghini, Pierrehumbert, et al., 2011). They need help in expressing their feelings and, when appropriate, referral for psychological or family counseling.

Many NICUs use volunteers in varying capacities. After they have gone through the orientation program, volunteers can perform tasks such as holding the infants, stocking bedside cabinets, assembling parent packets, and, in some nurseries, feeding the infants.

Parental Maladaptation. The incidence of physical and emotional abuse is increased in infants who, because of preterm

FIG 34-11 Sibling visits newborn in the neonatal intensive care unit. **A**, Father prepares older child for visit. **B**, Sibling observes neonate at a safe distance. **C**, He reaches out to touch the infant. (Courtesy Lauren and Brian LiVecchi, Raleigh, NC.)

birth or high risk condition, are separated from their parents for a time after birth. Physical abuse includes varying degrees of poor nutrition, poor hygiene, and bodily harm. Emotional abuse ranges from subtle disinterest to outright dislike of the infant. Appropriate resources should be made available to assess the parent's feelings regarding the preterm infant's birth. In addition, proper guidance and counseling are made available, including posthospital discharge, to help families adjust to and care for the preterm infant. The ultimate goal is for the family to accept the infant and incorporate this new member into the existing family structure.

Parent Education

The criteria showing an infant's readiness for discharge are that the infant's physiologic condition is stable, the infant is consuming adequate nutrition, and the infant's body temperature is stable. The parents or other caregivers, should demonstrate physical, emotional, and educational readiness to assume responsibility for the total care of the infant. Ideally, the home environment is adequate for meeting the needs of the infant. Resources for parents and health care providers include <http://premature-infant.com> and www.neonatology.org.

Complications in High Risk Infants

Respiratory Distress Syndrome

Respiratory distress syndrome (RDS) refers to a lung disorder usually affecting preterm infants. Maternal and fetal conditions associated with a decreased incidence and severity of RDS include female sex, African-American race, maternal gestational

hypertension, maternal drug abuse, maternal steroid therapy (betamethasone), chronic retroplacental abruption, prolonged rupture of membranes, and IUGR. The incidence and severity of RDS increase as gestational age decreases. Perinatal asphyxia, hypovolemia, male sex, Caucasian race, maternal diabetes (types 1 and 2), second-born twin, familial predisposition, maternal hypotension, cesarean birth without labor, hydrops fetalis, and third-trimester bleeding place an infant at increased risk for RDS. The incidence of RDS in infants weighing less than 1500 g (3.3 lb) is about 45% (Hamvas, 2011).

RDS is caused by a lack of pulmonary surfactant, which leads to progressive atelectasis, loss of functional residual capacity, and ventilation-perfusion imbalance with an uneven distribution of ventilation. This surfactant deficiency can be caused by insufficient surfactant production, abnormal composition and function, disruption of surfactant production, or a combination of these factors. The weak respiratory muscles and an overly compliant chest wall, common among preterm infants, contribute to the sequence of events that occurs. Lung capacity is further compromised by the presence of proteinaceous material and epithelial debris in the airways. The resulting decreased oxygenation, cyanosis, and metabolic or respiratory acidosis can cause the pulmonary vascular resistance (PVR) to be increased. This increased PVR can lead to right-to-left shunting and a reopening of the ductus arteriosus and foramen ovale (Fig. 34-12).

Clinical symptoms of RDS usually appear immediately after or within 6 hours of birth. Physical examination reveals crackles, poor air exchange, pallor, the use of accessory muscles (retractions) and, occasionally, apnea. Radiographic findings

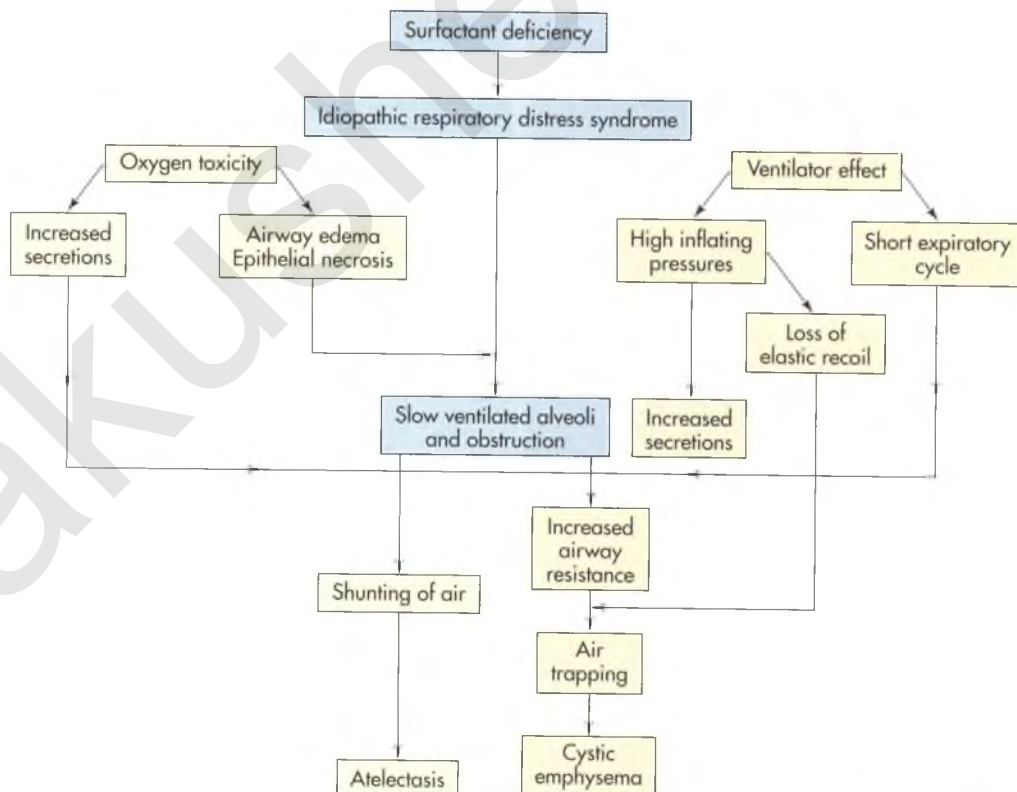

FIG 34-12 Pathogenesis of respiratory distress syndrome (RDS). (From Gardner, S., Enzman-Hines, M., & Dickey, L. [2011]. Respiratory diseases. In S. Gardner, B. Carter, M. Enzman-Hines, & J. Hernandez [Eds.], *Merenstein & Gardner's handbook of neonatal intensive care* [7th ed.]. St. Louis: Mosby.)

include a uniform reticulogranular appearance and air bronchograms (Gardner et al., 2011b; Orlando, 2012). The infant's clinical course is variable, usually with an increased oxygen requirement and increased respiratory effort, atelectasis, loss of functional residual capacity, and worsening of ventilation-perfusion imbalance.

RDS is a self-limiting disease that usually abates after 72 hours. This disappearance of respiratory signs coincides with the production of surfactant in the type 2 cells of the alveoli.

The treatment for RDS is supportive. Adequate ventilation and oxygenation must be established and maintained in an attempt to prevent ventilation-perfusion mismatch and atelectasis. Exogenous surfactant may be administered at birth or shortly after; this has the effect of shortening the typical course of RDS. Positive-pressure ventilation, nasal CPAP, and oxygen therapy may be necessary during the respiratory illness.

The mortality and morbidity rates associated with RDS are attributed to the infant's immature organ systems and the complications associated with the treatment of the disease (Hamvas, 2011). Preventing complications associated with mechanical ventilation is critical. These complications include pulmonary interstitial emphysema, pneumothorax, and chronic lung disease. Acid-base balance is evaluated by monitoring the ABG values (Table 34-2). Pulse oximetry documents trends in oxygenation. Capillary blood gas values indicate the pH and Pco_2 status in infants who are in more stable condition.

The maintenance of an NTE is critical to the care of infants with RDS. Infants with hypoxemia are unable to increase their metabolic rate when they experience cold stress (Hamvas, 2011).

The clinical and radiographic presentation (radiodense lung fields and air bronchograms) of neonatal pneumonia can be similar to that of RDS. Fluid in the minor fissure also can be noted in infants with neonatal pneumonia. Therefore, sepsis evaluation, including blood culture and complete blood count (CBC) with differential, is done in infants with RDS and risk factors to rule out neonatal pneumonia. Occasionally a lumbar puncture is done as part of the sepsis evaluation. Broad-spectrum antibiotics are begun while the results of cultures are awaited.

Fluid and nutrition must be maintained in the critically ill infant with RDS. Parenteral nutrition can be implemented to provide protein and fats to promote a positive nitrogen balance. Daily monitoring of the electrolyte values, urinary output, and weight help evaluate the infant's hydration status.

Frequent blood sampling can make blood transfusions necessary. The critically ill infant usually needs to have a

venous hematocrit level of more than 40% to maintain adequate oxygen-carrying capacity (Pranke & Onsten, 2011).

NURSING ALERT

When transfusion is needed, the family may request directed donor blood. This donor blood usually is obtained from a family member or close friend of the family who has the same blood type as the infant or a compatible blood type. It may be necessary to notify the infant's family of the potential need for blood transfusion on admission to allow for the processing of directed-donor blood.

Reassuring the family about stringent testing of all blood products can help alleviate some of their anxiety about the transmission of blood-borne pathogens such as human immunodeficiency virus (HIV) and hepatitis B. Because some religions prohibit the use of blood transfusions, it is critical to obtain a complete history from the family, including their religious preference. Alternative strategies for maintaining the infant's hematocrit may be used in these instances.

Retinopathy of Prematurity

Retinopathy of prematurity is a complex multicausal disorder that affects the developing retinal vessels of preterm infants. The normal retinal vessels begin to form in utero at approximately 16 weeks in response to an unknown stimulus. These vessels continue to develop until they reach maturity at approximately 42 to 43 weeks after conception. Once the retina is completely vascularized, the retinal vessels are not susceptible to ROP. The mechanism of injury in ROP is unclear. Oxygen tensions that are too high for the level of retinal maturity initially result in vasoconstriction. After oxygen therapy is discontinued, neovascularization occurs in the retina and vitreous, with capillary hemorrhages, fibrotic resolution, and possible retinal detachment. Scar tissue formation and consequent visual impairment can be mild or severe. The entire disease process in severe cases can take as long as several months to evolve. The infant is examined by an ophthalmologist before discharge, and follow-up examinations are recommended as needed (Fraser, 2012b; Gardner et al., 2011b).

The key to the management of ROP is prevention of preterm birth and early detection. Blood oxygen levels in the preterm infant should be closely monitored and significant fluctuations avoided. Oxygen and ventilator settings should be adjusted to keep oxygen saturations within acceptable levels. Cryotherapy and laser photocoagulation are common treatments for ROP (Gardner et al., 2011b). Researchers are examining the effect of the NICU environment on the development of ROP in relation to light that shines directly through the very thin eyelids of very immature infants. Ambient lighting in the NICU is known to have an effect on the developing eye; although it may not directly cause ROP, it does contribute to other visual problems for the preterm infant. Another potential contributor to ROP is hyperglycemia, which apparently fosters vasoproliferation (Chavez-Valdez, McGowan, Cannon, & Lehmann, 2011).

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) is a chronic pulmonary condition occurring most commonly in preterm infants requiring mechanical ventilation. The etiology of BPD is

TABLE 34-2 Normal Arterial Blood Gas Values for Neonates

VALUE	RANGE
pH	7.35-7.45
Arterial oxygen pressure (PaO_2)	60-80 mm Hg
Carbon dioxide pressure (Paco_2)	35-45 mm Hg
Bicarbonate (HCO_3^-)	18-26 mEq/L
Base excess	(-5) to (+5)
Oxygen saturation	92%-94%

From Wood, A., & Jones, D. (2011). Acid-base homeostasis and oxygenation. In S. Gardner, B. Carter, M. Enzman-Hines, & J. Hernandez (Eds.), *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis: Mosby.

multifactorial and includes pulmonary immaturity, surfactant deficiency, lung injury and stretch, barotrauma, inflammation caused by oxygen exposure, fluid overload, ligation of a PDA, and a familial predisposition. With the advent of prenatal use of maternal steroids when preterm birth is expected, coupled with use of exogenous surfactant in the neonate, the risk of BPD or chronic lung disease (CLD) has been reduced (Fraser, 2012b).

Clinical signs of BPD include tachypnea, retractions, nasal flaring, increased work of breathing, activity intolerance to handling and feeding, and tachycardia. Infants with BPD can have an increase in ventilatory requirements or are unable to be weaned from the ventilator. Auscultation of the lung fields in affected infants typically reveals crackles, decreased air movement, and occasionally expiratory wheezing. Hypoxia, hypercapnia, and respiratory acidosis are common (Bancalari, 2011).

The treatment for BPD includes oxygen therapy, nutrition, fluid restriction, and medications (diuretics, corticosteroids, and bronchodilators). However, the key to the management of BPD is prevention of prematurity and RDS. Other therapies that can aid in prevention of BPD include antenatal steroids, prophylactic surfactant, avoidance of mechanical ventilation when possible, use of CPAP, gentle ventilation in the delivery room, and administration of vitamin A (Gardner et al., 2011b).

The prognosis for infants with BPD depends on the degree of pulmonary dysfunction and on the infant's overall health status. Oxygen therapy may be continued in the home setting. There is usually progressive normalization of pulmonary function, although abnormalities of small airways can persist. Mortality after hospital discharge is usually due to complications such as respiratory infection (Bancalari & Walsh, 2011).

Patent Ductus Arteriosus

The ductus arteriosus is a normal muscular contractile structure in the fetus connecting the left pulmonary artery and the dorsal aorta, diverting blood to the placenta for gas exchange. The duct constricts after birth as oxygenation, the levels of circulating prostaglandins, and the muscle mass increase. Other factors that promote ductal closure include catecholamines, low pH, bradykinin, and acetylcholine. When the fetal ductus arteriosus fails to close after birth, **patent ductus arteriosus (PDA)** occurs. During the first few days of life when a preterm or sick infant is under stress, the ductus arteriosus can reopen, leading to mottling and cyanosis. It can last only a few minutes until the stress is past, or it can remain open if the infant is quite unstable. The incidence of PDA in infants born at less than 28 weeks of gestation is 70% (Clyman, 2013).

Although a small PDA can be asymptomatic, the clinical presentation in an infant with a significant PDA includes systolic murmur, active precordium, bounding peripheral pulses, tachycardia, tachypnea, crackles, and hepatomegaly. The systolic murmur is heard best at the second or third intercostal space at the upper left sternal border. An increased left ventricular stroke volume causes an active precordium.

Radiographic studies in infants with PDA typically show cardiac enlargement and pulmonary edema. ABGs indicate hypercapnia and metabolic acidosis. Definitive diagnosis is through echocardiography, which can visualize a PDA and measure the amount of blood shunting across the PDA (Kenney, Hoover, Williams, & Iskersky, 2011).

Medical management consists of ventilatory support, fluid restriction, and the administration of indomethacin or ibuprofen (Fraser, 2012b). Ibuprofen and indomethacin inhibit prostaglandin synthesis and cause the PDA to constrict. However, there is some concern that indomethacin reduces blood flow to the brain, kidneys, and GI tract (Clyman, Couto, & Murphy, 2012).

Ventilatory support is adjusted based on the ABG values. Fluid restriction and diuretic therapy are implemented to decrease cardiovascular volume overload. Surgical ligation is done when a PDA is clinically significant and medical management is ineffective.

Nursing management of the infant with PDA focuses on supportive care. The infant needs an NTE, adequate oxygenation, meticulous fluid balance, and parental support.

Germinal Matrix Hemorrhage–Intraventricular Hemorrhage

Germinal matrix hemorrhage–intraventricular hemorrhage (GMH-IVH) is one of the most common types of brain injuries in neonates and is among the most severe from the standpoint of both short- and long-term outcomes. It is the most common type of intracranial hemorrhage, occurring almost exclusively in preterm infants. The risk of GMH-IVH increases with decreasing gestational age. The incidence of GMH-IVH is estimated to be 5% to 11% and has shown a decline in recent years (de Vries, 2011). The decline is attributed to the prenatal use of corticosteroids and postnatal use of surfactant.

The germinal matrix is a loose network of cells abundantly supplied with tiny, fragile, thin-walled vessels. It lies beneath the lining of the lateral ventricles. This area is present and active until 34 to 35 weeks of gestation as a site for production of neurons and glial cells that gradually migrate to the cerebral cortex. The germinal matrix is especially vulnerable to alterations in cerebral blood flow related to blood pressure changes. Hemorrhage occurs when the tiny blood vessels rupture; the hemorrhage can extend into the lateral ventricles, then to the third and fourth ventricles, the subarachnoid space, and even into the white matter of the brain. Large clots can develop and create outflow obstruction from the ventricles (de Vries, 2011).

Infants who experience GMH-IVH are usually less than 34 weeks of gestation with a history of hypoxia, birth asphyxia, RDS, or other events causing impaired venous return or increased venous pressure. In the majority of cases GMH-IVH is diagnosed within the first 3 to 4 days of life. Infants with GMH-IVH can be asymptomatic, develop symptoms gradually, or have an acute catastrophic presentation. Clinical signs suggestive of hemorrhage include decreasing hematocrit, full anterior fontanel, changes in activity level, and decreased muscle tone. With a catastrophic incident, the infant can develop stupor, coma, respiratory distress that progresses to apnea, decerebrate posturing, and seizures; there is a high mortality rate in these cases (Bonifacio, Gonzalez, & Ferriero, 2012).

Morbidity and mortality related to GMH-IVH are based on the severity of the hemorrhage and the associated problems. Small hemorrhages are usually associated with good outcomes and high survival rates. Infants with more severe hemorrhages, posthemorrhagic ventricular dilation, or periventricular leukomalacia have higher mortality rates and greater long-term morbidity. Neurodevelopmental outcomes of GMH-IVH include hydrocephalus,

cerebral palsy, developmental delays, learning disorders, and sensory and attention problems (de Vries, 2011).

Care management begins with prevention of preterm birth, birth trauma, and hypoxic-ischemic injury. Antenatal steroids help reduce the risk of GMH-IVH. Prompt and skilled resuscitation at birth minimizes hypoxia and ischemia. Nursing care focuses on recognition of factors that increase the risk of GMH-IVH, interventions to decrease the risk of bleeding, and supportive care to infants who have bleeding episodes. Ongoing assessment of vulnerable infants involves monitoring oxygenation and perfusion and avoiding or minimizing activities that increase cerebral blood flow. If GMH-IVH occurs, care is focused on maintaining oxygenation and perfusion, an NTE, and normoglycemia. The infant is positioned with the head in midline and the head of the bed elevated slightly to prevent or minimize fluctuations in intracranial blood pressure. Rapid infusions of fluids should be avoided. Blood pressure is monitored closely for fluctuations. The use of developmental interventions such as swaddling or containment during painful procedures can help promote greater physiologic stability (Ditzenberger & Blackburn, 2014).

Nursing support for parents includes assessment of their understanding and concerns related to the infant's condition. They need opportunities to discuss their feelings and ask questions about the infant's condition and care as well as the long-term prognosis. Nurses can demonstrate to parents how they can interact with the infant in a developmentally appropriate manner. Nurses can provide anticipatory guidance regarding ways the infant's needs and care will change as he or she matures. For many of these infants a multidisciplinary approach to care is needed to address the neurodevelopmental sequelae of GMH-IVH and to plan for care after hospital discharge (de Vries, 2011).

Necrotizing Enterocolitis

Necrotizing enterocolitis is an acute inflammatory disease of the GI mucosa, commonly complicated by bowel necrosis and perforation. NEC occurs in up to 10% of all LBW infants. More than 90% of cases are preterm infants. Reported mortality rates due to NEC are around 30% (Caplan, 2011).

The exact etiology and pathophysiology of NEC are unclear, although many factors seem to contribute to its development (risk factors are listed in Box 34-6). Three primary conditions appear to be involved in the etiology of NEC. The first is intestinal ischemia that occurs as a result of asphyxia/hypoxia or events that cause a redistribution of blood flow away from the GI tract (e.g., hypotension, hypovolemia, severe stress). A second condition involved in the development of NEC seems to be bacterial colonization of the initially sterile GI tract with harmful organisms prior to the establishment of normal intestinal flora. *Klebsiella*, *Escherichia coli*, and *Clostridium* are common organisms involved in NEC. A third condition associated with the development of NEC is enteral feeding. The majority of infants with NEC had received some type of enteral feeding. It is thought that the feedings can provide a substrate for bacterial proliferation or that feedings can increase intestinal oxygen demand during absorption and results in tissue hypoxia. Breast milk seems to have a protective effect against the development of NEC—it is rare among infants who are exclusively fed breast milk. The use of probiotics shows promise in reducing the risk of NEC. Use of natural prophylic probiotics such

BOX 34-6 Risk Factors for Necrotizing Enterocolitis

- Asphyxia
- Respiratory distress syndrome
- Umbilical artery catheter
- Exchange transfusion
- Early enteral feedings/hyperosmolar feedings
- Patent ductus arteriosus
- Congenital heart disease
- Myelomeningocele
- Intrauterine growth restriction
- Polycythemia
- Anemia
- Shock
- Gastrointestinal infection

Data from Caplan, M.S. (2011). Neonatal necrotizing enterocolitis: Clinical observations, pathophysiology, and prevention. In R.J. Martin, A.A. Fanaroff, & M.C. Walsh (Eds.), *Fanaroff & Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* (9th ed.). St. Louis: Mosby; Lovvorn, H.N., Glenn, J.B., Pacetti, A.S., & Carter, B.S. (2011). Neonatal surgery. In S.L. Gardner, B.S. Carter, M. Enzman-Hines, & J.A. Hernandez (Eds.), *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis: Mosby.

as *Bifidobacterium infantis* and *Streptococcus thermophilus* to enhance bowel flora appears to decrease the incidence of NEC (AlFaleh & Anabrees, 2014). In addition, MEN can help reduce the risk of NEC.

The onset of NEC in the term infant usually occurs between 1 and 3 days after birth, but can occur as late as 1 month. In the preterm infant NEC usually occurs within the first 7 days but can be delayed for up to 30 days. The signs of NEC are nonspecific, which is characteristic of many neonatal diseases. Some generalized signs include decreased activity, hypotonia, pallor, recurrent apnea and bradycardia, decreased oxygen saturation values, respiratory distress, metabolic acidosis, oliguria, hypotension, decreased perfusion, temperature instability, and cyanosis. GI symptoms include abdominal distention, increasing or bile-stained residual gastric aspirates, grossly bloody stools, abdominal tenderness, and erythema of the abdominal wall (Caplan, 2011; Lovvorn, Glenn, Pacetti, & Carter, 2011).

A diagnosis is confirmed by a radiographic examination that reveals bowel loop distention, pneumatosis intestinalis (air in the wall of the bowel), pneumoperitoneum, portal air, or a combination of these findings. The abnormal radiographic findings are caused by the bacterial colonization of the GI tract associated with NEC, resulting in ileus. Pneumatosis intestinalis, pneumoperitoneum, and portal air are caused by gas produced by the bacteria that invade the wall of the intestines and escape into the peritoneum and portal system when perforation occurs. The laboratory evaluation in such infants consists of a CBC with differential, coagulation studies, ABG analysis, measurement of serum electrolyte levels, and blood culture. The white blood cell count can be either increased or decreased. The platelet count and coagulation study findings can be abnormal, showing thrombocytopenia and disseminated intravascular coagulation (DIC). Electrolyte levels can be abnormal related to leaking capillary beds and fluid shifts with the infection (Caplan, 2011; Lovvorn et al., 2011).

Management strategies are based on the degree of bowel involvement and the severity of the disease. The goal of treatment

is to prevent progression of the NEC, intestinal perforation, and shock.

For the infant with suspected or confirmed NEC, oral or tube feedings are discontinued to rest the GI tract. An orogastric tube is placed and attached to low wall suction to provide gastric decompression. Parenteral therapy (often TPN) is begun. Because NEC is an infectious disease, control of the infection is imperative, with an emphasis on careful hand hygiene before and after infant contact. Antibiotic therapy may be instituted, and surgical resection is performed if perforation or clinical deterioration occurs. Therapy is usually prolonged, and recovery can be delayed by the formation of adhesions, the development of the complications associated with bowel resection, the occurrence of short-bowel syndrome (especially if the ileocecal valve is removed), or the development of intolerance to oral feedings. Some of these infants are candidates for intestinal transplants if they truly have short-bowel syndrome (Caplan, 2011; Lovvorn et al., 2011).

Families need education and support when faced with the crisis of having an infant with NEC. As part of the health care team nurses can help parents understand the severity of the disease, treatment options, and care needed by the infant. When the disease is severe and the prognosis is poor, nurses are instrumental in supporting families with decision making and anticipatory grieving (Gardner & Dickey, 2011; Siegel et al., 2011).

Infant Pain Responses

The physiology of pain and pain assessment in the newborn are discussed in Chapter 24. This discussion focuses on pain assessment and management in the preterm infant.

Pain Assessment

Assessment of pain in the neonate is difficult because evaluation must be based on physiologic changes and behavioral observations. Pain is considered the fifth vital sign, and its assessment is a requirement of The Joint Commission (TJC, 2011). A scale that examines multiple dimensions facilitates accurate assessment of neonatal pain (Gardner, Enzman-Hines, & Dickey, 2011a). Although behaviors such as vocalizations, facial expressions, body movements, and general state are common to all infants, they vary with different situations. Crying associated with pain is more intense and sustained. Facial expression is the most consistent and specific characteristic; scales are available for systematic evaluation of facial features, such as eye squeeze, brow bulge, and open mouth and taut tongue (Prkachin, 2011) (see Fig. 24-19). Most infants respond with increased body movements but can be experiencing pain even when lying quietly with eyes closed. The preterm infant's response to pain can be behaviorally blunted or absent. An infant who receives a muscle-paralyzing agent such as vecuronium is incapable of mounting a behavioral or visible pain response (Box 34-7) yet still feels pain.

! NURSING ALERT

When in doubt about the presence of pain in infants, the nurse should base the need for interventions on the following rule: whatever is painful to an adult or child is painful to an infant unless proved otherwise. The nurse should anticipate pain and intervene promptly, without waiting for physiologic or behavioral signs of pain to appear.

BOX 34-7 Manifestations of Acute Pain in the Neonate

Physiologic Responses

Vital Signs

- Increased heart rate
- Increased blood pressure
- Rapid, shallow respirations

Oxygenation

- Decreased transcutaneous O₂ saturation (TcPo₂)
- Decreased arterial O₂ saturation (SaO₂)

Skin

- Pallor or flushing
- Diaphoresis
- Palmar sweating

Other Observations

- Increased muscle tone
- Dilated pupils
- Decreased vagal nerve tone
- Increased intracranial pressure
- Laboratory evidence of metabolic or endocrine changes
 - Hyperglycemia
 - Lowered pH
 - Elevated corticosteroids

Behavioral Responses

Vocalizations: Observe Quality, Timing, and Duration

- Crying
- Whimpering
- Groaning

Facial Expression

- Grimacing
- Brow furrowed
- Chin quivering
- Eyes tightly closed
- Mouth open and squarish

Body Movements and Posture

- Limb withdrawal
- Thrashing
- Rigidity
- Flaccidity
- Fist clenching

Change in State

- Changes in sleep-wake cycles
- Changes in feeding behavior
- Changes in activity level
- Fussiness, irritability
- Listlessness

Adapted from Blackburn, S. (2013). *Maternal, fetal, and neonatal physiology: A clinical perspective* (4th ed.). Maryland Heights, MO: Elsevier; Gardner, S.L., Enzman-Hines, M., & Dickey, L.A. (2011). Pain and pain relief. In S.L. Gardner, B.S. Carter, M. Enzman-Hines, & J.A. Hernandez (Eds.), *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis: Mosby.

Several tools have been developed for the assessment of pain in the neonate. The CRIES tool is discussed in Chapter 24 (see Table 24-5). Other instruments are the Pain Assessment Tool (PAT) (Hodgkinson, Bear, Thorn, & Van Blaricum, 1994); Scale for Use in Newborns (SUN) (Blauer & Gerstmann, 1998); Behavioral Pain Score (BPS) (Pokela, 1994); Distress Scale for

Ventilated Newborn Infants (DSVNI) (Sparshott, 1995); Neonatal Infant Pain Scale (NIPS) (Lawrence, Alcock, McGrath, et al., 1993); and Premature Infant Pain Profile (PIPP) (Stevens, Johnston, Petryshen, & Taddio, 1996). The PIPP is one of the most widely used scales for preterm infants because it considers behavioral, physiologic, and contextual indicators (Gardner et al., 2011a).

Memory of Pain

Preterm infants are subjected to a variety of repeated noxious stimuli, including multiple heelsticks, venipuncture, endotracheal intubation and suctioning, arterial sticks, chest tube placement, and lumbar puncture. The effects of pain caused by such procedures are not fully known, but researchers have begun to investigate potential consequences. From preliminary reports, it appears that a rewiring of the pain responses occurs in preterm infants who have been subjected to multiple painful treatments early in their lives. The nervous system networks of the preterm infant appear denser and have more branches than those in the average infant, leading to the conclusion that the pain threshold and sensitivity in once preterm infants is heightened for life. There are also changes when the infant has undergone anesthesia (Gardner et al., 2011a).

Consequences of Untreated Pain in Infants

Despite research on the neonate's experience of pain, infant pain remains inadequately managed. This mismanagement is partially due to misconceptions regarding the effects of pain on the neonate, as well as a lack of knowledge of immediate and long-term consequences of untreated pain. Infants respond to noxious stimuli through physiologic indicators (increased heart rate and blood pressure, variability in heart rate and intracranial pressure, and decreases in arterial oxygen saturations and skin blood flow) and behavioral indicators (muscle rigidity, facial expression, crying, withdrawal, and sleeplessness). The physiologic and behavioral indicators, as well as a variety of neurophysiologic responses to noxious stimulation, are responsible for short- and long-term consequences of pain.

Pain Management

The International Evidence-Based Group for Neonatal Pain developed a Consensus Statement for the Prevention and Management of Pain in the Newborn which states that pain must be anticipated and prevented to avoid long-term consequences (Anand and The International Evidence-Based Group for Neonatal Pain, 2001). Nonpharmacologic measures to alleviate pain include repositioning, swaddling, containment, cuddling, rocking, playing music, reducing environmental stimulation, providing tactile comfort measures and nonnutritive sucking, and using oral sucrose. However, nonpharmacologic measures may not be sufficient to decrease physiologic distress, even if behavioral responses such as crying are lessened. In preterm infants additional stimulation such as stroking or environmental light or noise can increase physiologic distress. The effect of the NICU environment must be considered along with other forms of stimuli that can produce stress and pain.

Morphine is the most widely used opioid analgesic for pharmacologic management of neonatal pain, with fentanyl as an effective alternative. Continuous or bolus epidural or IV

infusion of opioids provides effective and safe pain control. Other methods are epidural/intrathecal infusion, local and regional nerve blocks, and topical anesthetics, as well as general anesthesia for surgery (Walden, 2014).

Parents are universally concerned that their infants are feeling pain during procedures. Nurses need to address these concerns and encourage the parents to speak with the health care professionals involved. Parents have the right to withhold consent for invasive procedures and are entitled to honest answers from those responsible for the infant's care. When appropriate, they also can help provide comfort measures for the infant. Kangaroo care is one parental intervention that comforts and calms the infant (Cong et al., 2012).

Parents want to know that nurses recognize pain in their infants and that the infants will be comfortable when they (the parents) are not present. They want to know that the nurse will advocate for comfort care for their baby. Although pain is considered a fifth vital sign, it cannot be assessed only at the time of vital signs. There must be ongoing evaluation of the infant's pain level and the effectiveness of comfort measures used. This assessment is not lengthy but can be as simple as walking to the bedside and closely observing the infant's color, posture, movements, and breathing. Pain is a real phenomenon that is preventable in many instances. Pain management is a standard of care, and it is considered unethical not to prevent and effectively treat pain. Another growing area of neonatal nursing is end-of-life and palliative care. Most of this care centers on pain management. Palliative care is really comfort care that supports the needs of the preterm, sick neonate (Walden, 2014).

Late Preterm Infants

Late preterm infants are those born between 34 0/7 and 36 6/7 weeks of gestation (Raju, Higgins, Stark, & Leveno, 2006). Because birth weights of late preterm infants often range from 2000 g (4.4 lb) to 2500 g (5.5 lb) and they appear relatively mature in comparison to the smaller less mature infant, they are often cared for as if they are normal term infants. Risk factors for late preterm infants can easily be overlooked. Compared with term infants, late preterm infants are at increased risk for problems with thermoregulation, hypoglycemia, hyperbilirubinemia, feeding, sepsis, and respiratory function (Hwang, Barfield, Smith, et al., 2013; Phillips, Goldstein, Hougland, et al., 2013). Many of these healthy-appearing infants are admitted directly to postpartum units with their mothers or stay in the NICU only briefly (i.e., less than 24 hours). They are commonly discharged home at 2 to 3 days of age with their mothers. Discharge before 48 hours after birth is not recommended (Phillips et al.).

Recognition of late preterm infants is essential to providing effective care. Initial physical assessment and assessment of gestational age are crucial to identifying these infants. Although the mother's estimated date of birth (EDB) can indicate a longer gestation, infant appearance, behaviors, and/or weight can indicate otherwise. The obstetric estimate of gestational age is usually reliable if it is based on a first-trimester ultrasound. However, if there is a discrepancy between the gestational age based on the obstetric estimate and newborn examination, it is better to rely on the estimate based on the newborn examination. The Association of Women's Health, Obstetric and

TABLE 34-3 Late Preterm Infant Assessment and Interventions

RISK FACTORS	ASSESSMENT	INTERVENTIONS*
Respiratory distress (RD)	Assess for cardinal signs of RD (nasal flaring, grunting, tachypnea, central cyanosis, retractions), for presence of apnea especially during feedings, and for hypothermia and hypoglycemia.	Perform gestational age assessment; observe for signs of RD; monitor oxygenation by pulse oximetry; provide supplemental oxygen judiciously.
Thermal instability	Monitor axillary temperature every 30 minutes immediately after birth until stable, thereafter every 1-4 hours, depending on gestational age and ability to maintain thermal stability.	Provide skin-to-skin care immediately after birth for stable infant; implement measures to prevent excess heat loss (adjust environmental temperature, avoid drafts); bathe only after thermal stability has been maintained for 1 hour.
Hypoglycemia	Monitor for signs and symptoms of hypoglycemia; assess feeding ability (latch, nipple feeding); assess thermal stability, signs and symptoms of RD; monitor bedside glucose in infants with additional risk factors (mother with diabetes, prolonged labor, RD, poor feeding).	Initiate early feedings of human milk or formula; avoid dextrose water or water feedings; provide intravenous dextrose as necessary for hypoglycemia.
Jaundice	Observe for jaundice in first 24 hours; evaluate maternal-fetal history for additional risk factors that may cause increased hemolysis and circulating levels of unconjugated bilirubin (Rh, ABO, spherocytosis, bruising); assess feeding method, voiding, stooling patterns.	Monitor transcutaneous bilirubin, and note risk zone on hour-specific nomogram (see Fig. 24-7).
Feeding problems	Assess suck-swallow and breathing; assess for respiratory distress, hypoglycemia, thermal stability; assess latch-on, maternal comfort with feeding method; weight loss no more than 10% of birth weight.	Initiate early feedings—human milk or formula; ensure maternal knowledge of feeding method and signs of inadequate feeding (sleepiness, lethargy, color changes during feeding, apnea during feeding, decreased or absent urinary output).

*This list is not exhaustive of nursing interventions; additional interventions include those discussed under the care of the high risk infant in this chapter.

Portions adapted from Pappas, B.E., & Robey, D.L. (2015). Care of the late preterm infant. In M.T. Verklan & M. Walden (Eds.), *Core curriculum for neonatal intensive care nursing* (5th ed.). St. Louis: Elsevier; Santa-Donato, A., Medoff-Cooper, B., Bakewell-Sachs, S., et al. (2007). *Late preterm infant assessment guide*. Washington, DC: Association of Women's Health, Obstetric and Neonatal Nurses.

Neonatal Nurses (AWHONN) published evidence-based clinical practice guidelines, the *Assessment and Care of the Late Preterm Infant* (AWHONN, 2010), for the education of perinatal nurses regarding the late preterm infant's risk factors and appropriate care and follow-up (Table 34-3).

Components of nursing care for late preterm infants and their parents are discussed in the following text. Frequent assessment is essential for detecting problems early so that appropriate interventions can be initiated.

Respiratory Distress

Late preterm infants are at increased risk for respiratory problems, including apnea. Close monitoring of respiratory status is essential and any changes are reported promptly to the primary health care provider. An Infant Car Seat Challenge is done prior to discharge (see Chapter 24). Infants may go home on an apnea monitor. If possible, parents should attend an infant cardiopulmonary resuscitation (CPR) class or view a video about infant CPR. To help prevent respiratory infections the nurse should instruct the parents to limit the infant's contact with others outside the home. The nurse should review signs and symptoms of respiratory problems with the parents.

Thermoregulation

Late preterm infants have more difficulty with thermoregulation than term infants, and cold stress is a greater concern. They have less body fat than term infants, a higher ratio of surface area to body weight, decreased glycogen stores, and less mature mechanisms for increasing metabolism for heat. Stores of brown fat are smaller and quickly depleted. Cold stress can quickly lead to hypoglycemia. Nurses must closely monitor body temperature and teach parents to take the infant's temperature. Parents are encouraged to keep a record of this at home and to report high or low temperatures. It is important to remember that

temperature instability is often an early sign of neonatal sepsis (Phillips et al., 2013).

Nutrition

Late preterm infants are at greater risk of having breastfeeding difficulties and are more likely to have breastfeeding-associated rehospitalizations than term infants (Radtke, 2011). Feedings should occur at least every 2 to 3 hours and according to infant feeding cues. Late preterm infants eat less than term neonates and have fewer energy reserves to do so. They can have difficulty coordinating sucking, swallowing, and breathing. Breastfeeding can be more problematic if the infant is sleepy and difficult to arouse for feedings. Late preterm infants are prone to early fatigue during feedings and fall asleep before consuming adequate volumes of milk. Nurses should observe at least one feeding every 8 hours. Early and extended skin-to-skin contact promotes breastfeeding. If supplementation is needed, expressed breast milk is the best option. To maximize the milk supply and milk transfer to the infant, mothers should use the electric breast pump after feedings while in the hospital and continue this process at home until the infant is able to successfully remove milk from the breasts and until the milk supply is well established. The mother-baby nurse or lactation consultant can provide instruction and assist breastfeeding mothers with using a breast pump. Mothers also need information regarding safe milk handling and storage guidelines (Jones, 2011). Parents should keep an intake and output record until their health care provider tells them otherwise and should share this record with the health care provider at each visit (Phillips et al., 2013).

Hypoglycemia

Late preterm infants are three times more likely to develop hypoglycemia than term infants (Stuckey-Schrock & Schrock, 2013). Hospital protocols may require routine monitoring of

blood glucose until levels are stabilized and the infant is feeding adequately. Although the cut-off value for treatment remains uncertain, blood glucose values of less than 40 or 45 mg/dl, or symptoms of hypoglycemia, should be treated (Blackburn, 2013). Bedside monitoring of blood glucose levels at frequent intervals throughout the late preterm infant's hospital stay is recommended.

Hyperbilirubinemia

Hyperbilirubinemia is more common in late preterm infants because of immaturity of the liver, decreased gastric motility, and increased breakdown of red blood cells (RBCs) (Raju, 2012). They are less able to conjugate and excrete bilirubin. Serum bilirubin levels tend to peak at 5 to 7 days and persist longer than in term infants. Hyperbilirubinemia is the most frequent reason for hospital readmission during the first week of life. Bilirubin levels are closely monitored before discharge, and parents are instructed regarding signs of jaundice and when to notify the health care provider. Follow-up visits soon after hospital discharge are important for monitoring rising bilirubin levels (Phillips et al., 2013; Stuckey-Schrock & Schrock, 2013).

Infection

The immune systems of late preterm infants are immature; thus they are more likely to experience infections. Nurses should assess the late preterm infant for signs and symptoms of infection including temperature instability, lethargy, irritability, poor feeding, or vomiting. Before discharge, nurses provide education for the parents about the common signs and symptoms of infection and when to notify the health care provider.

Postmature Infants

A pregnancy that is prolonged beyond 42 weeks is a *postterm* pregnancy, and the infant who is born is called *postterm* or *postmature*. Postmaturity can be associated with placental insufficiency, resulting in a fetus that has a wasted appearance (dysmaturity) at birth because of loss of subcutaneous fat and muscle mass. However, not all postterm infants show signs of dysmaturity; some continue to grow in utero and are large at birth. Most postmature infants are oversized but otherwise normal, with advanced development and bone age. A postmature infant has some, but not necessarily all, of the following physical characteristics (McGrath & Hardy, 2011):

- Generally a normal skull, but the reduced dimensions of the rest of the body in the presence of dysmaturity make the skull look inordinately large
- Dry, cracked (desquamating), parchment-like skin at birth
- Firm nails extending beyond the fingertips
- Profuse scalp hair
- Depleted subcutaneous fat layers, leaving the skin loose and giving the infant an “old person” appearance
- Long and thin body
- Absent vernix
- Can have meconium staining (golden yellow to green) of skin, nails, and cord, indicative of a hypoxic episode in utero or a perinatal infection such as listeriosis
- Can have an alert, wide-eyed appearance symptomatic of chronic intrauterine hypoxia

FIG 34-13 Infant being resuscitated at birth. Meconium was present on the abdomen, and umbilical cord. Infant was not breathing, and heart rate was 65 beats/minute at birth. Respirations and heart rate were normal at 2 minutes. (Courtesy Shannon Perry, Phoenix, AZ.)

The perinatal mortality rate is significantly higher in the postmature fetus and neonate. One reason for this is that during labor and birth the increased oxygen demands of the postmature fetus are not fully met. Insufficient gas exchange in the postmature placenta also increases the likelihood of intrauterine hypoxia, which can result in the passage of meconium in utero, thereby increasing the risk for **meconium aspiration syndrome (MAS)**.

Parents may be concerned about the appearance of the postmature infant. Nurses can help them understand reasons for the dry, peeling, skin and other characteristics of postmaturity. Initial bathing should be done with a mild soap. It can be helpful to moisturize the skin with a petrolatum-based ointment. Nurses need to be alert to common problems associated with postmaturity such as meconium aspiration, fetal distress, macrosomia, and birth injury (De los Santos-Garate, Villa-Guillen, Villanueva-Garcia, et al., 2011).

Meconium Aspiration Syndrome

Meconium staining of the amniotic fluid can be indicative of fetal distress, especially in a vertex presentation. It appears in 10% to 15% of all births. Many infants with meconium staining exhibit no signs of depression at birth; approximately 5% of newborns who are exposed to meconium develop MAS (Ambalavanan & Carlo, 2011).

The presence of meconium in the amniotic fluid necessitates careful supervision of labor and close monitoring of fetal well-being. The presence of a team skilled in neonatal resuscitation is required at the birth of any infant with meconium stained amniotic fluid (Fig. 34-13). The mouth and nares of the infant are not routinely suctioned on the perineum before the infant's first breath. However, for infants with meconium staining who are not vigorous, endotracheal suctioning should be performed immediately. Vigorous infants need no special handling (Kattwinkel, AAP, & AHA, 2011).

If the infant is very depressed and the meconium is not removed from the airway at birth, it can migrate down to the

terminal airways, causing mechanical obstruction leading to MAS. It also is possible that the fetus aspirated meconium in utero. Such meconium aspiration can cause a chemical pneumonitis. These infants can develop persistent pulmonary hypertension of the newborn, further complicating their management. Infants with MAS who receive surfactant can experience improved oxygenation, decreased severity of respiratory failure, and reduced need for ECMO (Polin, Carlo, & Committee on Fetus and Newborn, 2014). Researchers are examining the use of surfactant lavage in treating meconium aspiration (Choi, Hahn, Lee, et al., 2012).

Persistent Pulmonary Hypertension of the Newborn

The term **persistent pulmonary hypertension of the newborn (PPHN)** is applied to the combined findings of pulmonary hypertension, right-to-left shunting, and a structurally normal heart. PPHN can occur either as a single entity or as the main component of MAS, congenital diaphragmatic hernia, RDS, hyperviscosity syndrome, or neonatal pneumonia or sepsis. PPHN also is called *persistent fetal circulation (PFC)* because the syndrome includes a reversion to fetal pathways for blood flow (Soltau & Carlo, 2014).

A brief review of the characteristics of fetal blood flow can help in visualizing the problems with PPHN (see Fig. 12-13). In utero, oxygen-rich blood leaves the placenta via the umbilical vein, goes through the ductus venosus, and enters the inferior vena cava. From there it empties into the right atrium and is mostly shunted across the foramen ovale to the left atrium, effectively bypassing the lungs. This blood enters the left ventricle, leaves via the aorta, and preferentially perfuses the carotid and coronary arteries. Thus the heart and brain receive the most oxygenated blood. Blood drains from the brain into the superior vena cava, reenters the right atrium, proceeds to the right ventricle, and exits via the main pulmonary artery. The lungs are a high-pressure circuit, needing only enough perfusion for growth and nutrition. The ductus arteriosus (connecting the main pulmonary artery and the aorta) is the path of least resistance for the blood leaving the right side of the fetal heart, shunting most of the cardiac output away from the lungs and toward the systemic system. This right-to-left shunting is the key to fetal circulation.

After birth, both the foramen ovale and the ductus arteriosus close in response to various biochemical processes, pressure changes within the heart, and dilation of the pulmonary vessels. This dilation allows virtually all of the cardiac output to enter the lungs, become oxygenated, and provide oxygen-rich blood to the tissues for normal metabolism.

PPHN characteristically proceeds into a downward spiral of exacerbating hypoxia and pulmonary vasoconstriction. Prompt recognition and aggressive intervention are required to reverse this process (Orlando, 2012).

The infant with PPHN is typically born at term or post-term and has tachycardia and cyanosis. Management depends on the underlying cause of the persistent pulmonary hypertension. The use of ECMO has improved the chances of survival in these infants (see earlier discussion); however, it is considered a very invasive procedure. Effective use of inhaled nitric oxide (INO) as a pharmacologic intervention has increased. It acts as a vasodilator to decrease the pulmonary hypertension while increasing

oxygenation (Bell, 2012). This therapy is proving to work well alone or with high-frequency ventilation. Another pharmacologic treatment is exogenous surfactant because some of these infants appear to be surfactant deficient. Use of environmental strategies such as decreasing adverse stimuli (excessive light and noise) to reduce stress is an area of ongoing research. This intervention is used in conjunction with other therapies.

Another mode of treatment for PPHN and other respiratory disorders of the newborn is high-frequency ventilation, a group of assisted ventilation methods that deliver small volumes of gas at high frequencies and limit the development of high airway pressure, thus reducing barotrauma. High-frequency ventilation decreases carbon dioxide while increasing oxygenation. It can be effectively used in conjunction with INO (Soltau & Carlo, 2014).

It is important to understand that PPHN is considered a cardiovascular and a respiratory problem. The lungs of these infants are healthy, but the hypertension of the cardiovascular system leads to their oxygenation problems.

Other Problems Related to Gestational Age Small for Gestational Age and Intrauterine Growth Restriction

Infants who are small for gestational age (SGA; e.g., weight is less than the 10th percentile expected at term) and infants who have IUGR (rate of growth does not meet expected growth pattern) are considered high risk. Among these infants perinatal mortality rates are 5 to 20 times greater than for normal term infants (Gardner & Hernandez, 2011).

Various conditions can affect and impede growth in the developing fetus. Conditions occurring in the first trimester that affect all aspects of fetal growth (e.g., infections, teratogens, chromosomal abnormalities) or extrinsic conditions early in pregnancy result in symmetric IUGR (i.e., head circumference, length, and weight, are all less than the 10th percentile). Conditions causing symmetric growth restriction result in an SGA infant, usually with a head circumference that is smaller than that of a term infant and reduced brain capacity. Growth restriction in later stages of pregnancy, as a result of maternal or placental factors, results in asymmetric growth restriction (with respect to gestational age, weight will be less than the 10th percentile, whereas length and head circumference will be greater than the 10th percentile). Infants with asymmetric IUGR have the potential for normal growth and development. There is relative sparing of head and brain growth while weight and somatic organ growth are more seriously altered (Carlo, 2011).

Several physical findings are characteristic of the SGA neonate (Kliegman, 2011):

- Generally a normal skull, but the reduced dimensions of the rest of the body make the skull look inordinately large
- Reduced subcutaneous fat stores
- Loose and dry skin
- Diminished muscle mass, especially over buttocks and cheeks
- Sunken abdomen (scaphoid) as opposed to the well-rounded abdomen seen in normal infants
- Thin, yellowish, dry, and dull umbilical cord (normal cord is gray, glistening, round, and moist)
- Sparse scalp hair
- Wide skull sutures (inadequate bone growth)

Care of the SGA infant is based on the presence of clinical problems and is the same for preterm infants with similar problems. Gas exchange is supported by maintaining a clear airway and preventing cold stress. Hypoglycemia is treated with oral feedings (e.g., breast, formula) or IV dextrose as the infant's condition warrants. An external heat source (radiant warmer or incubator) is used until the infant is able to maintain an adequate body temperature. Nursing support of parents is the same as that given to parents of preterm infants.

Common problems that affect SGA (IUGR) infants are perinatal asphyxia, meconium aspiration, hypoglycemia, polycythemia, and temperature instability.

Perinatal Asphyxia

Commonly IUGR infants have been exposed to chronic hypoxia for varying periods before labor and birth. Labor is a stressor to the normal fetus, but it is an even greater stressor for the growth-restricted fetus. The chronically hypoxic infant is severely compromised even by a normal labor and has difficulty compensating after birth. Appropriate management and resuscitation are essential for these depressed infants.

The birth of SGA babies with perinatal asphyxia can be associated with a maternal history of heavy cigarette smoking; preeclampsia; low socioeconomic status; multifetal gestation; gestational infections such as rubella, cytomegalovirus, and toxoplasmosis; advanced diabetes mellitus; and cardiac problems. The nursing staff must be alert to and prepared for possible perinatal asphyxia during the birth of an infant to a woman with such a history. Sequelae to perinatal asphyxia include MAS (see previous discussion) and hypoglycemia.

Hypoglycemia

All high risk infants have an increased likelihood of developing hypoglycemia (plasma glucose <40 mg/dl) (Armentrout, 2015). Infants who experience physiologic stress can experience hypoglycemia as a result of a decreased glycogen supply, inadequate gluconeogenesis, or overuse of glycogen stored during fetal and postnatal life. Preterm infants can also become hypoglycemic because of inadequate intake and increased metabolic demands as a result of illness. There is insufficient evidence to support the concept that the preterm or high risk infant can tolerate lower levels of serum glucose any better than healthy term infants (Blackburn, 2013) (see Chapter 24 for discussion of hypoglycemia). The SGA infant, like the preterm infant, is at increased risk for hypoglycemia as a result of decreased fetal stores and decreased rate of gluconeogenesis (McGowan, Rozance, Price-Douglas, & Hay, 2011).

Symptoms of hypoglycemia include poor feeding, hypothermia, and diaphoresis. CNS symptoms can include tremors and jitteriness, weak cry, lethargy, floppy posture, convulsions, or coma. Diagnosis is confirmed by blood glucose determinations performed by the laboratory, when suspected, or by point-of-care testing with products such as Accucheck or One-Touch. Blood glucose screening should be done on all high risk infants soon after birth and frequently during the first few hours until glucose levels stabilize.

Polycythemia

Polycythemia or hyperviscosity of the blood is another common problem of the SGA infant. With polycythemia there is an

excess in circulating RBC mass. This condition is a result of fetal hypoxia and intrauterine stress that forces the body to produce more RBCs in an attempt to provide oxygen to the developing fetus. Polycythemia is associated with maternal preeclampsia, maternal smoking, maternal diabetes, and delayed cord clamping (Diehl-Jones & Fraser, 2014). With hematocrit greater than 65% or venous hemoglobin greater than 22 g/dl, blood viscosity is increased. This can lead to compromised blood flow and reduced oxygenation of the body organs and increases the risk of neonatal stroke. Many infants with polycythemia are asymptomatic. Others present with plethora, cyanosis, CNS abnormalities (lethargy, jitteriness, seizures), respiratory distress, tachycardia, congestive heart failure, or hypoglycemia. Infants with polycythemia are at increased risk for hyperbilirubinemia. In some cases a partial exchange transfusion to reduce the viscosity of the blood is necessary.

Heat Loss

SGA infants are particularly susceptible to temperature instability as a result of decreased brown fat deposits, decreased adipose tissue, large body surface exposure, and, in many instances, poor flexion, as well as decreased glycogen storage in major organs such as the liver and heart. Therefore, close attention must be given to maintain an NTE. Nursing considerations focus on maintenance of thermoneutrality to promote recovery from perinatal asphyxia because cold stress jeopardizes such recovery.

Large for Gestational Age Infants

The large for gestational age (LGA) infant is defined as weighing 4000 g (8.8 lb) or more at birth. An infant is considered LGA despite gestation when the weight is more than the 90th percentile on growth charts or two standard deviations greater than the mean weight for gestational age. The LGA infant is at greater risk for morbidity than the SGA or preterm infant; such infants have an increased incidence of birth injuries, asphyxia, and congenital anomalies such as heart defects (Carlo, 2011).

All pregnancies of longer than 42 weeks of gestation must be thoroughly evaluated. All large fetuses are monitored during a trial of labor, and preparation is made for a cesarean birth if abnormal fetal heart pattern or poor progress of labor occurs. LGA newborns can be preterm, term, or postterm; they can be infants of mothers with diabetes; or they can be postmature. Each of these problems carries special concerns. Regardless of coexisting potential problems, the LGA infant is at risk by virtue of size alone.

The nurse assesses the LGA infant for hypoglycemia and trauma resulting from vaginal or cesarean birth. Any specific birth injuries are identified and treated appropriately (see Chapter 35).

Discharge Planning

Discharge planning for the high risk newborn begins early in the hospitalization. Throughout the infant's hospitalization the nurse gathers information from the health care team members and the family. This information is used to determine the infant's and family's readiness for discharge. Discharge teaching for the family of a high risk newborn is extensive, requires time and planning, and cannot be adequately accomplished on the day of discharge.

Information is provided about infant care, especially as it pertains to the particular infant's home care needs (e.g., supplemental oxygen, gastrostomy feedings, follow-up medical visits). Parents should be allowed to spend a night or two in a pre-discharge room providing care for the infant away from the NICU to become better acquainted with the necessary care and to have a time of transition in which questions can be answered regarding home care. Additional parent teaching should include bathing and skin care; requirements for meeting nutritional needs following discharge; safety in the home, including supine sleep position, avoiding exposure to cigarette smoke, prevention of infection (e.g., respiratory syncytial virus [RSV]); and medication administration.

COMMUNITY ACTIVITY

- Visit the March of Dimes website (www.marchofdimes.com/baby/holding-your-baby-close-kangaroo-care.aspx) and explore the resources available for parents of premature infants. Note the list of benefits of skin-to-skin holding. Think about some of the barriers that might prevent parents from holding their premature infant skin-to-skin. How might you overcome some of these barriers?
- Visit www.healthychildren.org, sponsored by the American Academy of Pediatrics. Under the Ages and Stages box, find the section on preemies. Review the information for parents about caring for and bringing home a premature infant. Research the availability of support groups for parents of premature infants in your community.

Durable medical equipment and supplies required for the care of the infant in the home should be delivered to the home before the infant is discharged; parents and care providers should have education in the use of the equipment and ample opportunity to practice. Parents of infants being discharged with special needs such as gavage or gastrostomy feedings, nasal cannula oxygen, tracheostomy, or colostomy should receive several days of thorough education in the procedure before discharge. Preterm infants have a high rate of emergency department visits and readmission to acute care centers; the family absolutely must have a health care provider they can contact for questions regarding infant care and behavior once they are home. Parents should obtain an age-appropriate car seat before the discharge of their infant and demonstrate its correct use. Car seat safety is an essential aspect of discharge planning. Infants who were born at less than 37 weeks of gestation should have an Infant Car Seat Challenge, consisting of a period of observation in an appropriate car seat to monitor for possible apnea, bradycardia, and decreased Sao_2 (Bull, Engle, Committee on Injury, Violence, and Poison Prevention, & Committee on Fetus and Newborn, 2009).

Before discharge all high risk or preterm infants should receive the appropriate immunizations, metabolic screening, hematologic assessment (bilirubin risk as appropriate), and hearing evaluation. Successful discharge of high risk infants to their homes requires a multidisciplinary approach. Medical, nursing, social services, and other professionals (physical therapy, occupational therapy, developmental follow-up specialist) are crucial to the smooth transition of these infants and their families to the home and community. If the infant is

transported back to the community hospital that referred either the mother before birth or the infant after birth, interfacility communication is essential to continuity of care.

Instruction in CPR is essential for parents of all infants but especially for those of infants at risk for life-threatening events. Infants considered at risk include those who are preterm, have apnea or bradycardia, or have a tendency to choke. Before taking their infant home, parents must be able to administer CPR. All parents should be encouraged to obtain instruction in CPR at their local Red Cross or other community agency, if it is not provided by the NICU.

Transport to and from a Regional Center

If a hospital is not equipped to care for a high risk mother and fetus or a high risk infant, transfer to a specialized perinatal or tertiary care center is arranged. Maternal transport ideally occurs with the fetus in utero because this has two distinct advantages: (1) the associated neonatal morbidity and mortality are decreased; and (2) infant-parent attachment is supported, thereby avoiding separation of the parents and infant. For a variety of reasons, however, it is not always possible to transport the mother before the birth. These reasons include imminent birth and unanticipated problems; therefore, physicians and nurses in level 1 and 2 facilities must have the skills and equipment necessary for making an accurate diagnosis and implementing emergency interventions to stabilize the infant's condition until transport can occur (Rojas, Shirley, & Rush, 2011). The goal of these interventions is to maintain the infant's condition within the normal physiologic range. Specific attention is given to the following areas:

- Vital signs
- Oxygen and ventilation
- Thermoregulation
- Acid-base balance
- Fluid and electrolyte levels
- Glucose level
- Developmental interventions

Transport teams can include physicians, nurse practitioners, nurses with expertise in neonatal intensive care, and respiratory therapists. The team must have expertise in resuscitation, stabilization, and provision of critical care during the transport, which can occur on the ground or in the air. In a neonatal transport the team should provide information for the parents about the tertiary center. Transport teams can integrate an individual developmental plan of care into their caregiving efforts, thereby initiating multidisciplinary interventions early in the infant's life.

Health care professionals who are responsible for the early stabilization of newborns need specialized training to provide timely, efficient, and effective care. The S.T.A.B.L.E. training program (Box 34-8) is an evidence-based continuing education program that focuses on the postresuscitation and pretransport stabilization of sick neonates (Kendall, Scott, & Karlsen, 2012). It has been endorsed by the March of Dimes and the AAP. Training includes an interactive didactic presentation and a posttest (www.stableprogram.org).

The birth of any high risk infant can cause profound parental stress. Parents may grieve the loss of the ideal infant. They are fearful of the possible eventual outcomes for the infant. They

BOX 34-8 S.T.A.B.L.E. Program on Postresuscitation and Posttransport Stabilization Care of Sick Infants

S—Sugar and safe care (safety, IV fluids, hypoglycemia, hyperglycemia, umbilical catheters)
 T—Temperature (hypothermia)
 A—Airway (respiratory distress, CPAP, mechanical ventilation, pneumothorax)
 B—Blood pressure (hypovolemic, cardiogenic, and septic shock)
 L—Lab work (lab tests related to infection, sepsis)
 E—Emotional support (for parents of infants in NICUs)

CPAP, Continuous positive airway pressure; IV, intravenous; NICU, neonatal intensive care unit.

must deal with the technologic world surrounding their infant, and amid all the equipment, it is sometimes difficult for them to perceive the infant and respond to his or her needs. Parents of high risk infants who have been transported to regional centers therefore need special support. As one way to deal with this problem, many intensive care units provide the family with a handbook or pictures of the tertiary care unit to help them understand what is going on around them. Parents should have the name and telephone number of a contact person at the regional center.

Infants are sometimes transferred back to the referring facility; however, in most cases the infant is discharged home from the tertiary care center. Preterm infants who require thermoregulation and gavage feedings may be cared for in community hospitals closer to home, which allows parents to visit their infant more easily and to work with their personal health care provider on the long-range outcomes for the infant. Specialized incubators make these trips possible (Fig. 34-14). However, parents may express mixed feelings about such return transports and may be reluctant to adapt to a different facility and group of caregivers. To minimize some of these concerns, giving the parents clear information about return transports during the initial discharge planning is important.

Anticipatory Grief

Families experience anticipatory grief when they are told of the impending death of their infant. Anticipatory grief prepares and protects parents who are facing a loss. Parents who have an infant with a debilitating disease (with or without a congenital deformity), but one that may not necessarily threaten the life of the child, also can experience anticipatory grief. An alteration in

FIG 34-14 Total life support system for transport of high risk newborns. (Courtesy UNC Hospitals, Carolina Air Care, Chapel Hill, NC.)

relationships, a change in lifestyle, and a very real threat to their hopes and dreams for the future can affect the day-to-day interaction of the family with their infant and the staff. Nurses can help facilitate the family's grieving process. If the nurse observes that a family member's daily interactions with the infant change, the nurse should assess the situation and request psychosocial support or intervention by a chaplain or social worker, if necessary.

Loss of an Infant

Parents who know their infant is going to die have a very difficult time. The parents need to direct their attention, energy, and caregiving activities toward the dying infant. However, some parents find it difficult to visit their infant even for short periods once a terminal diagnosis has been made. Grandparents also grieve but often are unsure how to comfort their own child (the infant's parent) during the period of impending death. Health care professionals can help by involving the family in the infant's care, providing privacy, answering questions, and preparing them for the inevitability of the death (see Chapter 37). There is a growing emphasis on hospice and palliative care for infants and their families.

Nurses also experience grief. Many primary staff nurses find themselves grieving as if the infant were their own because they often have worked closely with the infant and family for weeks or even months. Managers and other staff members must acknowledge this grief. Talking about the infant or attending the funeral can help the staff members resolve their feelings about the infant's death.

KEY POINTS

- Preterm infants are at risk for problems stemming from the immaturity of their organ systems.
- Nurses who work with preterm, late preterm, and other high risk infants observe them for respiratory distress and other early symptoms of physiologic disorders.
- The adaptation of parents to preterm, late preterm, or high risk infants differs from that of parents to normal term infants.
- Nurses can facilitate the development of a positive parent-child relationship.
- Nurses' skills in interpreting data, making decisions, and initiating therapy in newborn intensive care units are crucial to ensuring infants' survival.
- Complications of prematurity include respiratory distress syndrome, necrotizing enterocolitis, germinal matrix hemorrhage-intraventricular hemorrhage.

KEY POINTS—cont'd

- Close monitoring of oxygen levels as well as oxygen and ventilator settings can reduce the risk of retinopathy of prematurity.
- Bronchopulmonary dysplasia is a chronic pulmonary condition that may require oxygen therapy in the home setting.
- Pain management requires vigilant ongoing assessment, anticipation of painful events, and early interventions to prevent and diminish such a response.
- Nurses need to assess the macroenvironments and microenvironments of the infant and family to create a developmentally positive atmosphere.
- Developmental care is a philosophy that embraces family-centered care and awareness of the effect of environmental stimuli on the physical and psychologic well-being of the infant and family.
- Parents need special instruction (e.g., CPR, oxygen therapy, suctioning, developmental care) before they take home a high risk infant.
- SGA infants are considered at risk because of fetal growth restriction.
- The high incidence of fetal distress among postmature infants is related to the progressive placental insufficiency that can occur in a postterm pregnancy.
- Multidisciplinary health care teams including specially trained nurses transport high risk infants to and from special care units.
- Parents need assistance as they cope with anticipatory grief or loss and grief.

Acquired Problems of the Newborn

Debbie Fraser

ⓔ <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Describe assessment and care of infants with soft-tissue, skeletal, and nervous system injuries resulting from birth trauma.
- Develop a plan of care for the neonate of a mother with diabetes.
- Describe in detail the assessment and care of a newborn with a suspected infection.
- Formulate nursing diagnoses for infants and families experiencing common neonatal bacterial and viral infections.
- Interpret the evidence available to guide the care of the infant at risk for group B streptococcal (GBS) sepsis.
- Analyze fetal and neonatal effects of maternal substance abuse during pregnancy.
- Describe concerns for fetal and neonatal well-being related to maternal use of caffeine and selective serotonin reuptake inhibitors.
- Describe the assessment and care of a newborn experiencing drug withdrawal (neonatal abstinence syndrome); include the infant's family.

This chapter deals with acquired problems of the newborn. *Acquired problems* refer to those conditions resulting from environmental rather than genetic factors. The focus is on birth trauma, the infant of a mother with diabetes, neonatal infections, effects of maternal substance abuse on the fetus and neonate, and effects of maternal use of caffeine and antidepressant medications during pregnancy.

BIRTH TRAUMA

Birth trauma or **birth injury** refers to physical injury sustained by a neonate during labor and birth. According to the Agency for Healthcare Research and Quality (AHRQ), the incidence of birth injuries in the United States is 2.19 per 1000 live births, excluding preterm and osteogenesis imperfecta births (AHRQ, 2013). Despite improvements in obstetric techniques; increased use of cesarean surgery for births that would be difficult vaginally; and decreased use of forceps, vacuum extraction, and version and extraction; birth injuries still are an important source of neonatal morbidity. Therefore, the clinician should consider the broad range of birth injuries in the differential diagnosis of neonatal clinical disorders (Mangurten & Puppala, 2011). The nurse's contribution to the welfare of the newborn begins with early observation and accurate documentation. The prompt reporting of signs that indicate deviations from normal permits early initiation of appropriate therapy. In addition, nurses provide essential support and education to parents whose neonates experience birth injury.

In theory, some birth injuries are avoidable, especially with careful assessment of risk factors and appropriate planning for

birth. The use of ultrasonography allows antepartum diagnosis of macrosomia, hydrocephalus, and unusual presentations. Elective cesarean birth may be chosen for selected pregnancies to prevent significant birth injury. A small percentage of significant birth injuries are unavoidable despite skilled and competent obstetric care, as in especially difficult or prolonged labor or when the infant is in an abnormal presentation (Mangurten & Puppala, 2011). Some injuries cannot be anticipated until the specific circumstances occur during birth. Emergency cesarean birth can provide last-minute salvage, but in these circumstances the injury may be truly unavoidable. The same injury can be caused in several ways. For example, a cephalhematoma can result from an obstetric technique such as forceps- or vacuum-assisted birth or from pressure of the fetal skull against the maternal pelvis.

Many injuries are minor and resolve readily in the neonatal period without treatment. Other traumas require intervention. A few injuries are considered major trauma and serious enough to be fatal. Major trauma is often the result of instrumentation during birth (forceps or vacuum) and can occur concomitantly with other minor injuries. For example, a neonate who suffers a skull fracture is also likely to have a cephalhematoma (Linder, Linder, Fridman, et al., 2013; van Vleet, 2012).

Several factors predispose an infant to birth injuries. Maternal risk factors include age younger than 16 or older than 35, primigravida, uterine dysfunction that leads to prolonged or precipitous labor, preterm or postterm labor, and cephalopelvic disproportion. Oligohydramnios can increase the likelihood of birth trauma. Injury can result from dystocia caused by fetal

TABLE 35-1 Anatomic Classification of Birth Injuries

SITE OF INJURY	TYPE OF INJURY
Scalp	Caput succedaneum Subgaleal hemorrhage Cephalhematoma
Skull	Linear fracture Depressed fracture Occipital osteodiastasis
Intracranial	Epidural hematoma Subdural hematoma (laceration of falx, tentorium, or superficial veins) Subarachnoid hemorrhage Cerebral contusion Cerebellar contusion Intracerebellar hematoma
Spinal cord (cervical)	Vertebral artery injury Intraspinal hemorrhage Spinal cord transection or injury
Plexus	Erb-Duchenne palsy Klumpke paralysis Total (mixed) brachial plexus injury Horner syndrome Diaphragmatic paralysis Lumbosacral plexus injury
Cranial and peripheral nerve	Radial nerve palsy Medial nerve palsy Sciatic nerve palsy Laryngeal nerve palsy Diaphragmatic paralysis Facial nerve palsy

From Verklan, M., & Lopez, S. (2011). *Neurologic disorders*. In S. Gardner, B. Carter, M. Enzman-Hines, & J. Hernandez (Eds.), *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St Louis: Mosby.

macrosomia, multifetal gestation, abnormal or difficult presentation (not caused by maternal uterine or pelvic conditions), and congenital anomalies. Intrapartum events that can result in scalp injury include the use of internal monitoring of fetal heart rate (FHR) and collection of fetal scalp blood for acid-base assessment. Obstetric birth techniques can cause injury. Forceps- or vacuum-assisted birth and cesarean birth are potential contributory factors. Neonatal risk factors for birth injury include macrosomia, preterm or postterm birth, and congenital anomalies. Often more than one factor is present, and multiple predisposing factors can be related to a single maternal condition (Mangurten & Puppala, 2011; van Vleet, 2012; Verklan & Lopez, 2011).

Birth injuries are usually classified according to their etiology (predisposing factors or mechanisms of injury) or anatomically. Table 35-1 is an example of anatomic classification of birth injuries.

CARE MANAGEMENT

Nurses who perform initial and ongoing assessments of newborns are alert for clinical signs of birth trauma such as bruising; edema; abrasions; or absence, limitation, or asymmetry of movement. There can be immediate evidence of injury following birth or the signs of birth trauma may not appear until later. The neonate can experience impaired mobility, respiratory distress, or acute pain as a result of birth trauma. In some cases,

FIG 35-1 Marked bruising on the entire face of an infant born vaginally after face presentation. Less severe ecchymoses were present on the extremities. Phototherapy was required for treatment of jaundice resulting from the breakdown of accumulated blood. (From O'Doherty, N. [1986]. *Neonatology: Micro-atlas of the newborn*. Nutley, NJ: Hoffmann-La Roche.)

more serious consequences of birth trauma can occur such as seizures or coma.

Care of the infant with a birth injury is individualized based on the type of injury. Through prompt identification of birth injury and notification of the health care provider, the nurse can proceed as directed with appropriate care measures. Based on the severity of the injury, the newborn may be transferred to the intensive care nursery.

Parents are likely to react to neonatal birth trauma with concern and anxiety. The nurse provides explanations about the type of injury and the treatment plan. Parents may need assistance and support from the nurse as they provide care for the newborn. For example, the nurse can demonstrate how to hold the infant to prevent discomfort from the injury. If the newborn is in the NICU, parents need even greater support from the nursing staff.

Medical and nursing interventions for specific birth injuries are discussed in the following sections.

Soft-Tissue Injuries

Erythema, ecchymoses, petechiae, abrasions, lacerations, and edema of the face, head, buttocks, and extremities can be present. Localized discoloration can appear over presenting or dependent parts. Ecchymoses and edema can appear anywhere on the body and especially on the presenting body part from the application of forceps or vacuum cup. They also can result from manipulation of the infant's body during birth.

Bruises over the face can be the result of face presentation (Fig. 35-1). In a breech presentation, bruising and swelling can occur over the buttocks or genitalia (Fig. 35-2). The skin over the entire head can be ecchymotic and covered with petechiae caused by a tight nuchal cord. Petechiae, or pinpoint hemorrhagic areas, acquired during birth can extend over the upper portion of the trunk and face. These lesions are benign if they

FIG 35-2 Swelling of the genitals and bruising of the buttocks of a preterm infant after a breech birth. Note the position of the infant's legs. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

disappear within 2 days of birth and no new lesions appear. Ecchymoses and petechiae can be signs of a more serious disorder, such as thrombocytopenic purpura, if the hemorrhagic areas do not disappear spontaneously in 2 days.

! NURSING ALERT

To differentiate hemorrhagic areas from skin rashes and discolorations such as Mongolian spots, the nurse blanches the skin with two fingers. Because extravasated blood remains within the tissues, petechiae and ecchymoses do not blanch.

Forceps injury occurs at the site of application of the instrument. Forceps injury typically has a linear configuration across both sides of the face, outlining the placement of the forceps. The affected areas are kept clean to minimize the risk of secondary infection. These injuries usually resolve spontaneously within several days with no specific therapy.

Accidental lacerations can be inflicted with a scalpel during cesarean birth or with scissors during an episiotomy. These cuts can occur on any part of the body but most often are found on the scalp, buttocks, and thighs. Usually they are superficial, needing only to be kept clean. Butterfly adhesive strips or topical skin adhesive will usually hold together the edges of more serious lacerations. Rarely are sutures needed.

Two of the most commonly occurring birth injuries are subconjunctival (scleral) and retinal hemorrhages. These injuries result from rupture of capillaries caused by increased intracranial pressure (ICP) during birth. They usually clear within 5 days after birth and present no problems; however, parents need reassurance about their presence.

Caput succedaneum and cephalhematoma are commonly seen in neonates, often as the result of pressure on the fetal head pushing through a dilated cervix (see Fig. 23-10, A-B). These are discussed in Chapter 23.

A more serious injury is subgaleal hemorrhage, which is bleeding into the subgaleal compartment (see Fig. 23-10, C). The subgaleal compartment is a potential space that contains loosely arranged connective tissue; it is located beneath the galea aponeurosis, the tendinous sheath that connects the frontal and occipital muscles and forms the inner surface of the scalp. The

injury occurs as a result of forces that compress and then drag the head through the pelvic outlet (Verklan & Lopez, 2011). This can occur with midforceps birth and vacuum extraction. The bleeding extends beyond bone, often posteriorly into the neck, and continues after birth, with the potential for serious complications such as anemia, hypovolemic shock, or even death. Early detection of the hemorrhage is vital; serial head circumference measurements and inspection of the back of the neck for increasing edema and a firm mass are essential. A boggy scalp, pallor, tachycardia, and increasing head circumference can be early signs of a subgaleal hemorrhage (Mouhayar & Charafeddine, 2012). Another possible early sign of subgaleal hemorrhage is a forward and lateral positioning of the infant's ears because the hematoma extends posteriorly. Infants with risk factors for subgaleal hemorrhage, including those born by forceps- or vacuum-assisted birth, should have their head circumference monitored per unit protocol for up to 48 hours after birth or longer if the head circumference is increasing. Monitoring the infant for changes in level of consciousness and a decrease in hematocrit is also key to early recognition and management. An increase in serum bilirubin levels can be seen as a result of the breakdown of blood cells within the hematoma. Computed tomography (CT) or magnetic resonance imaging (MRI) is useful in confirming the diagnosis. Replacement of lost blood and clotting factors is required in acute cases of hemorrhage. If bleeding continues and the infant's condition deteriorates, neurosurgery may be needed (Mangurten & Puppala, 2011).

Skeletal Injuries

The newborn's immature, flexible skull can withstand considerable deformation (molding) before fracture results (see Fig. 23-9). Substantial force is required to fracture the newborn's skull. Two types of skull fractures typically are identified in the newborn: linear fractures and depressed fractures. The location of the fracture and involvement of underlying structures determine its significance. Linear fractures are most common in the parietal bones, require no treatment, and are usually of no clinical significance. Skull fractures are common in infants with a cephalhematoma (Mangurten & Puppala, 2011).

The soft skull can become indented without laceration of either the skin or the dural membrane. These depressed fractures, or "ping-pong ball" indentations, can occur during difficult births from pressure of the fetal head on the bony pelvis. They also can occur as a result of injudicious application of forceps. A CT scan is done to rule out bone fragments or underlying injury of the brain tissue. Management of depressed skull fractures is controversial; many resolve without intervention. Nonsurgical elevation of the indentation using a manual breast pump or vacuum extractor has been reported. Surgery may be required in the presence of bone fragments or signs of increased intracranial pressure (Basaldella, Marton, Bekelis, & Longatti, 2011).

The clavicle is the bone most often fractured during birth. Generally the break is in the middle third of the bone (Fig. 35-3). Difficult delivery of the shoulders with a vaginal birth or extension of the arms in a breech birth often results in clavicular fracture (Mangurten & Puppala, 2011). Other risk factors include vacuum-assisted birth and birth weight greater than 4000 g (8.8 lb). Limited movement of the arm, crepitus over the bone, and the absence of the Moro reflex on the affected side are

FIG 35-3 Fractured clavicle after shoulder dystocia. (From O'Doherty, N. [1986]. *Neonatology: Micro atlas of the newborn*. Nutley, NJ: Hoffmann-La Roche.)

diagnostic. Except for use of gentle rather than vigorous handling, no accepted treatment for fractured clavicle exists, and the prognosis is good. A sign posted on the bassinet will alert care providers to the need for careful handling. The figure-eight bandage appropriate for an older child should not be used for a newborn.

The humerus and femur can be fractured during a difficult birth. Fractures in newborns generally heal rapidly. Immobilization is accomplished with slings, splints, swaddling, and other devices.

The parents need support in handling these infants because they often are fearful of hurting them. Parents are encouraged to practice handling, changing, and feeding the affected neonate under the guidance of nursing staff prior to hospital discharge. This increases their confidence and knowledge and facilitates attachment. A plan for follow-up therapy is developed with the parents so that the times and arrangements for therapy are acceptable to them.

Peripheral Nervous System Injuries

Brachial plexus injury is the most common type of paralysis associated with a difficult birth, occurring at a rate of 0.6 to 4.6/1000 live births (Fig. 35-4). Approximately 45% of brachial plexus injuries occur with shoulder dystocia (Carlo, 2011a). An increased risk of brachial plexus injury occurs with birth weight greater than 4000 g (8.8 lb), vaginal breech birth, forceps- or vacuum-assisted birth, maternal diabetes, and a prolonged second stage of labor.

Erb-Duchenne paralysis or palsy is the result of injury to the upper plexus involving nerves C5 and C6 caused by stretching or pulling the head away from the shoulder during a difficult birth. The arm hangs limply alongside the body. The shoulder and arm are adducted and internally rotated. The elbow is extended, and the forearm is pronated, with the wrist and fingers flexed; a grasp reflex can be present because finger and wrist movement remains normal (Carlo, 2011a).

Damage to the lower plexus, also known as *Klumpke paralysis or palsy*, is less common. With lower arm paralysis the wrist and hand are flaccid, the grasp reflex is absent, and deep tendon reflexes are present; dependent edema and cyanosis can occur in the affected hand. There can also be a combination of

FIG 35-4 Brachial plexus injury (Erb-Duchenne palsy) in newborn infant. The Moro reflex was absent in right upper extremity. Recovery was complete. (From Chung, K.C., Yan, L., & McGillicuddy, J.E. [2012]. *Practical management of pediatric and adult brachial plexus palsies*. Philadelphia: Saunders.)

Erb-Duchenne and Klumpke's paralysis and the entire arm can be paralyzed (Verklan, 2015).

Treatment of brachial plexus injury involves intermittent immobilization across the upper abdomen, proper positioning, and range-of-motion (ROM) exercises. Gentle manipulation and ROM exercises are delayed for 1 week to prevent additional injury to the brachial plexus. Immobilization can be accomplished with a brace or splint or by pinning the infant's sleeve to his or her shirt. Treatment for Klumpke palsy consists of placing the hand in a neutral position, padding the fist, and gently exercising the wrist and fingers (Mangurten & Puppala, 2011).

If edema or hemorrhage is responsible for the paralysis, the prognosis is good, and recovery can be expected in a few weeks. If laceration of the nerves has occurred and healing does not result in return of function within a few months, surgery may be indicated; however, return of function is variable. Full recovery is expected in the majority of infants (Mangurten & Puppala, 2011).

Phrenic nerve injury almost always occurs as a component of brachial plexus injury rather than as an isolated problem. Injury is usually the result of traction on the neck and arm during birth. Injury to the phrenic nerve is usually unilateral, but can be bilateral, and results in diaphragmatic paralysis. Cyanosis and irregular thoracic respirations, with no abdominal movement on inspiration, are characteristic of paralysis of the diaphragm. Neonates with diaphragmatic paralysis usually require mechanical ventilatory support, at least for the first few days after birth, and are at risk of developing pneumonia. In the presence of persistent respiratory distress, diaphragmatic pacing or surgical correction may be necessary (Mangurten & Puppala, 2011).

FIG 35-5 Facial paralysis 15 minutes after forceps birth. Absence of movement on affected side is especially noticeable when infant cries. (From O'Doherty, N. [1986]. *Neonatology: Micro atlas of the newborn*. Nutley, NJ: Hoffmann-La Roche.)

Facial paralysis (palsy) (Fig. 35-5) generally is caused by pressure on the facial nerve during birth. Risk factors include a prolonged second stage of labor and forceps-assisted birth. The face on the affected side is flattened and unresponsive to the grimace that accompanies crying or stimulation and the eye remains open on the affected side. Moreover, the forehead does not wrinkle. Usually the infant's face appears distorted, especially when crying. Often the condition is transitory, resolving within hours or days of birth, although total recovery can take weeks or months. Permanent paralysis is rare (Mangurten & Puppala, 2011).

Treatment involves assistance with feeding, prevention of damage to the cornea of the open eye with the application of artificial tears or taping the eye closed, and supportive care of the parents. Feeding can be prolonged, with the milk flowing out the newborn's mouth around the nipple on the affected side. The parents will need understanding and sympathetic encouragement while learning how to feed and care for the infant, as well as how to hold and cuddle the baby (Verklan, 2015).

Central Nervous System Injuries

All types of intracranial hemorrhages (ICH) occur in newborns. ICH as a result of birth trauma is more likely to occur in a large term infant. Risk factors for ICH include vacuum- or forceps-assisted birth, precipitous or prolonged second stage of labor, and increased fetal size (Bode-Jänisch, Bültmann, Hartmann, et al., 2012). In the newborn more than one type of hemorrhage frequently occurs.

Subdural hemorrhage (hematoma), a collection of blood in the subdural space, most often is produced by the stretching and tearing of the large veins in the tentorium of the cerebellum, the dural membrane that separates the cerebrum from the cerebellum. When this type of bleeding occurs, the typical history includes a nulliparous mother, with the total labor and birth occurring in less than 2 or 3 hours; a difficult forceps-assisted birth; or a large for gestational age (LGA) infant. Subdural hematoma occurs less frequently today because of improvements in

obstetric care. However, it is especially serious because of its inaccessibility to aspiration by subdural tap. Neonates with subdural hemorrhage usually present with apnea, unequal pupils, tense fontanel, seizures, and even coma (Verklan & Lopez, 2011).

Subarachnoid hemorrhage, a common type of ICH, occurs in term infants as a result of trauma and in preterm infants as a result of hypoxia. Small hemorrhages are the most common. Bleeding is of venous origin, and underlying contusion also can occur. The clinical presentation of hemorrhage in the term infant can vary considerably. In many infants signs are absent and hemorrhaging is diagnosed only because of abnormal findings on lumbar puncture (e.g., red blood cells in the cerebrospinal fluid [CSF]). The initial clinical manifestations of neonatal subarachnoid hemorrhage can be the early onset of alternating depression and irritability, with refractory seizures or apnea. Occasionally the infant appears normal initially, then has seizures on the second or third day of life, followed by no apparent aftereffects (Verklan, 2015).

In general, nursing care of an infant with ICH is supportive and includes monitoring ventilatory and intravenous (IV) therapy, observing and managing seizures, and preventing increased ICP. Minimal handling to promote rest and reduce stress should guide nursing care (Askin & Wilson, 2011).

The most common cause of spinal cord injury in the neonate is a difficult breech birth. Stretching of the spinal cord, usually by forceful longitudinal traction on the trunk while the head is still firmly engaged in the pelvis, is the most common mechanism of injury. Fortunately this injury is rarely seen today because cesarean birth is typically used for breech presentation. However, it can also occur with shoulder dystocia when traction is applied to the head. Brow and face presentations, dystocia, preterm birth, maternal nulliparity, and precipitous birth also have been identified as predisposing factors in spinal cord injury (Mangurten & Puppala, 2011; Verklan & Lopez, 2011).

Clinical manifestations, treatment, and prognosis depend on the severity and location of the injury. Brainstem and high cervical cord injuries are likely to cause stillbirth or rapid death of the neonate. Upper or midcervical lesions may not be recognized at birth but cause death after a few days. Infants can appear normal at birth but show progressive respiratory deterioration and signs of spinal shock including flaccid extremities, diaphragmatic breathing, paralyzed abdominal movements, atonic anal sphincter, and distended bladder. Lower lesions can result in paraplegia and associated complications. Signs of partial spinal cord injuries such as spasticity can be less apparent (Mangurten & Puppala, 2011).

Therapy is supportive and usually unsatisfactory. Infants who survive present a therapeutic challenge that requires combined treatment from many health care providers: pediatrician, neurologist, neurosurgeon, urologist, orthopedist, nurse, physical therapist, and occupational therapist. Parents need to understand fully the implications of severe injury to the spinal cord and the overwhelming implications it presents for the family.

INFANTS OF MOTHERS WITH DIABETES

No single physiologic or biochemical event can explain the diverse clinical manifestations seen in the infants of mothers

with diabetes. A better understanding of maternal and fetal metabolism, resulting in stricter control of maternal diabetes and improved obstetric and neonatal intensive care, has led to a decrease in the perinatal mortality rate in diabetic pregnancy. However, maternal diabetes continues to play a significant role in neonatal morbidity and mortality. Compared with nondiabetic pregnancies, infants born to mothers with diabetes are at an increased risk for complications such as congenital anomalies, macrosomia, birth trauma, perinatal asphyxia, stillbirth, preterm birth, respiratory distress syndrome (RDS), hypoglycemia, hypocalcemia, hypomagnesemia, cardiomyopathy, hyperbilirubinemia, and polycythemia. The degree of risk depends on the severity and duration of maternal disease. For example, women with vascular complications are more likely to have infants who are small for gestational age (SGA). All infants born to mothers with diabetes are at some risk for complications. The likelihood of these complications is reduced when maternal glucose levels are maintained within normal limits during the periconception period and during pregnancy (Hawdon, 2011; Hay, 2012).

Pathophysiology

The mechanisms responsible for the problems seen in infants of mothers with diabetes are not fully understood. In early pregnancy fluctuations in blood glucose levels and episodes of ketoacidosis are believed to cause congenital anomalies. Later in pregnancy, when the mother's pancreas cannot release sufficient insulin to meet increased demands, maternal hyperglycemia results. Increased amounts of glucose cross the placenta and stimulate the fetal pancreas to release insulin. The combination of the increased supply of maternal glucose and other nutrients and increased fetal insulin results in excessive fetal growth called *macrosomia* (see later discussion).

Hyperinsulinemia accounts for many of the problems of the fetus or infant. In addition to fluctuating glucose levels, maternal vascular involvement or superimposed maternal infection adversely affects the fetus. Normally, maternal blood has a more alkaline pH than the carbon dioxide-rich fetal blood. This phenomenon encourages the exchange of oxygen and carbon dioxide across the placental membrane. When the maternal blood is more acidotic than the fetal blood, such as during ketoacidosis, little carbon dioxide or oxygen exchange occurs at the level of the placenta. The mortality rate for unborn babies resulting from an episode of maternal ketoacidosis can be as high as 35% (Frise, Mackillop, Joash, & Williamson, 2013).

Congenital Anomalies

The incidence of congenital anomalies among mothers with pregestational diabetes is two to five times that of pregnant women who do not have diabetes (Garne, Loane, Dolk, et al., 2012). Elevated fasting blood glucose levels are correlated with an increased risk for anomalies in women with type 1 and type 2 diabetes (Ali & Dornhorst, 2011). Gestational diabetes that is diagnosed in mid- to late pregnancy is usually not associated with an increased incidence of congenital anomalies. However, the risk of anomalies is increased in women with gestational diabetes with elevated fasting glucose or hemoglobin A_{1C} levels, especially during early pregnancy (Ali & Dornhorst). There is an increased incidence of congenital anomalies among infants

of women with prepregnancy obesity who develop gestational diabetes (Ornoy, 2011). In most defects associated with diabetic pregnancies, the structural abnormality occurs before the eighth week after conception. This reinforces the importance of controlling blood glucose both before conception and in the early stages of pregnancy.

The most frequently occurring anomalies involve the cardiac, renal, musculoskeletal, and central nervous systems. The incidence of congenital heart defects is two to three times higher than in the general population (Hay, 2012). Coarctation of the aorta, transposition of the great vessels, and atrial or ventricular septal defects are the most common cardiac anomalies occurring in infants of mothers with diabetes. In the genitourinary system, renal agenesis (failure of the kidney to develop) and obstruction of the urinary tract have been associated with maternal diabetes. Central nervous system (CNS) anomalies include anencephaly, encephalocele, myelomeningocele, and hydrocephalus. The musculoskeletal system can be affected by *caudal regression syndrome* (*sacral agenesis*, with weakness or deformities of the lower extremities; malformation and fixation of the hip joints; and shortening or deformity of the femurs). Other defects noted in this population include gastrointestinal (GI) atresia and urinary tract malformations (see Chapter 36). Neonatal small left colon syndrome, also called lazy colon syndrome, occurs in up to 50% of infants born to mothers with diabetes (Hay). This syndrome is suspected when the infant fails to pass meconium and has abdominal distention and bile-stained vomitus. Contrast enemas show a greatly diminished caliber of the left colon from the splenic flexure to the anus. The syndrome is transient, with normal bowel function developing early in infancy.

Macrosomia

Despite improvements in the control of maternal blood glucose levels, macrosomia is common (Hatfield, Schwoebel, & Lynyak, 2011). At birth the typical LGA infant has a round face, a chubby body, and a plethoric or flushed complexion. The infant has enlarged internal organs (hepatosplenomegaly, splanchnomegaly, cardiomegaly) and increased body fat, especially around the shoulders. The placenta and umbilical cord are larger than average. Because insulin does not cross the blood-brain barrier, the brain is the only organ that is not enlarged. Infants of mothers with diabetes can be LGA but physiologically immature (Fig. 35-6).

Insulin has been proposed as the primary growth hormone for intrauterine development. Maternal diabetes results in elevated maternal levels of amino acids and free fatty acids, along with hyperglycemia. As the nutrients cross the placenta, the fetal pancreas responds by producing insulin to match the fuel supply. The resulting accelerated protein synthesis, together with a deposition of excessive glycogen and fat stores, is responsible for the typical macrosomic infant. This is the infant most at risk for the neonatal complications of hypoglycemia, hypocalcemia, hyperviscosity, and hyperbilirubinemia. The excessive amounts of metabolic fuels transported to the fetus from the mother and the consequent fetal hyperinsulinism represent the basic pathologic mechanism in diabetic pregnancy (Hatfield et al., 2011).

The excessive shoulder size in these infants often leads to dystocia. Macrosomic infants, born vaginally or by cesarean

FIG 35-6 Large for gestational age infant. This infant of a diabetic mother weighed 5 kg (11 lb) at birth and exhibits the typical round face. (From Zitelli, B.J., & Davis, H.W. [2007]. *Atlas of pediatric physical diagnosis* [5th ed.]. Philadelphia: Mosby.)

birth after a trial of labor, can incur birth trauma such as clavicle fracture or brachial plexus injury. Despite increased vigilance in screening and improvements in ultrasound techniques, the prenatal determination of macrosomia can be difficult.

Birth Trauma and Perinatal Hypoxia

Birth injury (resulting from macrosomia or method of birth) and perinatal hypoxia occur more often in infants of mothers with diabetes. Examples of birth trauma include cephalhematoma; paralysis of the facial nerve (cranial nerve VII) (see Fig. 35-5); fracture of the clavicle or humerus; brachial plexus paralysis, usually Erb-Duchenne palsy (see Fig. 35-4); and phrenic nerve paralysis, invariably associated with diaphragmatic paralysis.

Respiratory Distress Syndrome

Respiratory distress syndrome in infants of mothers with diabetes is much less common than in the past because of improved protocols to manage maternal glucose levels and enhanced antepartum fetal surveillance techniques to assess lung maturity. Among infants born to women with well-controlled diabetes who give birth at term, the risk of RDS is similar to that of the general population. However, not all pregnant women with diabetes have well-controlled glucose levels. Maternal hyperglycemia can affect fetal lung maturity. In the fetus exposed to high levels of maternal glucose, synthesis of surfactant can be delayed because of the high fetal serum levels of insulin and/or glucose. In those infants born to women with poorly controlled type 1 diabetes the risk of RDS is six times higher than that of normal infants until 38 weeks of gestation (Hay, 2012). Late preterm birth may be indicated in cases where maternal diabetes is not well controlled. A number of factors including significant maternal and fetal risks should be taken into account in determining the need for early birth (American College of Obstetricians and Gynecologists [ACOG] Committee on Obstetric Practice & the Society for Maternal-Fetal Medicine (SMFM), 2013).

Hypoglycemia

Hypoglycemia (blood glucose levels less than 40 mg/dl in term infants) affects many infants of mothers with diabetes. LGA and preterm infants have the highest risk. After constant exposure

to high circulating levels of glucose, hyperplasia of the fetal pancreas occurs, resulting in hyperinsulinemia. Disruption of the fetal glucose supply occurs with the clamping of the umbilical cord, and the neonate's blood glucose level decreases rapidly in the presence of fetal hyperinsulinism. It can take several days for the newborn to regulate the secretion of insulin in response to a lower postnatal supply of glucose. Hypoglycemia is most common in the macrosomic infant, but the nurse should monitor blood glucose levels in all infants of mothers with known or suspected diabetes.

Asymptomatic or symptomatic hypoglycemia most frequently occurs within the first 1 to 6 hours after birth. Signs of hypoglycemia include jitteriness, apnea, tachypnea, and cyanosis. Many infants with hypoglycemia remain asymptomatic. Significant hypoglycemia can result in seizures. Hypoglycemia is worsened by the presence of hypothermia or respiratory distress.

Hypoglycemic infants of mothers with diabetes should receive IV glucose, whether or not they are symptomatic (Kalhan & Devaskar, 2011). These infants are typically treated in the neonatal intensive care unit.

Hypocalcemia and Hypomagnesemia

Hypocalcemia and hypomagnesemia can occur in infants of mothers with insulin-dependent diabetes although they are not usually present until 48 to 72 hours after birth. The likelihood of hypocalcemia is related to the severity and duration of maternal diabetes. It is often associated with preterm birth, birth trauma, and perinatal asphyxia. Hypomagnesemia is believed to develop because of maternal renal losses that occur in diabetes. Jitteriness is a sign of both hypocalcemia and hypomagnesemia as well as hypoglycemia. Supplemental calcium therapy may be required. Magnesium levels usually return to normal without treatment (Kalhan & Desvaskar, 2011).

Cardiomyopathy

All infants of mothers with diabetes need careful observation for cardiomyopathy (disease affecting the structure and function of the heart) because an increased heart size is often found in these infants. Cardiomyopathy is more likely to occur in cases of poorly controlled maternal diabetes. Two types of cardiomyopathies can occur: hypertrophic and nonhypertrophic. Clinicians must be alert to identify the type of lesion correctly so that appropriate therapy is instituted. Both types of lesions are associated with respiratory symptoms and congestive heart failure.

Hypertrophic cardiomyopathy (HCM) is characterized by a hypercontractile and thickened myocardium. The ventricular walls are thickened, as is the septum, which in severe cases results in outflow tract obstructions. The mitral valve is poorly functioning. In nonhypertrophic cardiomyopathy (non-HCM), the myocardium is poorly contractile and overstretched. The ventricles are larger, and no outflow obstruction is found. Most infants are asymptomatic, but severe outflow obstruction can cause left ventricular heart failure (Hay, 2012).

Hyperbilirubinemia and Polycythemia

Infants of mothers with diabetes are at increased risk of developing hyperbilirubinemia. Many infants also are polycythemic.

Polycythemia increases blood viscosity, thereby impairing circulation. In addition, this greater number of red blood cells to be hemolyzed increases the potential bilirubin load that the neonate must clear, thus increasing the likelihood of hyperbilirubinemia. Bruising associated with birth of a macrosomic infant contributes further to high bilirubin levels.

The excessive red blood cells are produced in extramedullary foci (liver and spleen) in addition to the usual sites in bone marrow; therefore, liver function and bilirubin clearance can be adversely affected. With the increased red blood cell production, iron deficiency can occur in developing neurons as iron is redistributed from the brain to the liver and bone marrow. This can result in limitations in cognitive development (Hay, 2012).

Nursing Interventions

Nursing care depends on the neonate's particular problems. General care of the compromised infant is addressed in Chapter 34. If the maternal blood glucose level was well controlled throughout the pregnancy, the infant may require only monitoring. Because euglycemia (normal blood glucose levels) is not always possible, the nurse must promptly recognize and treat any consequences of maternal diabetes that arise. The most common problems experienced by infants of diabetic mothers that require intervention include birth trauma and perinatal asphyxia; RDS; difficult metabolic transition, including hypoglycemia and hypocalcemia; and congenital anomalies (see previous sections and the Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Newborn Effects of Maternal Diabetes

Melissa is a female neonate born at 37 weeks of gestation to a G 2 P 1 mother, who was diagnosed with gestational diabetes. Following a spontaneous vaginal birth, Melissa received Apgar scores of 7 at 1 minute and 8 at 5 minutes. Melissa weighs 3900 g (8.6 lb) and appears plethoric pink with a moderate amount of subcutaneous fat. She is noted to be slightly jittery at 30 minutes of age. In planning your care for Melissa you need to take into consideration the effects of maternal diabetes on the newborn.

1. Evidence—What complications of maternal diabetes is Melissa at risk of developing?
2. Assumptions—Describe underlying assumptions about each of the following issues:
 - a. Symptoms of hypoglycemia
 - b. Plans for assessing an infant with hypoglycemia
 - c. Recommendations for care of an infant of a diabetic mother
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

NEONATAL INFECTIONS

Sepsis

Sepsis (presence of microorganisms or their toxins in blood or other tissues) continues to be one of the most significant causes of neonatal morbidity and mortality. The newborn infant is susceptible to infection because of the immature immune

system. Maternal immunoglobulin M (IgM) does not cross the placenta. IgG levels in term infants are equal to maternal levels; however, in preterm infants the amount of IgG is directly proportional to gestational age (Carlo, 2011b). IgA and IgM require time to reach optimal levels after birth. Phagocytosis is less efficient. Serum complement levels are inadequate; serum complement (C1 through C6) is involved in immunologic reactions, some of which kill or lyse bacteria and enhance phagocytosis. Dysmaturity seen with intrauterine growth restriction (IUGR) and preterm and postterm birth further compromises the neonate's immune system.

Table 35-2 outlines risk factors for neonatal sepsis. Special precautions for preventing infection, as well as prompt recognition when it occurs, are necessary for optimal newborn care. Neonatal infections can be acquired in utero, during labor and birth, during resuscitation, and during the hospital stay.

Prenatal acquisition of infection occurs by organisms placentally transferred directly into the fetal circulatory system or transmitted from infected amniotic fluid, such as with herpes simplex virus (HSV), cytomegalovirus (CMV), or rubella. Microorganisms can ascend from the vagina and pass through the cervix. The membranes become infected and can rupture, resulting in infection of the fetal skin and the respiratory or GI tract.

During birth, contact with an infected birth canal can result in generalized or local infection. The upper airway and the GI tract are the principal pathways for generalized infections.

TABLE 35-2 Risk Factors for Neonatal Sepsis

SOURCE	RISK FACTORS
Maternal	Low socioeconomic status
	Late or no prenatal care
	Poor nutrition
	Substance abuse
	Recently acquired sexually transmitted infection
	Untreated focal infection (urinary tract infection, vaginal, cervical)
	Systemic infection
Intrapartum	Fever
	Premature rupture of fetal membranes
	Maternal fever
	Chorioamnionitis
	Prolonged labor
	Premature labor
	Use of fetal scalp electrode
Neonatal	Multiple gestation
	Male
	Birth asphyxia
	Meconium aspiration
	Congenital anomalies of skin or mucous membranes
	Metabolic disorders (e.g., galactosemia)
	Low birth weight
	Preterm birth
	Malnourishment
	Formula feeding
Prolonged hospitalization	
Mechanical ventilation	
Umbilical artery catheterization or use of other vascular catheters	

Data from Edwards, M. (2011). Postnatal bacterial infections. In R. Martin, A. Fanaroff, & M. Walsh (Eds.), *Fanaroff and Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* (9th ed.). St. Louis: Mosby; Bodin, M.B. (2014). Immune system. In C. Kenner & J.W. Lott (Eds.), *Comprehensive neonatal nursing care* (5th ed.). New York: Springer.

The conjunctiva and the oral cavity are the usual sites of local infection.

Postnatal infection is sometimes acquired during resuscitation or through the introduction of foreign objects such as indwelling catheters or endotracheal tubes. Health care–acquired infections can be transferred to the infant by the hands of the parents or health care personnel or spread from contaminated equipment. The umbilicus is a receptive site for cutaneous infection leading to sepsis. Neonatal bacterial infection is classified into two patterns according to the time of presentation. Early-onset or congenital sepsis usually manifests within 24 to 72 hours after birth, progresses more rapidly than later-onset infection, and has a mortality rate between 2% and 40% (Hofer, Zacharias, Muller, & Resch, 2012). Early-onset infection is usually caused by microorganisms from the normal flora of the maternal vaginal tract, including group B streptococci, *Haemophilus influenzae*, *Listeria monocytogenes*, *Escherichia coli*, and *Streptococcus pneumoniae* (Venkatesh, Adams, & Weisman, 2011). It is associated with a history of obstetric complications such as preterm labor, premature rupture of membranes, maternal fever during labor, and chorioamnionitis (Polin, 2012).

Late-onset sepsis, occurring at approximately 7 to 30 days of age, can include maternally derived infection or health care–acquired infection; the offending organisms are usually staphylococci, *Klebsiella* organisms, enterococci, *E. coli*, and *Pseudomonas*, or *Candida* species (Hammoud, Al-Taiar, Thalib, et al., 2012). Coagulase-negative staphylococci, considered to be primarily a contaminant in older children and adults, are commonly found to be the cause of septicemia in extremely low-birth-weight (ELBW) and very low-birth-weight (VLBW) infants. Additional infections of concern include methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), and multidrug-resistant gram-negative pathogens (Fowler, 2013). Bacterial invasion can occur through sites such as the umbilical stump; the skin; mucous membranes of the eye, nose, pharynx, and ear; and internal systems such as the respiratory, nervous, urinary, and GI systems.

Viral infections that are acquired perinatally can cause stillbirth, intrauterine infection, congenital malformations, and acute disease. These pathogens also can cause chronic infection, with subtle manifestations that can be recognized only after a prolonged period. It is important to recognize the manifestations of infections in the neonatal period to treat the acute infection, to prevent health care–acquired infections in other infants, and to anticipate effects on the infant's subsequent growth and development.

Fungal infections are of great concern in the immunocompromised or premature infant. Occasionally fungal infections such as thrush are found in otherwise healthy term infants.

Septicemia refers to a generalized infection in the bloodstream. Pneumonia, the most common form of neonatal infection, is one of the leading causes of perinatal death and is caused by many of the same organisms that cause sepsis. Bacterial meningitis affects 0.25 to 1 of every 1000 live-born infants (Shah, Ohlsson, & Shah, 2012). Gastroenteritis is sporadic, depending on epidemic outbreaks. Local infections such as conjunctivitis and omphalitis occur frequently, but incidence rates are unavailable. Infection continues to be a significant factor in

fetal and neonatal morbidity and mortality. Sequelae to septicemia include meningitis, disseminated intravascular coagulation (DIC), and septic shock.

Septic shock results from the toxins released into the bloodstream. The most common sign is a decrease in blood pressure, a vital sign often not assessed in the care of the neonate. The infant will often appear gray or mottled and can be noted to have cool extremities. Other signs are rapid, irregular respirations and pulse (similar to septicemia in general).

CARE MANAGEMENT

The development of systemic infection in the newborn can be influenced by maternal, peripartum, and neonatal risk factors. Onset within the first 48 hours of life is more often associated with prenatal or perinatal predisposing factors. Onset after 2 or 3 days more frequently reflects disease acquired at or subsequent to birth.

Assessment

The earliest clinical signs of neonatal sepsis are nonspecific and include lethargy, poor feeding, poor weight gain, and irritability. The nurse or parent can simply note that the infant is just not doing as well as before. Differential diagnosis can be difficult because signs of sepsis are similar to signs of noninfectious neonatal problems such as anemia or hypoglycemia. Additional clinical and laboratory information and appropriate cultures supplement the findings described. Table 35-3 outlines signs and symptoms of sepsis.

TABLE 35-3 Signs and Symptoms of Infection

SYSTEM	SIGNS
Respiratory	Apnea, bradycardia Tachypnea Grunting, nasal flaring Retractions Decreased oxygen saturation Acidosis
Cardiovascular	Decreased cardiac output Tachycardia Hypotension Decreased perfusion
Central nervous	Temperature instability Lethargy Hypotonia Irritability, seizures
Gastrointestinal	Feeding intolerance Abdominal distention Vomiting, diarrhea
Integumentary	Jaundice Pallor Petechiae
Metabolic	Hypoglycemia Hyperglycemia Metabolic acidosis
Hematologic	Thrombocytopenia Neutropenia

Data from Edwards, M. (2011). Postnatal bacterial infections. In R. Martin, A. Fanaroff, & M. Walsh (Eds.), *Fanaroff and Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* (9th ed.). St. Louis: Mosby; Bodin, M.B. (2014). Immune system. In C. Kenner & J.W. Lott (Eds.), *Comprehensive neonatal nursing care* (5th ed.). New York: Springer.

Laboratory studies are important. Specimens for cultures include blood, CSF, and urine. Fluids such as urine and CSF can be evaluated by counterimmune electrophoresis or latex agglutination to help identify the bacteria. A complete blood cell (CBC) count with differential is performed. The leukocyte count is not a reliable indicator of sepsis; however, the total neutrophil count, immature to total neutrophil (I/T) ratio, absolute neutrophil count, and C-reactive protein can be used to determine the presence of sepsis. Detection of viral deoxyribonucleic acid (DNA) or antibodies by polymerase chain reaction (PCR) amplification in fluids is also an important diagnostic tool (Ohlin, Backman, Ewald, et al., 2012).

Interventions

Antepartum viral infection can be treated with antiviral medications to decrease viral replication and fetal transmission of disease; neonates can also be treated with antiviral medications such as acyclovir and ganciclovir. Treatment with antibiotics or antivirals is initiated after neonatal blood cultures are obtained. After the pathogen is identified, antibiotic, antiviral, or antifungal therapy can be modified.

Breastfeeding or feeding the newborn expressed breast milk from the mother is encouraged. Breast milk provides protective mechanisms (see Chapter 25). Colostrum contains IgA, which offers protection against infection in the GI tract. Human milk contains iron-binding protein that exerts a bacteriostatic effect on *E. coli*. Human milk also contains macrophages and lymphocytes. The vulnerability of infants to common mucosal pathogens such as respiratory syncytial virus (RSV) can be reduced by passive transfer of maternal immunity in the colostrum and breast milk. Some evidence indicates that early enteral feedings with human milk (trophic or minimal enteral feedings) can be beneficial in establishing a natural barrier to infection in ELBW and VLBW infants (Anderson, Wood, Keller, & Hay, 2011).

Nursing Considerations. Administering medications safely and correctly, taking precautions when performing treatments, and following isolation procedures are important interventions when a newborn has an infection. Monitoring the IV infusion rate and administering antibiotics are the nurse's responsibilities.

MEDICATION ALERT

If the IV fluid the infant is receiving contains electrolytes, vitamins, or other medications, the nurse should check with the hospital pharmacy before adding antibiotics. The antibiotic (or other medication) can be deactivated or can form a precipitate when combined with other substances. To prevent this, a secondary line of the prescribed solution is attached with a needleless connector at the infusion site.

Care must be taken in suctioning secretions from any newborn's oropharynx or trachea; the secretions can be infected. Routine suctioning is not recommended and can further compromise the infant's immune status, as well as cause hypoxia and increase ICP. Isolation procedures are implemented as indicated according to hospital policy. Isolation protocols change rapidly, and the nurse is urged to participate in continuing education and in-service programs to remain up-to-date.

Preventive Measures. Virtually all controlled clinical trials have demonstrated that effective hand hygiene is responsible for the prevention of health care-acquired infection in nursery units. Nurses play an essential role in minimizing or eliminating environmental sources of infectious agents in the nursery. Measures include implementing Standard Precautions, carefully and thoroughly cleaning the environment and equipment, frequently replacing used equipment (e.g., changing IV tubing per hospital protocol, cleaning resuscitation and ventilation equipment), and appropriately disposing of excrement and linens. Hand hygiene is the single most important measure in preventing the spread of infection. Appropriate hand hygiene protocols should be in place and frequent education provided to ensure that good hand hygiene practices are followed. Overcrowding must be avoided in nurseries. Guidelines for space, visitation, and general infection control in areas where newborns receive care have been established and published (American Academy of Pediatrics [AAP] & ACOG, 2012).

Specific newborn care procedures are intended to prevent infection. These include instilling antibiotic ointment in newborns' eyes 1 to 2 hours after birth, bathing, and cord care (see Chapter 24).

Transplacental Infections

The occurrence of certain maternal infections during early pregnancy is known to be associated with various congenital malformations and disorders. An acronym that is often used in clinical practice is TORCH, which stands for toxoplasmosis, other (gonorrhea, hepatitis B, syphilis, varicella-zoster virus, parvovirus B19, and human immunodeficiency virus [HIV]), rubella, cytomegalovirus, and herpes simplex virus (see also Chapter 7). Additional organisms known to cause congenital infection include enteroviruses and parvovirus, leading some clinicians to suggest the need for a new more comprehensive acronym (Del Pizzo, 2011). With the advent of newer diagnostic methods, these viral infections can be diagnosed in utero and interventions planned based on the availability of intrauterine treatments.

Toxoplasmosis

Toxoplasmosis is a multisystem disease caused by the protozoan *Toxoplasma gondii* parasite, commonly found in cats, dogs, pigs, sheep, and cattle, with cats being the definitive host. In the United States, risk factors for acquisition of toxoplasmosis include exposure to contaminated soil and consumption of raw or undercooked meats or seafood (oysters, clams, or mussels) (Jones & Roberts, 2012). Changing cat litter is a known risk for toxoplasmosis. The risk of maternal-fetal transmission of acute infection is approximately 40% with the risk of transmission increasing as the pregnancy progresses. However, the earlier in pregnancy that fetal infection occurs, the greater the severity of congenital disease (Duff, 2012). Because many women are already seropositive for toxoplasmosis, the overall risk of a primary infection in pregnancy is quite low. The diagnosis of toxoplasmosis in the neonate is supported by elevated levels of cord blood serum IgM.

Most neonates infected with *T. gondii* in utero are asymptomatic at birth, although many develop chorioretinitis and signs

of CNS involvement such as learning disabilities (Moncada & Montoya, 2012). For some infected neonates, hydrocephalus is the only clinical sign of the disease (Sanchez, Patterson, & Ahmed, 2012). Up to 30% of infected infants are born with severe manifestations at birth. Clinical features ascribed to *T. gondii* infection include three key findings (classic triad) first described by Sabin (1942): hydrocephalus, chorioretinitis, and cerebral calcifications (Del Pizzo, 2011). Severe toxoplasmosis is associated with preterm birth, growth restriction, microcephaly or hydrocephaly, microphthalmos, chorioretinitis, CNS calcification, thrombocytopenia, jaundice, and fever. Petechiae or a maculopapular rash also can be evident.

Infants with congenital toxoplasmosis are treated with pyrimethamine, combined with oral sulfadiazine; folic acid supplement is used to prevent anemia. Treatment should be continued for 1 year (Kaye, 2011).

Gonorrhea

The incidence of gonococcal infection in pregnant women ranges from 2.5% to 7.3%. Many women with gonorrhea often have a concurrent *Chlamydia trachomatis* infection (Engelkirk, Duben-Engelkirk, & Burton, 2011). After rupture of membranes, ascending infection can result in orogastric contamination of the fetus. The organism can also invade mucosal surfaces such as the conjunctiva (ophthalmia neonatorum), the rectal mucosa, and the pharynx. Contamination can occur as the infant passes through the birth canal, or it can occur postnatally from an infected adult. Neonatal gonococcal arthritis, septicemia, meningitis, vaginitis, and scalp abscesses also can develop.

Eye prophylaxis (e.g., with 0.5% erythromycin ointment) is administered within the first hour after birth to prevent ophthalmia neonatorum. This practice has reduced the incidence of gonococcal conjunctivitis to less than 0.5% (Anderson & Gonik, 2011).

Eye prophylaxis alone does not prevent systemic infection; therefore, infants with a gonococcal eye infection should receive one dose of ceftriaxone (Zuppa, D'Andrea, Catenazzi, et al., 2011). Infants with systemic gonococcal infection require hospitalization and 7 days of IV antibiotic therapy. Infants rarely die of overwhelming infection in the early neonatal period.

Syphilis

Congenital and neonatal syphilis have reemerged in recent years as significant health problems. In the United States in 2012, 322 cases of congenital syphilis were reported in children less than 1 year of age (CDC, 2014b). It is estimated that for every 100 women diagnosed with primary or secondary disease, 2 to 5 infants will contract congenital syphilis. If syphilis during pregnancy is untreated, approximately 50% of neonates born to these women will have symptomatic congenital syphilis. Treatment failure can occur, particularly when treatment is given in the third trimester; therefore, infants born to women treated within 4 weeks of birth should be evaluated for congenital syphilis (De Santis, De Luca, Mappa, et al., 2012). The following factors have been identified as placing the neonate at high risk for congenital syphilis: late or no prenatal care, maternal substance abuse, crack cocaine use in the mother or partner, multiple

sexual partners, history of a sexually transmitted infection (STI), poverty, homelessness, and HIV infection (Patterson & Davies, 2011).

The fetus is usually infected in utero by transplacental infection, but infection of the amniotic fluid can occur. The infant can contract syphilis during contact with an active genital lesion at birth (Sweet & Gibbs, 2012). The risk to the fetus and neonate varies according to the stage of maternal infection, with transmission during primary or secondary syphilis being more common. Untreated maternal disease results in fetal or perinatal death in 40% of cases (Patterson & Davies, 2011). Prompt maternal treatment eliminates most fetal infections; however, delayed treatment or a failure to obtain treatment can result in fetal effects that range from minor anomalies to preterm birth or fetal death. Damage to the fetus depends on when in gestation the infection occurred and the time that has elapsed before treatment. Congenital syphilis infection can be asymptomatic at birth in up to two thirds of infected infants. A portion of these infants will become symptomatic in the first 2 years of life, whereas others may take up to 20 years before displaying the effects of congenital infection (De Santis et al., 2012).

Early congenital syphilis can result in prematurity, hydrops fetalis, and failure to thrive. Hepatosplenomegaly and jaundice are common. Hematologic findings include anemia, leukocytosis, and thrombocytopenia. Characteristic bony lesions occur in the long bones, the cranium, and the spine and include osteochondritis, osteomyelitis, and periostitis. Other findings include snuffles (copious clear mucous discharge from the nose); mucocutaneous lesions, edema, and a copper-colored maculopapular dermal rash first noticeable on the palms of the hands, the soles of the feet, and in the diaper area; and around the mouth and the anus by the end of the first week of life in untreated infants (Fig. 35-7). *Condylomata* (elevated wartlike lesions) can be seen on mucous membranes, moist surfaces, or areas of the body affected by friction. Rough, cracked, mucocutaneous lesions of the lips heal to form circumoral radiating scars known as *rhagades*. Other involvement results in exfoliation (separation, flaking) of nails and loss of hair. Iritis and choroiditis are characteristic of infection of the eyes. The following can be noted: nephrotic syndrome secondary to renal infection; hepatitis with jaundice,

FIG 35-7 Neonatal syphilis lesions on hands and feet. (Courtesy Mahesh Kotwal, MD, Phoenix, AZ.)

lymphadenopathy, and inflammation of the pancreas, the testes, and the colon; and a pseudoparalysis of the extremities. In some infants signs of congenital syphilis do not appear until late in the neonatal period. In these newborns early signs such as slight hyperthermia and snuffles can be nonspecific (Sanchez et al., 2012).

Medical Management. Treatment of the newborn should be initiated when the diagnosis of congenital syphilis is confirmed or suspected or when maternal treatment status is unknown or not well documented. The neonate should be treated when the mother was treated within 1 month of giving birth or does not respond to treatment, when medications other than penicillin were used for the mother, or when the mother was treated appropriately but did not have sufficient serologic follow-up to assess response to treatment (Lago, Vaccari, & Fiori, 2013).

The infant with symptomatic congenital syphilis should have a lumbar puncture, CBC, and long-bone radiography prior to treatment. If the results of these tests are normal, a single intramuscular dose of benzathine penicillin is recommended (Lago et al., 2013). If results are abnormal or there is concern about appropriate follow-up, a 10-day course of IV penicillin or intramuscular (IM) procaine penicillin may be given. If the mother was adequately treated before giving birth and serologic testing of the infant does not show syphilis, the infant is usually not treated with antibiotics. The infant is checked for antibody titer (received from the mother through the placenta) every 2 weeks for 3 months, at which time the test result should be negative. Some physicians recommend antibiotic therapy for asymptomatic or inconclusive cases.

Prognosis. In general, treatment of syphilis is more effective if it begins early rather than late in the course of the disease. However, a recurrence rate of 5% can be expected. Even adequate treatment of congenital syphilis after birth does not always prevent late complications (5 to 15 years after initial infection). Potential complications include neurosyphilis, deafness, Hutchinson teeth (notched incisors), saber shins, joint involvement, saddle nose (depressed bridge), gummas (soft, gummy tumors) over the skin and other organs, interstitial keratitis (inflammation of the cornea), rhagades, frontal bossing, and mulberry molars (De Santis et al., 2012).

Varicella Zoster

The varicella zoster virus, responsible for chickenpox and shingles, is a member of the herpes family. Approximately 90% of women in the childbearing years are immune; therefore, the risk of infection in pregnancy is low: 0.7 to 3 per 1000 pregnancies (Lamont, Sobel, Carrington, et al., 2011).

Varicella transmission to the fetus can occur across the placenta when the disease is contracted in the first half of pregnancy, but this is relatively infrequent (about 2%). When transmission to the fetus does occur in the early part of pregnancy, the effects on the fetus include limb atrophy, neurologic abnormalities (hydrocephalus or microcephaly), and eye abnormalities (Lamont et al., 2011).

When maternal infection occurs in the last 3 weeks of pregnancy, 23% of infants born to these mothers will develop clinical varicella. The severity of the infant's illness increases greatly if maternal infection occurred within 5 days before or 2 days

after birth. The mortality rate in severe illness is 7% (Ghosh & Chaudhuri, 2013).

Seroimmune pregnant women exposed to active chickenpox can be given varicella zoster immune globulin (VZIG), which does not reduce the incidence of infection but should decrease the effects of the virus on the fetus. The immune globulin must be given within 72 hours of exposure to be effective (AAP & ACOG, 2012).

Infants born to mothers in whom chickenpox develops between 5 days before birth and 48 hours after birth should be given VZIG at birth because of the risk of severe disease. Acyclovir can be used to treat infants with generalized involvement (Ghosh & Chaudhuri, 2013).

Term infants exposed to chickenpox after birth will have a mild or no infection if they are born to immune mothers. In those born to nonimmune mothers, chickenpox can develop, but the course is not usually severe. Experts are divided as to whether this group of infants should receive VZIG. Infants born before 28 weeks of gestation are at risk regardless of their mother's status, and probably benefit from VZIG if exposed to chickenpox (Kett, 2013).

Hepatitis B Virus

Hepatitis B virus (HBV) infection during pregnancy is not associated with an increase in malformations, stillbirths, or IUGR; however, almost twice as many mothers with HBV give birth prematurely compared with noninfected mothers (Reddick, Jhaveri, Gandhi, et al., 2011). The transmission rate of HBV to the newborn ranges from 85% to 90% when the mother is seropositive for both hepatitis B surface antigen (HBsAg) and hepatitis B e antigen (HBeAg) (Ott, Stevens, & Wiersma, 2012). Transmission occurs transplacentally, serum to serum, and by contact with contaminated urine, feces, saliva, semen, or vaginal secretions during birth. Infants are most frequently infected during birth or in the first few days of life. The rate of transmission is highest when the mother contracts the virus in the third trimester or early in the postpartum period (Pol, Corouge, & Fontaine, 2011). These mothers are positive for HBsAg. Transmission can occur through breast milk, but antigens also develop in formula-fed infants at the same or a higher rate; thus breastfeeding is not contraindicated. Diagnosis is made by viral culture of amniotic fluid, as well as by the presence of HBsAg and IgM in the cord blood or infant serum.

The majority of infants who become HBsAg positive are asymptomatic at birth, whereas some show evidence of acute hepatitis with changes in liver function. The mortality rate for full-blown hepatitis is 75%. Infants who become carriers are at high risk for chronic hepatitis, cirrhosis of the liver, or liver cancer even years later (Chang, 2011).

MEDICATION ALERT

Infants whose mothers have antibodies for HBsAg or in whom hepatitis developed during pregnancy or the postpartum period should be treated with hepatitis B immune globulin (HBIG), 0.5 ml intramuscularly, as soon as possible after birth—within the first 12 hours of life (CDC, 2014a). Hepatitis B vaccine also should be given at the same time but in a different site (Schillie & Murphy, 2013) (see Chapter 24).

Human Immunodeficiency Virus (HIV) and Acquired Immunodeficiency Syndrome (AIDS)

Approximately 8700 pregnant women infected with HIV give birth each year in the United States. Due to the success of preventive strategies during pregnancy, the incidence of mother-to-child transmission has been reduced to less than 1%. Universal HIV testing for all pregnant women allows for early identification and treatment of HIV-positive women during pregnancy, which decreases the risk of transmission to the fetus. Other strategies to prevent neonatal HIV infection include administration of antiviral medications during pregnancy and labor to women who are infected with the virus, administration of antiretrovirals to neonates for 6 weeks, and elective cesarean birth for women with HIV viral loads greater than 1000 copies per ml. In the United States and Canada, an additional strategy is the total avoidance of breastfeeding (CDC, 2013; MacDonald & Canadian Paediatric Society Infectious Diseases and Immunization Committee, 2012). The World Health Organization recommends that in resource-limited settings such as developing countries HIV-positive mothers who are taking antiretroviral medications should breastfeed for at least 12 months. For those who do not have access to antiretroviral therapy, exclusive breastfeeding for 6 months is recommended. After 6 months complementary foods are introduced and breastfeeding is continued until a safe, nutritional diet without breast milk can be provided for the infant (WHO, UNAIDS, UNFPA, & UNICEF, 2010).

Transmission of HIV from the mother to the fetus can occur transplacentally at various gestational ages. The risk of infection in an infant born to an HIV-positive mother (not treated) is approximately 12% to 40%. Transmission most often occurs during birth. Globally, up to one half of cases of mother-to-child transmission occur through breastfeeding (KiBS Study Team, 2011).

Diagnosis of HIV infection in the neonate is complicated by the presence of maternal IgG antibodies that cross the placenta after 32 weeks of gestation. The most accurate test for newborns and infants younger than 18 months is the HIV-1 DNA PCR assay, which is performed on neonatal blood, not cord blood (National Institutes of Health [NIH] Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children, 2012). Follow-up testing for infants born to HIV-positive mothers is recommended at several intervals within the first year of life.

Typically the HIV-infected neonate is asymptomatic at birth. Early-onset illness (i.e., virus detected within 48 hours of birth) is attributed to prenatal infection. These infants develop opportunistic infections (*Candida* and *Pneumocystis jirovecii* pneumonia) and experience rapid progression of immunodeficiency that often results in death during the first 1 to 2 years of life.

The remainder of infants seroconvert over a period of months to years. By 1 year of age the vast majority of perinatally infected infants show signs of infection. Some children infected at birth show no signs of disease 8 to 10 years later. The age of onset of symptoms predicts the length of survival.

The presenting signs and symptoms of HIV infection vary from severe immunodeficiency to nonspecific findings such as growth failure, parotitis, and recurrent or persistent upper respiratory tract infections. In the first year of life, lymphadenopathy and hepatosplenomegaly are common. The infant can

have fever, chronic diarrhea, chronic dermatitis, interstitial pneumonitis, persistent thrush, and AIDS-defining opportunistic infections. Common secondary opportunistic infections include pneumonia, candidiasis, CMV, cryptosporidiosis, herpes simplex or herpes zoster, and disseminated varicella (Yogev & Chadwick, 2011).

Although it is rare for an infant to be born with symptoms of HIV infection, all infants born to seropositive mothers should be presumed to be HIV positive until proven otherwise. Management begins by implementing Standard Precautions. Measures also should be taken to protect the infant from further exposure to maternal blood and body fluids. Regimens for the prevention of HIV transmission include antepartum, intrapartum, and neonatal treatment with highly active retroviral therapy (HAART).

The goal in the administration of antivirals is to suppress the virus to undetectable concentrations; the available antiviral drugs do not, however, cure the child's disease. HIV diagnosis in the neonatal period combined with aggressive antibiotic treatment of opportunistic infections has the potential to prolong survival (NIH Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children, 2012). Studies of HIV symptoms in children treated in the era of HAART show a significant decrease in the incidence of secondary opportunistic infections (NISDI Pediatric Study Group, 2012).

Counseling regarding the care of the mothers themselves, the family's care of the infant, and future pregnancies should be provided. The risk for transmission among members of the same household is minimal. Social services are required in these cases. If the parent chooses to keep the infant, home health care may be arranged. The family must be counseled about vaccinations. All HIV-1–exposed infants should receive routine immunizations. There are specific guidelines for those with confirmed HIV infection (CDC, 2014c). It is usually safe to administer all inactivated vaccines to HIV-1–infected children. In the absence of severe immunosuppression, children with HIV-1 can receive varicella vaccine (CDC).

Rubella Infection

Since the rubella vaccination program was begun in 1969, cases of congenital rubella infection have been reduced significantly; however, it is still seen occasionally in the newborn. Vaccination failures, lack of compliance, and the migration of nonimmunized persons result in periodic outbreaks of rubella, also known as German measles.

The risk of a congenitally infected infant varies with the gestational age of the fetus when maternal infection occurs. Abnormalities are most severe if the mother contracts the virus during the first trimester and rare if the disease occurs after that time (Schleiss & Patterson, 2012).

More than two thirds of infected infants show no apparent symptoms at birth, but sequelae can develop years later. Hearing loss, the most common result, appears to be progressive after birth. **Congenital rubella syndrome** includes cataracts or glaucoma, hearing loss, and cardiac defects (pulmonary artery stenosis, patent ductus arteriosus, or coarctation of the aorta). Multiple other abnormalities also are present, including IUGR, microphthalmia, hypotonia, hepatosplenomegaly, thrombocytopenic purpura, dermatoglyphic abnormalities, bony radiolucencies,

FIG 35-8 Neonatal cytomegalovirus infection. Typical rash seen in a severely affected infant. (Courtesy David A. Clarke, Philadelphia, PA.)

microcephaly, and brain wave abnormalities. Severe infection can result in fetal death. Delayed effects of infection manifest as thyroid dysfunction, diabetes mellitus, growth restriction, myocarditis, and glaucoma (Nielsen-Saines, 2011).

SAFETY ALERT

The rubella virus has been cultured in infants for up to 18 months after birth. These infants are a serious source of infection to susceptible individuals, particularly women in the childbearing years. Extended pediatric isolation is mandatory until the non-contagious stage of rubella has been reached. The infant should be isolated until pharyngeal mucus and urine are free of virus (Motacki, Kapoian, & O'Mara, 2011).

Cytomegalovirus Infection

Cytomegalovirus (CMV) infection during pregnancy can result in miscarriage, stillbirth, or congenital or neonatal cytomegalic inclusion disease (CMID). It is the most common cause of congenital viral infections in humans, occurring in 40,000 newborns in the United States every year. Maternal-fetal transmission of CMV occurs in 40% to 50% of mothers with a primary CMV infection during pregnancy (Schleiss & Patterson, 2012).

The neonate with classic, full-blown CMID typically displays IUGR and has microcephaly, seizures, and lethargy. The neonate also has a rash, jaundice, and hepatosplenomegaly (Fig. 35-8). Anemia, thrombocytopenia, and hyperbilirubinemia are common (Schleiss & Patterson, 2012). Intracranial, periventricular calcification often is noted on x-ray films. Mortality rates in symptomatic infants are 5% to 10% (Walker, Palma-Dias, Wood, et al., 2013). Congenital CMV can cause a variety of neurologic problems such as cognitive disabilities, hearing loss, or visual impairment (Schleiss & Patterson). Most (90%) affected infants are asymptomatic at birth (Walker et al., 2013), although there is a 10% to 15% risk that they will develop later sequelae such as hearing loss and learning disabilities (Schleiss & Patterson). Hearing loss can be present at birth or may not be apparent until after the first year of life. The hearing loss is often progressive. Chorioretinitis, microcephaly, intellectual

disability, and neuromuscular deficits can occur by 2 years of age. Some children are at risk for a defect in tooth enamel, resulting in severe caries (Salanitri & Seow, 2013).

Elevated levels of cord blood IgM are suggestive of disease. The virus can be isolated from urine or saliva of the newborn. Differential diagnoses include other causes of jaundice, syphilis (positive Venereal Disease Research Laboratory [VDRL] findings), toxoplasmosis (positive Sabin-Feldman dye test result), hemolytic disease of the newborn (positive Coombs' test reaction), or coxsackievirus infection (positive culture).

CMV can be transmitted through breast milk while the mother has acute CMV infection. CMV infections acquired after birth are often asymptomatic and have no sequelae. Exceptions to this occur in preterm infants in whom postnatal acquisition of CMV can result in pneumonia, hepatitis, thrombocytopenia, and long-term neurologic sequelae.

Treatment of the infected newborn with ganciclovir is effective in decreasing neurologic sequelae, in particular sensorineural hearing loss. There is some evidence that administration of CMV-specific human immunoglobulin to the pregnant woman with primary CMV infection can help protect the fetus (Schleiss & Patterson, 2012).

Herpes Simplex Virus

Neonatal herpes simplex virus infection is being diagnosed more frequently although the exact incidence is difficult to determine because it is not a reportable condition in all states in the United States (Cherpes, Matthews, & Maryak, 2012). It may occur in as many as 1 in 2500 births (Schleiss & Patterson, 2012).

Women with a history of herpes infection may be prescribed antiviral medication beginning at 36 weeks of gestation, a practice that has been shown to reduce the likelihood of recurrent infection at birth (Kimberlin, Baley, Committee on Infectious Diseases, & Committee on Fetus and Newborn, 2013).

The neonate can acquire the virus through transplacental infection, ascending infection by way of the birth canal, direct contamination during passage through an infected birth canal, or direct transmission from infected personnel or family (Schleiss & Patterson, 2012).

Transplacental transmission of HSV infection to the neonate can occur during maternal infection; however, an ascending transcervical infection first involves the intact fetal membranes, causing chorioamnionitis. Transcervical infection can be accelerated by the use of internal fetal monitoring. The scalp electrodes break the fetal skin barrier and increase the risk of infection.

Congenital infection is rare and characterized by in utero destruction of normally formed organs. Affected infants are growth restricted and have skin lesions and scarring. They have severe psychomotor delays, with intracranial calcifications, microcephaly, hypertonicity, and seizures. They have eye involvement, including microphthalmos, cataracts, chorioretinitis, blindness, and retinal dysplasia. Some infants have patent ductus arteriosus, limb anomalies, and recurrent skin vesicles, with a short life expectancy (Baley & Toltzis, 2011).

In 85% of cases, HSV is transmitted from mother to neonate through viral shedding during labor and birth. This can occur whether or not the mother has active lesions. Primary maternal infections after 32 weeks of gestation present a higher risk for the fetus and newborn than early or recurrent infections.

Approximately 10% of neonates infected with HSV acquire the virus after birth from the mother, family member, or hospital personnel. Five percent of newborns are infected with HSV in utero (Kimberlin et al., 2013).

SAFETY ALERT

Due to concern regarding symptomatic and asymptomatic shedding of HSV among hospital personnel, nursery personnel with cold sores should practice strict hand hygiene and wear a mask. However, no evidence indicates that they should be removed from the nursery unless they have a herpetic whitlow (primary HSV infection of the terminal segment of a finger) (Baley & Toltzis, 2011).

Clinically, neonatal HSV infections are classified as disseminated infection (25%), CNS disease (30%), or localized infection of the skin, eye, or mouth (45%). Although the incubation period for HSV is 1 to 7 days, the onset of symptoms varies with the type of infection (Baley & Toltzis, 2011).

Disseminated infections are sepsis-like and can involve virtually every organ system but are most likely to involve the liver, adrenal glands, and lungs. By 5 to 11 days of age affected infants show signs of bacterial sepsis or shock. Death often results within 1 week of the onset of symptoms and is related to respiratory failure, pneumonitis, DIC with shock, and CNS complications (Baley & Toltzis, 2011; White & Magee, 2011).

In CNS disease, blood-borne seeding of the brain results in multiple lesions of cortical hemorrhagic necrosis. It also can occur alone or in association with oral, eye, or skin lesions. Brain involvement usually manifests in the second to fourth weeks of life. Skin lesions are apparent in 60% to 70% of infants, and the CSF of less than 50% of infants reveals the virus. The presenting manifestations include lethargy, poor feeding, irritability, and local or generalized seizures. If untreated, the mortality rate in CNS disease approaches 50%; the vast majority of survivors experience severe sequelae such as microcephaly and blindness (Baley & Toltzis, 2011).

Localized HSV infections most often occur with skin findings or rarely with isolated oral cavity lesions (Fig. 35-9). Without treatment CNS or disseminated disease develops in 70% of the infants with skin vesicles. Ocular involvement, which can occur alone, can be secondary to either HSV-1 or HSV-2. Ocular disease may not be discovered for months. Microphthalmos, cataracts, and corneal scarring can result from chorioretinitis, keratitis, and retinal hemorrhage (Baley & Toltzis, 2011).

Gloves should be worn when caregivers are in contact with these infants. The neonate's eyes, oral cavity, and skin are inspected carefully for the presence of any lesions. Cultures are obtained from the mouth, eyes, and any possible lesions. The infant can be discharged with the mother if the infant's cultures are negative for the virus. As long as no suspicious lesions are present on the mother's breasts, breastfeeding is allowed. For the infant at risk, prophylactic topical eye ointment (vidarabine) is administered for 5 days for prevention of keratoconjunctivitis. If there is a history of active lesions at delivery in a woman with no previous history of HSV infection neonatal prophylaxis with acyclovir is recommended (Kimberlin et al., 2013). Blood, urine, and CSF specimens should be cultured

FIG 35-9 Neonatal herpes simplex virus oral lesions. (Courtesy David A. Clarke, Philadelphia, PA.)

when indicated clinically. Therapy includes general supportive measures, as well as treatment with acyclovir. Duration of treatment is 14 to 21 days for infants with disseminated or CNS disease and 14 days for the skin-eye-mouth form of the disease (Baley & Toltzis, 2011). After completing the course of IV acyclovir, an oral acyclovir is given for 6 months to prevent recurrence (Kimberlin et al.). When there is ocular involvement, ophthalmic ointment should be administered simultaneously (Schleiss & Patterson, 2012).

Parvovirus B19

Parvovirus B19 is well known in older children as fifth disease or “slapped cheek illness” because of the characteristic facial appearance of the affected child. During pregnancy, infection can result in miscarriage, fetal anemia, hydrops fetalis, IUGR, or stillbirth. Vertical transmission of parvovirus to the fetus occurs in about one third of maternal infections, and the overall fetal loss rate after infection is about 6% (Schleiss & Patterson, 2012).

The virus can be isolated from amniotic fluid, fetal blood, or tissues using DNA PCR assay. Viral load is not predictive of fetal morbidity and mortality (Baley & Toltzis, 2011).

There are no specific antiviral medications to treat parvovirus B19 infection and there is no vaccine. If a pregnant woman is confirmed with the infection, the fetus should be closely monitored for the development of fetal hydrops using serial ultrasound examinations (Schleiss & Patterson, 2012). Protocols for intrauterine management have not been well developed, but intrauterine transfusion to treat anemia is the only currently accepted therapy. There is insufficient evidence about the long-term effects of parvovirus (de Jong, Walther, Kroes, & Oepkes, 2011).

Enterovirus

Enteroviruses include poliovirus, coxsackievirus, and echovirus. Nonpolio enteroviruses are among the most common viruses that infect humans. Enterovirus is the third most common cause of viral outbreaks in the NICU (following rotavirus and respiratory syncytial virus) (Civardi, Tziella, Baldanti, et al., 2013). Group B coxsackieviruses and echovirus 11 are the serotypes

most commonly affecting neonates and can be transmitted transplacentally or through exposure to maternal blood or secretions during birth. The risk of transmission is increased with maternal enterovirus illness around the time of birth and a lack of maternal antibodies to the specific type of enterovirus. Antenatal transmission increases the risk of severe disease and death (Baley & Toltzis, 2011).

The onset of infection following perinatal transmission is usually within 1 to 2 weeks after birth. Usual presenting symptoms are fever, irritability, lethargy, and poor feeding; rash, respiratory symptoms, and GI symptoms can occur. Clinical manifestations can be severe and include myocarditis, meningitis, respiratory distress, and hepatitis. Deaths are usually due to multiorgan involvement (Schleiss & Patterson, 2012).

There is no vaccine or any treatment approved by the U.S. Food and Drug Administration (FDA) for nonpolio enteroviruses. Immunoglobulin is sometimes used to treat symptomatic infants. Pleconaril is under investigation as a treatment for enteroviral infection in neonates and infants (Schlapbach, Ersch, Balmer, et al., 2013).

Bacterial Infections

Group B Streptococcus

GBS infection is a leading cause of neonatal morbidity and mortality in the United States (Tudela, Stewart, Roberts, et al., 2012). The practice of giving prophylactic antibiotics to women in labor who are GBS positive has significantly reduced the incidence and severity of early-onset GBS infection in the newborn (Fairlie, Zell, & Schrag, 2013). The incidence of both early- and late-onset neonatal GBS infection is 0.3 per 1000 live births (Ferrieri & Wallen, 2012; GBS Prevention Working Group, 2013).

Early-onset GBS infection in the neonate usually occurs in the first 7 days of life but most commonly manifests in the first 24 hours after birth. Risk factors for the development of early-onset GBS include low birth weight, preterm birth, rupture of membranes of more than 18 hours, maternal fever, previous GBS infant, maternal GBS bacteriuria, use of intrauterine fetal monitoring, maternal age less than 20 years, and Hispanic or African-American ethnicity. Early-onset disease usually results from vertical transmission from the birth canal and manifests as systemic infection or respiratory illness that mimics the symptoms of severe respiratory distress. The infant can rapidly develop pneumonia, shock, or meningitis. The mortality rate for early-onset infection is 5% to 20%, with higher rates among preterm infants (Anderson & Gonik, 2011; Ferrieri & Wallen, 2012).

Late-onset GBS infections occur between 1 week and 3 months of age, with an average age at onset of 24 days. Infection can result from vertical transmission or from health care-acquired infection or community exposure. Approximately 30% of infants with late-onset GBS develop meningitis (Anderson & Gonik, 2011). Mortality rates are less than for early-onset infection. Survivors often have neurologic damage (Libster, Edwards, Levent, et al., 2012).

For newborns with suspected GBS infection, the usual treatment is ampicillin in combination with an aminoglycoside. If GBS is identified as the cause of infection, penicillin G alone may be given (Aneja, Varughese-Aneja, Vetterly, & Carcillo, 2011).

Figure 35-10 provides a sample algorithm for managing a neonate whose mother received intrapartum antibiotics for prevention (IAP) of GBS disease in the newborn or suspected chorioamnionitis.

COMMUNITY ACTIVITY

- Visit the American Pregnancy Association website pages related to group B streptococcal infection in pregnancy at <http://americanpregnancy.org/pregnancycomplications/groupbstrepinfection.html>. Review the client information about the disease and prevention strategies.
- Explore the Centers for Disease Control and Prevention (CDC) Group B Strep Home Page at <http://www.cdc.gov/groupbstrep/index.html>. Compare the information on this website with the information on the American Pregnancy Association site.

Escherichia coli

E. coli is responsible for approximately 40% of cases of early-onset neonatal sepsis and 25% of cases of neonatal meningitis in the United States (Edwards, 2011). It is found in the GI tract soon after birth and makes up the bulk of human fecal flora. *E. coli* can cause a variety of neonatal infections including omphalitis, diarrheal illness, pneumonia, peritonitis, urinary tract infection, and meningitis. Risk factors for the development of *E. coli* infections in the newborn include preterm birth, low birth weight, maternal infection, and prolonged rupture of membranes (Edwards).

Neonates most often acquire *E. coli* from the maternal birth canal or rectum during birth, although it also can be hospital acquired through person-to-person transmission or from the hospital environment. Exposure to *E. coli* can result in no infection, infection without illness, gastroenteritis, or rarely, septicemia. Symptoms can appear within the first 24 hours after birth or several weeks later. Clinical signs of *E. coli* sepsis are relatively nonspecific and include fever, temperature instability, apnea, cyanosis, jaundice, hepatomegaly, lethargy or irritability, vomiting, abdominal distention, and diarrhea.

The usual treatment for *E. coli* infection in the newborn is ampicillin or an extended-spectrum cephalosporin and an aminoglycoside. Treatment is continued for 7 to 10 days for bacteremia and at least 14 days for meningitis (Ferrieri & Wallen, 2012). Use of ampicillin in labor as prophylaxis against GBS disease has not been found to increase the risk of early-onset *E. coli* infection (Weston, Pondo, Lewis, et al., 2011) but can cause more virulent *E. coli* disease resulting from ampicillin-resistant organisms (Ferrieri & Wallen).

Staphylococcus aureus

Most staphylococcal infections in the newborn develop within the first few days after birth and involve the skin and soft tissue. Conjunctivitis, presenting with purulent eye discharge, is also a common manifestation of *S. aureus* infection. Skin lesions are typically small vesicles or pustules that are easily treated with topical antimicrobial agents. The skin lesions can appear as large fragile bullae containing clear or purulent fluid. These bullae rupture easily and leave moist, red, denuded areas of skin. A more severe bullous eruption due to staphylococcal infection is scalded skin syndrome characterized by widespread bullous lesions that easily rupture; fever and irritability are also present

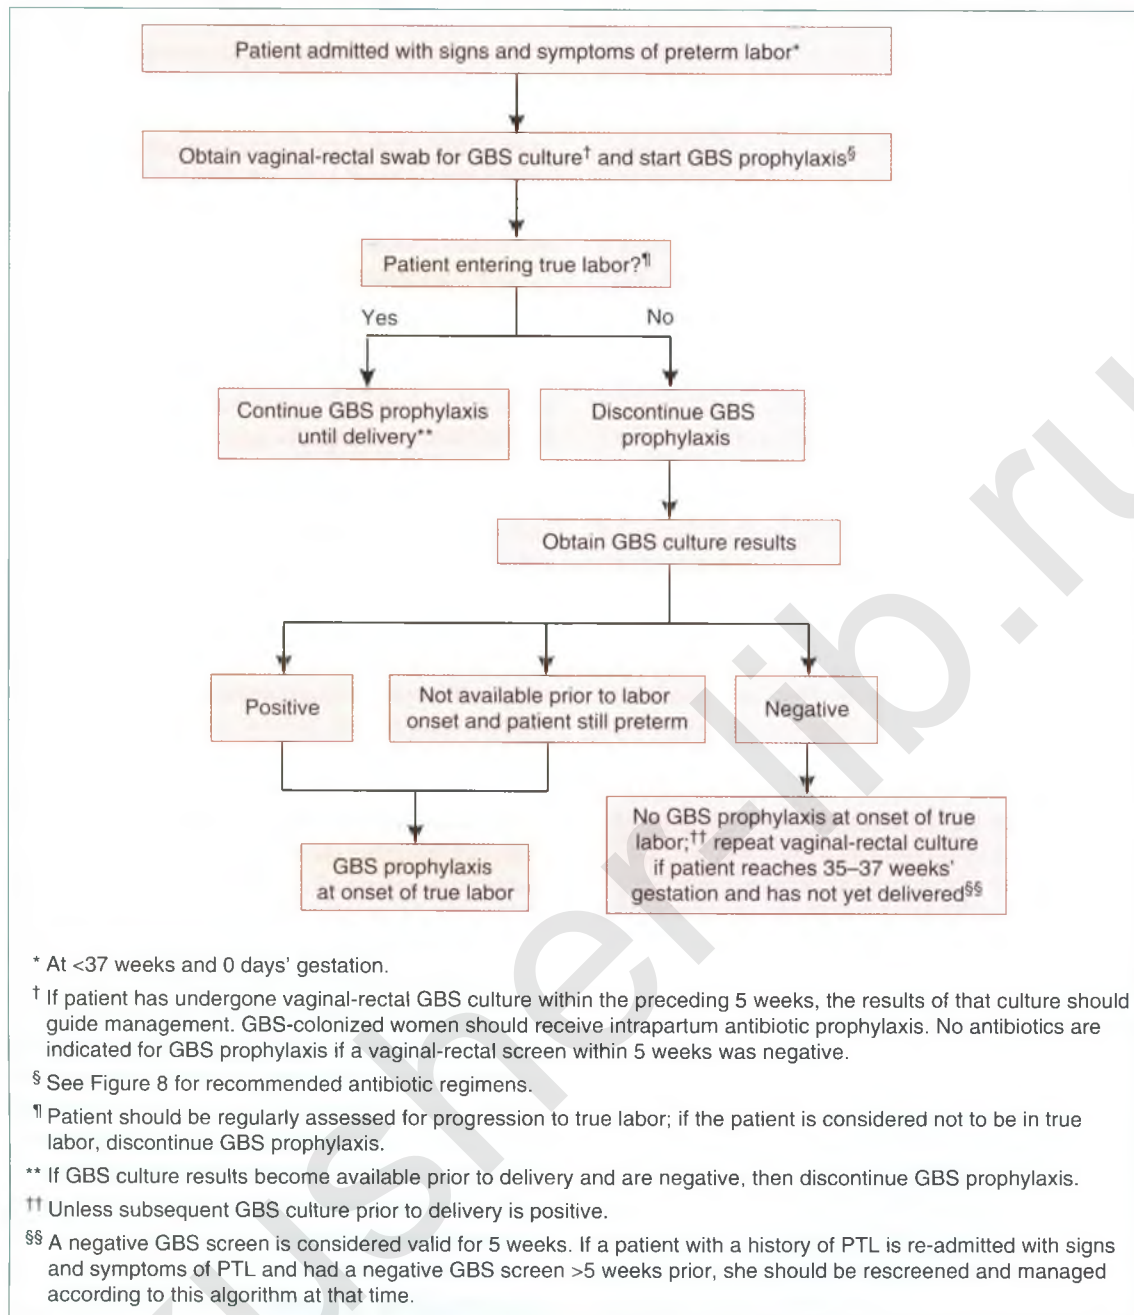

FIG 35-10 Sample algorithm for secondary prevention of early-onset group B streptococcal disease among newborns. (From Verani J.R., McGee L., & Schrag S.J. [2010]. Prevention of perinatal group B streptococcal disease. Revised guidelines from CDC. *MMWR Morbidity and Mortality Weekly Report*, 59[RR10], 1-32.)

(Wright & Cohen, 2012). *S. aureus* can cause serious problems such as abscesses, osteomyelitis, endocarditis, and septic arthritis. Breaks in the skin from IV catheters or scalp electrodes present an opportunity for the development of *S. aureus* abscesses. Colonization of the maternal genital tract with *S. aureus* is not uncommon although the potential for vertical transmission to the neonate is unclear (Jimenez-Truque, Tedeschi, Saye, et al., 2012). The major sources of colonization by *S. aureus* are the hands of medical and nursing personnel.

Although most strains of *S. aureus* are sensitive to semisynthetic penicillins, there are increasing concerns about methicillin-resistant strains. MRSA has caused outbreaks of health

care-acquired infection in neonatal intensive care units and hospital nurseries (Heinrich, Mueller, Bartmann, et al., 2011).

Listeriosis

Listeriosis, caused by *Listeria monocytogenes*, is primarily a food-borne infection that can cause maternal and neonatal illness. Mother-to-infant transmission occurs transplacentally through ascending infection or during birth. Prenatal infection causes chorioamnionitis or endometritis and should be suspected in cases of brown-stained amniotic fluid. It can also cause miscarriage, preterm birth, and stillbirth. Two forms of neonatal listeriosis are recognized: early and late onset. Signs of early-onset

infection are present at birth or in the first 1 to 2 days. Manifestations of infection are sepsis-like symptoms, acute respiratory distress, pneumonia, and more rarely, meningitis or myocarditis. With severe infection the infant can have granulomatosis infantiseptica, which is a widely disseminated granuloma, causing an erythematous rash with pale papules and organ abscesses (Mani & Stocker, 2012). Late-onset listeriosis is more insidious and usually manifests as meningitis. Listeriosis in the newborn is treated with ampicillin and an aminoglycoside (Cekmez, Tayman, Saglam, et al., 2012).

Chlamydia

Chlamydia trachomatis infection is one of the most prevalent sexually transmitted infections in the United States. The highest incidence is among adolescents and young adults aged 15-24 years (CDC, 2014d). Neonatal infection is acquired by newborns in approximately 25% to 60% of all vaginal births by infected mothers and is known to occur in some infants born by cesarean with intact membranes. *Chlamydia trachomatis* causes neonatal conjunctivitis (25% to 50% of exposed infants) and pneumonia (5% to 20% of exposed infants). Chlamydial infection in pregnancy has been suggested as a cause of early and late pregnancy loss, stillbirth, premature labor, and postpartum endometritis (Anderson & Gonik, 2011).

Neonatal chlamydial conjunctivitis, with redness of the eyes, edema of the eyelids, and minimal discharge, develops within a few days to several weeks after birth and usually lasts 1 to 2 weeks. If untreated it can progress to chronic follicular conjunctivitis with conjunctival scarring and corneal microgranulations.

Chlamydial pneumonia usually has a gradual onset, between 4 and 11 weeks of age, beginning with rhinorrhea and progressing to tachypnea and coughing (Anderson & Gonik, 2011). Signs can be subtle and often go unrecognized. It is speculated that pneumonia can occur as a result of movement of the organism from the conjunctiva into the lower respiratory tract; however, conjunctivitis is not a prerequisite to pneumonia.

Chlamydial conjunctivitis is treated with oral erythromycin or azithromycin. The recommended treatment for chlamydial pneumonia is oral azithromycin for 3 days or a 14-day regimen of erythromycin. Erythromycin administration in infants younger than 6 weeks has been associated with an increased risk of infantile hypertrophic pyloric stenosis; therefore, parents should be educated regarding the symptoms of the condition (feeding intolerance, projectile vomiting, and abdominal distention) (Parashette & Croffie, 2013).

Fungal Infections

Candidiasis

Candida infections, formerly known as moniliasis, can occur in the newborn. *Candida albicans*, the organism usually responsible, can cause disease in any organ system. It is a yeastlike fungus (producing yeast cells and spores) that can be acquired during birth from a maternal vaginal infection; by person-to-person transmission; or from contaminated hands, bottles, nipples, or other articles. It usually is a benign disorder in the neonate, often confined to the oral and diaper regions (Edwards, 2011).

Candidal diaper dermatitis appears on the perianal area, inguinal folds, and lower portion of the abdomen. The affected

area is intensely erythematous, with a sharply demarcated, scalloped edge, frequently with numerous satellite lesions that extend beyond the larger lesion. The source of the infection is through the GI tract. Treatment is an antifungal ointment, such as nystatin (Mycostatin) or miconazole 2% (Monistat), applied three times a day for 7 to 10 days. The infant also can be given an oral antifungal preparation to eliminate any GI source of infection (Edwards, 2011).

Oral candidiasis (**thrush**, or mycotic stomatitis) is characterized by the appearance of white plaques on the oral mucosa, gums, and tongue. The white patches are easily differentiated from milk curds; the patches cannot be removed and tend to bleed when touched. In most cases the infant does not seem to be in discomfort from the infection. A few infants seem to have some difficulty swallowing.

Infants who are sick, debilitated, or receiving antibiotic therapy are more susceptible to thrush. Those with cleft lip or palate, neoplasms, and hyperparathyroidism seem to be more vulnerable to fungal infection.

The objectives of management are to eradicate the causative organism, to control exposure to *C. albicans*, and to improve the infant's resistance. Interventions include maintaining scrupulous cleanliness to prevent reinfection. Careful hand hygiene and proper cleanliness of the equipment and environment are essential.

Topical application of nystatin to the mouth is usually sufficient to treat oral thrush. Gentian violet solution can be used in addition to one of the antifungal drugs in chronic cases of thrush; however, it does not treat GI candida and can irritate the oral mucosa. Systemic candida infection is usually limited to critically ill neonates receiving antibiotic therapy for bacterial infections. For these infants antifungal agents such as amphotericin B (Fungizone), fluconazole (Diflucan), or miconazole (Monistat, Micatin) are given intravenously. Infants who are breastfed can acquire candida infection from the mother. If the mother is colonized, treatment for mother and infant is recommended. Breastfeeding can continue even if the mother is receiving systemic antifungal medications (Wright & Cohen, 2011).

SUBSTANCE ABUSE

Substance abuse during pregnancy is associated with significant fetal and neonatal risks. Other than alcohol and tobacco, cocaine and marijuana are the most commonly used substances by pregnant women. Maternal substance abuse is discussed in Chapter 31.

The adverse effects of exposure of the fetus to drugs are varied. They include transient behavioral changes such as alterations in fetal breathing movements or irreversible effects such as fetal death, IUGR, congenital anomalies, or intellectual disability. Critical determinants of the effect of the drug on the fetus include the specific drug, the dosage, the route of administration, the genotype of the mother or fetus, and the timing of the drug exposure. Determining the specific effects of individual drugs on the fetus is made difficult by the common practice of polydrug use, errors or omissions in reporting drug use, and variations in the strength, purity, and types of additives found in street drugs. Maternal conditions such

FIG 35-11 Critical periods in human embryogenesis. (From Reed, M., Aranda, J., & Hales, B. [2006]. *Developmental pharmacology*. In R. Martin, A. Fanaroff, & M. Walsh (Eds.), *Fanaroff and Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* [8th ed.]. St. Louis: Mosby.)

as poverty and malnutrition and comorbid conditions such as STIs further compound the difficulty in identifying the presence and consequences of intrauterine drug exposure. Figure 35-11 shows critical periods in human embryogenesis and the teratogenic effects of drugs. Table 35-4 summarizes the effects of commonly abused substances on the fetus and neonate.

Physiologic signs of withdrawal have been reported in neonates of mothers who use to excess such drugs as barbiturates, alcohol, opioids, or amphetamines. Prescription opioids such as oxycodone (Percodan, OxyContin) have been identified as increasingly popular drugs of abuse that can cause withdrawal symptoms in neonates. Serious withdrawal reactions can be seen in neonates whose mothers abuse psychoactive drugs. Withdrawal symptoms are described as **neonatal abstinence syndrome (NAS)**. This syndrome is characterized by symptoms of CNS irritability, respiratory distress, GI dysfunction, and autonomic dysfunction (Table 35-5). Withdrawal symptoms are more severe in newborns exposed to larger amounts of drugs for longer periods of time. The severity of withdrawal is also related to the timing of maternal drug use in relation to birth. Drug use close to the time of birth increases the severity of withdrawal but delays the onset of symptoms (Nash & Smith, 2012).

Tobacco

Infants born to women who smoke are about 25% more likely to be preterm, weigh on average 200 g (7 oz) less, and have twice the risk of sudden infant death syndrome (SIDS) as compared with infants born to nonsmokers (Bailey, McCook, Hodge, & McGrady, 2012; Brookfield, Wilkinson, Luke, et al., 2011). Some researchers have found links between maternal smoking and birth defects (Hackshaw, Rodeck, & Boniface, 2011). However, others have found that when other variables have been controlled for, no clear association has been found

TABLE 35-4 Summary of Neonatal Effects of Commonly Abused Substances

SUBSTANCE	NEONATAL EFFECTS
Alcohol	Fetal alcohol syndrome (FAS): craniofacial anomalies, including short eyelid opening, flat midface, flat upper lip groove, thin upper lip; microcephaly; hyperactivity; developmental delays; attention deficits Alcohol-related birth defects (ARBDs): milder forms of FAS, cardiac anomalies, failure to thrive
Cocaine	Prematurity, small for gestational age, placental or cerebral infarctions, hyperactivity, difficult to console, hypersensitivity to noise and external stimuli
Heroin	Low birth weight, small for gestational age, neonatal abstinence syndrome (see Table 35-5)
Marijuana	Deficits in attention, cognition, memory, motor skills
Amphetamines	Small for gestational age, prematurity, poor weight gain, lethargy
Tobacco	Prematurity, low birth weight, increased risk for sudden infant death syndrome, increased risk for bronchitis, pneumonia, developmental delays

Data from Bandstra, E., & Accornero, V. (2011). Infants of substance-abusing mothers. In R. Martin, A. Fanaroff, & M. Walsh (Eds.), *Fanaroff and Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* (9th ed.). St. Louis: Mosby; Behnke, M., Smith, V.C., American Academy of Pediatrics (AAP) Committee on Substance Abuse, & Committee on Fetus and Newborn (2013). Prenatal substance abuse: Short- and long-term effects on the exposed fetus. *Pediatrics*, 131(3), e1009-e1024.

between maternal smoking and congenital anomalies (Bandstra & Accornero, 2011).

Maternal smoking exposes the fetus to nicotine and more than 4000 other compounds including carbon monoxide, dioxin, cyanide, and cadmium; adverse health effects have been identified in relation to approximately 30 of these compounds (Behnke, Smith, Committee on Substance Abuse, & Committee

TABLE 35-5 Signs of Neonatal Abstinence Syndrome

SYSTEM	SIGNS
Respiratory	Irregular respirations, tachypnea, apnea, nasal flaring, chest retractions, intermittent cyanosis, rhinorrhea, nasal congestion
Neurologic	Irritability, tremors, shrill cry, incessant crying, hyperactivity, disturbed sleep pattern, seizures, hypertonicity, increased deep tendon reflexes, exaggerated Moro reflex
Autonomic dysfunction	Frequent yawning, frequent sneezing, tearing, excessive generalized sweating, mottling of skin, fever
Gastrointestinal	Abnormal feeding pattern, uncoordinated and ineffectual sucking and swallowing reflexes, incessant hunger, frantic sucking, refusal to feed, vomiting, regurgitation, diarrhea

Data from Weiner, S.M., & Finnegan, L.P. (2011). Drug withdrawal in the neonate. In S.L. Gardner, B.S. Carter, M. Enzman-Hines, & J.A. Hernandez (Eds.), *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis: Mosby.

on Fetus and Newborn, 2013). Nicotine's vasoconstrictive effects on the placenta and umbilical vessels contribute to fetal hypoxia and undernourishment of the fetus. Nicotine has harmful effects on fetal brain development, resulting in deficits in intellectual ability, emotional development, and behavior (Behnke et al., 2013). The effects include poor auditory responsiveness, fine motor tremors, hypertonicity, and decreased verbal comprehension (Rosenthal & Weitzman, 2011).

Nicotine and cotinine, the two pharmacologically active substances in tobacco, are found in higher concentrations in infants whose mothers smoke. These substances can be secreted in breast milk for up to 2 hours after the mother has smoked. Smoking is related to low milk supply and poor infant weight gain (AAP Section on Breastfeeding, 2012).

Increasing concern surrounds secondhand smoke and its potential effects on infants and children. Exposure to secondhand smoke increases the risk of ear infections, respiratory illnesses such as asthma and bronchitis, and SIDS (Aguilera, Pedersen, Garcia-Esteban, et al., 2013; Brookfield et al., 2011). It is not clear whether the association between smoking and SIDS reflects in utero exposure or passive exposure postnatally, or both.

Smoking cessation during pregnancy greatly decreases the chance of fetal complications; therefore, women should be counseled regarding smoking cessation programs. Mothers and all others should refrain from smoking near the infant.

Alcohol

Alcohol consumption during pregnancy is a growing concern. Alcohol ingestion during pregnancy is associated with short- and long-term effects on the fetus and newborn, which are subsumed under the term *fetal alcohol spectrum disorders (FASDs)*. FASDs include specific conditions such as fetal alcohol syndrome, alcohol-related neurodevelopmental disorder, and alcohol-related birth defects. FASDs are estimated to occur in as many as 10 of every 1000 births in the United States. However, the full extent of the problem is unknown and more prevalence studies are needed (Riley, Infante, & Warren, 2011).

Ethanol easily crosses the placenta. The quantity of alcohol required to produce fetal effects is unclear, but it is known that infants born to heavy drinkers are at higher risk of congenital

FIG 35-12 Infant with fetal alcohol syndrome. (From Markiewicz, M., & Abrahamson, E. [1999]. *Diagnosis in color: Neonatology*. St. Louis: Mosby.)

abnormalities than those born to moderate drinkers. Alcohol withdrawal can occur in neonates, particularly when maternal ingestion occurs near the time of birth. Signs and symptoms include jitteriness, increased tone and reflex responses, and irritability. Seizures are also common.

Fetal alcohol syndrome (FAS) is based on minimal criteria of signs in each of three categories: prenatal and postnatal growth restriction; CNS malfunctions, including cognitive impairment; and craniofacial features such as microcephaly, small eyes or short palpebral fissures, thin upper lip, flat midface, and an indistinct philtrum. Neurologic problems in FAS children include some degree of IQ deficit, attention deficit disorder, diminished fine motor skills, and poor speech. These children have been shown to lack inhibition, have no stranger anxiety, and lack appropriate judgment skills (Bandstra & Accornero, 2011).

Infants exposed prenatally to alcohol who are affected but do not meet the criteria for FAS can be said to have **alcohol-related neurodevelopmental disorders (ARNDs)** or **alcohol-related birth defects (ARBDs)**. These disorders run the gamut from learning disabilities and behavioral problems to speech or language problems and hyperactivity. Often these problems are not detected until the child goes to school and learning problems become evident. Similar birth defects can be seen with other disorders, such as fetal hydantoin syndrome (from exposure to antiepileptic drugs); therefore, a careful history is needed.

Predictable abnormal patterns of fetal and neonatal morphogenesis are attributed to severe, chronic alcoholism in women who continue to drink heavily during pregnancy. The pattern of growth deficiency begun in prenatal life persists after birth, especially in the linear growth rate, rate of weight gain, and growth of head circumference.

Ocular structural anomalies are common findings (Fig. 35-12). Limb anomalies and a variety of cardiovascular anomalies,

especially ventricular septal defects, pose problems for the child. Cognitive impairment (IQ of 79 or less at age 7 years), hyperactivity, and fine motor dysfunction (poor hand-to-mouth coordination, weak grasp) add to the handicapping problems that maternal alcoholism can impose. Genital abnormalities are seen in daughters of alcohol-addicted mothers. Two thirds of newborns with FAS are girls; the cause of this altered fetal sex ratio is unknown. High alcohol levels are lethal to the developing embryo. Lower levels cause brain and other malformations. Long-term prognosis is discouraging even in an optimal psychosocial environment, when one considers the combination of growth failure and intellectual disability (Kuehn, Aros, Cassorla, et al., 2012; Kully-Martens, Denys, Treit, et al., 2012; Kully-Martens, Treit, Pei, & Rasmussen, 2013; Pei, Job, Kully-Martens, & Rasmussen, 2011).

Heroin

Heroin crosses the placenta and often results in IUGR in exposed infants, although the exact mechanisms of growth inhibition are not clear. There is an increased rate of stillbirths but not of congenital anomalies. Maternal heroin use increases the risk for meconium aspiration, increased neonatal death, microcephaly, neurobehavioral problems, and SIDS (Madgula, Groshkova, & Mayet, 2011). If heroin users are placed on methadone maintenance treatment during pregnancy, perinatal outcomes are improved (Bandstra & Accornero, 2011).

Many of the medical complications attributed to heroin result from prematurity. Other risks include physical dependence in the fetus and the risk of exposure to infections, including hepatitis B and C viruses and HIV. Drug withdrawal in the mother is accompanied by fetal withdrawal, which can lead to fetal death. Maternal detoxification in the first trimester carries an increased risk of miscarriage. Detoxification in pregnancy is not recommended because of possible withdrawal-induced fetal distress. Methadone is often used in pregnancy to treat maternal drug cravings and prevent withdrawal.

Heroin withdrawal (neonatal abstinence syndrome) occurs in the majority of infants born to addicted mothers, usually within the first 12 to 48 hours of life. The signs depend on the length of maternal addiction, the amount of drug taken, and the time of injection before birth. The infant whose mother is taking methadone may not demonstrate signs of withdrawal until a week or so after birth. The symptoms of infants whose mothers used heroin or methadone are similar. Initially the infant can be depressed. The withdrawal syndromes can manifest as a combination of any of the following signs. Most commonly, the infant is jittery and hyperactive. Usually the infant's cry is shrill and persistent. The infant may yawn or sneeze frequently. Tendon reflexes are increased, but the Moro reflex is decreased. The neonate can exhibit poor feeding and sucking, tachypnea, vomiting, diarrhea, hypothermia or hyperthermia, and sweating. In addition, an abnormal sleep cycle, with absence of quiet sleep and disturbance of active sleep, has been described in these infants (Bandstra & Accornero, 2011).

If withdrawal is not treated, vomiting, diarrhea, dehydration, apnea, and convulsions can develop. Death can follow. Therapy is individualized. Dehydration and electrolyte imbalance are prevented or treated. Usually one of the following drugs is ordered: phenobarbital, methadone, or clonidine, singly or in combination.

Methadone

Methadone, a synthetic opiate, has been the therapy of choice for heroin addiction since 1965. Methadone crosses the placenta. An increasing number of infants have been born to methadone-maintained mothers, who seem to have better prenatal care and a somewhat better lifestyle than those taking heroin (Bandstra & Accornero, 2011).

NAS (Table 35-5) occurs in the majority of neonates born to women taking methadone. Neither the incidence nor severity of symptoms has been correlated with methadone dose at birth (Wisner, Sit, Reynolds, et al., 2012). Methadone withdrawal resembles heroin withdrawal but tends to be more severe and prolonged. In addition, the incidence of seizures is higher. Seizures usually occur between days 7 and 10. Infants exhibit a disturbed sleep pattern similar to that seen in heroin withdrawal and have a higher birth weight than those in heroin withdrawal, usually appropriate for gestational age. No increased incidence of congenital anomalies is seen.

Late-onset withdrawal occurs at 2 to 4 weeks and can continue for weeks or months. A higher incidence of SIDS also has been reported in these infants (Bandstra & Accornero, 2011). This factor is important for perinatal nurses who coordinate follow-up care for the infant and education for the mother or other caregiver. Pediatric and community health nurses must know about the potential for withdrawal symptoms.

Therapy for methadone withdrawal is similar to the therapy for heroin withdrawal. Buprenorphine, a partial agonist–partial antagonist synthetic opioid with a long duration of action, has gained acceptance and FDA licensing for treating opioid addiction. Preliminary studies indicate that this drug has advantages over methadone in relation to neonatal outcomes such as severity of NAS and length of hospital stay (Gaalema, Scott, Heil, et al., 2012; Pritham, Paul, & Hayes, 2012).

Methadone is not contraindicated during breastfeeding. Minimal amounts are transferred to the infant through breast milk. However, infants exposed to methadone are at greater risk for feeding problems (Wisner et al., 2012).

The long-term effects of methadone exposure are primarily related to neurodevelopmental outcomes. These neonates are at increased risk for developmental delays, poor fine motor coordination, lower intelligence, hyperactivity, learning and behavior disorders, and poor social adjustment. Researchers have noted that it is difficult to separate the effects of methadone from other factors in the environment that can influence neurobehavioral outcomes (Bandstra & Accornero, 2011).

Marijuana

Marijuana use is prevalent among young adults, including women of childbearing age. The primary chemical compound in marijuana—9-tetrahydrocannabinol (THC)—easily crosses the placenta and can remain in the body for as long as 30 days, increasing fetal exposure and potential risk (Behnke et al., 2013).

Marijuana use during pregnancy can result in a shortened gestation and a higher incidence of IUGR. A review of studies examining the effects of marijuana during pregnancy found inconsistent results regarding the drug's effect on birth weight and gestational age (Soto & Bahado-Singh, 2013). No specific teratogenic effects have been identified. Marijuana affects neurotransmitters and brain chemistry in the developing fetus

which can have long-term effects such as deficits in memory, attention, or cognitive function. Marijuana smoking during pregnancy can increase carbon monoxide levels in the blood, which can reduce the amount of oxygen available to the fetus (Bandstra & Accornero, 2011; Behnke et al., 2013).

Compounding the issue of the effects of marijuana is multdrug use, especially among adolescents, that combines the harmful effects of marijuana, tobacco, alcohol, and cocaine. Long-term follow-up studies on exposed infants are needed.

Cocaine

Cocaine crosses the placenta and is found in breast milk. Considerable controversy exists regarding the effects of cocaine on the fetus and neonate. There is a strong association between maternal cocaine use and both tobacco and marijuana use, which makes determining cocaine effects difficult. A meta-analysis did not find an association between illicit drug use and congenital anomalies (Behnke et al., 2013). However, it is possible that habitual cocaine use in pregnancy has negative effects, many of which are too subtle to notice in the newborn and infancy periods. Cocaine is a recognized cause of placental abruption. Infants born to cocaine-abusing mothers show a high rate of perinatal morbidity, IUGR, low birth weight, and preterm birth (Bandstra & Accornero, 2011) (Box 35-1).

Cocaine-dependent neonates do not experience a process of withdrawal as do narcotic-exposed infants but rather show neurotoxic effects of the drug. Signs of exposure have some of the same characteristics as those of heroin withdrawal but can be highly varied. There can be an increased risk for SIDS. The effects of prenatal exposure to cocaine on neonatal behavior

have been studied extensively. Findings indicate that cocaine-exposed infants have limited ability to habituate to stimuli. As these children enter school they demonstrate a reduced capacity for verbal reasoning and difficulties maintaining attention (Bandstra & Accornero, 2011).

Methamphetamine

The fetal and neonatal effects associated with maternal use of methamphetamines in pregnancy are not well known. The limited data regarding the risk of congenital anomalies suggest little or no effect on organogenesis. A higher incidence of placental abruption, preterm birth, and IUGR is associated with methamphetamine use during pregnancy (Geary & Wells, 2013; Ladhani, Shah, & Murphy, 2011; Narkowicz, Plotka, Polkowska, et al., 2013). Behavioral changes in infants exposed prenatally to methamphetamines include decreased arousal, increased stress, and alterations in movement (Bandstra & Accornero, 2011).

Neonatal manifestations of methamphetamine withdrawal have not been clearly identified because of maternal polydrug use. After birth, infants can experience bradycardia or tachycardia that resolves as the drug is cleared from the infant's system. Lethargy can continue for several months, along with frequent infections and poor weight gain. Emotional disturbances and delays in gross and fine motor coordination can be seen during early childhood.

MDMA/Ecstasy

Increasing use of 3,4-methylenedioxymethamphetamine (MDMA), also known as ecstasy, by adolescents and young adults of childbearing age heightens concerns related to fetal and neonatal effects of this substance. This illegal synthetic psychoactive drug has hallucinogenic and stimulant properties. It alters the activity of neurotransmitters in the brain and causes increased heart rate and blood pressure. Animal studies have demonstrated that MDMA can be toxic to nerve cells containing serotonin, causing long-term damage. MDMA alters the body's temperature regulatory abilities and in high doses can cause a sharp increase in body temperature (hyperthermia) leading to liver, kidney, and cardiovascular system failure, and death (National Institute on Drug Abuse, 2012). This substance is transferred to the fetus through the placenta, but the effects on the developing fetus are not well substantiated in human studies. It is thought that maternal use of MDMA increases the risk of congenital anomalies in the fetus and that it can cause long-term problems with learning and memory. More research studies are needed to identify the effects of MDMA on the fetus and neonate (Bandstra & Accornero, 2011).

Other Drugs of Concern

Caffeine

Caffeine is a mild CNS stimulant that is consumed on a regular basis by the majority of Americans. Coffee is the primary source of caffeine for most Americans, although caffeine is also found in tea, chocolate, colas, energy drinks, guarana, and mate (a tea consumed primarily in South America).

The average half-life of caffeine ranges from about 3 to 7 hours, with individual variation in metabolism related to genetic and environmental factors. During the second and third trimesters of pregnancy, caffeine metabolism is slowed due to

BOX 35-1 Fetal and Neonatal Effects of Maternal Cocaine Use During Pregnancy

Physical

- Preterm birth
- Decreased length
- Decreased head circumference
- Low birth weight
- Cerebral infarction
- Abnormal electroencephalogram (EEG)
- Seizures
- Abnormal breathing pattern

Behavioral

- Irritability
- Tremors
- Abnormal sleep pattern
- Hypertonicity
- Increase in auditory startle response
- High-pitched cry
- Excessive sucking
- Disorganized behavior
- Hyporeactivity
- Poor interaction with caregivers
- Inattention and learning problems

Data from Weiner, S.M., & Finnegan, L.P. (2011). Drug withdrawal in the neonate. In S.L. Gardner, B.S. Carter, M. Enzman-Hines, & J.A. Hernandez (Eds.), *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis: Mosby; Hudak, M.L., Tan, R.C., Committee on Drugs, & Committee on Fetus and Newborn. (2012). Neonatal drug withdrawal. *Pediatrics*, 129(2), e540-e560.

hormonal influences. Caffeine readily crosses the placenta and is distributed to all fetal tissues. Because of immature liver function, fetuses metabolize caffeine very slowly (Gregory, Niebyl, & Johnson, 2012).

Although caffeine has not been implicated as a teratogen in humans, there are concerns about its consumption during pregnancy. Moderate intake of caffeine (less than 200 mg/day) is not associated with an increased risk of miscarriage, preterm birth, or low birth weight. There is a lack of evidence regarding the risks of higher caffeine consumption (ACOG Committee on Obstetric Practice, 2010). The American College of Obstetricians and Gynecologists (ACOG) and the March of Dimes recommend that caffeine intake in pregnant women should not exceed 200 mg/day (ACOG Committee on Obstetric Practice, 2010; March of Dimes, 2012).

Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) are the mainstay of treatment for depression and anxiety, with widespread use during pregnancy. Commonly prescribed SSRIs include citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline (Patil, Kuller, & Rhee, 2011). All medications that have been studied are known to cross the placenta and are transferred in breast milk. Their use should be determined by a risk-benefit analysis of the risks to the fetus or neonate with use of the medication weighed against risks of not treating the mother's psychiatric condition. The dosage of SSRIs during pregnancy should be at the lowest effective level (Hudak, Tan, Committee on Drugs, & Committee on Fetus and Newborn, 2012).

There is a lack of definitive evidence related to teratogenic effects of SSRI use during pregnancy (Koren & Nordeng, 2012). A meta-analysis showed an increased risk for cardiovascular defects associated with fetal exposure to antidepressant medications, especially paroxetine. The same meta-analysis did not report an increase of other congenital malformations with maternal antidepressant use (Grigoriadis, VonderPorten, Mamisashvili, et al., 2013).

Maternal use of SSRIs during the second trimester has been associated with preterm birth and low birth weight (Grzeskowiak, Gilbert, & Morrison, 2012; Hayes, Pingsheng, Shelton, et al., 2012). Fetal exposure to SSRIs during the third trimester predisposes the neonate to a behavioral syndrome resembling NAS. Symptoms during the first week of life can be related to drug toxicity or withdrawal and include irritability, agitation, tremors, hypoglycemia, tachypnea, vomiting, and diarrhea. This syndrome is usually mild and lasts for no longer than 2 days. In rare cases the syndrome is severe, with seizures, hyperpyrexia, excessive weight loss, and respiratory problems (Hayes et al., 2012; Patil et al., 2011). Persistent pulmonary hypertension in the newborn (PPHN) has been associated with exposure to maternal SSRIs after 20 weeks of gestation (Kieler, Artama, Engeland, et al., 2012; Patil et al.). There is no increased risk of stillbirth, neonatal mortality, or postneonatal mortality associated with SSRI use during pregnancy (Jimenez-Solem, Andersen, Petersen, et al., 2013; Stephansson, Kieler, Haglund, et al., 2013).

For parents who are concerned about maternal use of psychiatric medications and the fetal or neonatal effects, the nurse can direct them to the following websites: REPROTOX (www.reprotox.org) and TERIS (<http://depts.washington.edu/terisweb>).

CARE MANAGEMENT

The maternal history is the key to identification of newborns who are at risk because of maternal substance abuse or use of other drugs during pregnancy and lactation. Review of the prenatal record can reveal a medical and social history of drug use or abuse and any detoxification treatment used. There can be other factors that contribute to neonatal outcomes and complications. For example, the woman who is addicted to narcotics or cocaine can have infections that compound the risk to the infant, including hepatitis, septicemia, and STIs, including AIDS (Narkowicz et al., 2013). In some cases there is no information in the prenatal record to suggest maternal substance abuse when the woman has, in fact, been using one or more substances during pregnancy.

A thorough assessment of the newborn is performed as described in Chapter 24. The infant's gestational age and maturity are noted. The infant can have IUGR or be preterm with low birth weight. In utero exposure to some drugs results in observable malformations or dysmorphism (abnormality of shape). Neonatal behavior can arouse suspicion. Figure 35-13 shows the most commonly used scoring system for assessing withdrawal symptoms (NAS) (Finnegan, 1990; Hudak et al., 2012). Because many women are multidrug users, the newborn initially can exhibit a confusing complex of signs. The nurse often is the first to observe the signs of drug withdrawal. The nurse's observations help the health care provider differentiate between signs of NAS and other conditions, such as CNS disorders, sepsis, hypoglycemia, and electrolyte imbalance.

Urine or meconium screening can be used to identify substances abused by the mother. Urine screening is most commonly used, but its sensitivity is limited. Initially costly and of limited availability, tests of meconium collected on day 1 or 2 of life have been shown to be sensitive and reliable in detecting the metabolites of several street drugs, including cocaine (Launiainen, Nupponen, Halmesmaki, & Ojanpera, 2013).

Nursing Interventions

Planning for care of the infant born to a substance-abusing mother presents a challenge to the health care team. Parents are included in the planning for the newborn's care and for the care and support of the mother and her newborn at home. A multidisciplinary approach includes home health or community resource personnel (e.g., regulatory agencies such as child protective services).

Education and social support to prevent drug abuse provide the ideal approach. However, given the scope of the drug abuse problem, total prevention is an unrealistic goal.

Nursing care of the drug-dependent neonate involves supportive therapy for fluid and electrolyte balance, nutrition, infection control, and respiratory care. Swaddling, holding, and reducing stimuli, can be helpful in easing withdrawal (see the Nursing Care Plan: The Infant Experiencing Drug Withdrawal [Neonatal Abstinence Syndrome]). Specific suggestions for providing care to infants experiencing withdrawal are listed in Box 35-2.

NEONATAL ABSTINENCE SCORING SYSTEM

System	Signs and Symptoms	Score	AM	PM	Comments
Central Nervous System Disturbances	Excessive high-pitched (or other) cry	2			Daily weight:
	Continuous high-pitched (or other) cry	3			
	Sleeps <1 hour after feeding	3			
	Sleeps <2 hours after feeding	2			
	Sleeps <3 hours after feeding	1			
	Hyperactive Moro reflex	2			
	Markedly hyperactive Moro reflex	3			
	Mild tremors disturbed	1			
	Moderate-severe tremors disturbed	2			
	Mild tremors undisturbed	3			
Moderate-severe tremors undisturbed	4				
Increased muscle tone	2				
Excoriation (specific area)	1				
Myoclonic jerks	3				
Generalized convulsions	5				
Metabolic/Vasomotor/Respiratory Disturbances	Sweating	1			
	Fever <101° (99–100.8° F/37.2–38.2° C)	1			
	Fever >101° (38.4° C and higher)	2			
	Frequent yawning (>3 or 4 times/interval)	1			
	Mottling	1			
	Nasal stuffiness	1			
	Sneezing (>3 or 4 times/interval)	1			
	Nasal flaring	2			
Respiratory rate >60/min	1				
Respiratory rate >60/min with retractions	2				
Gastrointestinal Disturbances	Excessive sucking	1			
	Poor feeding	2			
	Regurgitation	2			
	Projectile vomiting	3			
	Loose stools	2			
Watery stools	3

FIG 35-13 Neonatal Abstinence Scoring System. (From Finnegan, L.P. [1990]. Neonatal abstinence syndrome; assessment and pharmacotherapy. In N. Nelson [Ed.], *Current therapy in neonatal-perinatal medicine* [2nd ed.]. St. Louis: Mosby.)

 **NURSING CARE PLAN**
The Infant Experiencing Drug Withdrawal (Neonatal Abstinence Syndrome)

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
<i>Risk for Injury related to hyperactivity, seizures secondary to passive drug addiction resulting from maternal substance abuse during pregnancy</i>	Infant exhibits no signs of seizure activity.	Administer phenobarbital, clonidine, or other medication per physician order. Decrease environmental stimuli. Plan care activities carefully. Wrap infant snugly and hold tightly. If infant was cocaine exposed, position to avoid eye contact; swaddle infant, use vertical rocking techniques, and use a pacifier. Monitor activity level, note the relation between activity level and external stimulation, and stop external stimulation if it causes activity increase.	To decrease central nervous system (CNS) irritability and prevent seizure activity To minimize stimulation To minimize stimulation To reduce self-stimulation behaviors and protect skin from abrasions To counter poor organizational response to stimuli and depressed interactive behaviors To prevent overstimulation
<i>Imbalanced Nutrition: Less than Body Requirements related to CNS irritability, poor suck reflex, vomiting, and diarrhea</i>	Infant exhibits ingestion and retention of adequate nutrients and appropriate weight gain.	Feed in frequent, small amounts; elevate head during and after feeding, and burp well. Experiment with various nipples. Monitor weight daily and maintain strict intake and output. If intake is insufficient, feed by oral gavage per provider order. Have suction available as required. Administer oral and parenteral fluids per provider order. Monitor hydration status (skin turgor, weight, mucous membranes, fontanels, urine specific gravity, electrolytes) and intake and output.	To diminish vomiting and aspiration To find one most effective in compensating for poor suck reflex To evaluate success of feeding To ensure ingestion of needed nutrients To reduce chances of aspiration To maintain fluid balance
<i>Risk for Deficient Fluid Volume related to diarrhea and vomiting</i>	Infant exhibits evidence of fluid homeostasis.	Monitor hydration status (skin turgor, weight, mucous membranes, fontanels, urine specific gravity, electrolytes) and intake and output.	To evaluate for evidence of dehydration
<i>Ineffective Maternal Coping, Anxiety, Powerlessness related to drug use, infant distress during withdrawal</i>	Mother will accept newborn's condition and participate in care activities, showing evidence of maternal-infant bonding process.	Explain in a nonjudgmental way the effects of maternal drug use on the newborn and the withdrawal process. Encourage open communication (e.g., inform mother of ongoing condition, procedures, and treatment; answer questions; correct misperceptions; actively listen to her concerns). Encourage mother to interact with infant and to become involved in care routines. Explain how to do care procedures, how to avoid excess stimulation, and how to hold and rock infant. If the mother is addicted to cocaine, explain infant's inability to interact, gaze aversion, arching back, and lack of response to cuddling. Make appropriate referrals to social agencies for treatment of maternal drug addiction, infant development programs, and other needed support services.	To provide understanding and reality concerning effects of drug use To provide a sense of respect, provide support, and encourage a sense of control To foster emotional connection To enhance mother's care abilities and her sense of confidence and control To enhance understanding of infant behaviors To ensure adequate resources for care of self and infant

BOX 35-2 Care of the Infant Experiencing Withdrawal (Neonatal Abstinence Syndrome)

- Swaddle the infant with the legs flexed.
- Position the infant's hands in midline with the arms at the side.
- Carry the infant in a flexed position, holding firmly and close to your body. Use a soft-pack baby carrier.
- When interacting with the infant, introduce one stimulus at a time when the infant is in a quiet, alert state.
- Watch for time-out or distress signals (gaze aversion, yawning, sneezing, hiccups, arching, mottled color).
- When the infant is distressed, rock in a slow, rhythmic fashion.
- Offer pacifier for nonnutritive sucking.
- Put the infant in a sitting position with the chin tucked down for feeding.
- Try feeding small amounts at frequent intervals or use a demand-feeding schedule.
- During feedings, avoid eye contact or talking.
- Reduce environmental stimuli (lights, noise).
- Organize care to minimize handling.

Data from Weiner, S.M., & L.P. Finnegan. (2011). Drug withdrawal in the neonate. In S. Gardner, B. Carter, M. Enzman-Hines, & J. Hernandez (Eds.), *Merenstein & Gardner's handbook of neonatal intensive care* (7th ed.). St. Louis: Mosby.

Pharmacologic treatment is usually based on the severity of withdrawal symptoms, as determined by an assessment tool (see Fig. 35-13). When indicated, medications are given as ordered. Neonatal tincture of opium (0.4 mg/ml of morphine equivalent), phenobarbital, and, less commonly, paregoric may be used to control symptoms. Treatment may be needed for 2 weeks or more.

MEDICATION ALERT

The use of naloxone (Narcan) is contraindicated in infants born to narcotic addicts because it can cause severe signs and symptoms of narcotic abstinence syndrome and seizures.

KEY POINTS

- A small percentage of significant birth injuries can occur despite skilled and competent obstetric care.
- The nurse's primary contribution to the welfare of the neonate begins with early observation, accurate recording, and prompt reporting of abnormal signs.
- Metabolic abnormalities of diabetes mellitus in pregnancy adversely affect embryonic and fetal development.
- Prepregnancy planning and good diabetic control, coupled with strict diabetic control during pregnancy, can prevent the embryonic, fetal, and neonatal conditions associated with pregnancies complicated by diabetes mellitus.
- Infection in the neonate can be acquired in utero, during birth, during resuscitation, and from within the nursery.
- The most common maternal infections during early pregnancy that are associated with various congenital malformations are caused by viruses.
- HIV transmission from mother to infant occurs transplacentally at various gestational ages, perinatally by maternal blood and secretions, and by breast milk.
- The nurse often is the first to observe signs of newborn drug withdrawal.
- Providing high-quality perinatal care to a varied population with multiple conditions is complicated by the special needs of high risk drug-dependent clients.
- Signs and symptoms of withdrawal in an infant vary in time of onset depending on the type and dose of drug involved.

The issue of breastfeeding in this population is a difficult one. Although breast milk remains the optimal source of nutrition for these infants, care must be taken to avoid exposing the infant to additional drugs through the breast milk. According to the AAP, mothers who use street drugs should not breastfeed. They also recommend that women enrolled in a supervised methadone treatment program can breastfeed if they are adequately nourished and have negative screening for illicit drugs and HIV (AAP Section on Breastfeeding, 2012). The Society of Obstetricians and Gynecologists of Canada (SOGC) states that methadone maintenance is not a contraindication to breastfeeding (Wong, Ordean, Kahan, & SOGC, 2011). The Academy of Breastfeeding Medicine (ABM) has published a clinical protocol with specific evidence-based guidelines about breastfeeding and drug-dependent women (Jansson & ABM Protocol Committee, 2009).

Drug dependence in the neonate is physiologic, not psychologic. Thus a predisposition to dependence later in life is not believed to be a factor. However, the psychosocial environment in which the infant is raised can create a tendency to addiction.

The mother requires considerable support. Her ability to cope can be impaired due to her history of substance abuse and her life circumstances. She may blame herself for the infant's problems. The infant's withdrawal signs and decreased consolability stress her coping abilities even further. Family members also need support as they assist in caring for the infant. Home health care, treatment for addiction, and education are important. Sensitive exploration of the woman's options for the care of her infant and herself and for future fertility management may help her see that she has choices. This approach helps communicate respect for the new mother as a person who can make responsible decisions.

Hemolytic Disorders and Congenital Anomalies

Debbie Fraser

<http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Differentiate between physiologic and pathologic jaundice in the newborn.
- Develop a nursing plan of care for preventing, identifying, and managing neonatal hyperbilirubinemia.
- Compare Rh and ABO incompatibility and the implications for neonatal outcomes.
- Explain nursing management to prevent the pathologic consequences of hyperbilirubinemia.
- Review prenatal diagnosis of neonatal disorders.
- Present assessment strategies during the postnatal period to aid in diagnosing congenital disorders.
- Describe each congenital disorder presented in this chapter and identify the priority of nursing care for each.
- Describe preoperative and postoperative nursing care of the newborn.
- Develop a nursing care plan for parents of a newborn with a defect or disorder.

Many physiologic alterations occur in infants during the newborn period. The nurse must be alert to any deviations from normal, ranging from an obvious congenital anomaly, such as myelomeningocele, to a less obvious deviation such as a congenital heart defect that can be asymptomatic at birth. The nurse must possess the assessment skills necessary to detect any deviation from normal, as well as the knowledge base to participate in the skilled care of affected infants. The nurse also must be cognizant of the special needs of the family with a child who is born with or acquires an abnormal condition.

The complications that affect newborns can stem from three basic problems: (1) problems relating to gestational age or intrauterine growth that do not follow normal patterns, such as a preterm birth; (2) acquired problems resulting from maternal or newborn physiologic factors, such as ABO incompatibility or infection; and (3) congenital defects. This chapter focuses on acquired problems and congenital anomalies in the neonate.

HYPERBILIRUBINEMIA

Hyperbilirubinemia is a condition in which the total serum bilirubin level in the blood is increased. Normal values are determined by gestational age, days of life, and the baby's general physical condition. Hyperbilirubinemia is characterized by a yellow discoloration of the skin, mucous membranes, sclera, and various organs. This discoloration is referred to as jaundice, or **icterus**. Jaundice is caused primarily by the accumulation in

the skin of unconjugated bilirubin, a breakdown product of hemoglobin formed after its release from hemolyzed red blood cells (RBCs). Jaundice first appears in the infant's face and head and progresses toward the toes. It dissipates in the reverse order. Physiologic jaundice, discussed in Chapters 23 and 24, is the most common finding in newborns and is usually benign. The challenge in the care of neonates with hyperbilirubinemia is to distinguish physiologic jaundice from a serious clinical pathologic condition.

Physiologic Jaundice

Physiologic jaundice occurs in over 60% of healthy term newborns and almost all preterm infants (Lauer & Spector, 2011). Beginning after 24 hours of age, unconjugated bilirubin levels in Caucasian and African-American neonates gradually increase from 2 mg/dl to peak levels of 5 to 6 mg/dl at 72 to 96 hours of age. In Asian-American infants, the level can increase to 10 to 14 mg/dl between 72 and 120 hours of age. In Caucasian and African-American newborns there is a rapid decline in the unconjugated bilirubin level to 3 mg/dl by 5 days after birth; in Asian-American infants, this takes 7 to 10 days (Kaplan, Wong, Sibley, & Stevenson, 2011).

Physiologic jaundice is more common in preterm infants, with the serum bilirubin level typically reaching a mean peak of 10 to 12 mg/dl by the fifth or sixth day of life. It takes longer for the maximal concentration to be reached in preterm than in full-term infants because of the preterm infant's immature liver function and slower metabolic processes.

Pathologic Jaundice

Pathologic jaundice is the result of an increased level of total serum bilirubin that if left untreated can result in acute bilirubin encephalopathy or kernicterus. Although the terms are often used interchangeably, **acute bilirubin encephalopathy** describes the acute central nervous system manifestations seen in the first weeks after birth, whereas **kernicterus** is used to describe the chronic and permanent results of bilirubin toxicity (Hansen, 2011). Kernicterus, though rare, still occurs. Adherence to guidelines by the American Academy of Pediatrics (AAP) (Bhutani & Committee on Fetus and Newborn, 2011) and a clinical position statement by the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN, 2005) should result in kernicterus becoming largely preventable.

The following findings support a diagnosis of pathologic jaundice and, if encountered in an infant, warrant further investigation (Khan & Rahman, 2011):

- Serum bilirubin concentrations of greater than 5 mg/dl in cord blood
- Clinical jaundice evident within 24 hours of birth
- Total serum bilirubin levels increasing by more than 5 mg/dl in 24 hours or increasing at a rate of 0.5 mg/dl/hr
- A serum bilirubin level in a term newborn that exceeds 12.9 mg/dl at any time
- A serum bilirubin level in a preterm newborn that exceeds 15 mg/dl at any time
- Any case of visible jaundice that persists for more than 14 days of life in a term infant

AAP guidelines (Bhutani & Committee on Fetus and Newborn, 2011) and the clinical position statement by AWHONN (2005) note the need for universal screening to identify elevated bilirubin levels in newborns to facilitate the prevention of acute bilirubin encephalopathy and kernicterus. The use of hour-specific serum bilirubin levels to predict newborns at risk for rapidly rising levels is an official recommendation by the AAP Subcommittee on Hyperbilirubinemia (2004) for the monitoring of healthy neonates at 35 weeks of gestation or more before discharge from the hospital. Use of a nomogram helps determine which newborns might need further evaluation after discharge. In many institutions the nomogram is used to determine the infant's risk for development of hyperbilirubinemia requiring medical treatment or closer screening (see Fig. 24-7). Risk factors recognized to place infants in the high risk category for developing severe hyperbilirubinemia include gestational age less than 37 weeks, exclusive breastfeeding, previous sibling who required phototherapy, predischARGE transcutaneous bilirubin TcB or total serum bilirubin (TSB) level in the high risk zone, cephalhematoma or other significant bruising, blood incompatibility with positive direct antiglobulin test, other known hemolytic disease such as glucose-6-phosphate dehydrogenase (G6PD), and East Asian race (AAP Subcommittee on Hyperbilirubinemia, 2004; Kamath, Thilo, & Hernandez, 2011).

It is recommended that healthy infants (35 weeks of gestation or greater) who are considered at low to intermediate risk for hyperbilirubinemia should receive follow-up care within 2 days, with assessment of bilirubin levels based on a risk assessment using tools such as the hour-specific nomogram. Infants at higher risk for hyperbilirubinemia should be seen by the health care provider within 24 hours or sooner, with assessment

BOX 36-1 Potential Causes of Pathologic Hyperbilirubinemia in Neonates

Maternal Factors

- Rh and ABO or other blood group incompatibilities
- Maternal infections
- Maternal diabetes
- Oxytocin administration during labor
- Maternal ingestion of sulfonamides, diazepam, or salicylates near time of birth

Fetal/Newborn Factors

- Prematurity
- Hepatic cell damage by infection or drugs
- Neonatal hyperthyroidism
- Polycythemia
- Intestinal obstruction such as meconium ileus
- Pyloric stenosis
- Biliary atresia
- Sequestered blood (e.g., from cephalhematomas, ecchymosis, or hemangiomas)
- Maternal blood swallowed by neonate
- Glucose-6-phosphate dehydrogenase (G6PD) deficiency
- Thalassemia

of TSB level. Other key recommendations include promoting successful breastfeeding; recognizing that visual estimation of the degree of jaundice, particularly in darkly pigmented infants, can lead to errors; and providing parents with written and verbal information about newborn jaundice (AAP Subcommittee on Hyperbilirubinemia, 2004).

Many potential causes of pathologic hyperbilirubinemia are found in neonates (Box 36-1). The most common are hemolytic diseases of the newborn.

Hemolytic Disease of the Newborn

Hemolytic diseases of the newborn occur most often when the blood groups of the mother and baby are different. The most common are ABO and Rh factor incompatibilities.

The four major blood groups in the ABO system are A, B, AB, and O. People with type A blood have A antigen; those with type B have B antigen; those with type AB have both A and B antigens; and those with type O have no antigens. In turn, people with type A blood have plasma antibodies to type B blood; those with type B blood have antibodies to type A blood; those with type AB blood have no antibodies; and those with type O blood have antibodies to types A and B blood. If a person receives or is exposed to an incompatible blood type, he or she will form antibodies against the antigen in that blood, with agglutination, or clumping, occurring as the antibodies in the plasma mix with the antigens of the different blood group.

The Rh factor, a genetically determined factor present on RBCs, can be a major source of incompatibility. Of the several forms of the Rh antigen, the D antigen is the most significant because it causes the most antibody production in a person who is Rh negative. A person who has the Rh factor is considered Rh positive; a person without it is Rh negative. For example, a mother who has A-negative blood has the A antigen, plasma antibodies to the B antigen, and no Rh factor on her RBCs.

Hemolytic disorders occur when maternal antibodies are present naturally or form in response to an antigen from the

fetal blood crossing the placenta and entering the maternal circulation. The maternal antibodies of the immunoglobulin G (IgG) class in turn cross the placenta, causing hemolysis of the fetal RBCs, resulting in hyperbilirubinemia and jaundice.

Rh Incompatibility

Rh incompatibility, or **isoimmunization**, occurs when an Rh-negative mother has an Rh-positive fetus who inherits the dominant Rh-positive gene from the father. If the mother is Rh negative and the father is Rh positive and homozygous for the Rh factor, all the offspring will be Rh positive. If the father is heterozygous for the factor, there is a 50% chance that each infant born of the union will be Rh positive and a 50% chance that each will be Rh negative. An Rh-negative fetus is in no danger because it has the same Rh factor as the mother. An Rh-negative fetus with an Rh-positive mother also is in no danger. Only the Rh-positive fetus of an Rh-negative mother is at risk. From 10% to 15% of all Caucasian couples and about 5% of African-American couples have Rh incompatibility. It is rare in Asian couples due to the high incidence of ABO incompatibility, which is protective against Rh isoimmunization because of rapid destruction of the fetal RBCs, which prevents Rh antigen exposure and maternal antibody production (Diehl-Jones & Fraser, 2015).

The pathogenesis of Rh incompatibility is as follows. Hematopoiesis (the formation, production, and maintenance of blood cells) in the fetus is well established by the ninth week of gestation (Blackburn, 2013). When fetal RBCs that contain the Rh antigen pass through the placenta into the maternal circulation of an Rh-negative woman the maternal immune system produces antibodies against the foreign fetal antigens. The process of antibody formation is called *maternal sensitization*. Sensitization can occur during pregnancy, birth, miscarriage or induced abortion, amniocentesis, external cephalic version, or trauma. Usually Rh-negative women become sensitized in their first pregnancy with an Rh-positive fetus but do not produce enough antibodies to cause lysis (destruction) of fetal blood cells. During subsequent pregnancies, antibodies form in response to repeated contact with the antigen from the fetal blood, and lysis of fetal RBCs results. The overall incidence of isoimmunization is less than 1% (Kaplan, Wong, & Stevenson, 2012). Multiple gestation, placental abruption, placenta previa, manual removal of the placenta, and cesarean birth increase the incidence of transplacental hemorrhage and the risk of isoimmunization.

Severe Rh incompatibility results in marked fetal hemolytic anemia because the fetal erythrocytes are destroyed by maternal Rh-positive antibodies. Although the placenta usually clears the bilirubin resulting from the RBC breakdown, in extreme cases fetal bilirubin levels increase. This results in fetal jaundice, also known as *icterus gravis*.

The fetus compensates for the anemia by producing large numbers of immature erythrocytes to replace those hemolyzed, thus the name for this condition: **erythroblastosis fetalis**. In **hydrops fetalis**, the most severe form of this disease, the fetus has marked anemia, cardiac decompensation, cardiomegaly, and hepatosplenomegaly. Hypoxia results from the severe anemia. In addition, because of decreased intravascular oncotic pressure, fluid leaks out of the intravascular space. This results in generalized edema, as well as effusions into the peritoneal (ascites), pericardial, and pleural (hydrothorax) spaces (Maheshwari

& Carlo, 2011). The placenta is often edematous, which, along with the edematous fetus, can cause uterine rupture.

Intrauterine or early neonatal death can occur as a result of hydrops fetalis, although intrauterine transfusions and early birth of the fetus can help to avert this. Intrauterine transfusion involves the infusion of Rh-negative, type O blood into the umbilical vein. The frequency of intrauterine transfusions varies according to institution protocol and fetal hydropic status, but it can be as often as every 2 weeks until the fetus reaches pulmonary maturity at approximately 37 to 38 weeks of gestation. Studies of the use of intrauterine transfusions have demonstrated a high survival rate and low risk of disabilities in the surviving infant (LOTUS Study Group, 2012).

ABO Incompatibility

ABO incompatibility is the most common cause of hemolytic disease in the newborn, although the anemia that results is usually mild. ABO maternal blood group incompatibility occurs in almost 25% of infants; however, only about 1% to 5% have clinical manifestations (Posenchev & Dennery, 2013). It occurs if the fetal blood type is A, B, or AB, and the maternal type is O. It occurs rarely in infants with type B blood born to mothers with type A blood. The incompatibility arises because naturally occurring anti-A and anti-B antibodies are transferred across the placenta to the fetus. Unlike the situation that pertains to Rh incompatibility, first-born infants can be affected because mothers with type O blood already have anti-A and anti-B antibodies in their blood (Manco-Johnson, Rodden, & Hays, 2011). Such a newborn can have a weakly positive direct Coombs' test (also referred to as a direct antiglobulin test [DAT]). The cord bilirubin level usually is less than 4 mg/dl, and any resulting hyperbilirubinemia usually can be treated with phototherapy. Exchange transfusions are required only occasionally. Although ABO incompatibility is a common cause of hyperbilirubinemia, it rarely precipitates significant anemia resulting from the hemolysis of RBCs.

Other Causes of Hemolytic Jaundice

It is not within the scope of this text to discuss the many potential causes of hemolytic jaundice in childhood. However, among African-Americans and people of Mediterranean heritage there is a high incidence of G6PD deficiency (Kaplan et al., 2012). Because it is a sex-linked disease, male offspring are affected more often than females. A deficiency of a red blood cell enzyme in combination with exposure to an oxidant stressor (such as sepsis) results in hemolysis and a decreased RBC life (Nabavizadeh, Rezaie, Sabzali, et al., 2012). The increase in the destruction of RBCs overwhelms the immature neonatal liver's ability to conjugate the indirect bilirubin. Treatment is the same as for any newborn with rapidly rising serum bilirubin levels. Other metabolic and inherited conditions that increase hemolysis and can cause jaundice in the infant include galactosemia, Crigler-Najjar disease, and hypothyroidism (Blackburn, 2013).

Acute Bilirubin Encephalopathy

The goal of care for the infant with hyperbilirubinemia is to prevent acute bilirubin encephalopathy (ABE) and kernicterus. Acute bilirubin encephalopathy is caused by the deposition of bilirubin in the brain, especially within the basal ganglia, the

cerebellum, and the hippocampus. Normally bilirubin does not cause harm because it is bound to albumin and carried to the liver to undergo conjugation. However, once albumin binding sites are saturated, the bilirubin circulates as unconjugated (indirect) bilirubin, which is highly lipid soluble and capable of crossing the blood-brain barrier. Circulation of unconjugated bilirubin can reach toxic levels and become deposited in the basal ganglia, resulting in the yellowish staining of the brain tissue and the necrosis of neurons.

Acute bilirubin encephalopathy, which can develop in newborns with no apparent signs of clinical jaundice, is directly related to the total serum bilirubin level, although these levels alone do not predict the risk of brain injury. In a term infant, a serum bilirubin level of 25 mg/dl is considered the upper limit, beyond which the risk for acute bilirubin encephalopathy increases. However, the condition can occur at much lower levels in premature infants or infants with other complications.

Some of the perinatal events that increase the likelihood of acute bilirubin encephalopathy, even at these lower bilirubin levels, include hypoxia, asphyxia, acidosis, hypothermia, hypoglycemia, sepsis, treatment with certain medications, and hypoalbuminemia. In essence, any condition that interferes with the conjugation of bilirubin or competes for albumin-binding sites increases the risk that unconjugated bilirubin can pass through the blood-brain barrier and cause damage to the central nervous system (CNS).

Acute bilirubin encephalopathy is associated with acute and long-term signs of neurologic damage (Gazzin & Tiribelli, 2011; Hansen, 2011). The clinical manifestations typically appear between 2 and 6 days after birth and go through several phases as the disease progresses. During the first phase the newborn is hypotonic and lethargic and has a poor suck and depressed or absent Moro reflex. These subtler signs are followed by the appearance of a high-pitched cry, opisthotonos (severe muscle spasm that causes the back to arch acutely), spasticity, hyperreflexia, and fever. If allowed to progress to the third phase, the neonate will demonstrate a shrill cry, apnea, deep stupor to coma, seizures, and hearing and visual disturbances. Death can occur from cardiovascular collapse (Watchko, 2012).

About half of affected infants survive, although they often have permanent sequelae including extrapyramidal movement disorders (especially dystonia and athetosis), gaze abnormalities (especially an upward gaze), auditory disturbances (especially sensorineural hearing loss), cognitive impairment, and enamel dysplasia of the deciduous teeth. Movement abnormalities and auditory disturbances are almost always present. Kernicterus is the irreversible, chronic consequence of bilirubin toxicity (Hansen, 2011; Gazzin & Tiribelli, 2011). It develops in approximately 30% of infants with untreated hemolytic disease and hyperbilirubinemia greater than or equal to 25 to 30 mg/dl. The classic symptoms of kernicterus include severe dystonia with or without athetosis, deafness or severe hearing impairment, impaired oculomotor function, and dental enamel dysplasia of the deciduous teeth. Over the first year of life a baby demonstrates the characteristic findings of hypotonia, active deep tendon reflexes, persistent tonic neck reflex, upward gaze, sensorineural hearing loss, and difficulty meeting developmental milestones. Severe cognitive impairment and

spastic quadriplegia often occur. Treatment for kernicterus is supportive (Ambalavanan & Carlo, 2011; Blackburn, 2013).

CARE MANAGEMENT

It is important to determine the blood type and Rh factor of the pregnant woman prenatally. Early identification of the Rh-negative woman is critical, and care must be taken to prevent sensitization. The nurse must obtain a thorough history to assess for events that could have caused the woman to develop antibodies to the Rh factor. Such events include (1) previous pregnancy with an Rh-positive fetus; (2) transfusion with Rh-positive blood, which causes immediate sensitization; (3) miscarriage or induced abortion after 8 or more weeks of gestation; (4) amniocentesis performed for any reason; (5) premature separation of the placenta; (6) external version; and (7) trauma. See Nursing Care Plan.

Because hematopoiesis is well developed in the fetus by the ninth week of gestation, a woman who has had a miscarriage or induced abortion after this time or has previously given birth may have been inoculated with fetal blood at the time of placental separation. During amniocentesis the needle can cause localized damage to the single layer of cells that separates the maternal and fetal circulation in the placenta, thereby allowing fetal RBCs to enter the maternal circulation.

If any of these events has occurred, the nurse checks the woman's record to determine whether she has received **Rh immune globulin**, such as RhoGAM (WinGAM), which is a commercial preparation of passive antibodies against the Rh factor (see the Medication Guide, Chapter 21). This injection of anti-Rh antibodies destroys any fetal RBCs in the maternal circulation and blocks the maternal antibody production. Rh immune globulin is 90% effective in preventing sensitization. It is recommended that it be given to an Rh-negative mother at 28 weeks of gestation; within 72 hours after delivery; after an invasive procedure such as amniocentesis, chorionic villus sampling (CVS), or percutaneous umbilical blood sampling (PUBS); and any time there is a risk of fetal-maternal hemorrhage. It is also recommended after induced abortion, miscarriage, and ectopic pregnancy (Box 36-2) (Griffey, Chen, & Krehbiel, 2012; Kaplan et al., 2011).

At the first prenatal visit of an Rh-negative woman with a fetus who may be Rh positive, an indirect **Coombs' test** should be done to determine whether she has antibodies to the Rh antigen. In this test the maternal blood serum is mixed with Rh-positive RBCs. If the Rh-positive RBCs agglutinate or clump, this indicates that maternal antibodies are present or that the mother has been sensitized. The dilution of the specimen of blood at which clumping occurs determines the titer, or level, of maternal antibodies. This titer indicates the degree of maternal sensitization. A level of 1:8 rarely results in fetal jeopardy. If the titer reaches 1:16, amniocentesis is performed to determine optical density (ΔOD) of amniotic fluid to estimate fetal hemolytic process (see Chapter 26). Rising bilirubin levels can indicate the need for an intrauterine transfusion. Genetic testing allows early identification of paternal zygosity at the RhD gene locus, thus allowing earlier detection of the potential for isoimmunization and precluding further maternal or fetal testing.

The indirect Coombs' test is repeated at 28 weeks. If the result remains negative, indicating that sensitization has not occurred, the woman is given an intramuscular injection of

BOX 36-2 Indications for Amount of Rh Immune Globulin to Be Administered

50 mcg

- After chorionic villus sampling, ectopic pregnancy, miscarriage, or abortion before 13 weeks of gestation

300 mcg

- After any of the following events:
 - Miscarriage or induced abortion after 13 weeks of gestation
 - Percutaneous umbilical blood sampling
 - Amniocentesis
 - Placental abruption or placenta previa
 - Trauma
 - At 28 weeks of gestation
 - Within 72 hours after the birth of a preterm or term Rh-positive infant

More than 300 mcg

- After a large transplacental hemorrhage
- After a mismatched blood transfusion
- After third-trimester fetal demise

Data from Moise, K. J. (2014). Hemolytic disease of the fetus and newborn. In R. K. Creasy, R. Resnik, J. D. Iams, et al. (Eds.), *Creasy & Resnik's maternal-fetal medicine: Principles and practice* (7th ed.). Philadelphia: Saunders

Rh₀(D) immune globulin. If the test result is positive, showing that sensitization has occurred, it is then repeated every 4 to 6 weeks to monitor the maternal antibody titer as just described.

Prevention of hyperbilirubinemia is the primary prenatal focus of care. The implementation of interventions focused on the care of the woman whose fetus is at risk for hyperbilirubinemia is essential to prevent problems in the newborn. Prenatal control of diabetes mellitus, prevention of maternal infection, avoidance of drugs such as diazepam and salicylates near the time of birth, and prevention of preterm birth reduce the risk.

The fetus and maternal antibody titers are monitored prenatally. Several methods are used to detect fetal anemia: amniocentesis to measure ΔOD 450, PUBS or cordocentesis, and middle cerebral artery peak systolic velocity (MCA-PSV). Although ultrasound-guided cordocentesis is the gold standard for detecting fetal anemia, MCA-PSV is being used increasingly as an accurate, noninvasive means to detect fetal anemia. This study is done using Doppler ultrasound (Kelly & Moore, 2012).

If amniocentesis reveals that the ΔOD is high or the MCA-PSV is increased, cordocentesis is performed to assess fetal hematocrit. If the hematocrit is less than 30%, intrauterine transfusion is indicated (Fox & Saade, 2012). Intrauterine transfusion can be done every 1 to 2 weeks between 26 and 32 weeks. If the endangered fetus is at more than 32 weeks of gestation, a preterm birth may be indicated, usually by cesarean.

Postpartum interventions focus on preventing sensitization in the mother, if it has not occurred already, and treating any complications in the neonate resulting from the hemolysis of RBCs (see the Nursing Care Plan). The unsensitized Rh-negative mother whose baby is Rh positive should receive Rh₀(D) immune globulin within 72 hours of birth to prevent her from producing antibodies to the fetal blood cells that entered her bloodstream during the birth. One dose accommodates approximately 15 ml of fetal RBCs (Mendez-Figueroa, Dahlke, Vrees, & Rouse, 2013).

At birth the neonate's cord blood is sent to the laboratory to determine the infant's blood type and Rh status. A Coombs' test is performed on this cord blood to determine whether there are maternal antibodies in the fetal blood. The antibody titer indicates the degree of maternal sensitization. If the titer is high, **exchange transfusion** may be indicated. In addition, the prevention of or prompt therapy for perinatal asphyxia, acidosis, cold stress, sepsis, and hypoglycemia will decrease the newborn's risk for severe hemolytic disease and the susceptibility to kernicterus. Early feeding is initiated to stimulate stooling and thus facilitate the removal of bilirubin. See Chapter 24 for a discussion of phototherapy.

Exchange transfusion is needed infrequently because of the improved recognition of neonates at risk of hemolytic disease that can result from isoimmunization. Other factors must always be considered as well, particularly the clinical condition of the infant because it is a procedure with potential complications. Guidelines for the initiation of exchange transfusion in relation to serum bilirubin levels in infants of more than 35 weeks of gestation can be found in the 2004 AAP Clinical Practice Guideline (AAP Subcommittee on Hyperbilirubinemia, 2004).

Exchange transfusion is accomplished by alternately removing a small amount of the infant's blood and replacing it with an equal amount of donor blood. Exchange transfusion replaces the RBCs that would otherwise be hemolyzed by circulating maternal antibodies, removes the antibodies responsible for hemolysis, and corrects the anemia caused by hemolysis of the infant's sensitized RBCs. It also reduces the serum bilirubin level in infants who have severe hyperbilirubinemia from any cause. If the infant has Rh incompatibility, type O Rh-negative blood is used for transfusion so the maternal antibodies still present in the infant do not hemolyze the transfused blood. Depending on the infant's size, maturity, and condition, amounts of 5 to 20 ml of the infant's blood are removed at one time and replaced with donor blood. The double volume or two-volume exchange replaces approximately 170 ml/kg of body weight, or 86% of the infant's total blood volume. The procedure requires approximately 1 hour. After the procedure, phototherapy is continued and the bilirubin levels are monitored every 4 hours (Gregory, Martin, & Cloherty, 2012; Kaplan et al., 2011; Murki & Kumar, 2011).

The infant is monitored closely during and after the procedure, including assessment of heart rate and rhythm, respirations, blood pressure, temperature, and perfusion. Preservatives in donor blood lower the infant's serum calcium and magnesium levels. It is not uncommon for calcium gluconate to be given during the exchange transfusion if symptoms of hypocalcemia become evident. Symptoms of hypocalcemia include jitteriness, irritability, convulsions, tachycardia, and electrocardiogram changes. The nurse monitors the neonate for hypoglycemia during the several hours after the exchange because the high glucose content of the preservatives can stimulate insulin secretion. These high risk neonates typically have dextrose support through an intravenous route (Gregory et al., 2012; Kamath et al., 2011).

Planning for rehabilitative measures is necessary if kernicterus occurs. The family will need the services of many community resources to care for the affected child. An interdisciplinary approach that includes social services must be taken.

 **NURSING CARE PLAN**
The Infant with Hyperbilirubinemia

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
<i>Risk for Injury related to hemolytic disease and treatment effects</i>	Bilirubin levels decrease with treatment; no evidence of harmful effects from phototherapy (e.g., no eye irritation, dehydration, temperature instability, or skin breakdown); and no complications from exchange transfusions.	<p>Initiate early feedings and feed frequently (breastfeeding at least every 3 hours; formula feeding at least every 3-4 hours).</p> <p>Assess skin and mucous membranes for signs of jaundice, indicative of increasing bilirubin levels; monitor total serum bilirubin levels.</p> <p>Note time of jaundice onset.</p> <p>Assess for signs of hypoxia, hypothermia, hypoglycemia, and metabolic acidosis.</p> <p>Initiate phototherapy per physician's order.</p> <p>Provide care consistent with mode of phototherapy.</p> <p>Shield infant's eyes if under phototherapy light.</p> <p>Keep infant nude except for diaper and change positions frequently.</p> <p>Keep skin clean and avoid use of lotions or creams.</p> <p>Maintain adequate fluid intake.</p> <p>Monitor body temperature.</p> <p>Before exchange transfusion, keep infant on nothing by mouth (NPO) status (2 to 4 hours).</p> <p>Check donor blood for compatibility.</p> <p>Have resuscitation equipment (oxygen, Ambu bag, endotracheal tubes, laryngoscope) at bedside.</p> <p>Assist physician with exchange transfusion procedure.</p> <p>Track amounts of blood withdrawn and transfused.</p> <p>Maintain body temperature.</p> <p>Monitor vital signs and observe.</p> <p>After transfusion, continue to monitor vital signs.</p>	<p>To enhance excretion of bilirubin in stools</p> <p>To determine rate of increase and treatment response</p> <p>To help distinguish physiologic from other causes of jaundice</p> <p>Occur as a result of hyperbilirubinemia and increase the risk of brain damage</p> <p>To decrease bilirubin levels</p> <p>To prevent harmful effects of therapy</p> <p>To prevent damage to corneas and retinas</p> <p>To expose maximal body surface</p> <p>To prevent irritation</p> <p>To prevent dehydration</p> <p>To prevent hyperthermia</p> <p>To prevent aspiration</p> <p>To prevent transfusion reaction</p> <p>To prepare for emergency action</p> <p>To promote safety and monitor infant's condition</p> <p>To maintain balanced blood volume</p> <p>To avoid hypothermia and cold stress</p> <p>To recognize signs of hypocalcemia and hypomagnesemia</p> <p>To check for signs of hypocalcemia, hypomagnesemia, hypoglycemia, and umbilical cord for bleeding; to assess for transfusion reaction</p>
<i>Interrupted Breastfeeding related to discharge of mother and continued hospitalization of infant</i>	Mother states desire to continue breastfeeding as much as possible and expresses and stores milk when she cannot come to the hospital to breastfeed the infant.	<p>Encourage the mother to come to the hospital to breastfeed infant as often as feasible and to continue to express and store her breast milk.</p> <p>Provide private and comfortable space for nursing that is available 24 hours a day.</p> <p>Encourage and assist the mother to hold her baby skin-to-skin.</p> <p>Instruct the mother in methods to express and store breast milk.</p> <p>Provide written educational materials and audiovisual aids.</p>	<p>To establish and maintain milk supply and encourage bonding and to provide safe milk for the infant</p> <p>To support the mother in breastfeeding</p> <p>To facilitate attachment and breastfeeding</p> <p>To ensure a safe and adequate milk supply</p> <p>To demonstrate proper techniques for expressing and storing milk and to allow the mother to learn at her own pace</p>

 **NURSING CARE PLAN—cont'd**
The Infant with Hyperbilirubinemia

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
<i>Interrupted Breastfeeding related to discharge of mother and continued hospitalization of infant—cont'd</i>		<p>Recommend using a breast pump and pump according to established guidelines (e.g., pump a minimum of five times a day; pump a minimum of 100 minutes a day; pump long enough to soften breasts).</p> <p>Reassure the mother that infant's nutritional needs will be met through expressed milk or other methods.</p> <p>Review the daily routine of the mother to advise her on ways to incorporate pumping into her daily schedule.</p> <p>Arrange for lactation consultant to meet with mother for education and support.</p> <p>Provide information about breastfeeding support groups.</p>	<p>To provide maximum stimulation for milk production</p> <p>To allay anxiety</p> <p>To promote adequate milk supply</p> <p>To promote successful breastfeeding and milk expression</p> <p>To help the mother obtain emotional support from other breastfeeding mothers</p>
<i>Parental Role Conflict related to separation from hospitalized infant and interruptions of family life due to travel to hospital to see infant</i>	Parents will share responsibilities for child care and home maintenance; parents will visit infant in hospital as often as feasible.	<p>Suggest to parents that they mutually establish a routine for child care for siblings and home maintenance.</p> <p>Encourage the parents to seek assistance and support from friends, relatives, and community groups such as their church.</p> <p>Encourage the parents to travel to the hospital as often as is desirable and feasible.</p>	<p>To enhance communication and provide necessary home activities</p> <p>To meet their needs and ensure that a minimal level of appropriate functioning is maintained</p> <p>To promote breastfeeding and bonding with infant</p>
<i>Deficient Knowledge related to use of home phototherapy</i>	Family demonstrates ability to safely provide home phototherapy for the infant with hyperbilirubinemia.	<p>Explore the family's willingness to try home phototherapy.</p> <p>Assess the family's understanding of hyperbilirubinemia (jaundice) and proposed therapy.</p> <p>Teach the family about use of phototherapy equipment using demonstration—return demonstration, allowing for several practice sessions, and supplement with written materials with pictorial representations.</p> <p>Instruct the family regarding placement of phototherapy light or fiberoptic unit; proper eye care and patching; proper skin care; proper positioning under light; provision of increased fluid intake; monitoring of time under light; monitoring of temperature, skin, eyes, feeding patterns, stooling and voiding patterns; and observation for complications.</p> <p>Stress importance of obtaining the prescribed bilirubin tests on schedule.</p> <p>Give parents a contact number if they have any questions while carrying out therapy.</p>	<p>To evaluate feasibility of home therapy option</p> <p>To establish baseline for teaching</p> <p>To promote safe and effective use of equipment</p> <p>To enable the family to safely and competently care for the infant</p> <p>To assess infant response to therapy</p> <p>To offer ongoing support and increase parent comfort</p>

CONGENITAL ANOMALIES

A **congenital anomaly** is a defect that is present at birth and can be caused by genetic or environmental factors, or both. It is defined as a structural or functional deviation from the normal pattern of development. Congenital defects are reported to occur in 3% of all live births, but this number increases to approximately 6% by 5 years when more anomalies are diagnosed (World Health Organization [WHO], 2012). In addition, the incidence of congenital malformations in fetuses that are aborted is higher than that in infants who are born alive, thus adding to the overall incidence. Congenital defects, including malformations, deformations, and chromosomal abnormalities, are the leading cause of death in infants younger than 1 year of age in the United States, occurring at the rate of 127.7 per 100,000 live births and accounting for 20.8% of infant deaths (Murphy, Xu, & Kochanek, 2013).

The desired and expected outcome of every wanted pregnancy is a normal, functioning infant with a good intellectual potential. Fulfillment of this hope depends on numerous hereditary and environmental factors. Probably all human characteristics have a genetic component, including those that produce symptoms or physical abnormalities that impair a person's fitness. Some disorders or diseases occur through the influence of a single gene or the combined action of many genes inherited from the parents; others result from the action of the intrauterine environment. Many defects appear to occur as the result of multifactorial inheritance, the interaction of multiple genes with environmental factors that affect the embryonic development of the affected system. In about two thirds of all cases of congenital anomalies, there is no identifiable cause. A chromosomal abnormality or gene alteration is responsible for approximately 10% of the major congenital anomalies (Parikh & Wiesner, 2011). Evidence indicates that maternal obesity is significantly linked to spina bifida, cardiac defects, diaphragmatic hernia, hypospadias, omphalocele, anorectal atresia, and limb reductions (Racusin, Stevens, Campbell, & Aagaard, 2012).

Ways of detecting and preventing some of the congenital anomalies are improving continually, as are surgical techniques for the care of the fetus and newborn with certain anomalies. Promoting the availability of these services to populations at risk challenges community health care systems. An interdisciplinary team approach is vital for providing holistic care: the surgical treatment, rehabilitation, and education of the child, as well as psychosocial and financial assistance for the parents. Parental disappointment and disillusion add to the complexity of the nursing care needed for these infants.

The most common congenital anomalies that cause serious problems in the neonate are congenital heart disease, neural tube defects, cleft lip or palate, clubfoot, and developmental dysplasia of the hip. These are thought to result from the interaction of multiple genetic and environmental factors. Minor anomalies are less apparent but are important to identify because they can be a part of a characteristic pattern of malformations. That is, they can point to the presence of a more serious major anomaly and aid in its diagnosis. The presence of a minor anomaly indicates the need for further evaluation of the neonate for other anomalies. Minor malformations are more common in areas of the body that have variable features, such

as the face and distal extremities. Some of the most common minor malformations include the lack of a helical fold of the pinna, simian creases, absent philtrum, or clinodactyly of the fifth finger (Parikh & Wiesner, 2011).

Cardiovascular System Anomalies

During fetal development cell division and differentiation of the organs and tissues of a particular body system sometimes occur rapidly. During these critical periods particular body systems are more susceptible to environmental influences than they are later in gestation. For example, the critical period for the cardiovascular system is from week 3 of embryonic development to week 8, when many women are not aware that they are pregnant.

Congenital cardiac anomalies, with an overall prevalence of approximately 80 per 10,000 births, are the most common of all congenital malformations (Dolk, Loane, & Garne, 2011; Van der Linde, Konings, Slager, et al., 2011). Congenital heart defects (CHDs) are anatomic abnormalities in the heart that are present at birth, although they may not be diagnosed immediately. Congenital heart disease occurs more frequently in preterm infants. There is an increased likelihood of cardiac disease in neonates that are small for gestational age (SGA), as well as in those with congenital infections.

Ventricular septal defect, the most common type of heart defect, with increased pulmonary blood flow (cyanotic lesion) has a prevalence of 1.5 to 3.5 per 1000 births and accounts for about 30% of all congenital heart defects. Tetralogy of Fallot has an incidence of 0.24 to 0.56 per 1000 births and is the most common cardiac defect with decreased pulmonary blood flow (cyanotic lesion) (Rajiah, Mak, Dubinsky, & Dighe, 2011). CHDs are often associated with other extracardiac defects such as renal agenesis, omphalocele, tracheoesophageal fistula, and diaphragmatic hernia. Congenital heart disease is the leading cause of death in children with congenital defects (Bernstein, 2011).

COMMUNITY ACTIVITY

Visit the National Heart, Lung, and Blood Institute website (www.nhlbi.nih.gov/health/health-topics/topics/chd). Under the Types (of defects), review the information on septal defects. In particular, familiarize yourself with the features of ventricular septal defects, the most common type of congenital heart defect. How could you explain this defect in simple terms to parents? Determine where infants from your community go to receive treatment for congenital heart defects.

The etiology of CHDs is multifactorial, chromosomal and/or genetic, and due to environmental teratogens (Kenney, Hoover, Williams, & Iskresky, 2011). This is important information for parents because they often feel guilty thinking that they have done something to cause the defect. The etiology is also important when it comes to counseling the family regarding recurrence risks for future pregnancies. If a sibling is diagnosed with a CHD, the recurrence risk is 1% to 6%, and if two siblings have a CHD, the recurrence risk is 10%; the risk is significantly higher if the person affected is a parent, particularly the mother (Blue, Kirk, Sholler, et al., 2012). Maternal factors known to be associated with a higher incidence of CHDs

include the following (Blackburn, 2013; de Silva, 2013; Fung, Manlhot, Naik, et al., 2013):

- Rubella and cytomegalovirus
- Ingestion of lithium, warfarin (Coumadin), or anticonvulsants such as phenytoin
- Alcohol intake
- Poor nutrition
- Radiation exposure
- Metabolic disorders such as diabetes mellitus and phenylketonuria
- Systemic lupus erythematosus
- Maternal age ≥ 40 years

Maternal smoking is associated with a greater risk of congenital heart disease. Infants born to women who are heavy smokers (≥ 25 cigarettes per day) have an increased risk of having a congenital septal defect (Alverson, Strickland, Gilboa, & Correa, 2011).

Maternal obesity can increase the risk of congenital heart anomalies. An above normal body mass index has been associated with an increased risk for all congenital heart defects, and specifically total anomalous pulmonary venous return, hypoplastic left heart syndrome, left and right ventricular outflow tract defects, and septal defects (Madsen, Schwartz, Lewis, & Mueller, 2013).

Genetic factors are implicated in the pathogenesis of CHDs. It now appears that a much greater percentage of CHDs than believed to be true in the past can be attributed to single gene mutations. This recognition is based on animal models, studies of human familial patterns of inheritance, and the finding of cardiovascular defects as a part of syndromes exhibiting mendelian patterns of inheritance. An example of this is the identification of chromosome 22q11 deletions in infants with DiGeorge syndrome. This syndrome affects an estimated 1 in 4000 live births, making it one of the most frequent genetic disorders with CHDs. The gene or genes located in the chromosomal region involved with DiGeorge syndrome appear to play a major role in the development of cardiovascular defects, particularly truncus arteriosus, absent pulmonary valve syndrome, tetralogy of Fallot, pulmonary atresia, and other abnormalities involving the aortic arch. Congenital heart disease is found in more than 50% of children with trisomy 21 (Down syndrome), 99% of neonates with trisomy 18 (Gilbert syndrome), and 35% of neonates with Turner syndrome (Kenney et al., 2011).

Although traditionally a CHD was classified as either cyanotic or acyanotic, a classification that categorizes cardiac defects physiologically by physiologic consequence is now considered more descriptive (Table 36-1 and Fig. 36-1).

Approximately 25% of congenital heart anomalies are considered severe and may be referred to as critical congenital heart defects (CCHDs). These are often evident immediately after birth, especially defects that cause cyanosis such as transposition of the great vessels. Infants with these anomalies are transferred directly to neonatal intensive care units, preferably those that are equipped to diagnose and medically or surgically treat these types of cardiac emergencies. Even though the structural or functional anomalies are always present at birth, the affected newborns can be asymptomatic because the defect is too small to interfere with sufficient blood flow to the lungs for oxygenation or does not interfere with delivery of oxygenated blood to

TABLE 36-1 Classification of Congenital Cardiac Disease

CLASSIFICATION	EXAMPLES
Severe cyanosis caused by separate circulations and poor mixing	Transposition of the great arteries with or without ventricular septal defect
Severe cyanosis caused by restricted pulmonary blood flow	Tetralogy of Fallot Tricuspid atresia Persistent pulmonary hypertension
Mild cyanosis caused by complete mixing with normal or increased pulmonary blood flow	Total anomalous pulmonary venous connection Truncus arteriosus
Systemic hypoperfusion and congestive heart failure with mild or no cyanosis	Aortic stenosis* Coarctation of the aorta and aortic arch interruption Hypoplastic left heart syndrome
Acyanosis with no or mild respiratory distress	Normal murmurs Pulmonary stenosis Ventricular septal defect Atrial septal defect Patent ductus arteriosus†

*No symptoms with mild forms of disease.

†Congestive heart failure can develop as left-to-right shunt increases with decrease in pulmonary vascular resistance.

Modified from Zahka, K.G. (2011). Approach to the neonate with cardiovascular disease. In R.J. Martin, A.A. Faranoff, & M.C. Walsh (Eds.), *Neonatal-perinatal medicine: Diseases of the fetus and newborn* (9th ed.). St. Louis: Mosby.

the tissues. With growth and maturation the defect can become apparent as the infant or child is exposed to stressors such as growth demands or infection.

In an effort to identify those infants with CCHDs who do not manifest symptoms prior to hospital discharge, current published recommendations for newborn screening include routine pulse oximetry assessment. Infants in well-baby and intermediate nurseries should have pre-discharge pulse oximetry monitoring according to an established algorithm. Infants with a positive screen are evaluated with an echocardiogram and other diagnostic measures as warranted (Kemper, Mahle, Martin, et al., 2011).

If symptoms are present at birth, they can be obvious with the first cry, which can be weak and muffled or loud and breathless. Affected newborns can exhibit cyanosis that is not relieved when given supplemental oxygen, with the cyanosis increasing whenever the child cries or is in the supine position. The bluish gray, dusky color of cyanotic infants can be mild, moderate, or severe. Other infants can be acyanotic and pale, with or without mottling on exertion, which includes crying, feeding, or stooling.

The affected newborn's activity level varies from restlessness to lethargy, and possibly unresponsiveness, except to pain. Persistent bradycardia (a resting heart rate of less than 80 beats/minute) or tachycardia (a rate exceeding 160 beats/minute) can be noted. The cardiac rhythm can be abnormal, and various murmurs may be heard. Signs of congestive heart failure and decreased tissue perfusion can also become evident (Kenney et al., 2011).

Because the cardiac and respiratory systems function together, cardiac disease can be manifested by respiratory signs and symptoms. The nurse assesses the respiratory rate while the newborn is in a resting state. Tachypnea, a respiratory rate greater than 60 breaths/minute without dyspnea, is typically a

subtle clue that the baby possibly has a cardiac malformation. Increased respiratory depth or hyperpnea is often noted when the neonate has a cardiac lesion that is obstructing blood flow to the lung. Signs that can indicate the development of congestive heart failure are feeding difficulties and increasing respiratory

distress, especially tachypnea such that the infant has to stop feeding to breathe.

A major role of the nurse is to assess infants for abnormal findings, which must be reported immediately. Newborns exhibiting these symptoms require prompt diagnosis and appropriate

Atrial septal defect (ASD)

An ASD is an abnormal opening between the right and left atria. Basically, three types of abnormalities result from incorrect development of the atrial septum. An incompetent foramen ovale is the most common defect. The high ostium secundum defect results from abnormal development of the septum secundum. Improper development of the septum primum produces a basal opening known as an *ostium primum defect*, frequently involving the atrioventricular valves. In general, left-to-right shunting of the blood occurs in all atrial septal defects.

Atrioventricular canal (AVC) defect

An AVC defect is an incomplete fusion of the endocardial cushions. It consists of a low atrial septal defect that is continuous, with a high ventricular septal defect and clefts of the mitral and tricuspid valves, creating a large central atrioventricular valve that allows blood to flow between all four chambers of the heart. Flow is generally from left to right. It is the most common cardiac defect in children with Down syndrome.

Coarctation of the aorta (COA)

COA is characterized by localized narrowing of the aorta near the insertion of the ductus arteriosus, resulting in increased pressure proximal to the defect (head and upper extremities) and decreased pressure distal to the defect (body and lower extremities).

Pulmonic stenosis (PS)

PS is a narrowing at the entrance to the pulmonary artery. Resistance to blood flow causes right ventricular hypertrophy and decreased pulmonary blood flow. Pulmonary atresia is the extreme form of PS: no blood flows to the lungs.

Tricuspid atresia

Tricuspid valvular atresia is characterized by a small right ventricle, a large left ventricle, and usually a diminished pulmonary circulation. Blood from the right atrium passes through an atrial septal defect into the left atrium, mixes with oxygenated blood returning from the lungs, flows into the left ventricle, and is propelled into the systemic circulation. The lungs may receive blood through one of three routes: (1) a small ventricular septal defect, (2) a patent ductus arteriosus, or (3) bronchial vessels.

Ventricular septal defect (VSD)

A VSD is an abnormal opening between the right and left ventricles. VSDs vary in size and may occur in either the membranous or muscular portion of the ventricular septum. Because of higher pressure in the left ventricle, a shunting of blood from the left to the right ventricle occurs during systole. If pulmonary vascular resistance produces pulmonary hypertension, the shunt of blood is then reversed from the right to the left ventricle, with cyanosis resulting.

Patent ductus arteriosus (PDA)

PDA is a vascular connection that, during fetal life, bypasses the pulmonary vascular bed and directs blood from the pulmonary artery to the aorta. Functional closure of the ductus normally occurs soon after birth. If the ductus remains patent after birth, the direction of blood flow in the ductus is reversed by the higher pressure in the aorta.

Aortic stenosis (AS)

AS is a narrowing or stricture of the aortic valve, causing resistance to blood flow in the left ventricle, decreased cardiac output, left ventricular hypertrophy, and pulmonary vascular congestion. AS can be valvular, subvalvular, or supra-valvular (rare). The most serious sequelae relate to the left ventricular hypertrophy (increased end-diastolic pressure, pulmonary hypertension, decreased coronary artery perfusion).

Tetralogy of Fallot (TOF)

TOF is characterized by the combination of four defects: (1) pulmonary stenosis, (2) ventricular septal defect, (3) overriding aorta, and (4) hypertrophy of the right ventricle. It is the most common defect, causing cyanosis in children surviving beyond 2 years of age. The severity of symptoms depends on the degree of pulmonary stenosis, the size of the ventricular septal defect, and the degree to which the aorta overrides the septal defect.

Transposition of the great vessels (TGV)

TGV is an embryologic defect caused by a straight division of the bulbar trunk without normal spiraling. As a result, the aorta originates from the right ventricle and the pulmonary artery from the left ventricle. An abnormal communication between the two circulations must be present to sustain life.

FIG 36-1 Congenital heart abnormalities. (Modified from Hockenberry, M., & Wilson, D. [2011]. *Wong's nursing care of infants and children* [9th ed.]. St. Louis: Mosby.)

Total anomalous pulmonary venous connection (TAPVC)

TAPVC is a rare defect characterized by a failure of the pulmonary veins to join the left atrium. Instead, the pulmonary veins are abnormally connected to the systemic venous circuit via the right atrium or various veins draining toward the right atrium (e.g., superior vena cava). The abnormal attachment results in mixed blood being returned to the right atrium and shunted from the right to the left through an atrial septal defect.

Truncus arteriosus (TA)

TA is a retention of the embryologic bulbar trunk. It results from the failure of normal septation and division of this trunk into an aorta and pulmonary artery. This single arterial trunk overrides the ventricles and receives blood from them through a ventricular septal defect. The entire pulmonary and systemic circulation is supplied from this common arterial trunk.

Hypoplastic left heart syndrome (HLHS)

HLHS is characterized by underdevelopment of the left side of the heart, resulting in a hypoplastic left ventricle and aortic atresia. Most blood from the left atrium flows across the patent foramen ovale to the right atrium, to the right ventricle, and out the pulmonary artery. The descending aorta receives blood from the patent ductus arteriosus supplying systemic blood flow.

FIG 36-1, cont'd Congenital heart abnormalities.

therapy in a neonatal or pediatric intensive care unit. Interventions include administering oxygen as ordered, administering cardiotoxic and other medications such as diuretics that rid the body of accumulated fluid, decreasing the workload of the heart by maintaining a thermoneutral environment, feeding with the gavage method if necessary, and preventing crying if this precipitates cyanosis. Various diagnostic tests such as echocardiography and cardiac catheterization are performed to obtain specific information about the defect and the need for surgical intervention. Significant improvements in diagnosis, medical management, and surgical treatment of CHDs have caused the death rate to decrease significantly, with the result that more of these children are reaching adulthood (Kennedy et al., 2011).

Central Nervous System Anomalies

Most congenital anomalies of the CNS result from defects in the closure of the neural tube during fetal development. Although the cause of **neural tube defects (NTDs)** is unknown, they are thought to stem from the interaction of many genes that can be influenced by factors in the fetal environment. Environmental influences such as maternal treatment with anticonvulsants (e.g., valproic acid or carbamazepine), treatment with methotrexate (a chemotherapeutic medication), folic acid deficiency, and maternal diabetes have been implicated (Kennedy & Koren, 2012). Excessive maternal body heat exposure during the early first trimester, significant febrile illness, and lower socioeconomic status can increase the risk of an NTD (Clements, Challis, & Kennedy, 2012).

Maternal folic acid deficiency has a direct bearing on failure of the neural tube to close. Therefore, as a preventive measure, folic acid supplementation (0.4 mg/day) is recommended for women of childbearing age. Women who are pregnant should take 0.6 mg per day (CDC, 2012).

The incidence of NTD is about 1 per 1000 live births. However, this varies according to race, geographic area, and socioeconomic status (Clements et al., 2012). Prevalence estimates indicate that

the most common NTD, spina bifida, occurs in approximately 3.5 of every 10,000 live births (Parker, Mai, Canfield, et al., 2010). Approximately 95% of all NTDs occur in families that have no history of NTDs. Primary NTDs have an increased recurrence rate in subsequent pregnancies although secondary NTDs do not. Primary NTDs are the result of failure of the anterior neuropore to close or a disruption of an already closed neural tube between 18 and 25 days of gestation. Myelomeningocele, encephalocele, and anencephaly are examples of primary NTDs. Secondary neural tube defects account for 5% of NTDs. They are due to disruption in development of the lower sacral or coccygeal segments during secondary neurulation between 26 days and 8 weeks of gestation (Blackburn, 2013). Examples of secondary NTDs are meningocele, and sacral agenesis or dysgenesis.

Although an NTD is usually an isolated defect, it can occur with some chromosomal abnormalities and syndromes and with other defects such as cleft palate, ventricular septal defect, tracheoesophageal fistula, diaphragmatic hernia, imperforate anus, and renal anomalies. Some NTDs are diagnosed prenatally with fetal ultrasonography and the finding of elevated levels of alpha-fetoprotein in the amniotic fluid and maternal serum. Increased use of prenatal diagnostic techniques and termination of pregnancies have also had an effect on the overall incidence of birth of infants with NTDs.

Encephalocele and Anencephaly

Encephalocele and anencephaly are abnormalities resulting from failure of the anterior end of the neural tube to close. An **encephalocele** is a herniation of the brain and meninges through a skull defect, usually in the occipital area. The prevalence is 0.8 of every 10,000 live births (Parker et al., 2010). Treatment consists of surgical repair and shunting to relieve hydrocephalus, unless a major brain malformation is present. Most of these infants will have some degree of cognitive deficit. **Anencephaly** is the absence of both cerebral hemispheres

and of the overlying skull. It occurs in approximately 2 of every 10,000 births (Parker et al., 2010). This condition is incompatible with life; many of the infants are stillborn or die within a few days of birth. Comfort measures are provided until the infant eventually dies of respiratory failure.

Spina Bifida

Spina bifida, the most common defect of the CNS, results from failure of the neural tube to close at some point. The two categories of spina bifida are spina bifida occulta and spina bifida manifesta, also known as open spina bifida. *Spina bifida occulta*, the milder form, is a malformation in which the posterior portion of the laminae fails to close, but the spinal cord or meninges do not herniate or protrude through the defect and there is no abnormality of the spinal cord, nerve roots, or meninges (Kinsman & Johnston, 2013). Skin typically covers the opening in the spinal cord. There can also be a bulge under the skin where the ends of the spinal cord terminate in fatty tissue. Often a birthmark or a hairy patch is present above the defect.

Spina bifida manifesta occurs predominantly in the lumbar or lumbosacral region and includes meningocele and myelomeningocele. A meningocele is a herniation of the meninges at the site of the defect in the vertebral column and is typically covered by skin. The baby's neurologic function tends to be normal unless other abnormalities are present. A **myelomeningocele** is a herniation of the meninges and spinal cord at the site of the defect, with or without skin or vertebral covering (Fig. 36-2). The sac can tear easily, allowing cerebrospinal fluid (CSF) to leak out and providing an entry for infectious agents into the CNS. Because the nerves are involved, there are motor and sensory deficits below the lesion. Seventy-five percent of the lesions occur in the lumbar area and 80% of affected neonates will have hydrocephalus, typically due to a Chiari malformation (Kinsman & Johnston, 2013). A Chiari malformation results from the improper development and downward displacement of the hindbrain into the cervical spinal canal, which blocks the flow of CSF from communicating with the spinal column and results in the development of hydrocephalus. The long-term prognosis in an affected infant can be determined to a large extent at birth, with the degree of neurologic dysfunction related to the level of the lesion, as the level determines the nerves involved. Prenatal diagnosis makes possible a scheduled cesarean birth, allowing for more careful delivery of the infant's back to try to prevent rupture of the meningeal sac.

Postnatal surgery for myelomeningocele is usually performed within the first 24 hours to close the defect in an effort to prevent further deterioration of the exposed spinal cord, to prevent infection, and to treat hydrocephalus with a ventriculoperitoneal shunt (Adzick, 2013). A major preoperative nursing intervention for a neonate with a myelomeningocele is to protect the protruding sac from injury, rupture, and resultant risk of CNS infection. Such infants should be positioned in a prone-kneeling position and the knees protected from skin breakdown. The sac should be covered with a sterile, moist, nonadherent dressing and cared for using sterile technique. A drape should be placed over the buttocks below the lesion and secured using the drape's adhesive to keep the lesion free of meconium or stool. Neurosurgery and urology consultations should occur as soon as possible after birth. A thorough physical examination is done to evaluate the level of the injury, sensory involvement, sphincter control

(anal wink), and measurement of the fronto-occipital circumference to assess for hydrocephalus (Wilson, Montagnino, & Wilson, 2011). Intake and output are recorded to document the number and character of the voidings and stools as well as the leakage of urine and stool. Nursing assessment includes observations of movement or absence of movement as well as the quality of movements of the lower extremities.

Nurses provide support and information to parents as they begin to learn to cope with an infant who has immediate needs for intensive care and who probably will have long-term needs as well. Based on the type and position of the lesion, along with the neonate's clinical condition, early surgical repair is advocated to preserve cognitive function, decrease the risk of sepsis, and improve the prognosis for ambulation (Verklan & Lopez, 2011). Surgical shunt procedures to prevent increasing hydrocephalus may be needed, such as a ventriculoperitoneal shunt.

SAFETY ALERT

Infants with myelomeningocele are at increased risk for developing latex sensitivity, so they must not come into direct or secondary contact with any products or equipment containing latex (Kinsman & Johnston, 2013).

FIG 36-3 Mother providing kangaroo care to preterm twins; the one on the right has hydrocephalus. The characteristic appearance is an enlarged head, thinning of the scalp, distended scalp veins, and a full fontanel. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

Intrauterine fetal surgery may be performed prior to 26 weeks of gestation to repair a myelomeningocele. The rationale for this intervention is based on direct and indirect evidence that some of the neural damage resulting from the myelomeningocele is acquired in the later part of gestation, caused by amniotic fluid exposure or trauma to the exposed neural elements. Fetal surgery for myelomeningocele is associated with preservation of neurologic function and a reduced risk of hindbrain herniation of the Chiari malformation. There is also a decreased risk of hydrocephalus and the need for a ventriculoperitoneal shunt. Fetal surgery is associated with risk of spontaneous rupture of membranes and preterm birth as well as problems related to the uterine scar such as partial separation of the wound (Adzick, 2013; Gupta, Farrell, Rand, et al., 2012).

Hydrocephalus

Hydrocephalus is a condition in which there is excess CSF in the ventricles of the brain due to overproduction (rare) or a decrease in reabsorption. The most common etiology for the neonate is excess ventricular CSF due to aqueductal flow obstruction. The obstruction prevents the CSF from leaving the head and flowing into the spinal column. Other etiologies include congenital viral infections, myelomeningocele with Chiari malformation, intracranial bleeding, and congenital masses or tumors (Cohen, 2011).

The neonate presents with an increasing frontal-occipital circumference because the head circumference is increasing at an abnormal rate as a result of the increase in CSF pressure (Fig. 36-3). The sutures are widened and the fontanels are full or bulging and tense. Classic signs of increasing intracranial pressure (vomiting, lethargy, and irritability) can be attributed to feeding intolerance. It is thought that “setting sun eyes,” (eyes that are rotated downward) indicate permanent damage to the brain tissue. Serial head ultrasound is used to evaluate the evolving condition. Neurosurgery and genetics services are consulted to evaluate for the placement of a ventriculoperitoneal

shunt versus placement of a reservoir and to assess for the presence of congenital anomalies (Verklan & Lopez, 2011).

The nurse provides support to the family by teaching and involving them in their infant’s care as much as possible. Minimal stimulation protocols that promote the use of limited handling, dim lighting, and attention to the baby’s cues will help keep the infant calm. The head needs to be positioned carefully, repositioned at least once every 4 hours, and attention given such that the head is not positioned on the shunt side postoperatively. Gel-filled pillows can provide some comfort for the neonate. The frontal-occipital circumference needs to be measured serially, and depending on the rate of increase, every 4 hours to every 24 hours. Neurologic assessments and observation for signs of increasing intracranial pressure should be done every 4 to 8 hours, depending on the baby’s clinical condition.

The baby should be fed in a semi-reclining position with the head well supported. The method, amount, and frequency of feeding depend on the infant’s tolerance and energy level. The nurse should be alert to the possibility of emesis, a frequent occurrence in the presence of increased intracranial pressure, and should maintain aspiration precautions. Nonnutritive sucking, touching, and cuddling needs should be met.

In addition to serial intracranial ultrasonography, the diagnosis is also made using computed tomography (CT) and magnetic resonance imaging (MRI); antenatal diagnosis can be made by fetal ultrasonography. The surgical correction of hydrocephalus involves the placement of a shunt that goes from the ventricles of the brain usually to the peritoneum to allow the drainage of excess CSF. Damaged or destroyed brain tissue cannot be restored. The long-term prognosis in affected infants depends on the presence and extent of such tissue damage, along with the cause of the hydrocephalus, the presence of concurrent neurologic problems, and the long-term success of the shunt procedure.

Parent teaching regarding the shunt should be done both pre- and postoperatively. Providing handouts or, if possible, seeing an infant with a shunt already in place can be helpful. Parents also need to be taught signs of a blocked shunt and signs of infection such as increasing intracranial pressure and changes in the baby’s feeding patterns.

Microcephaly

Microcephaly refers to a head circumference that measures two or more standard deviations below the mean for age and sex (Gressens & Huppi, 2011). Brain growth is usually restricted and thus cognitive impairment is common. Maternal risk factors include congenital viral infections, chromosomal disorders, and malnutrition. Fetal and neonatal factors include inflammation, birth trauma, and sequelae of hypoxic-ischemic encephalopathy. If the result of an in utero insult, the baby is typically born with a small head and brain, which gives the forehead a backward-sloping appearance. Diagnostic evaluations include a complete maternal history, evaluation of the events surrounding the birth, CT or MRI to evaluate brain volume, and a neurologic assessment. Typically genetics and infectious disease consults are also obtained. Although neurologic deficits are not present at birth, developmental delays will become evident. The baby’s outcome and prognosis depend on the severity of the microcephaly. Treatment for the infant

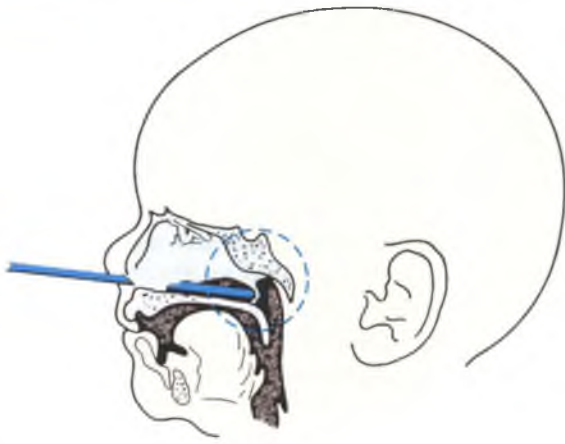

FIG 36-4 Choanal atresia. Posterior nares are obstructed by membrane or bone either bilaterally or unilaterally. Infant becomes cyanotic at rest. With crying, newborn's color improves. Nasal discharge is present. Snorting respirations often are observed with increased respiratory effort. Newborn may be unable to breathe and eat at the same time. Diagnosis is made by noting inability to pass small feeding tube through one or both nares. (Used with permission of Ross Products Division, Abbott Laboratories, Inc., Columbus, OH 43216. From Clinical Education Aid #6, Copyright 1963, Ross Products Division, Abbott Laboratories, Inc.)

is supportive. The parents will need support and education to help them learn to care for a child with cognitive impairment and developmental delays.

RESPIRATORY SYSTEM ANOMALIES

Screening for congenital anomalies of the respiratory system is necessary even in infants who are apparently normal at birth. Respiratory distress at birth or shortly thereafter can be the result of lung immaturity or anomalous development. Congenital laryngeal web and bilateral choanal atresia are readily apparent at birth. Respiratory distress caused by diaphragmatic hernia and tracheoesophageal fistula can appear immediately or be delayed, depending on the severity of the defect.

Laryngeal Web and Choanal Atresia

A **laryngeal web**, which is uncommon, results from the incomplete separation of the two sides of the larynx and is most often between the vocal cords. This is a surgical emergency such that perforation of the web using an endotracheal tube can be life-saving. **Choanal atresia** (Fig. 36-4) is the most common congenital anomaly of the nose. The posterior nares can be blocked by a bony or soft-tissue obstruction. The obstruction can be unilateral or bilateral. The baby can display symptoms of respiratory distress and cyanosis or pallor that are relieved whenever the infant is crying. Inability to pass a suction catheter through the nose into the pharynx is highly suggestive of the diagnosis. Securing an oral airway into the posterior pharynx and maintaining the baby in the prone position will provide a patent airway and time to evaluate for the presence of other abnormalities. Definitive therapy involves creating a patency through the bony or soft-tissue obstruction and use of serial obturators to dilate the new airway passages (Sprecher & Arnold, 2011).

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) results from a defect in the formation of the diaphragm, allowing the abdominal organs to be displaced into the thoracic cavity. It occurs in approximately 1 in 2000 to 1 in 4000 live births, and despite improvements in care management, the mortality rate remains high, at about 35% (Congenital Diaphragmatic Hernia Study Group, 2013). The etiology is unknown; however, it is not uncommon to find concomitant chromosomal anomalies, especially trisomies 12, 18, and 21, as well as abnormalities of the gastrointestinal (GI), genitourinary, and central nervous systems. Intestinal malrotation is also associated with CDH. Approximately 70% of the hernias occur on the left side in the posterior diaphragm known as the foramen of Bochdalek (Haroon & Chamberlain, 2013). Poorer outcomes are associated with left-sided defects (Schaible, Kohl, Reinshagen, et al., 2012).

A small defect may not be detected on an early prenatal ultrasound. Fetuses with CDH tend to have polyhydramnios, which typically prompts the obstetrician to obtain an ultrasound. A major advantage of diagnosing CDH prenatally is that it allows the baby to be born in a tertiary hospital that is equipped to manage all the cardiorespiratory problems associated with the defect and to rapidly stabilize the neonate's precarious condition. CDH can be repaired by fetal surgery in some research institutions; however, intrauterine surgical correction of CDH has met with poor neonatal outcomes in many cases (Shue, Miniati, & Lee, 2012). When CDH is diagnosed antenatally the infant is usually intubated and ventilated immediately after birth and thereafter with the minimum amount of support necessary to achieve adequate ventilation (Haroon & Chamberlain, 2013).

Depending on the size of the defect and how much developed lung tissue is present, the neonate may not be in any significant distress at birth. A small defect can distress the infant when feeding such that symptoms of respiratory distress (tachypnea, pallor, mottled, cyanosis) become evident. Newborns with a large defect will have significant distress at birth because the viscera present in the thoracic cavity during embryonic life prevented the normal development of the lung (Fig. 36-5). Characteristic symptoms include respiratory distress, cyanosis, heart sounds shifted to the right, and low blood pressure. There will be increasing distress as the bowels fill with air. The abdomen is scaphoid shaped and the chest appears barrel shaped due to the abdominal contents being in the chest. Diagnosis can be made on the basis of the x-ray finding of loops of intestine in the thoracic cavity and the absence of intestine in the abdominal cavity.

Surgical repair is performed as soon as the infant is stable. Preoperative nursing interventions include participating in the stabilization of the infant's cardiopulmonary condition until surgical repair can be done. Inhaled nitric oxide (INO) has not been shown to improve long-term outcome in CDH but it may provide temporary benefit in treating the accompanying persistent pulmonary hypertension (Haroon & Chamberlain, 2013). Gastric contents are aspirated and suction applied to decompress the GI tract and prevent further cardiothoracic compromise. Oxygen therapy, mechanical ventilation, and the correction of acidosis are necessary in infants with large defects.

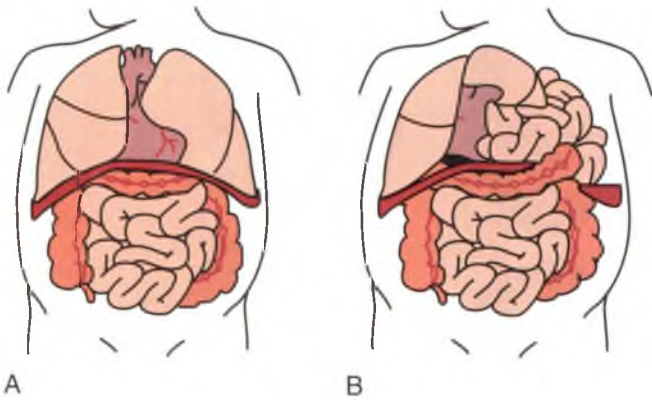

FIG 36-5 A, Normal diaphragm separating the abdominal and thoracic cavities. B, Diaphragmatic hernia with a small lung and abdominal contents in the thoracic cavity. (From Erlich P., & Coran, A. [2007]. Diaphragmatic hernia. In R. Kliegman, R. Behrman, H. Jenson, & B. Stanton [Eds.], *Nelson textbook of pediatrics* [18th ed.]. Philadelphia: Saunders.)

Pulmonary hypertension can occur as a result of the lung hypoplasia. Extracorporeal membrane oxygenation (ECMO) or high-frequency oscillatory ventilation can be used in infants with severe circulatory and respiratory complications (see Chapter 34) (Haroon & Chamberlain).

The prognosis depends largely on the degree of fetal pulmonary development and the success of surgical diaphragmatic closure, but the prognosis in severe cases is often poor. As a rule, finding the liver in the thorax is associated with the worst prognosis. Some infants with CDH die before they are able to have surgical repair. It is unclear whether the timing of the surgery or the condition of the infant at the time of repair is more important to improved outcomes. Overall survival rates have improved with the advent of INO, improved management of high-frequency ventilation, and ECMO. Of those who survive, some have chronic lung disease with long-term oxygen dependency, feeding difficulties, and gastroesophageal reflux (GER).

GASTROINTESTINAL SYSTEM ANOMALIES

Anomalies in the GI system can occur anywhere along the GI tract, from the mouth to the anus. Some anomalies, such as cleft lip, omphalocele, and gastroschisis, are apparent at birth. Others, including cleft palate, esophageal atresia, pyloric stenosis, intestinal obstructions, and imperforate anus, become apparent as the infant is further assessed or becomes symptomatic.

Cleft Lip and Palate

Orofacial clefts are among the most common congenital anomalies. **Cleft lip** or **palate** is a congenital midline fissure, or opening, in the lip or palate resulting from failure of the primary palate to fuse (Fig. 36-6). One or both deformities can occur, and nasal deformity can be present. Multiple genetic and, to a lesser extent, environmental factors (e.g., maternal infection, maternal smoking, radiation exposure, alcohol ingestion, and treatment with medications such as corticosteroids, lithium, retinoids, and phenytoin) appear to be involved in their development. Approximately one third of cases of cleft lip or palate

are associated with a major anomaly such as Pierre Robin syndrome (Maarse, Rozendaal, Pajkrt, et al., 2012).

Cleft lip with or without cleft palate occurs in approximately 11 per 10,000 live births in the United States. Cleft palate alone occurs in 2651 births annually; 4437 babies are born each year with a cleft lip with or without a cleft palate (Parker et al., 2010). Canada has one of the highest prevalence rates of orofacial clefts in the world at 12.7 per 10,000 live births (Pavri & Forrest, 2013).

Cleft lip occurs more frequently than cleft palate. The defect can range from a simple notch in the lip to complete separation of the lip that extends to the floor of the nose. The treatment for a cleft lip is surgical repair, which usually is done by 12 weeks of age, if the infant is healthy and free of infection. Repair of a cleft palate is usually performed by 1 year of age in order to optimize speech development (Tinanoff, 2011). Advances in surgical techniques have made it possible for some infants, particularly those with unilateral cleft lip, to have a near-normal appearance. The results of the repair depend on the severity of the defect, with more severe bilateral cleft lip requiring surgical repair done in stages.

Anomalies of the palate often occur in association with cleft lip. Cleft palate alone is more common in female infants and occurs more frequently as a constituent of certain syndromes. This defect can range from a cleft in the uvula to a complete cleft of the hard and soft palates that can be unilateral, bilateral, or midline. Feeding is difficult because the cleft lip renders the newborn unable to maintain a seal around a nipple; the cleft palate renders the infant unable to form a vacuum to maintain suction when feeding. In addition, the inability to suck and swallow normally allows milk to pool in the nasopharynx, which increases the likelihood of aspiration. Furthermore, as the infant attempts to suck, milk often comes out through the cleft and the nares. Although the degree of difficulty depends on the size of the cleft, feeding problems are greater in infants with a cleft palate than in those with a cleft lip. Breastfeeding is often possible if the infant has a cleft lip alone. Bottle feeding can be successful in some infants. There are special nipples, bottles, and appliances available to aid in feeding. In general, parents of infants with these defects need education, support, and encouragement as they learn to feed their baby. This can help minimize anxiety and frustration while promoting competence and confidence in providing infant care.

Initial and ongoing care for children with orofacial defects involves the combined efforts of a multidisciplinary health care team that includes **pediatrics, plastic surgery, orthodontics, otolaryngology, speech/language pathology, audiology, nursing, and social work.** Repair of the defects can involve a series of surgical procedures to allow the child to have a near-normal appearance and function (Wilson, 2014).

Parents of infants with a cleft lip or palate need much support, particularly in the case of a cleft lip, because this is both a cosmetic and functional defect. Recognizing that this can interfere with normal parent-infant bonding in the neonatal period, the nurse must assess for this and intervene appropriately. Some communities have support groups for parents of children with orofacial clefts. Parents may also be referred to the following organizations for information and services: the American Cleft Lip and Palate-Craniofacial Association (www.acpa-cpf.org), the

CLINICAL REASONING CASE STUDY

Cleft Lip and Cleft Palate

Michael, a 3.7-kg (8.2-lb) Caucasian neonate, is admitted to the newborn nursery after an uncomplicated vaginal birth. At birth Michael was noted to have a unilateral cleft lip and a cleft palate. Physical examination reveals no other congenital abnormalities, and Michael is otherwise vigorous and healthy.

- Evidence—What factors have been linked to the development of cleft lip and palate?
- Assumptions—What assumptions can be made about the following items?
 - The immediate plan of care for Michael after a diagnosis of cleft lip and palate
 - The ability for Michael's mother to breastfeed her son
 - The effect of having an infant with a congenital disorder
 - The trajectory of Michael's treatment
- What implications and priorities for nursing care can be made at this time?
- Does the evidence objectively support your conclusion?

Esophageal Atresia and Tracheoesophageal Fistula

Esophageal atresia (EA) and **tracheoesophageal fistula (TEF)**, the most life-threatening anomalies of the esophagus, typically occur together, although they can occur singly. More than 1 in 4000 infants are born with EA and more than 90% also have TEF (Khan & Orenstein, 2011).

Esophageal atresia is a congenital anomaly in which the esophagus ends in a blind pouch, thus failing to form a continuous passageway to the stomach. TEF is an abnormal connection between the esophagus and the trachea. The most common variant is the combination of a proximal EA, in which the esophagus ends in a blind pouch, with a distal TEF, in which the lower esophagus exits the stomach and is connected to the trachea by a fistula, rather than forming a continuous tube to the upper esophagus (Fig. 36-7). Variations of the anomalies are possible, depending on the presence or absence of a TEF, the site of the fistula, and the location and degree of the esophageal obstruction.

The presence of a midline defect such as EA or TEF is often accompanied by another significant embryonic defect such as a cardiac anomaly; cleft lip and/or palate; or vertebral,

FIG 36-7 Congenital atresia of esophagus and tracheoesophageal fistula. **A**, Upper and lower segments of esophagus end in blind sac, occurring in 5% to 8% of such infants. **B**, Upper segment of esophagus ends in atresia and connects to trachea by fistulous tract, occurring rarely. **C**, Upper segment of esophagus ends in blind pouch; lower segment connects with trachea by small fistulous tract, occurring in 80% to 95% of such infants. **D**, Both segments of esophagus connect by fistulous tracts to trachea, occurring in less than 1% of such infants. Infant may aspirate with first feeding. **E**, Esophagus is continuous but connects by fistulous tract to trachea; known as *H-type*. (From Hockenberry, M., & Wilson, D. [2011]. *Wong's nursing care of infants and children* [9th ed.]. St. Louis: Mosby.)

genitourinary, or abdominal wall defect (Lovvorn, Glenn, Pacetti, & Carter, 2011). The affected infant who is preterm or small for gestational age typically has other malformations such that a good outcome is not expected.

The defect can be diagnosed prenatally. A small or absent stomach can be detected during a fetal ultrasound. There is usually a history of polyhydramnios because the fetus is unable to swallow the amniotic fluid. At birth the clinical presentation depends on the type of anomaly present. Infants with the life-threatening anomaly EA with TEF show significant respiratory difficulty immediately after birth. Esophageal atresia with or without TEF results in excessive oral secretions, drooling, and feeding intolerance. When fed, the infant may swallow but then cough and gag and return the fluid through the nose and mouth. Respiratory distress can result from aspiration or from the acute gastric distention produced by the TEF. Choking, coughing, and cyanosis occur after even a small amount of fluid is taken by mouth.

SAFETY ALERT

Any infant with excessive oral secretions and respiratory distress should not be fed orally until a physician is consulted.

Nursing interventions are supportive until surgery is performed. The infant with EA and TEF should be kept in a supine position with the head of the bed elevated about 30 degrees to facilitate respiratory efforts and prevent reflux and aspiration of gastric contents. Antireflux and antacid medication may be given to minimize gastroesophageal reflux (GER) and prevent acid-induced pneumonitis. An orogastric tube (Replogle tube) is placed in the proximal esophageal pouch and attached to low continuous suction to remove secretions and decrease the possibility of aspiration (Lovvorn et al., 2011). The infant requires close observation and intervention to maintain a patent airway. Other supportive measures include thermoregulation, maintaining fluid and electrolyte balance intravenously as well

as acid-base balance, and preventing any further complications as a result of an associated defect. Surgical correction, done in one stage if possible, consists of ligating the fistula and anastomosing the two segments of the esophagus. The chances for survival in these infants depends on the presence of associated defects and the infant's birth weight. Preterm infants with cardiac or chromosomal anomalies have the highest mortality rate. Many infants with EA and TEF will have postoperative issues related to feeding difficulties such as GER and esophageal strictures requiring periodic dilation (Barksdale, Chwals, Magnuson, & Parry, 2011).

Omphalocele and Gastroschisis

Omphalocele and gastroschisis are two of the more common congenital defects of the abdominal wall. Omphalocele occurs in approximately 2 of every 10,000 live births, whereas the prevalence of gastroschisis is nearly 5 in 10,000 live births (Parker et al., 2010). An **omphalocele** is a covered defect of the umbilical ring into which varying amounts of the abdominal organs can herniate (Fig. 36-8, A). The peritoneal sac covering the defect can rupture during or after birth. Many of the infants born with an omphalocele are preterm and nearly 50% have an underlying chromosomal abnormality, usually trisomy 12, 18, or 21. Congenital heart defects are often associated with omphalocele (Lovvorn et al., 2011).

Gastroschisis is the herniation of the bowel through a defect in the abdominal wall to the right of the umbilical cord (see Fig. 36-8, B). No membrane covers the contents as it does with an omphalocele. The incidence of gastroschisis is increasing worldwide and is three to four times more common than omphalocele. Gastroschisis is not usually associated with other major congenital anomalies or syndromes. **Intestinal atresia can occur with gastroschisis** (Lovvorn et al., 2011).

The preoperative nursing care is similar for infants with either defect. Exposure of the viscera causes problems with thermoregulation and fluid and electrolyte balance. Immediately after birth, the neonate's torso should be placed in an

FIG 36-8 A, Omphalocele. B, Gastroschisis of bowel and stomach. (A, From O'Doherty, N. [1986]. *Neonatology: Micro atlas of the newborn*. Nutley, NJ: Hoffmann-La Roche; B, courtesy Cheryl Briggs, RNC, Annapolis, MD.)

impermeable, clear plastic bowel bag to decrease insensible water losses, maintain thermoregulation, and prevent contamination of the exposed viscera. It is essential that the nurse assesses the exposed viscera frequently to detect any changes in perfusion to the exposed abdominal contents. The infant should be placed in a side-lying position and the viscera supported with a blanket roll to prevent vascular compromise to a torqued intestine. Prior to surgery the exposed viscera should be kept covered with sterile moistened saline gauze and plastic wrap. Gastric decompression with a Replogle tube (a special type of gastric tube) connected to low intermittent wall suction is also necessary to prevent aspiration pneumonia and to allow as much bowel as possible to be placed into the abdomen during surgery. Antibiotics, fluid and electrolyte replacement, and thermoregulation are needed for physiologic support (Lovvorn et al., 2011; Wilson, 2014).

Surgery is usually performed soon after birth. If complete closure is impossible because of the small size of the defect and the large amount of viscera to be replaced, a Silastic silo or patch is placed. This protects the contents as they are gradually placed back into the abdominal cavity and minimizes symptoms of respiratory distress as the increasing intraabdominal pressure pushes against the diaphragm. The defect is closed surgically after the exposed visceral contents have been reduced; this reduction process usually takes 7 to 10 days. The prognosis depends on the size of the defect and the presence of associated anomalies. It is generally expected that there will be complications related to intestinal dysfunction, such as feeding difficulties, dysmotility, or short-gut syndrome if a substantial amount of the intestine was removed.

Parental support is essential because the infant has an obvious disfiguring anomaly that can be shocking and repulsive in appearance. Depending on the size of the defect, the infant can also be critically ill before surgery. The nurse must be aware of the effect this can have on parental bonding and intervene appropriately as the parents cope with this crisis.

Gastrointestinal Obstruction

Congenital intestinal obstruction can occur anywhere in the GI tract and takes one of the following forms: atresia, which is a complete obliteration of the passage; partial obstruction, in which the symptoms can vary in severity and sometimes are not detected in the neonatal period; or malrotation of the intestine, which leads to twisting of the intestine (volvulus) and obstruction. Esophageal atresia, discussed previously, is a type of GI obstruction. Duodenal atresia, midgut malrotation and volvulus, jejunoileal atresia, necrotizing enterocolitis, and meconium ileus are the most common causes of neonatal intestinal obstruction. Meconium ileus is an obstruction caused by impacted meconium; more than 90% of infants who are born with meconium ileus have cystic fibrosis (Lovvorn et al., 2011).

GI obstruction may be suspected when polyhydramnios is present during pregnancy. It can be detected in the fetus through the use of prenatal ultrasound imaging (Song, Upperman, & Niklas, 2011).

Signs of neonatal intestinal obstruction occur early. The neonate with an intestinal obstruction displays the following cardinal signs: bilious vomiting, abdominal distention, and failure to pass normal amounts of meconium in the first 24 hours. High intestinal obstruction is characterized by vomiting, even if the infant is not being fed orally. Distention usually indicates a low obstruction, with vomiting occurring later. Abdominal distention can elevate the diaphragm, which can cause respiratory difficulties (Song et al., 2011).

Nursing care is aimed at supporting the infant until surgical intervention can be carried out to eliminate the obstruction. Oral feedings are withheld, an orogastric tube is placed to low intermittent wall suction, and intravenous therapy is initiated to provide needed fluid and electrolytes. In infants with an intestinal obstruction, surgery consists of resecting the obstructed area of bowel and anastomosing the nonaffected bowel or creating an ostomy and allowing the bowel to rest.

FIG 36-9 Types of anorectal malformations (imperforate anus). Anal sphincter muscle may be present and intact. **A**, High lesion opening onto perineum through narrow fistulous tract. **B**, High lesion ending in fistulous tract to urinary tract. **C**, Low lesion in bowel passes through puborectal muscle. **D**, High lesion ending in fistulous tract to vagina.

Anorectal Malformations

Anorectal malformations, or **imperforate anus**, include a range of congenital defects involving the anus, rectum, and genitourinary system (Fig. 36-9). These anomalies are relatively common, with an incidence of approximately 1 in 4000 to 5000 live births (Barksdale et al., 2011). Occurring more in male than in female infants, they result from the failure of the urogenital sinus and cloaca to differentiate during weeks 7 and 8 of gestational life (Blackburn, 2013). Such infants have no anal opening, and commonly there is also a fistula from the rectum to the perineum or genitourinary system. Types of anorectal malformations include the typical cloaca (fistula) in females, which involves the vagina, colon, and urethra forming a single common passage in the perineum. Others include the low rectovaginal fistula (female) and rectourethral bulbar fistula (male). Imperforate anus can occur in isolation or in combination with other congenital defects such as esophageal atresia, duodenal atresia, renal anomalies, or vertebral anomalies. Extensive surgical repair is often required in stages for the more complex types of anorectal malformations. Infants with high imperforate anus typically have bowel incontinence even after surgical repair. In some cases the anomaly involves stenotic areas, or a thin translucent membrane can cover the anal opening. Treatment for such a membrane is anoplasty followed by daily dilation, which parents learn to do. The preoperative nursing care is similar to that described for other GI obstructions. Imperforate anus is often associated with other anomalies, with nearly half

having additional genitourinary anomalies, which can complicate long-term care. Outcome is excellent with low imperforate anus (Gourlay, 2013).

MUSCULOSKELETAL SYSTEM ANOMALIES

The two most common musculoskeletal system anomalies in neonates are developmental dysplasia of the hip (DDH) and congenital clubfoot. Both of these conditions must be detected and treated early for successful correction.

Developmental Dysplasia of the Hip

The broad term **developmental dysplasia of the hip** describes a spectrum of disorders related to abnormal development of one or all of the components of the hip joint that can develop at any time during fetal life, infancy, or childhood. A change in terminology from congenital hip dysplasia and congenital dislocation of the hip to DDH more accurately reflects a variety of hip abnormalities in which there is a shallow acetabulum, subluxation, or dislocation.

Although as many as 1 in 100 to 1 in 250 infants have some degree of hip instability, the prevalence of DDH is approximately 1 to 1.5 per 1000 live births (Sankar, Horn, Wells, & Dormans, 2011). Prevalence of DDH is variable across populations, which may be related to genetic and environmental factors. It is rare among African infants and more common among ethnic groups such as Navajo Indians and those from other countries who traditionally swaddle infants with legs extended and hips adducted (Bracken, Tran, & Ditchfield, 2012). The etiology is unknown and believed to be multifactorial. Certain factors such as sex, birth order, family history, intrauterine position, birth type, joint laxity, and postnatal positioning are believed to affect the risk of DDH. Predisposing factors associated with DDH can be divided into three broad categories: (1) physiologic factors, which include female sex and maternal hormone secretion causing pelvic relaxation during birth, and intrauterine positioning; (2) mechanical factors such as breech presentation, multiple gestation, oligohydramnios, and large infant size; other mechanical factors can include continued maintenance of the hips in adduction and extension that will in time cause a dislocation; and (3) genetic factors, including a family history of DDH and generalized ligamentous laxity (Sankar et al., 2011). Figure 36-10 illustrates the three degrees of DDH, which are described as follows.

- **Acetabular dysplasia (or preluxation)**—mildest form of DDH in which there is neither subluxation nor dislocation. There is a delay in acetabular development evidenced by osseous hypoplasia of the acetabular roof that is oblique and shallow, although the cartilaginous roof is comparatively intact. The femoral head remains in the acetabulum; 80% of mild cases of DDH resolve spontaneously (Price & Ramo, 2012).
- **Subluxation**—accounts for the largest percentage of DDH. Subluxation implies incomplete dislocation of the hip and is sometimes regarded as an intermediate state in the development from primary dysplasia to complete dislocation. The femoral head remains in contact with the acetabulum, but a stretched capsule and ligamentum teres cause the head of the femur to be partially displaced. Pressure on the cartilaginous roof inhibits ossification and produces a flattened socket.

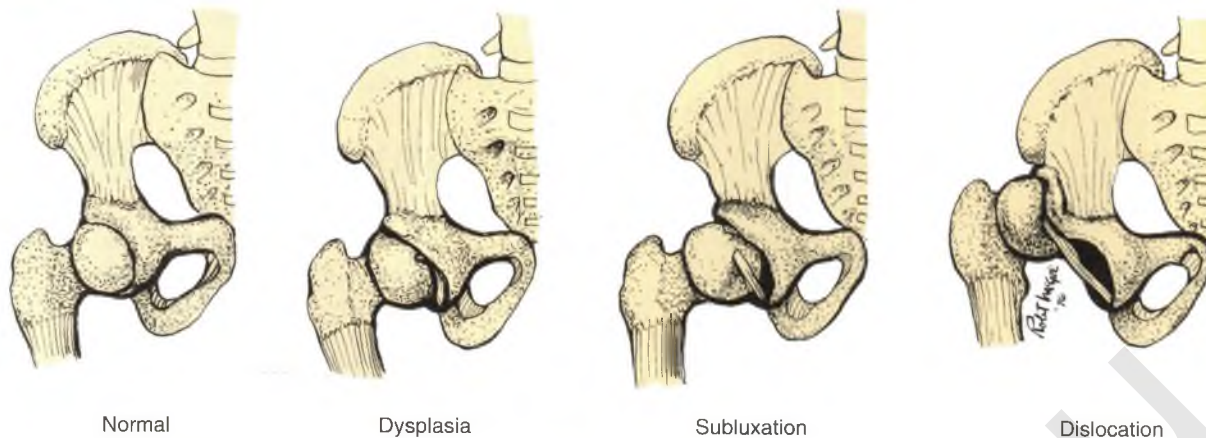

FIG 36-10 Configuration and relationship of structures in developmental dysplasia of the hip.

- **Dislocation**—The femoral head loses contact with the acetabulum and is displaced posteriorly and superiorly over the fibrocartilaginous rim. The ligamentum teres is elongated and taut. DDH is often not detected at the initial examination after birth; thus all infants should be carefully monitored for hip dysplasia at follow-up visits throughout the first year of life. In the newborn period, dysplasia usually appears as hip joint laxity rather than as outright dislocation. Subluxation and the tendency to dislocate can be demonstrated by the Ortolani or Barlow tests. The Ortolani and Barlow tests are most reliable from birth to 2 or 3 months of age (see Fig. 23-11). Other signs of DDH are shortening of the limb on the affected side (Galeazzi sign, Allis sign), asymmetric thigh and gluteal folds, and broadening of the perineum (in bilateral dislocation). In some countries screening programs using ultrasound evaluation of infants with risk factors for DDH have been instituted; however, evidence supporting the efficacy of these programs is limited (Bracken et al., 2012).

FIG 36-11 Infant in Pavlik harness. (Courtesy Amanda Politte, St. Louis, MO.)

⚡ SAFETY ALERT

The Ortolani and Barlow tests must be performed by an experienced clinician to prevent fracture or other damage to the hip.

Treatment is begun as soon as the condition is recognized because early intervention is more favorable to the restoration of normal bony architecture and function. The longer treatment is delayed, the more severe the deformity, the more difficult the treatment, and the less favorable the prognosis. The treatment varies with the age of the infant and the extent of the dysplasia. The goal of treatment is to obtain and maintain a safe, congruent position of the hip joint to promote normal hip joint development and ambulation.

The hip joint is maintained by dynamic splinting in a safe position with the proximal femur centered in the acetabulum in an attitude of flexion and abduction. Of the numerous devices available, the Pavlik harness (Fig. 36-11) is the most widely used, and with time, motion, and gravity, the hip works into a more abducted, reduced position. The harness is worn continually until the hip is proved stable on clinical and radiographic examination, typically around 3 months. It has an 80% success

rate for the treatment of classic DDH. If not effective, traction, casting, and even surgery may be necessary to stabilize the hip (Bracken et al., 2012).

⚡ SAFETY ALERT

The former practice of double- or triple-diapering for DDH is not recommended because it promotes hip extension, thus interfering with proper hip development.

In addition to the major intervention of assessing and helping identify the disorder, another key nursing intervention is teaching the parents about the care of the infant because he or she will remain in the harness continually during the treatment. Because the harness is worn during a time of maximal growth, it is necessary for the parents to adjust the infant's care to accommodate the infant's changing needs. The infant can develop brachial plexus palsy due to increased tension of the shoulder harness if the harness is not modified according to the neonate's growth. Thorough and ongoing follow-up care is necessary, as is psychosocial support for the family.

Clubfoot

Congenital **clubfoot** is a deformity of the foot and ankle that includes forefoot adduction, midfoot supination, hindfoot varus, and ankle equinus. Deformities of the foot and ankle are described according to the position of the ankle and foot. The more common positions involve the following variations:

- *Talipes varus*—an inversion or a bending inward
- *Talipes valgus*—an eversion or bending outward
- *Talipes equinus*—plantar flexion in which the toes are lower than the heel
- *Talipes calcaneus*—dorsiflexion, in which the toes are higher than the heel

Most cases of clubfoot are a combination of these positions. The most frequently occurring type is the composite deformity *talipes equinovarus* (TEV). In this abnormality the foot appears C-shaped, pointing downward and inward; the ankle is inverted; and the Achilles tendon is shortened. The foot appears small, wide, and stiff, and the lower leg appears small because of hypoplasia of the calf muscles. Unless treated, further stiffening occurs, and bony changes will result. Unilateral clubfoot is somewhat more common than bilateral clubfoot and can occur as an isolated defect or in association with other disorders or syndromes, such as chromosomal aberrations, arthrogryposis (a generalized immobility of the joint), cerebral palsy, or spina bifida.

Clubfoot is classified as positional or congenital. A positional clubfoot was held in a deformed position in utero and is flexible when manipulated during examination. A congenital clubfoot is structural, is more rigid, and has a wide range of severity. Clubfoot is one of the most common congenital anomalies, occurring in approximately 1 in 1000 live births, with two times more male than female infants affected. Bilateral defects occur in 50% of cases. The etiology is thought to be multifactorial and can involve a genetic predisposition, chromosomal anomalies, abnormalities of the uterine environment, and neuromuscular pathologies (Hosalkar, Spiegel, & Davidson, 2011). Treatment is initiated soon after birth and most often involves serial casting. Successive casts allow for gradual stretching of skin and tight structures on the medial side of the foot. Manipulation and casting are repeated frequently (every week) to accommodate the rapid growth of early infancy. The extremity or extremities are often casted or splinted until maximum correction is achieved, usually within 8 to 12 weeks. If needed, surgical correction is done before the infant begins to walk (Hosalkar et al.).

Because these infants are often placed in a cast before discharge, the nurse must teach parents necessary care, including how to protect the cast and assess the toes for neurovascular compromise. This is particularly important because of the potential for the infant to outgrow the cast. The nurse should be supportive of the parents as they learn the ways to meet the infant's normal needs, as well as those brought about by the infant's physical problem.

Polydactyly

Occasionally an infant is born with extra digits on the hands or feet. In some instances, *polydactyly* is hereditary. If there is little or no bone involvement, the extra digit is tied with silk suture soon after birth. The finger or toe falls off within a few days, leaving a small scar. When there is bone involvement, surgical repair is indicated.

GENITOURINARY SYSTEM ANOMALIES

Anomalies involving the genitourinary system can be distressing to parents because they can be readily apparent and, in the case of some conditions, because of the concern about sexuality and reproductive functioning. These anomalies range from obvious anomalies of the external genitalia, such as hypospadias, to those involving internal organs that are not obvious but can cause damage to the urinary tract. An example of the latter is an obstruction in the urinary tract that can cause hydronephrosis, which is the abnormal collection of urine in the renal pelvis that can eventually destroy the kidney.

Hypospadias and Epispadias

The term *hypospadias* encompasses a range of penile anomalies associated with an abnormally located urinary meatus. The meatus can open below the glans penis or anywhere along the ventral surface of the penis, the scrotum, or the perineum. It is one of the most common congenital anomalies, occurring in approximately 3 to 5 per 1000 births (Canon, Mosley, Chipolini, et al., 2012). Hypospadias is classified according to the location of the meatus and the presence or absence of chordee, which is a ventral curvature of the penis (Figs. 36-12 and 36-13). The cause is unknown, although it is thought to be of multifactorial inheritance.

FIG 36-12 Classification of hypospadias by position of the urethral meatus.

FIG 36-13 Hypospadias. (Courtesy H. Gil Rushton, MD, Children's National Medical Center, Washington, DC.)

Mild cases of hypospadias are often repaired for cosmetic reasons and involve a single surgical procedure. In more severe cases, several surgeries are required to reconstruct the urethral opening and correct the chordee, thereby straightening the penis. The goals are to improve the appearance of the genitalia, make it possible for the child to urinate in a standing position, and have a sexually adequate organ. These infants are not circumcised because the foreskin may be needed during surgical repair. Repair is done early, between 1 and 2 years of age, so that the child's body image is not impaired (Steven, Cherian, Yankovic, et al., 2013). There is a correlation between hypospadias and testicular cancer and also with cryptorchidism; therefore, children with a history of hypospadias require long-term follow-up (Serrano, Chevrier, Multigner, et al., 2013).

Epispadias, a rare anomaly, results from failure of urethral canalization. The affected infants are males who have a widened pubic symphysis and a broad spadelike penis with the urethral opening on the dorsal surface. In females there is a wide urethra and a bifid clitoris. Severity ranges from a mild anomaly to a severe one that is associated with exstrophy of the bladder. Surgical correction is necessary, and affected male infants should not be circumcised (Elder, 2011).

Exstrophy of the Bladder

The most common bladder anomaly is **exstrophy** (Fig. 36-14), which often occurs in conjunction with epispadias. It is rare, occurring in approximately 2 in 100,000 live births, and males are affected twice as often as females (Siffel, Correa, Amar, et al., 2011). It results from the abnormal development of the bladder, abdominal wall, and pubic symphysis that causes the bladder, urethra, and ureteral orifices to be exposed. The bladder is visible in the suprapubic area as a red mass with numerous folds, with urine draining from it onto the infant's skin. Immediately after birth the exposed bladder should be covered with a sterile, non-adherent dressing to protect its delicate surface until closure can be performed. It is recommended that reconstructive surgery be started in the neonatal period, such that the bladder is closed within 48 hours. Parents will need detailed instructions along with support and encouragement as they deal with caring for an infant who has such an obvious defect. Repair is completed before school age, if possible, although some children never

FIG 36-14 Exstrophy of bladder. (Courtesy H. Gil Rushton, MD, Children's National Medical Center, Washington, DC.)

attain normal voiding patterns and later may be considered for surgery for urinary diversion.

Ambiguous Genitalia

The nurse is often the one to discover ambiguous genitalia in the newborn (Fig. 36-15) during a physical assessment. Erroneous or abnormal sexual differentiation can be a genetic aberration, such as congenital adrenal hyperplasia, which can be life threatening because it involves the deficiency of all adrenal cortical hormones. Other possible causes of sexual ambiguity include chromosomal abnormalities, defective sex hormone synthesis in male infants, and the placental transfer of masculinizing agents to female fetuses. Diagnosis should be based on data gathered from the following sources: maternal and family history, including the ingestion of steroids during pregnancy, and relatives with ambiguous genitalia or who died during the neonatal period; physical examination; chromosomal analysis; endoscopy, ultrasonography, and radiographic contrast studies; biochemical tests, such as analysis of urinary steroid excretion, which helps detect several of the adrenal cortical syndromes; and, in some instances, laparotomy or gonad biopsy.

Assessment and management of a newborn with ambiguous genitalia require urgency and sensitivity. Therapeutic intervention, including any counseling and surgery, should be started as soon as possible. Care is best managed by a multidisciplinary team consisting of the primary physician, pediatric endocrinologist, geneticist, surgeon, social worker, and nurses. An infant born with ambiguous genitalia should not receive a sex assignment until diagnostic testing provides enough information for a well-informed decision (Lee & Houk, 2013).

An appropriate gender assignment should be based on the following: diagnosis, genital development and surgical options, cultural pressures, most likely adult gender identity, potential for mature sexual function, potential fertility, and the long-term psychological and intellectual effect on the child and family

FIG 36-15 Ambiguous external genitalia (i.e., structure can be enlarged clitoral hood and clitoris or malformed penis). (Courtesy Edward S. Tank, MD, Division of Urology, Oregon Health Science University, Portland.)

(Lee & Houk, 2013). Parents need much support as they learn to deal with this very challenging situation.

INBORN ERRORS OF METABOLISM

Congenital defects of the metabolic and endocrine systems can be identified during fetal development but more often are not apparent until after birth. Although there are numerous disorders resulting from defects in these systems, the discussion focuses on selected disorders that can be identified during routine newborn screening.

Inborn errors of metabolism (IEMs) are biochemical genetic disorders that result from defects in single genes; the majority of disorders are inherited as autosomal recessive conditions (Cederbaum, 2012). The genetic defect causes a blockage in a critical metabolic pathway. There can be absence of an essential enzyme resulting in accumulation of precursors preceding a blocked step in a metabolic pathway. The defect can also result in a deficiency of a critical metabolic product (Stokowski, 2014). IEMs encompass a wide variety of disorders including defects of amino acid, carbohydrate, and organic acid metabolism; lysosomal storage disorders; energy metabolism disorders; and disorders of purine metabolism (Cederbaum).

The majority of infants with an IEM appear normal at birth. However, the presence of other congenital anomalies should not rule out the possibility of an IEM (Matthews & Robin, 2011). Signs of an IEM may not be evident until after the infant has consumed several feedings. Some infants exhibit nonspecific signs of IEMs such as feeding problems or respiratory distress. Signs of an IEM can resemble those of sepsis. Infants can present with more acute signs of an IEM such as hypoglycemia, lethargy, seizures, metabolic acidosis or respiratory alkalosis, or cardiac arrhythmias (Cederbaum, 2012).

Diagnostic testing for IEMs is often ordered when other explanations for an infant's symptoms are not satisfactory. For example, if a neonate demonstrates signs of sepsis but testing fails to confirm the diagnosis, the provider may proceed with diagnostic measures for a metabolic disorder. Initial testing includes a broad range of blood and urine tests that are not diagnostic for IEMs but instead serve as screening measures. Further testing is required to confirm the diagnosis of an IEM, and a metabolic specialist is often involved. Biochemical studies for specific IEMs may only be performed by specialized laboratories that require compliance with very specific guidelines for collecting, storing, and shipping tissue samples (Matthews & Robins, 2011).

It is critical that IEMs are identified as early as possible. When IEMs are undiagnosed and untreated, infants can suffer severe consequences such as cognitive impairment or even death. Presymptomatic identification of many IEMs is possible through routine newborn screening (see Chapter 24). Tandem mass spectrometry allows for identification of more than 50 IEMs from a single blood spot. Newborn screening for specific IEMs varies from state to state. The screening test is most reliable if the sample is collected at least 24 hours after the infant has been feeding; if the sample is collected before 24 hours, a repeat test is done before the age of 2 weeks. This is only a screening test; positive results warrant further testing (Matthews & Robin, 2011).

Care of an infant who has an IEM is managed by a health care team including neonatal and pediatric providers, metabolic and genetic specialists, nutritionists, and nursing staff. If the infant is hospitalized when the diagnosis is made, all protein sources are eliminated, including feedings and amino acid solutions. IV solutions of 10% glucose and electrolytes are administered until a specific diagnosis is made. Supportive care includes correction of volume and electrolyte imbalances, hypoglycemia, and metabolic acidosis. Neonates may be transferred to regional referral centers for further treatment. In severe cases, hemodialysis, ECMO, or even liver transplant may be needed (Stokowski, 2014).

Phenylketonuria (PKU) is an amino acid disorder that results from a deficiency of the enzyme phenylalanine dehydrogenase (see Chapter 3), which is needed to metabolize the essential amino acid phenylalanine. Classic PKU is one among a spectrum of disorders known as hyperphenylalaninemia; severity varies according to the degree of enzyme deficiency. This deficiency can cause elevated levels of phenylalanine that result in CNS damage. Severe effects of PKU are rare because of early recognition through newborn screening (Blackburn, 2013). The test for PKU is not reliable, however, until the newborn has ingested adequate amounts of breast milk or formula.

! NURSING ALERT

The nurse must document the initial ingestion of milk. The test for PKU is performed at least 24 hours after that time.

The prevalence of classic PKU in the United States is approximately 1 in 11,400 live births (Hertzberg, Hinton, Therrell, & Shapira, 2011). Incidence varies widely across ethnic groups. PKU is rare among African nations; the highest incidence is in Turkey (Cleary, 2011).

If the infant has PKU, treatment includes a diet low in protein plus the addition of a special amino acid-containing formula that does not contain phenylalanine. Despite compliance with treatment, many affected children have some degree of cognitive impairment. Successful management and outcome are largely dependent on early identification of the condition, modifying the diet, and compliance with the treatment regimen throughout life (Viau, Wengreen, Ernst, et al., 2011).

Galactosemia, caused by a deficiency of the enzyme galactose 1-phosphate uridylyltransferase, results in the inability to convert galactose to glucose. Galactosemia can be detected by measuring the blood levels of galactose in the urine of newborns suspected of having the disease who have ingested formula containing galactose. Early symptoms are vomiting, weight loss, persistent jaundice, and CNS symptoms, including poor feeding, drowsiness, and seizures (Sulchy & Kerkar, 2012). *Escherichia coli* sepsis occurs in a large number of affected infants. If the disorder goes untreated, the galactose levels continue to increase, and the affected infant shows failure to thrive, developmental delay, cataracts, jaundice, hepatomegaly, and cirrhosis of the liver, with death possibly occurring in the first month of life. Therapy consists of eliminating galactose from the diet. Breastfeeding is contraindicated because lactose is present in breast milk (Lawrence, 2013).

Congenital hypothyroidism results from a deficiency of thyroid hormones and can be permanent (requires treatment

for life) or transient (spontaneously resolves). It is the most common endocrine disorder found in neonates, with an incidence of 1 in 4000 births (Clause, 2013; Grütters & Krude, 2011). It can be caused by a single gene defect or familial autoimmune factors; however, in the majority of causes, it is caused by a non-familial embryogenic defect. Congenital hypothyroidism affects female infants twice as often as males (Blackburn, 2013).

The majority of neonates with congenital hypothyroidism appear normal at birth, although some may exhibit signs of the disorder such as hypotonia, large fontanel, or macroglossia (Blackburn, 2013). If the infant is untreated, symptoms usually appear after 6 weeks and include bradycardia; hypothermia; hypotension; hyporeflexia; abdominal distention; umbilical hernia; coarse, dry hair; thick, dry skin that feels cold; anemia; widely patent cranial sutures; and delayed bone age beginning at birth. The most disabling problem, however, is delayed development of the nervous system, leading to severe developmental delay. Once identified, treatment is started immediately using synthetic thyroxine (T_4 , L-thyroxine) as a thyroid replacement (Clause, 2013).

Early diagnosis and treatment of congenital hypothyroidism are associated with a greater likelihood of normal mental development. Early recognition of the disorder is possible through routine newborn screening. All U.S. states and Canadian provinces routinely screen for hypothyroidism by measuring T_4 or thyroid-stimulating hormone (TSH) levels. Screening is most accurate after 48 hours of age. Early screening can have false-positive results; preterm infants are more likely to have false-positive results. Any infant whose screening test is positive should be further evaluated for congenital hypothyroidism (Blackburn, 2013).

CARE MANAGEMENT

Assessment

Congenital anomalies and disorders may be identified prenatally, at the time of birth, or in the days or weeks following birth. Although some prenatal and postnatal screening tests are routinely performed, diagnostic testing for specific congenital defects is performed based on a variety of factors such as results of screening tests, maternal and family history, prenatal course, and neonatal symptoms.

Prenatal. Refined prenatal testing procedures are available to monitor fetal development. Diagnostic techniques such as amniocentesis, ultrasonography, alpha-fetoprotein measurements, CVS, PUBS, fetal nuchal translucency (FNT) screening, and gene probes contribute information to the database (see Chapter 26). Although they are a valuable adjunct to prenatal care, these tests cannot identify all congenital disorders. Furthermore, ethical issues surround such testing, and the nurse must be prepared to support the family's decision regarding these tests. If a disorder is detected and the family decides to proceed with the pregnancy, the advantage is that appropriate care can be made available for the infant immediately at birth.

The nurse reviews the maternal history and medical information in the prenatal record for risk factors associated with congenital disorders. These factors include various medical, surgical, and social conditions and their treatments (see Chapter 30); maternal infection (see Chapter 7); maternal endocrine and metabolic

BOX 36-3 Routine Screening for Critical Congenital Heart Disease

- Screen healthy newborns after 24 hours of life or as close to the time of discharge as possible.
- Use a motion-tolerant pulse oximeter.
- Obtain pulse oximeter readings from the right hand and one foot.
- Pulse oximetry <90% in right hand or foot is considered a positive screening that warrants additional testing such as echocardiogram.
- 90% to 95% in right hand or foot or >3% difference between the two extremities warrants repeat testing in 1 hour. If screening values remain the same as the first time, consider repeating the screen in 1 hour. If parameters remain unchanged after the second screen, repeat a third time. If unchanged, consider it a positive screen.
- >95% in the right hand or foot and <3% difference between the two extremities is a negative screen and no further testing is needed.

Data from Kemper, A.R., Mahle, W.T., Martin, G.R., et al. (2011). Strategies for implementing screening for critical congenital heart disease. *Pediatrics*, 128(5), e1259-e1267.

disorders (see Chapter 29); and infection and drug dependence in the newborn (see Chapter 35).

Postnatal. Diagnostic procedures for the detection of genetic disorders are performed after birth at any time from the postnatal period through adulthood. Many tests exist for various disorders.

Apgar scoring and a brief assessment are completed for all neonates after birth. Any deviations from normal are reported to the health care provider immediately. A thorough assessment of all body systems is performed to identify anomalies. Both minor and major malformations are noted. There can be mild malformations that in isolation are not clinically significant, but a pattern or combination of minor malformations can suggest a specific disorder or syndrome (Matthews & Robin, 2011).

The most widespread use of postnatal testing for congenital disorders is the routine screening of newborns in the United States and Canada for IEMs such as PKU and galactosemia, hemoglobinopathies (sickle cell disease and thalassemias), and hypothyroidism (Howell, Terry, Tait, et al., 2012). Screening for hearing loss is recommended at the same time as disease screening. The use of pulse oximetry to screen for critical congenital heart disease in healthy term infants (Box 36-3) has been endorsed by the U.S. Department of Health and Human Services and is being implemented in numerous states; this should be included in the recommended uniform newborn screening panel (Bradshaw & Martin, 2012; Mahle et al., 2012).

Cytogenic studies must be done to rule out or confirm a suspected genetic diagnosis. Chromosome analysis and molecular deoxyribonucleic acid (DNA) analysis are often ordered. Test results may not be available for weeks; however, in urgent situations, chromosome analysis from bone marrow samples can be available within hours (Matthews & Robin, 2011).

A variety of biochemical studies may be done, especially in seeking to diagnose an IEM. X-ray examination and organ imaging with MRI or CT scan may be used to identify skeletal abnormalities and structural anomalies of major organs (Matthews & Robin, 2011).

Family history is integral to diagnosing a congenital disorder. Data collection should include a three-generation pedigree (parents, siblings, grandparents, aunts, uncles, cousins) with information such as miscarriages, stillbirths, congenital anomalies, or childhood deaths (Matthews & Robin, 2011).

Nursing Diagnoses

The nursing diagnoses formulated for an infant with a congenital anomaly depend on the type and severity of the abnormality. General nursing diagnoses pertaining to the care of newborns with congenital abnormalities include the following:

Newborn:

- *Risk for Injury* related to:
 - presence of a congenital abnormality
- *Risk for Infection* related to
 - anomaly or its treatment
- *Impaired Gas Exchange, Imbalanced Nutrition: Less than Body Requirements or Impaired Mobility* related to
 - congenital anomaly
- *Delayed Growth and Development* related to
 - inborn error of metabolism

Parents and Family:

- *Grieving or Spiritual Distress* related to
 - birth of a child with a disorder or abnormality
- *Compromised Family Coping* related to
 - birth of a child with an abnormality
- *Deficient Knowledge* related to
 - cause of the anomaly, its management, alternative courses of action, community resources, prognosis, and the care needed by the infant after discharge
- *Anxiety* related to
 - uncertainty about the prognosis or their ability to care for the child
- *Risk for Impaired Parenting* related to
 - birth of a child with a disorder or anomaly

Interventions

Newborn Care

Many congenital anomalies require intervention soon after birth. A collaborative health team approach that includes specialists and community service representatives is needed in the care of infants with some disorders. Surgical intervention in the neonatal period may be necessary for the infant requiring either immediate correction or a palliative procedure to relieve the symptoms of the anomaly until definitive correction can be done. There is a higher morbidity and mortality rate in neonates than in older children or adults undergoing similar procedures. However, despite these problems unique to neonates, advances in surgical techniques, anesthesia, and the nursing care given in intensive care nurseries have been responsible for decreasing the risk of surgery in neonates.

The health care team must be highly skilled to meet the needs of these high risk infants. In addition to stabilizing the infant's condition (oxygenation and perfusion of tissues), other preoperative interventions, such as placing an orogastric tube for abdominal decompression, attending to thermoregulation and pain management, and maintaining fluid and electrolyte balance, are implemented to manage specific problems.

Parents and Family Support

While the infant is receiving optimal care, the parents have needs that must be met as they deal with the crisis of having an infant with an abnormal condition. The nurse carefully assesses their reactions, which are likely to be those typical of a grief response. Facilitating their understanding of the information given them about their infant's condition is a vital nursing intervention. A newly diagnosed disorder often implies the need for implementing a therapeutic regimen. For example, the disorder can be an IEM, such as PKU, which requires consistent and rigid adherence to a special diet. The family may need help with securing the required formula and receiving counseling from the clinical dietitian. The nurse stresses the importance of maintaining the diet, keeping an adequate supply of special preparations, and not using unauthorized substitutions.

Referral to appropriate agencies is another essential component of follow-up management, and the nurse should make the parents aware of all possible sources of aid, including pertinent literature, parent groups, and national organizations. Many organizations and foundations provide services and counseling for families of affected children. There are also numerous parent groups the family can join. There they can share experiences and receive mutual support in coping with problems similar to those of other group members. Nurses should be familiar with the services available in their community that provide assistance and education to families with these special problems.

A major nursing function is providing emotional support to the family during all aspects of the care of the infant born with a defect or disorder. The feelings stemming from the real or imagined threat posed by a congenital anomaly are as varied as the people being counseled. Responses can include apathy, denial, anger, hostility, fear, embarrassment, grief, and loss of self-esteem (see Chapter 37).

Some parents benefit from seeing before-and-after pictures of other babies born with the same defect. Coupled with other verbal and nonverbal supportive care, this visual reassurance may be effective in allaying their concerns. Families need much information, guidance, and support as they make decisions regarding the care of their infants. Once they have been given the facts and possible consequences and all the assistance they need in problem solving, the final decision regarding a course of action must be their own. It is then incumbent on health care providers to support the family's decision.

Genetic Evaluation and Counseling

Genetic counseling is a communication process concerned with the human problems associated with the occurrence, or risk of occurrence, of a genetic disorder in a family. It involves relaying information about the diagnosis, treatment options, recurrence risk, and availability of prenatal diagnosis. It is essential that nurses understand the basic principles of heredity and how heredity contributes to disorders. They should be aware of the types of genetic testing available (see Chapter 3).

Nurses frequently encounter infants with genetic disorders and families for whom there is a risk that a disorder can be transmitted to or occur in an offspring. Nurses are responsible for identifying situations in which individuals can benefit from genetic evaluation and counseling. They should be aware of the local genetic resources, aid families in finding

services, and offer support and care for children and families affected by genetic conditions. Nurses can direct families to appropriate resources. The Genetic Alliance (www.geneticalliance.org) is a nonprofit organization that has a database of support groups for genetic conditions. The National Society of

Genetic Counselors (www.nsgc.org) lists genetic counselors by state. GeneTests (www.ncbi.nlm.nih.gov/sites/GeneTests) is a publicly funded medical genetics information resource developed for health care professionals; it is available at no cost to everyone.

KEY POINTS

- Hyperbilirubinemia is caused by a variety of factors, including maternal-fetal Rh and ABO incompatibility.
- Acute bilirubin encephalopathy and kernicterus are serious neurologic complications resulting from high levels of unconjugated bilirubin.
- Erythroblastosis fetalis leads to anemia, edema, and the cytotoxic effects of unconjugated bilirubin.
- The administration of Rh₀(D) immune globulin to Rh-negative and Coombs' test-negative women provides passive immunity and minimizes the possibility of isoimmunization.
- Neonatal exchange transfusion with type O, Rh-negative RBCs serves to treat anemia and acidosis and remove bilirubin, maternal antibodies, and fetal RBCs that are beginning to hemolyze.
- Major congenital defects are the leading cause of death in term neonates.
- The most common major congenital anomalies that cause serious problems in the neonate are congenital heart disease, neural tube defects, cleft lip or palate, and developmental dysplasia of the hip.
- Minor anomalies can be part of a characteristic pattern of malformations.
- Current technology permits the prenatal diagnosis of many congenital anomalies and disorders.
- The most widespread use of postnatal testing for genetic disease is the routine screening of newborns for inborn errors of metabolism.
- The curative and rehabilitative problems of an infant with a congenital disorder are often complex and require a multidisciplinary approach to care.
- Parents often need special instructions (e.g., meeting nutrition requirements, cast care, or home phototherapy) before they take a high risk infant home.
- The supportive care given to the parents of infants with an abnormal condition must begin at birth or at the time of diagnosis and continue for years.

Perinatal Loss, Bereavement, and Grief

Beth Perry Black

 <http://evolve.elsevier.com/Lowdermilk/MWHC/>

LEARNING OBJECTIVES

- Define perinatal loss, bereavement, and grief.
- Describe the causes of perinatal loss.
- Describe the various responses parents and families may have to perinatal loss.
- Analyze the personal and societal issues that can complicate responses to perinatal loss.
- Formulate appropriate nursing diagnoses for people experiencing perinatal loss.
- Identify specific nursing interventions to meet the special needs of bereaved women, their partners, and their families related to perinatal loss and grief.
- Differentiate between helpful and hurtful responses in caring for women and their partners experiencing a perinatal loss.
- Define complicated grief related to perinatal loss and how nurses can assess for it.

Expectant parents anticipate the birth of their baby with joy and hope. For some women, their partners, and their families, however, pregnancy becomes a time of loss, resulting in profound grief and a period of bereavement in which they mourn the loss of their expected child. Loss associated with reproduction covers a wide range of conditions and events. Grief and loss in perinatal settings can be especially upsetting to nurses (Jonas-Simpson, Pilkington, MacDonald, & McMahon, 2013); caring for healthy pregnant women who give birth to healthy infants is the more typical expectation for nurses in these settings. Understanding grief and bereavement as a human response to loss is important, however, because nurses in a variety of settings associated with women's health will encounter clients for whom the childbearing process results in loss.

The study of loss surrounding childbearing and the subsequent grief and bereavement is relatively new. For purposes of this chapter, **perinatal bereavement** is defined as the complex emotional responses experienced by women and men beginning immediately after the death of an expected child through miscarriage, stillbirth, neonatal death, or termination of pregnancy for fetal anomalies. Perinatal bereavement usually is characterized by grief that can vary in intensity and duration across genders and is influenced by many situational, internal, and external factors (Fenstermacher & Hupcey, 2013). The focus of this chapter is to prepare the nurse to provide sensitive and supportive care to women, their partners, and families experiencing losses related to childbearing. An overview of loss, grief, and bereavement is presented as a

guide for assessing and understanding the responses of persons experiencing perinatal loss.

LOSS, BEREAVEMENT, AND GRIEF: BASIC CONCEPTS AND THEORIES

Much of the current understanding of loss, bereavement, and grief is based on the initial work of Elisabeth Kübler-Ross, a Swiss-American psychiatrist who in 1969 published *On Death and Dying* (Kübler-Ross, 1969). In this book Kübler-Ross first described five stages of grief—denial, anger, bargaining, depression, and acceptance—that she understood as being central to a person's movement through the experience of loss. Her work was groundbreaking in that she began the conversation about how people experience loss, particularly death. Most researchers and clinicians who now study or work with dying clients and their families understand that the process of grief is not linear, that is, people do not move uniformly through the stages in a particular order at a specific time. Rather, the grief experience is individual and is influenced by many factors, including the meaning of the loss. This is not to say that Kübler-Ross was incorrect in identifying these stages; in fact, many grieving people experience these exact responses. The problem occurs when grieving individuals' responses are considered out-of-sequence or "abnormal" when they do not fit these stages as she described them. Despite the limits of Kübler-Ross's model, the value of understanding grief responses is significant in assisting grieving individuals in working through their sense of loss and sadness.

Nurses in perinatal settings may not feel comfortable discussing grief and loss with women and families facing a pregnancy loss, stillbirth, or death of their newborn. Grief responses such as crying or questioning by the woman can be upsetting to the nurse who may not feel adequate in helping grief-stricken women and their families. Nurses may have their own grief responses that can be distressing, making it difficult to turn attention to the care of the client. In fact, nurses are susceptible to traumatic stress secondary to the perinatal loss and should be proactive in garnering support for themselves, especially from their peers, when a perinatal loss occurs (Puia, Lewis, & Beck, 2013). Providers with little experience in managing loss are at highest risk for clinically significant distress in perinatal settings, and formal training does not appear to be protective from distress related to perinatal loss (Wallbank & Robertson, 2013). The following two sections contain definitions of loss, bereavement, grief, and mourning commonly used in end-of-life care settings and theoretic orientations to loss that may be useful for nurses in perinatal settings in understanding the responses of their clients. This in turn can increase nurses' expertise and comfort in providing care when a pregnancy ends in loss.

Defining Loss, Bereavement, Grief, and Mourning

Losses are any experiences in which a valued person or object can no longer be seen, touched, heard, known, or otherwise experienced. In childbearing settings the losses can be complicated in that the extent of the fetus being "known" is typically limited to the pregnant woman through fetal movements, ultrasound images, and pregnancy signs and symptoms. Her partner may have felt fetal movement through the woman's abdomen if the pregnancy is advanced; many partners are present for ultrasound exams. Early in pregnancy, couples may not yet have even told their close family and friends of the pregnancy prior to a miscarriage.

The meaning of a loss will have a significant effect on how the loss is experienced. For many women and families, a perinatal loss at any stage can mean the loss of hope for a planned-for child, plans for the future, an heir or legacy, or a "perfect" or healthy baby. Meanings of pregnancy are highly variable—a loss can hold great meaning for one woman and her family, whereas a woman in a different circumstance may feel relief (possibly guilt) that the pregnancy is over. The wise nurse is cautious, however, in making assumptions about the meaning of a pregnancy loss for any one woman and family.

Bereavement is the state of being without a valued other, especially by death. Sometimes bereaved individuals are described as "bereft" or "the bereaved." Bereavement is characterized by the emotional state of **grief**, the profound sadness and despair that accompanies a loss. Grief is now recognized as a process through which bereft persons work in coming to terms with their loss. In a concept analysis of grief, Cowles and Rodgers (2000) identified attributes of grief: (a) grief is *dynamic* and involves complex emotions, thoughts, and behaviors that shift and change; (b) grief is a *process* that is enduring and has no time limit; (c) grief is *highly individualized* and manifested differently from person to person; and (d) grief is *pervasive* involving psychological, social, physical, cognitive, behavioral, and affective responses and can affect every aspect of a person's life. Grief is particularly affected by the meaning of the

loss to the person. Note that Kübler-Ross's stages of grief were described as a process; the current understanding of grief is that it is a process but one that is not linear. This means that people may return to earlier states of grief over time as their grief resolves and they heal.

Mourning, another word often associated with loss, involves the culturally mandated traditions and rituals in the time after a death. Bereaved persons are sometimes described as being "in mourning" for some time after the death of a loved one. Funerals, memorial services, wearing black, or otherwise acknowledging the death are some common mourning rituals in the United States. Mourning rituals are intertwined with cultural norms and expectations and can vary greatly across families, religions, nationalities, and ethnicities.

Useful Grief Theories in Perinatal Settings

End-of-life care theories provide an important basis for the care of women and their families who are experiencing pregnancy loss. Although it is beyond the scope of this chapter to fully explain the theoretic foundations of end-of-life care, familiarity with these concepts allows perinatal nurses to understand individual and family experiences of loss in a deeper way.

Perinatal loss can be an ambiguous loss, a type of loss in which the object of grief is missing (Boss, 2006), such as a fetus that has never been physically seen or held by his or her parents and is unknown to others. For women experiencing a miscarriage and their partners, for instance, the loss may be of a developing fetus whose sex is yet unknown and may never be known. Some losses associated with miscarriage are the experience of being pregnant, a hoped-for baby, and a future with this child. Furthermore, the reason for the miscarriage can remain unclear, adding to the ambiguity of the loss. The conventional customs of mourning might not be observed in this case, thereby hindering coping and circumventing the solace that is found in these rituals (Lang, Fleischer, Duhamel, et al., 2011).

Losses surrounding pregnancy are sometimes not openly acknowledged and mourned publicly, thereby limiting social support. This is known as **disenfranchised grief** (Doka, 1989), which leads to a sense of isolation in bereaved individuals. Perinatal losses are often characterized as ambiguous because the loss is undefined or unseen and disenfranchised because the grief of bereaved mothers, partners, and families is unacknowledged. This situation can result in complicated grief, a complex situation in which grief may not resolve over time and the bereaved person grieves chronically (Rando, Doka, Fleming, et al., 2012). Cacciatore (2013) noted that failure by others to recognize the significance of a pregnancy loss—specifically stillbirth—implies that the expected baby's life had no value and that the mother herself may lack value in this time when life and death converge.

Two current theories of grief and bereavement—continuing bonds theory and dual process model—are helpful to perinatal nurses. These models reflect what contemporary grief theorists believe are more realistic views of the grief experience than older models (e.g., Kübler-Ross) in which grief resolution was expected to always occur (Mallon, 2011). The *continuing bonds theory* was developed by Klass, Silverman, & Nickman (1996) and maintains that bonds of attachment that were forged in life continue into the future of the survivors. Because these bonds continue, the full resolution of grief is not detachment from the

one who has died, but the incorporation of the lost loved one into the bereaved person's own life. Perinatal losses pose a challenge because the bonds of attachment are newly formed and time is often short to create meaningful memories to sustain parents and families in the future. Much of current nursing care of women and families who experience stillbirth or neonatal death is oriented around the creation of meaningful rituals to carry forward into the future (Limbo & Kobler, 2010).

The *dual process model* described by Stroebe and Schut (1999) and emphasizes the processes and strategies individuals use to manage grief and bereavement, as opposed to stages of grief. Individuals move between behaviors oriented toward their losses (focusing on grief, their loss, and the past) and those oriented toward the restoration of their lives without their loved ones (focusing on the future, avoiding grief). Individuals can oscillate rapidly between these two orientations. Nurses who do not understand this phenomenon may be confused by what they construe as “denial” of a loss by their clients. For instance, a mother whose baby died at birth may stop crying soon thereafter, ask for food, take a shower, and talk on the phone. This is *not* a sign that she is not grieving or that she is “in denial.” She may be strategic in alleviating her profound grief by focusing for a while on less dramatic, day-to-day activities. Denial is a psychological defense mechanism by which a person protects oneself from a distressful reality by removing that reality from conscious awareness. It is different from the restorative behaviors explained by the dual process model, in which the person is conscious of the loss but is seeking temporary relief from the expression of profound grief.

Caring Theory to Guide Nursing Practice When Pregnancy Ends in Loss

Women, their partners, and extended families look to the nursing staff for support and understanding during the time of loss. Caring theory provides a model for practice by which nurses can be particularly helpful to grieving individuals. Swanson developed her caring theory from her research with women and their partners experiencing a perinatal loss, specifically miscarriage (Swanson, Chen, Graham, et al., 2009). Swanson's caring theory has five concepts that describe key elements in the nurse-client relationship:

1. Knowing
2. Being with
3. Doing for
4. Enabling
5. Maintaining belief

Knowing means that the nurse must assess the woman, partner, and family (as applicable and appropriate) in order to understand how they perceive the loss and what the loss means to them. *Being with* denotes the caring presence of the nurse, who as a function of professional caring conveys acceptance of the various feelings and perceptions of each family member. *Doing for* refers to those activities and interventions that the nurse performs on behalf of the woman and her family that provide physical care, comfort, and safety. *Enabling* occurs when the nurse offers the woman and her family options for care. Providing information, giving guidance, articulating choices for decision making, and giving support help the family feel more in control of a situation in which they can feel out of control. Enabling allows them to feel more comfortable in asking

for what they need such as creating memories, spending time with their infant or with the infant's body, or garnering support from other sources such as friends and clergy. Women and their families then have more autonomy in working through their grief within the family's own traditions and needs. *Maintaining belief* involves encouraging the woman and her family to believe in their ability to survive their loss. By spending time with the family, the nurse becomes familiar with their strengths and coping abilities and helps them draw on these resources to grow from the loss (Swanson et al., 2009).

TYPES OF LOSSES ASSOCIATED WITH PREGNANCY

End-of-life care in perinatal settings brings together death—one of the most difficult of human experiences—and birth, one of life's most joyous occasions. When death and birth coexist, nurses face great challenges. Intervening effectively for these women and families in this situation takes great skill, which can be cultivated by a thorough understanding of the implications of types of pregnancy losses.

Defining Perinatal Losses

Losses associated with reproduction include infertility, miscarriage, intrauterine fetal death (IUID), stillbirth, and deaths of live-born infants soon after birth. In 2011 the American Academy of Pediatrics (AAP) Committee on Fetus and Newborn recommended standard terminology for deaths associated with pregnancy (Barfield & Committee on Fetus and Newborn, 2011). **Miscarriage** is any in utero death prior to 20 weeks of gestation. **Fetal death** refers to any death prior to birth after 20 weeks of gestation. Fetal deaths are subdivided as early (20 to 27 weeks of gestation) or late (≥ 28 weeks of gestation). A **stillbirth** is a fetal death that occurs at 20 weeks or later. Death of a live-born infant less than 7 days old is referred to as an **early neonatal death**; those occurring between 7 and 28 days are **late neonatal deaths**. Any live birth resulting in death within the first year is defined as an **infant death** (Barfield & Committee on Fetus and Newborn). It is important to understand that these events not only represent emotional distress for women and families but also are indicators of the health of women and infants. Health care practitioners are required to report fetal deaths, live births, and infant deaths, which collectively are used to determine perinatal and neonatal mortality rates at a national level. These rates are in turn used to influence policy decisions related to allocation of resources to improve care and outcomes.

Types of Perinatal Losses

Perinatal loss is a general term commonly used to describe losses associated with childbearing, particularly those losses that occur after conception has occurred and the woman has recognized that she is pregnant. The complex emotional issues of infertility including loss and grief for women and men are discussed in Chapter 9. For the remainder of this chapter, the focus is on losses specific to pregnancy and the early neonatal period.

Miscarriage

Losses associated with childbearing are common. Early spontaneous losses are typically referred to as miscarriages. Specific

information about the causes, symptoms, and signs of miscarriages are presented in Chapter 28. Although some providers refer to these losses as “spontaneous abortions,” miscarriage is becoming the accepted term among providers to differentiate this form of loss from elective abortions. Losses that occur early in pregnancy are often suffered in isolation because other people in the women’s family and social network may not even know about the pregnancy and subsequent loss. Because family and friends may not feel comfortable bringing up the loss with the woman and her partner, they may experience both grief and loneliness (Brier, 2008).

Serious Fetal Diagnosis

Diagnosis of a serious fetal defect is a newly described form of perinatal loss. Current standards of maternity care include at least one ultrasound examination, often done between 17 and 20 weeks of gestation, at which point the fetal anatomy can be assessed for growth and the presence of congenital defects. The increased use of ultrasonography in prenatal care has resulted in increased diagnosis of fetal defects; note that this is an increase in the *diagnosis* of defects, not in the actual *incidence* of defects. Women and their partners who find out that their expected baby has a defect face difficult decisions about the whether to continue or to terminate the pregnancy. These decisions are often made based on the severity of the defect and the certainty of the prognosis.

The diagnosis of a severe fetal defect causes several losses for couples, including “loss of the joy of pregnancy, possibilities inherent in pregnancy, the dream child, innocence, and the world as they knew it” (Sandelowski & Barroso, 2005, p. 311). Many fetuses with particularly severe defects die in utero. Some live-born infants survive only a few minutes or hours after birth, while others stay days, weeks, or months in a neonatal intensive care unit (NICU), where complex technologies and invasive treatments may be used to try to save their lives. Once these fragile infants are admitted to the NICU, parents can be confronted with making difficult end-of-life decisions about their baby (Kenner, 2014).

CLINICAL REASONING

Care of a Couple with a New Diagnosis of a Severe Fetal Defect

Diana is a 36-year-old multipara who is pregnant with her third child. She and her husband, James, are excited about today’s 18-week ultrasound exam because they are hoping to find out the sex of the baby. They already have two sons and are hoping this baby is a girl. The pregnancy has been advancing without difficulty. Diana has felt fetal movement for about 2 weeks and her early nausea and vomiting have resolved. The ultrasound, however, reveals that their expected baby has a hypoplastic left heart syndrome and a severe diaphragmatic hernia. Diana and James learn that either one of these defects is life threatening when they occur alone; when they occur together, death is almost certain. They are devastated. Several consulting physicians come in to talk to them about the problems and what, if anything, can be done. Diana and James ask if they can go home and come back in 2 days once they have the chance to process the news. Diana is crying and tells the nurse that she “can’t take in any more information today.” When the nurse tells James that she is sorry about what they have found out, he snaps at

her, “Mistakes happen all the time. This is one of those times. Our baby is fine.” He appears angry and tells Diana to “pull herself together.”

1. Evidence—What can the nurse discern from the encounter in the clinic with Diana and James?
2. Assumptions—What assumptions can be made about the following factors?
 - a. Each partner’s grief responses
 - b. The relationship between Diana and James
 - c. The level of information that can be assimilated at once
3. What are the priorities for nursing care based on the couple’s immediate responses to the diagnosis?
4. Does the evidence objectively support your conclusion?

Pregnancy Termination

Few topics in women’s health are more controversial than elective abortion; however, nurses in perinatal settings sometimes encounter women who have chosen to terminate the pregnancy or who have had an abortion in the past. These decisions are shaped by numerous, varied, and often complex circumstances, and women choosing pregnancy termination or seeking care afterward require sensitive attention.

The diagnosis of a severe congenital fetal defect often results in pregnancy termination, sometimes referred to as TOPFA (termination of pregnancy for fetal anomalies), especially if the prognosis for the fetus or newborn is dire or clearly fatal. Sandelowski and Barroso (2005) described a severe fetal diagnosis as posing an “existential crisis” that required women and their partners to “choose the fate of their unborn child and, in the process, confront, reconcile, and subsequently act on their beliefs about human imperfection and disability, the obligations of parenthood, and the acceptability of abortion” (p. 311). Couples receiving the news that their expected baby has a severe, life-threatening problem must often, in a very short time, make a decision whether to terminate the pregnancy. The gestational age limit for legal abortion shortens the time that women have to decide because the diagnosis is often made in midpregnancy. The gestational age limit for abortion varies across states.

A difficult situation of loss occurs when a woman is found to have a multifetal pregnancy (occurring most commonly after infertility treatments) and a procedure known as **selective reduction** is recommended to reduce the number of developing embryos to a number (usually one to three) that can be safely carried to near term. Morbidity and mortality of higher-order gestations (more than two fetuses) are significant and are often related to complications from preeclampsia, preterm labor, and other conditions requiring significantly early birth. The loss and grief experienced by the expectant parents can moderate their joy if selective reduction of multifetal pregnancy is recommended (Little, 2010). Women who have selective reductions or TOPFAs may benefit from ongoing psychosocial support in order to prevent or reduce psychological distress over time (Mashiach, Anter, Melamed, et al., 2013).

Women who choose abortion as a result of social and financial obstacles that preclude continuing the pregnancy can have coexisting, seemingly opposite feelings (Stotland, 2011). The majority (69%) of women who have elective abortions have incomes below 200% of the official poverty levels and 61% have one or more children (Jones, Finer, & Singh, 2010). Stotland

noted that among women who have an abortion, sadness is not uncommon despite their relief afterward. Women can mourn the end of the pregnancy despite determining that ending the pregnancy was the best option available at the time. Nurses who provide care for women in settings where pregnancy terminations are performed must be nonjudgmental and recognize that women experience a sense of loss and grief even when the abortion is elective.

Other Losses

Other losses associated with childbearing can result in distress or even grief, even if the loss does not involve death. In the United States, 11.5% of births occur prematurely (<37 weeks) (Martin, Hamilton, Osterman et al., 2013). Preterm birth disrupts the pregnancy trajectory and can result in a transition to parenthood for women and their partners that is unexpected and for which they are unprepared. The baby that they had dreamed of and hoped for may be replaced by the reality of a small baby that is sick or requires lengthy hospitalization before going home. Breastfeeding can be delayed or foregone, resulting in another loss.

Other women grieve the loss of the birth experience they have dreamed of and planned for, specifically a vaginal birth. Despite being happy for the birth of their newborn that may have otherwise not survived a serious obstetric complication, some women feel sadness and even grieve the fact that they required a cesarean birth. Sadness can be compounded when the cesarean surgery is done as an emergency procedure under general anesthesia, meaning that the woman and her partner are separated during the birth and the new mother does not hear her baby's first cries. The reality of the birth experience is inconsistent with the parents' hopes and dreams.

Perinatal Care Settings Where Nurses Encounter Loss

Nurses have a significant influence on how women, their partners, and families experience and cope with perinatal loss. Nurses encounter situations of loss in a variety of settings, including antepartum, labor and birth, neonatal, postpartum, and gynecologic inpatient units and prenatal, gynecologic, and infertility outpatient clinics, family planning settings, and general medical offices. In each of these settings nurses can provide sensitive care to persons experiencing loss. Nurses in many inpatient settings have developed protocols that provide clear direction to all staff about how to help women and families through this difficult event. In some units experienced nurses or social workers who are particularly comfortable in helping bereaved families are designated as perinatal grief consultants. They are available to help parents and assist, educate, and support staff in caring for grieving parents and families. In addition, many institutions have follow-up programs involving phone calls, home visits, and support groups that are effective in helping parents after discharge.

Perinatal palliative care, sometimes referred to as perinatal hospice, is a formalized end-of-life (EOL) interdisciplinary care model specifically aimed at intervening when pregnancy is expected to end in stillbirth or neonatal death. Perinatal care providers, including nurses, view perinatal palliative care as a positive means that allows families a voice in the planning and preparation for the birth and death of their expected baby

(Wool, 2013a), although not all factors that can benefit expectant parents in this situation have been identified (Wool, 2013b). In a review of intervention studies of support for mothers, fathers, and families after a perinatal death, Koopmans, Wilson, Cacciatore, and Flenady (2013) found that little is yet known about the role and effectiveness of different types of perinatal bereavement support.

Most palliative and hospice care for older clients with terminal illness is delivered by community-based palliative care and hospice agencies whose main purpose is to provide symptom management and grief and bereavement care. Perinatal palliative care occurs in three settings: large referral centers such as academic medical centers with maternal-fetal medicine specialists and neonatal intensive care units; community hospital settings where staff members occasionally provide care for women and families experiencing stillbirth, preterm birth, or other types of perinatal losses; and traditional palliative care or hospice agencies that have expanded care options to families experiencing a perinatal loss.

Each of these models has strengths and weaknesses. Large referral centers encounter perinatal losses frequently as a function of the number of high risk pregnancies followed in these settings. Providers in these settings have a great deal of experience with loss, and some medical centers have well-developed perinatal palliative care teams and protocols. Follow-up grief and bereavement care, however, can be difficult because the bereaved families often live in communities far from the medical center. Community hospitals are increasingly developing interdisciplinary perinatal palliative care programs in response to the needs of bereaved families in the local community. Importantly, the programs may serve families for whom the expected baby has a congenital defect that is incompatible with life (e.g., anencephaly, bilateral renal agenesis) and for whom the high-tech interventions of a medical center would be futile. EOL care agencies have extensive experience in symptom management and grief and bereavement care; however, the specific needs of families with losses related to childbearing may be outside their usual expertise. Many of these agencies are developing specific programs to assist with perinatal losses with specific staff identified to provide care under these circumstances. A comprehensive list of agencies providing perinatal palliative care or hospice across the United States and in other parts of world can be found at www.perinatalhospice.org. This website is updated frequently and contains other information about perinatal loss and EOL care that is helpful to both nurses and families.

MILES'S MODEL OF PARENTAL GRIEF RESPONSES

The previous section contained definitions of grief and several related concepts, and different types of perinatal loss were explained. Putting concepts into practice, however, involves using care models. For instance, perinatal palliative care involves using concepts germane to care of childbearing families and EOL care. A key goal of all care for women and families with a perinatal loss is helping them through their grief. Understanding key elements of grief can help nurses be prepared to encounter the poignant, painful loss for families when their expected baby dies.

The model of grief presented here is based on years of clinical work by Margaret Miles, who worked with bereaved parents in several settings and in community support groups throughout her career (Miles, 1984). Miles usually referred to pregnant women and their male partners as parents and often referred to them as mothers and fathers. It is important, however, to recognize that not all pregnant women see themselves as mothers yet; neither are all of their partners necessarily male nor do they always see themselves as fathers. Miles's work remains relevant with regard to grief responses of women and their partners; to be consistent with Miles's model, however, the terms *parents* and *parental* are used in the broadest manner possible across pregnancy and the early postpartum period.

Miles hypothesized that parental grief responses occur in three overlapping phases (Box 37-1). An early period of *acute distress* and shock is followed by a period of *intense grief* that includes emotional, cognitive, behavioral, and physical responses. *Reorganization* occurs when they return to their usual level of functioning, although the pain associated with the death remains. Grief is a long-term process that can extend for months and years; some aspects of grief endure through life. This is consistent with continuing bonds theory discussed previously, in which the goal of the grief process is not resolution but rather the incorporation of the person who has died into one's own life moving forward.

Acute Distress

Pregnancy loss or the death of an infant can be an acute and distressing experience for women and their partners. The loss encompasses a loss of their identity or anticipated identity as a mother or father to this particular child and their dreams related to parenthood. A period of acute distress characterized by shock and numbness is initiated after learning of an intrauterine death, impending stillbirth, or infant death. Parents experience a sense

of unreality, loss of innocence, and powerlessness, described as being devastated or feeling like they are in a bad dream, a fog, or trance. Disbelief and even denial can occur. Profound sadness accompanied by intense outbursts of emotion and crying is common. Occasionally a lack of affect, calmness, or even euphoria can reflect their numbness. For some, their way of coping with a profound loss is to avoid emotional displays. Women can develop mental health problems such as depression and anxiety from overwhelming grief and sense of loss.

Depression is a medical condition that differs from grief. Recognizing symptoms of depression, especially in the presence of grief, can be very difficult. Nurses must be aware of the difference between grief and depression. Screening tools for depression are easily administered in clinical settings and can be very useful in helping determine if an individual has symptoms of depression. Nurses must seek referrals for those women and partners who show symptoms of depression. The coexistence of depression and grief can have serious implications for a person's health and daily functioning. Much of the literature and research on grief after perinatal loss or infant death has focused on the woman or mother. Similarly, much of the attention at the time of a loss is on the woman, and her partner is usually expected to be her main support. The partner's grief is sometimes not recognized or acknowledged. The response of men can be more variable than that of women and can depend on the level of identification with the pregnancy. With early miscarriage or ectopic pregnancy, for instance, some partners or fathers may not yet have developed a strong investment in the expected child. However, many fathers are profoundly affected and grieve deeply after perinatal loss, yet their feelings are often ignored (O'Leary & Thorwick, 2006). The nonbiologic mother in a lesbian couple may be profoundly affected by the biologic mother's loss; sometimes she may have a prior history of infertility or loss of her own that she is grieving again (Black & Fields, 2014). Partners may hide their feelings from each other to protect the other during times of loss (Stroebe, Finkenauer, Wijngaards-de Meij, et al., 2013).

Men are distressed by the grief of their partner and often feel helpless as to how to help her with the intense pain (O'Leary & Thorwick, 2006). Some men appear stoic in response to a sense of need to remain "strong" for the mother and other family members when in fact they are experiencing deep pain and need help in acknowledging these feelings. Because many men do not easily share feelings or ask for help, nurses may need to be intentional in addressing their grief and in helping them realize that they too need to receive support from others as they grieve. Experiences of grief are complex, and each partner within a couple (heterosexual or same sex) must come to terms with both the loss and the effects of the loss on their partner as they determine the resultant effect on their relationship with each other (Avelin, Rådestad, Säflund, et al., 2013).

During the acute distress period, parents face the first task of grief, accepting the reality of the loss. The pregnancy has ended or the baby has died, thereby changing their lives. They are often required to make many decisions during this period when normal functioning is impeded and decisions are difficult to make. This can be especially painful and difficult for young couples who have limited or no previous experience with death. These couples may turn to their own parents to help make difficult decisions regarding funeral arrangements or disposition of the

BOX 37-1 Conceptual Model of Parental Grief

Phase of Acute Distress

- Shock
- Numbness
- Intense crying
- Depression

Phase of Intense Grief

- Loneliness, emptiness, yearning
- Guilt
- Anger, resentment, bitterness, irritability
- Fear and anxiety (especially about getting pregnant again)
- Disorganization
- Difficulties with cognitive processing
- Sadness and depression
- Physical symptoms

Reorganization

- Search for meaning
- Reduction of distress
- Reentering normal life activities with more enthusiasm
- Can make plans, including decision about another pregnancy

Adapted from Miles, M. (1980). *The grief of parents...when a child dies*. Oak Brook, IL: Compassionate Friends; Miles, M. (1984). Helping adults mourn the death of a child. In H. Wass, & C. Orr (Eds.), *Childhood and death*. New York: Hemisphere.

body because they have more life experience. However, some well-meaning grandparents and other family members may try to make all the decisions in order to spare the bereaved parents additional grief associated with disposal of the baby's body or making funeral arrangements. The nurse as advocate can be very important in making sure that the bereaved parents are comfortable with the extent to which well-meaning family members are involved. An important goal of perinatal palliative care services is to help families make as many decisions as possible in advance of the birth, freeing them from having to make choices in the early acute phase of grief when decision making is very difficult.

Intense Grief

The phase of intense grief encompasses many difficult emotions as the parents work through their pain and adjust to life without the child they were expecting. This phase displaces the acute grief and will likely take longer to move through. In the early months after the loss parents often experience feelings of loneliness, emptiness, and yearning. Women may report that their arms literally ache to hold the baby or they may think they hear a baby crying. Milk production still occurs for most women as part of the normal postpartum physiologic changes, even though there is no infant to feed. Lactation is a poignant reminder of the loss and requires careful planning by the nurse to assist the woman in managing the milk and breast discomfort that can occur.

Preoccupation with the expected baby that died is not uncommon. Women who have recently given birth often want to talk about details of the experience; women who had a stillbirth or whose baby died may have a particularly strong need to share details about the birth. Nurses can actively listen, taking time to allow women to work through their birth and loss stories as they try to make sense and meaning of the experience.

Going home without the baby is particularly difficult, and bereaved parents may face a decision about what to do with the nursery and baby items that they have collected or been given. Some women may want the nursery taken down before they go home, whereas others want the room left intact until they have had time to grieve their loss. Well-meaning grandparents, relatives, or friends may rush to put away nursery furniture and baby items with the thought that they would be sparing the bereaved parents additional pain. In fact, their actions might only complicate the grief if parents were not involved in the decision. The bereaved parents should have the opportunity to make the decision about when, and by whom, the nursery and baby items are stored or given away.

Guilt can accompany intense grief. During this phase women may wonder what they did to cause the loss or if there was anything that they could have done to prevent it. Women are particularly vulnerable to feelings of guilt because of their sense of responsibility for the well-being of the fetus and baby. Often losses occur with no clear cause, leaving the woman to speculate about the cause of the loss and her role in it. Sometimes the guilt can be intense if the woman believes she is being punished for some unrelated event. Pressure to be “perfect” in one's lifestyle such as nutrition, exercise, and rest can encumber women with guilt if a pregnancy loss ensues. Women sometimes analyze their behaviors in detail in an effort to explain the loss; they may focus on occasions when they may have had a glass of wine or a cigarette, or stayed out late, blaming themselves for something

that was inevitable or unavoidable. Women engaging in self-blame need emotional reassurance that they were not at fault. As their sadness begins to resolve, couples may experience guilt when they begin to socialize, enjoy their family and friends, and experience pleasure again despite the loss of their baby.

Anger, resentment, bitterness, or irritability are common during this phase of grief. Anger can be focused on the health care team who, in the opinion or belief of the bereaved parents, failed to save the pregnancy, fetus, or infant. Some parents direct their anger toward God, blaming God for allowing the loss to occur. Sometimes people experience a spiritual crisis as a result of the loss. Anger may be focused toward family, friends, and peers when they do not provide the support that bereaved parents need and want. Feeling anger at mothers and fathers who appear not to “deserve” or appreciate their children is common; bereaved parents may find that news of neglected or abused children is more intolerable than it was before their loss. Being around pregnant women can be very upsetting. Prolonged anger and generalized irritability may be signs of depression that needs treatment by a mental health care provider.

When couples begin to consider the next pregnancy, they are likely to experience fear and anxiety due to concerns about another tragic outcome (DeBackere, Hill, & Kavanaugh, 2008). Some women want to become pregnant again right away; tension can arise between partners when one is ready to pursue pregnancy again and the other is not. Deep sadness occurs when the parent faces the full awareness of the reality of the loss; this time can be characterized by *disorganization*, a time when individuals can experience a variety of changes. Cognitive changes can occur, such as an inability to concentrate, confused thought processes, difficulty in problem solving, and poor decision making. Disorganization often causes difficulties in keeping up with work and family expectations. Returning to work can be painful as bereaved parents face their colleagues and coworkers. Some people find a great deal of comfort in returning to work, however; it gives them a sense of normalcy and routine in their grief. Families of children who have died have reported finding support from their friends as particularly useful, as is informal support from health care providers acting outside of their formal role as nurse, social worker, or physician (Gear, 2014).

Physical symptoms of grief include fatigue, headaches, dizziness, or musculoskeletal aches and pains. Bereaved individuals can be immunosuppressed, leading them to contract respiratory and gastrointestinal infections more easily than before their loss. Lack of sleep, a common complaint among grieving individuals, contributes to their risk for health problems. Weight changes are common: appetites can be poor or individuals can turn to food as a coping response. Changes in health behaviors are common in grieving people.

Grief is very personal, ongoing, and difficult to endure. It is important for nurses to help grieving parents understand their responses and make sense of their feelings. Giving them a safe place to express their feelings is a key nursing intervention. The path to healing can be difficult but is eased to a degree when bereaved clients feel supported and their profound loss is affirmed.

Reorganization

From the time of the pregnancy loss or infant death, parents attempt to understand “why?” This leads to a long and intense

search for meaning. At first the question of “why” is focused on the cause of death. Finding few good answers, parents focus next on “why me, why mine?” These questions lead some parents into an existential search about the meaning of life and death. The search for meaning involves questions such as “What does this loss mean to my life?” “What is life all about?” “What do I do now?” This search continues into the phase of reorganization and can lead to profound changes in the bereaved parents’ views and philosophies about life.

Time helps to ease the painful feelings of grief. Although some grief models focus on “letting go” as an important step in the grief process, bereaved parents often want to hold on to their relationship with their child (Davies, 2004). With perinatal loss, however, parents have few, if any, memories of their infant to provide a balance to their sense of loss. They usually cherish relics and mementos of birth and evidence of the life of their baby, even if by ultrasound photos. Some perinatal EOL settings provide numerous forms of mementos to memorialize the baby, such as hand molds, footprints, locks of hair, clothing, and blankets. One bereaved mother described her plan to preserve her baby daughter’s scent by storing in a sealed bag the cap that was placed on the baby at birth. This live-born baby with known serious defects died at 8 hours of age after lengthy resuscitation efforts in the NICU. The mother created an elaborate set of memorabilia, did online blogging, and joined a support group of bereaved mothers who reach out to newly bereaved mothers. She sought to make meaning of her daughter’s short life by helping other mothers through their pain. Wisely, she recognized that she had to resolve some of her own grief before she could safely provide support for other bereaved mothers.

Like the bereaved mother just described, overwhelming feelings become less painful as time passes. Reorganization occurs when the parent is better able to function at home and work, experiences a return of self-esteem and confidence, can cope with new challenges, and has placed the loss in perspective. Reorganization often—but not always—occurs after several months or a year as parents begin to move on with their lives. Enjoying pleasures without guilt, nurturing self and others, developing new interests, and reestablishing relationships are signs of moving on. For some women and families, another pregnancy and the birth of a subsequent child are important steps in moving on with their lives (Swanson, Connor, Jolley, et al., 2007). However, the term *recovery* is not appropriate because the grief related to perinatal loss, as with any loss, can continue for life. Parents have reported that they will never forget the baby who died, and they are changed from the loss. They note certain anniversary dates related to the pregnancy and birth, such as the day they found out that the baby had a congenital defect, the date of a miscarriage, the date of birth, and the date of death.

Resuming sexual activity can very complicated for grieving couples. Often women are physically ready to resume sexual activity before they are emotionally ready. Some women and their partners find that sexual activity is important for emotional closeness and healing, whereas others have a decreased desire for sex. Partners may have divergent views about when and how to resume sex; nurses can help couples to understand that this is common. Continuing conflicts around sex can be

detrimental to a couple’s relationship and may require professional counseling to help resolve this issue. Through careful assessment nurses can help women and their partners determine if they can benefit from professional counseling as they work through the many complicated issues, including sexuality, that are involved in living through grief.

Deciding to become pregnant again can involve intense and conflicting emotions (DeBackere et al., 2008). Fear of another loss can impede the decision. Couples may believe that their risk for another loss is higher than it actually is, so it is important that they understand why the previous loss occurred if possible. Often this is not possible; they need to understand that most losses are very unlikely to repeat, especially the first one. If a couple has had more than one pregnancy loss, genetic counselors may help determine if there is an explanation for the losses. Ambivalence is common. Expectant parents may feel anxiety during a subsequent pregnancy that tempers their excitement (Côté-Arsenault & Donato, 2007). This distress can continue even after the birth of a healthy infant and affect maternal attachment to the new baby (Armstrong, 2007). Men also report anxiety about the outcome of the next pregnancy (Armstrong; O’Leary & Thorwick, 2006). Expectant parents may delay emotional investment in a subsequent pregnancy and the developing fetus until after the midpregnancy ultrasound exam; some who had a loss late in the prior pregnancy will feel anxiety and distress throughout the subsequent pregnancy. At an extreme, mothers may withhold attachment to their new infant as a means of protecting themselves against the painful prospect of another loss.

FAMILY ASPECTS OF GRIEF

Nurses who care for grieving parents also often care for the extended family, including siblings of the expected baby and the parents of the bereaved woman and her partner (grandparents of the expected baby). The grief of grandparents is often complex because they are experiencing intense emotional pain related to the loss while witnessing and feeling the immense grief of their own child. It is extremely difficult to watch their son or daughter experience profound sadness with very few ways to comfort and ease their pain. As a result, the grief response can be complicated or delayed for grandparents. Some experience immense “survivor guilt” because they feel the death is out of order because they are alive and their grandchild has died.

The siblings of the expected infant also experience loss. Most parents begin to prepare their children for the arrival of a new baby at some point during the pregnancy. In assisting families in dealing with pregnancy loss, the children’s age, development, and level of understanding must be considered. Understanding death requires some ability to think abstractly and children do not fully understand the concept often until their early school years. Parents may create their own explanation to their children based on religious beliefs and their knowledge of their own child’s development and abilities. Children can have a great deal of difficulty understanding why there suddenly is no baby or the baby has not come home (Limbo & Kobler, 2009). A young child will respond to the reactions of his or her parents, picking up on cues related to parents’ sadness and behaviors. Young children may respond with clinging, changes in eating and sleeping patterns, or uncharacteristic behavior at the time when parents have limited patience

for responding to and meeting the child's needs. Older children have a more complete understanding of the loss. School-aged children can be frightened by their parents' sadness, whereas teens can understand more fully but feel awkward in responding. Teenagers may feel more comfortable in talking with their friends than with adults in dealing with their loss and grief.

Nurses can help to include siblings in grieving rituals to the extent the parents and the child feel comfortable, including seeing the baby's body. Nurses should follow the parents' lead but can suggest rituals and activities at the time of the loss that may be helpful for the children. The extent of the involvement of children at the time of a loss is likely to be determined by the length of the pregnancy. An early miscarriage will be managed differently from an unexpected stillbirth at term. Nurses who are specifically interested in perinatal loss may want to consider additional training such as that offered by Resolve Through Sharing (<http://www.bereavementservices.org/resolve-through-sharing>) to increase their skills in working with families experiencing these distressful losses.

CARE MANAGEMENT

Nursing care of mothers and their partners experiencing a perinatal loss begins the first time the parents are faced with the potential loss of their pregnancy or death of their infant. Supportive interventions are important when parents are anticipating loss, at the time of the loss, and after the parents have returned home. In order to provide competent, compassionate, individualized care to grieving parents and their families, the nurse first does a thorough assessment. Several key areas to address include the following:

- The nature of the parental attachment to the pregnancy and developing fetus or infant, the meaning of the pregnancy and infant to the parent, and the related losses they are experiencing. Whether a woman has experienced a miscarriage or ectopic pregnancy, stillbirth, or death of an infant, it is important to understand parents' perceptions of their unique loss.
- Complex family and cultural systems that influence the meaning of the loss. Feelings about perinatal loss can range from feeling devastated to feeling relieved. Listening to parents tell their story and being sensitive to the language used to describe their experience can help nurses gain an understanding of the meaning of the loss. For example, if a woman refers to a miscarriage as "losing a pregnancy," nurses should be careful to edit their language not to refer to "your baby" but to use the cues the woman has given with regard to her view of the loss. Similarly, if a woman refers to the fetus by name or as her daughter or son, nurses should do the same. For instance, a woman who elects to terminate the pregnancy when the fetus is found to have a fatal defect may not even mention the fetus at all or may refer to the fetus as "it" or "the pregnancy." This is a distancing behavior that is protective and normal. Nurses' language surrounding grief and loss should follow the cues given by the bereaved woman and partner, who may model the terms they prefer in referring to the loss.
- The circumstances surrounding the loss, including the time to prepare for the loss and the parents' level of understanding about the cause of the loss or death, and any related

unresolved issues. As nurses come to know their clients, they may discover special experiences that make their losses even more poignant. A history of infertility, repeated pregnancy losses, a previous stillbirth, or infant death can make this loss even more painful. In addition, other life circumstances such as illness of another family member, loss of a job, or other family stresses can increase distress. The nonbiologic mother in a lesbian relationship may have a history of losses of her own that are revisited when her partner experiences a loss. Also, losses for which the expectant parents are unprepared such as an obstetric accident late in pregnancy can constitute a traumatic event that requires a great deal of sensitive and intense intervention.

- The immediate responses of the mother and partner to the loss, whether their responses are similar or different, and if their responses are consistent with their past experiences and sociocultural contexts. An understanding of common responses to grief described earlier can be helpful in attempting to understand the unique grief responses of the mother, partner, and other family members. As nurses work with families, they can find out how the individual or family responded to a previous loss or a personality or behavioral trait that may be involved in their responses to this grief. For instance, if a woman who has usually been outgoing and talkative is now withdrawn and silent, the nurse can ask her if in the past this is how she has grieved other losses. People tend to grieve various losses in their lives similarly, even though the meaning of each loss is unique. In helping women and their partners through a perinatal loss, it is important to know if there is a history of infertility, previous pregnancy losses, or infant deaths. The accumulation of losses can negatively affect grief responses. It also is important to be sensitive to varied expectations during grief for men and women from different cultural groups (see section on cultural and spiritual needs of parents later in this chapter).
- The social support network of the woman and her partner (e.g., extended family, friends, coworkers, church) and the extent to which it has been engaged. Social support in response to a perinatal loss can be very important; however, nurses should assess the amount and type of support that the bereaved family desires. Some prefer a few days alone to recover physically, whereas others find comfort in being surrounded immediately with supportive family and friends. In inpatient settings the nurse may need to be an advocate for a woman desiring solitude by limiting visitors. Other women want or need assistance in communicating with family members about the loss, in making necessary decisions, and in contacting clergy. The nurse should not assume that all women who have had a perinatal loss will want to be visited by clergy, but should ask if the woman would like a visit by the hospital chaplain or her own pastor and if so, to identify the specific religious tradition.

Nursing diagnoses can include physiologic and psychosocial problems experienced by the individual woman or her partner, or problems occurring within the couple or family because of the loss and subsequent grief. Examples of nursing diagnoses include the following:

- *Anxiety* related to
 - lack of experience regarding how to manage the loss

 **NURSING CARE PLAN**
Fetal Death and Stillbirth at 35 Weeks of Gestation

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
<p><i>Risk for Complicated Grieving related to fetal death, as evidenced by intense expressions of grief for prolonged period of time</i></p>	<p>Parents will experience fewer expressions of grief as evidence of improved coping with their loss.</p>	<p>Prepare family for viewing infant by cleaning body and wrapping in clean blanket.</p> <p>Allow family quiet time to hold and view infant. Take pictures for family to keep if they want them.</p> <p>Provide a certificate for the family with vital statistics, along with identification bands, lock of hair (with parental permission), and footprints.</p> <p>Provide spiritual support as needed to assist with religious services, such as baptism and memorial services.</p> <p>Refer to appropriate community support groups or web-based resources.</p>	<p>To initiate and support them in their grief in a supportive setting</p> <p>To provide evidence of the reality of the death while honoring the existence of their baby</p> <p>To provide tangible evidence and memories of their baby's life as a means of creating bonds that they can incorporate into their lives</p> <p>To engage additional forms of support and to assist in creating meaning of their baby's life and death</p> <p>To facilitate grieving through interactions with others who have had the same experience</p>
<p><i>Situational Low Self-Esteem related to fetal death as evidenced by woman's sense of failure to become a mother</i></p>	<p>Woman will exhibit positive self-comments as evidence of her decreasing sense of failure.</p>	<p>Provide private time for expressions of feelings through therapeutic communication and active listening.</p> <p>Identify woman's perception and feelings about fetal death.</p> <p>Assist woman to identify positive coping mechanisms and support systems.</p> <p>Refer to appropriate health professionals for further evaluation and counseling, such as social services.</p>	<p>To have her express her feelings openly and without judgment</p> <p>To correct any misconceptions and alleviate guilt</p> <p>To promote feelings of self-worth</p> <p>To provide ongoing assistance as needed</p>
<p><i>Spiritual Distress related to perinatal loss</i></p>	<p>Individuals will verbalize a decrease in spiritual distress.</p>	<p>Assess individual's spiritual preference.</p> <p>Assist with or facilitate spiritual rituals.</p> <p>Provide opportunity for individuals to express feelings about perinatal loss.</p> <p>Attend memorial service/funeral if feasible.</p>	<p>To seek appropriate assistance in reinforcing the belief system</p> <p>To promote comfort for parents</p> <p>To acknowledge their grief</p> <p>To provide support to parents and to help process grief of health care provider</p>
<p><i>Interrupted Family Processes related to inadequate communication of feelings between partners and other family members</i></p>	<p>Partners will discuss feelings involving relationship with each other and family members.</p>	<p>Provide information to partners about how grief affects a family.</p> <p>Encourage partners to talk about their loss and its meaning to the family.</p> <p>Include other children as appropriate and the partners' parents in discussions of the loss.</p> <p>Offer follow-up contact (e.g., phone calls, grief conference).</p> <p>Refer family to perinatal or family support group if appropriate.</p>	<p>To facilitate expression of grief and sadness among family members</p> <p>To clarify the possible effects on the family</p> <p>To acknowledge and respect differences of feelings and grief among family members</p> <p>To provide opportunity for partners to ask questions, share feelings, and to receive information to help them understand the changing nature of grief over time</p> <p>To minimize a sense of isolation and facilitate communication and sharing of the experience of loss with other who have had similar experiences</p>

- worry about the partner
- intense concern over not achieving a pregnancy
- becoming pregnant again with risk of another loss
- *Ineffective Family Coping* related to
 - inability to make decisions as a family
 - difficulties in communication within the family
 - conflicting coping patterns between mother and father
- *Powerlessness* related to
 - high risk pregnancy and birth
 - unexpected cesarean birth
 - inability to prevent the infant's death
- *Ineffective Sexuality Patterns* between the mother and father related to
 - guilt and fear associated with sexuality
 - loss of pleasure in sexual intercourse
 - differences in desires of each partner
 - fear of getting pregnant again
- *Fatigue and Disturbed Sleep Pattern* related to
 - inability to fall asleep because of grief
 - waking in the night and thinking about the loss
 - loss of sleep

Nursing care for women, partners, and families grieving the end of a pregnancy and death of their expected child or newborn is complex and should be comprehensive. The initial shock and numbness that accompany early grief can be misread if the nurse is not aware of the ebb and flow of sadness related to grief and misinterprets important cues (see Nursing Care Plan.)

WHEN A LOSS IS DIAGNOSED: HELPING THE WOMAN AND HER FAMILY IN THE AFTERMATH

Learning of a loss or a potential loss is very distressing to most individuals. Under a great deal of stress, people are likely to have limited ability to take in anything but the most basic information and sometimes appear to “shut down.” Simple, unambiguous, and consistent language is crucial. For example, a woman visiting the United States for whom English was her second language began bleeding heavily at 32 weeks of gestation and noticed that her uterus was very hard. Her partner immediately transported her to a local medical center, where she was admitted directly to the high risk maternal-fetal care unit. Her bleeding had subsided but there were no fetal heart tones, and fetal death was confirmed by ultrasound. The resident physician told her that her “baby had passed,” which she understood to mean that her pain was related to labor and that she had given birth. She asked where the baby was and began to look under the sheets. The nurse realized her misunderstanding of the word “passed” (as in “passed away” or “had died”) and explained to the client that the doctor meant that the baby had died. Although the use of words like “death,” “died,” and “dying” are difficult in any setting, euphemisms or other veiled language can be misunderstood by women and their families under stress. The nurse's presence is crucial in hearing what other providers have told the woman and family and in clarifying any misunderstandings.

With early pregnancy loss, the word “miscarriage” should be used consistently (Cameron & Penney, 2005). With fetal or neonatal death, providers should use the words “has died” or

“there is no heartbeat,” rather than “lost,” “gone,” or “passed” to eliminate ambiguity. Providing the opportunity for women and partners to ask questions, ask for more evidence of the loss, and get a referral for a second opinion gives them some element of control at a time when they have little if any control. Furthermore, in the case of a severe fetal defect, the couple may face a decision about whether to terminate the pregnancy and will want to make the decision with as little ambiguity or unanswered questions as possible.

Helping Parents with Holding Their Fetus or Infant

Research evidence supports the importance of parents' seeing or holding their fetus or infant (Gold, Dalton, & Schwenk, 2007). Many parents find this experience valuable and indicate that they would have liked more time or more opportunities to do so. Seeing and holding the fetus or baby is important because it can help them face the reality of the loss, reduce painful fantasies, and facilitate their grief. It should be noted, however, that although this can be a beneficial experience, it can increase feelings of sadness about their loss and can even be traumatic for some individuals (Badenhorst & Hughes, 2007). Parents should be allowed to choose whether they want to see or hold the body of the fetus or baby. They should never be made to feel they “should” see or hold their baby when this is something that they do not really want. Encouraging reluctant individuals to hold or see the body by telling them that not seeing the body could make grieving more difficult is inappropriate. The nurse might ask question such as, “Some parents have found it helpful to see or hold their baby. Would you like time to consider this?” is helpful. Because the need or willingness to see also can vary among family members, it is important to determine what each person desires and needs. Occasionally only one partner will desire to see or hold the baby's body, or a couple may want to limit holding the baby to themselves without involving other family members. These are difficult situations that have to be handled with extreme tact and sensitivity by the nurse, always with the expectation that the nurse is advocating for what the client wants.

In preparation for the visit with the baby, parents appreciate explanations about what to expect. In preparing the baby's body for the parents to see, nurses generally cover the head with a small cap and clothe the baby. Many hospitals have volunteer groups that provide handcrafted hats and infant gowns for such use, items that may then be taken home by the family. The bodies of fetuses that died in utero must be handled extremely gently because of a process called *maceration* in which the upper layer of the skin begins to peel away from the deeper layers. Maceration often begins at the baby's lips, which then appear redder than usual. Bereaved parents often notice this redness, which actually enhances the baby's appearance. The nurse should remember that parents see their baby with different eyes from health care professionals. Bathing the baby, applying lotion to the baby's skin, combing hair, placing identification bracelets on the arm and leg, dressing the baby in a diaper and special outfit, sprinkling powder in the baby's blanket, and wrapping the baby in a soft blanket convey to the parents that their baby has been cared for in a special way. Sometimes families will want to see the baby's body for a last time after the body has been taken to the morgue. There is no contraindication to this

practice related to infection control. If the baby has been in the morgue, the nurse can place the body underneath a warmer for 20 to 30 minutes then wrap the body in a warm blanket.

When bringing the baby's body to the parents, it is important to treat the baby as one would a live baby. Holding the baby close, touching a hand or cheek, using the baby's name, and talking with the parents about the special features of their child conveys that it is all right for them to do likewise. If a baby has a congenital anomaly that the family wants to see, the nurse can help explain what they are seeing. It is not unusual for parents to compare what they are seeing in "real life" with what they had seen on the ultrasound screen. Nurses can help parents explore the baby's body as they desire. Parents often seek to identify family resemblance and will point out characteristics of the baby that are similar to themselves or their previous children. Some families like to have the opportunity to bathe and dress their baby. Although the skin is fragile, parents can still apply lotion with cotton balls, sprinkle powder, tie ribbons, fasten the diaper, and place amulets, medallions, rosaries, or special toys or mementos in their baby's hands or alongside their baby. Parents may want to perform other parenting activities, such as combing the hair, dressing the baby in a special outfit, or wrapping the baby in a blanket (Fig. 37-1).

Parents need to be given time alone with their baby. They also need to know when the nurse will return and how to call if they should need anything. When possible, the family is placed in a private room with a rocking chair. This offers the parents time together with their baby and with other family members (Fig. 37-2). Marking the door to the room with a special card helps remind the staff that this family has experienced a loss (Fig. 37-3).

Parents and families vary in the amount of time they wish to have the baby's body with them. These moments are the only ones they will have to parent their child while their child's physical presence is still with them. Some parents need only a few minutes; others need hours. It is extremely painful for some parents to say goodbye to their baby. They will tell the nurse when they are ready verbally or the nurse will observe nonverbal cues such as when parents and other family members are no longer holding their child close to them or have placed the baby back in the crib. There should be no institutional restrictions on how long a baby's body can remain in the room with the parents. Most parents become ready to hand the baby over to the nurses or to a funeral home at the time the baby's body shows obvious signs of deterioration, which for a baby that dies at birth will occur in about 24 to 36 hours. Stillborn babies, depending on how long they have been dead in utero prior to birth, will show signs of deterioration sooner. A position paper developed by the Perinatal Loss and Infant Death Alliance (PLIDA, 2005) (PLIDA.org/pdf/infectionRisks.pdf) notes that infection risks "are insignificant" in having the body of a deceased baby in the mother's room. Bereaved mothers and families should have unrestricted access to the baby's body, which allows them to "process the traumatic events surrounding their baby's death" in addition to allowing for a "more gradual goodbye, both of which are productive components of healthy grieving" (PLIDA, 2005, p. 1).

Helping Parents with Decisions Regarding Autopsies, Organ Donation, and Disposition of the Body

At a time when they are experiencing the great distress of a perinatal loss, parents have many decisions to make. Women, partners, and extended families often consult nurses for guidance in discerning what must be done immediately and what can wait and in understanding their options relative to each decision. The nurse's primary responsibility is to help them and to advocate for them, because choices made during the time of their loss will influence their memories for a lifetime.

Deciding on whether to agree to an autopsy can be challenging. An autopsy can be very important in answering the question "why" if there is a chance that the cause of death can be determined, and parents have reported that the need for knowledge eclipsed any barriers to agreeing to an autopsy (Breeze, Statham, Hackett, et al., 2012). This information can be helpful in decision making about future pregnancies and in working through grief. However, asking parents about an autopsy takes great sensitivity to personal, cultural, and religious views about an autopsy. Some religions prohibit autopsy or limit the choice to times when it may help prevent another loss. Options for the type of autopsy, such as excluding the head, are available to parents. Note that the cost of an autopsy must be considered because it is not covered by insurance and is expensive. The question of autopsy is often brought up in the prenatal period when the fetus has a life-limiting diagnosis for which the cause is unknown or the anatomic details of which are unclear. Despite the difficulty in approaching families about autopsy after stillbirth or neonatal death, it is important to note in at least one study, twice as many parents who declined an autopsy regretted their decision (34%) compared with those who regretted having agreed to an autopsy (17%) (Heazell, McLaughlin, Schmidt, et al., 2012).

If an infant is live-born but is expected to die soon after birth, organ donation may be a possibility. Organ donation can be an aid to grieving and an opportunity for the family to see something positive associated with their experience. The federal Gift of Life Act and HCFA-3005-F, enacted in 1998, shifted the responsibility for determining organ donation potential from

the hospital staff to the state's organ procurement organization (OPO). States and hospitals have clear procedures for how and when to call the OPO. Generally, if a death certificate is issued, a call must be made to the OPO. Once contacted, they will decide whether to talk to the family, and either an OPO representative or a designated requester will contact them. This allows requests to be made by trained personnel in a consistent and compassionate manner. The most common donation is corneas; donation of corneas from a baby can occur if the baby was born alive at 36 weeks of gestation or later. In some hospitals these situations are handled by descendent services, which manage a number of legal and practical issues related to a death that occurs in the hospital.

Another important decision relates to spiritual rituals that can be helpful and important to parents and families. The opportunity for support from the clergy should be offered to all bereaved individuals unless prior to the death they have made it clear that they do not want a clergy visit. Families may wish to have their own pastor, priest, rabbi, or spiritual leader contacted, or they may wish to see the hospital chaplain. Clergy or spiritual care providers can offer parents the opportunity for a blessing, naming ceremony, anointing, ritual of the sick, memorial service, baptism, or prayer as is appropriate to a family's beliefs and wishes.

One of the major decisions parents must make has to do with disposition of the body. Parents should be given information about the choices for the final disposition of their baby's body, regardless of gestational age. Nurses must be aware, however, of cultural and spiritual beliefs that can dictate the choices of parents, issues related to the cost of burial, alternatives to burial, and state laws related to burial. A fetus of less than 20 weeks of gestation is considered a product of conception, whereas embryos, uterine tubes removed with an ectopic pregnancy, and tissue from a pregnancy obtained during a dilation and curettage are considered tissue. Many hospitals will make arrangements for the cremation. The nurse should know the hospital's policies and procedures and answer the parents' questions honestly.

Respectful disposition refers to the safe handling and disposition of fetal tissue or remains by burial in a designated area. An increasing number of institutions are offering respectful disposition, and nurses can be at the forefront of establishing these procedures that honor women's preferences and wishes for disposition of fetal remains after an early pregnancy loss (Limbo, Kobler, & Levang, 2010). In most states if a fetus is at least 20 weeks and 1 day of gestational age or is born alive, it is the parents' responsibility to make the final arrangements for their baby's body, although some hospitals offer free cremation. In this case the family does not receive the ashes.

Final disposition of bodies, regardless of gestational age, can include burial or cremation. Depending on the cemetery's policies, caskets or ashes can be buried in a special place designated for babies, at the foot of a deceased relative, in a separate plot, or in a mausoleum. Ashes also may be scattered in a designated area; many states have regulations regarding where ashes may be scattered. A local funeral director or a state's vital statistics bureau should have information about the state's rules, codes, and regulations regarding live births, burial requirements, transportation of the body, and cremation.

Some parents want a special memorial or funeral service. They can choose to have a funeral service in the hospital chapel or in

their own church, visitation at a funeral home or their own home, or a graveside service. Parents can make any of these services as special, personal, and memorable as they like. They can choose special music, poetry, or prose written by themselves or others.

If the family has decided on a funeral and burial, they still have decisions about which funeral home to call and where to bury the baby. Many couples live in an area distant from their family homes, and they may want to bury their child in their hometown or family cemetery. If the family desires cremation, they may want to have the option of obtaining the ashes. It is important to determine whether this will be done by the facility that does the cremation. Some families will keep the ashes (“cremains”) in a small urn or other container in their home, and others will eventually take the ashes to a special place for release, such as the beach, the mountains, or a place with special sentimental meaning.

Families become unaware of time frames and do not care about the change of shifts or any needs the hospital system might have in “moving things along.” When families are pushed or rushed into making decisions, in most cases they make a decision in response to the health care institution’s needs, not their own. Actions such as naming the baby, seeing and holding the body, disposition of the body, and funeral arrangements should never be rushed. In some cases the mother is discharged home before these decisions are made. Then the family can think about them in the comfort of their home and contact the hospital in the following days to give their answers.

Helping the Bereaved Parents Acknowledge and Express Their Feelings

One of the most important goals of the nurse is to validate the experience and feelings of the parents by encouraging them to tell their stories and listening with care. Helping the parents to talk about their loss and the meaning it has for their lives and to share their emotional pain is the next step. Because nurses tend to be very focused on the physical and emotional needs of the mother, it is especially important to ask the father or partner directly about his or her views of what happened and the associated feelings of loss. At the very least, the nurse should acknowledge the loss with a simple but sincere “I am sorry.”

The nurse should listen patiently during the story of loss or grief; however, listening can be difficult and painful. The feelings and emotions of expressed grief can overwhelm health care professionals. Being with someone who is terribly sad and crying or sobbing can be extremely difficult. The initial impulse to reduce one’s sense of helplessness is to say or do something to reduce his or her pain. Although such a response seems supportive at the time, it can stifle the further expression of emotion. Bereaved parents have identified many unhelpful responses made to them by well-meaning health care professionals, family, and friends. The nurse should resist the temptation to give advice or use clichés in offering support to the bereaved (Box 37-2). Nurses need to be comfortable with their own feelings of loss and grief to support and care for bereaved individuals effectively. The nurse should have a presence of self and the willingness to be alongside, quietly supporting the bereaved in whatever expressions of feelings or emotions are appropriate for them. This presence is comforting for parents. Leaning forward, nodding the head, and saying “Uh-huh” or “Tell me more” is often encouragement enough for the bereaved person to tell his or her story. Sitting

BOX 37-2 What to Say and What Not to Say to Bereaved Parents

What to Say

- “I’m sad for you.”
- “How are you doing with all of this?”
- “This must be hard for you.”
- “What can I do for you?”
- “I’m sorry.”
- “I’m here, and I want to listen.”

What Not to Say

- “God had a purpose for her.”
- “Be thankful you have another child.”
- “The living must go on.”
- “I know how you feel.”
- “It’s God’s will.”
- “You have to keep on going for her sake.”
- “You’re young; you can have others.”
- “We’ll see you back here next year, and you’ll be happier.”
- “Now you have an angel in heaven.”
- “This happened for the best.”
- “Better for this to happen now, before you knew the baby.”
- “There was something wrong with the baby anyway.”

Used with permission of Bereavement Services. Copyright Lutheran Hospital-La Crosse, Inc., a Gundersen Lutheran Affiliate, La Crosse, WI.

through the silence can be therapeutic; silence gives the bereaved person an opportunity to collect thoughts and to process what he or she is sharing. Furthermore, careful assessment is important before using touch as a therapeutic technique. For some, touch is a meaningful expression of concern, but for others it is an invasion of privacy or contrary to their cultural or religious beliefs.

Bereaved parents have many questions surrounding the event of their loss that can leave them feeling guilty. This is particularly true for mothers. Such questions include “What did I do?” “What caused this to happen?” “What do you think I should have, could have done?” Part of the grief process for bereaved parents is figuring out what happened, their role in the loss, why it happened to them, and why it happened to their baby. The nurse should recognize that the answers to these questions must be answered by the bereaved themselves; it is part of their healing. For example, a bereaved mother might ask, “Do you think that this was caused by painting the baby’s room?” An appropriate response is, “Let’s talk about what you are thinking.” Trying to give bereaved parents answers when there are no clear answers or trying to squelch their guilt feelings by telling them they should not feel guilty does not help them process their grief. Trying to figure out why something bad happened is a common human response, but often there are no answers. Sometimes simple factual information, such as the frequency of miscarriages in pregnant women or the fact that there usually is no clear cause of a stillbirth, can be helpful; however, for many people understanding that something happens frequently is no consolation when it happens to them.

Feelings of anger, guilt, and sadness can occur immediately but often become more problematic in the early days and months after a loss. When a bereaved person expresses feelings of anger, it can be helpful to identify the feeling by simply saying, “You sound angry,” or “You look angry.” The nurse’s willingness to sit down and listen to these feelings of anger can help

the bereaved explore underlying feelings of powerlessness and helplessness in not being able to control the many aspects of the situation, which for many people will result in anger.

A key element of nursing care for bereaved individuals is allotting enough time to engage with them without being rushed. Nurses in inpatient settings who are caring for women and families whose baby has died may need light client assignments for their shift in order to have enough time to give adequate attention to newly bereaved individuals in helping address their profound grief.

Helping the Bereaved Family Understand Differing Responses to Loss

Bereaved parents may need help in understanding their responses to their loss, and in realizing that they are not alone in these painful responses. Most parents are not prepared for the raw feelings that they experience or the fact that these painful, complex feelings and related behavioral reactions continue for many weeks or months. Thus reassuring them that their responses are normal and preparing them for grief's potentially lengthy process can be useful.

The nurse can help parents prepare for the emptiness, loneliness, and yearning; for the feelings of helplessness that can lead to anger, guilt, and fear; for the cognitive processing problems, disorganization, difficulty making decisions; and for the sadness and depression that are part of the grief process. Many parents have reported feelings of fear that they were "going crazy" because of the many emotions and behavioral responses that leave them feeling totally out of control in the months after the loss.

It is essential for the nurse to reassure and educate bereaved parents about the grief process, including the physical, social, and emotional responses of individuals and families. Written materials about parental grief that are sensitive and brief can be very helpful. Offering health teaching on the bereavement process alone is not enough, however. In the initial days after a loss, other strategies might include follow-up phone calls, referral to a perinatal grief support group, or providing a list of publications or websites intended for helping parents who have experienced a perinatal loss. Some important websites include www.compassionatefriends.org (death of a child), www.resolve.org (infertility), www.plida.org (perinatal loss and infant death), www.sidscenter.org (sudden infant death), www.bereavementservices.org (perinatal loss), and www.marchofdimes.com (information on prematurity and congenital defects, in addition to information about healthy pregnancy). As with any referral, however, the nurse should first review the materials or the websites for accuracy and appropriateness.

To reduce relationship problems that can occur in grieving couples, nurses can help them understand that they may respond and grieve in very different ways. Interventions that include both partners and that are focused on the quality of communication within the partnership may be helpful in improving psychological and emotional outcomes after a perinatal loss (Scheidt, Hasenburg, Kunze, et al., 2012). Incongruent grieving can lead to serious relationship problems and can be a risk factor for complicated bereavement. It is important to remind couples of the importance of being understanding and patient with one another. Partners will often hide their sadness to protect the woman who experienced a miscarriage or

COMMUNITY ACTIVITY

- Visit the Healing Hearts Baby Loss Comfort website at www.babylosscomfort.com. Review the client information about the appropriate words to say, full-term baby loss, and stillbirth and grief resources. Also visit the websites of the National Stillbirth Society (www.stillnomore.org) and International Stillbirth Alliance (www.stillbirthalliance.org).
- Research the availability of a perinatal loss support group in your community or find online perinatal support groups. Visit the websites of the Compassionate Friends (www.compassionatefriends.org), Perinatal Loss and Infant Death Alliance (PLIDA) (www.plida.org), and Resolve Through Sharing (www.bereavementservices.org) for up-to-date information about organizations that provide support for bereaved parents.

other pregnancy loss; this, however, can be counterproductive because it is sometimes interpreted as a lack of caring. In a study of fathers whose partners experienced a stillbirth, Cacciatore, Erlandsson, and Rådestad (2013) found that they were grateful for the respectful treatment of the baby's body and when their fatherhood was validated by care providers. Although this study focused on fathers, the findings are applicable in lesbian couples, so that the partner's role and place in the life of the mother and expected infant should be recognized and validated by providers.

People cope with grief in positive and negative ways. Nurses can reinforce positive coping efforts and attempt to prevent negative coping. Many women use the Internet to locate other women who have experienced a pregnancy loss. Blogging and online support groups are increasingly used as means of sharing the experience, especially among well-educated Caucasian women. Many women have found decreased isolation in the convenience, access, privacy, and anonymity of message boards dedicated to perinatal loss (Gold, Boggs, Mugisha, & Palladino, 2012). These sources of support should not be used to the exclusion of close friends and family. Many women have had children previously and find that care of their children day to day is healing. At the negative extreme, bereaved individuals can turn to alcohol, drugs, and/or overeating as a means of anesthetizing their pain.

Meeting the Physical Needs of the Bereaved Mother in the Postpartum Period

Coping with loss and grief after birth can be overwhelming for the woman and her family. While in the hospital or birthing center, it is especially difficult for them to hear the sound of crying babies and to witness the happiness of other families on the unit who have given birth to healthy infants. The mother should have the opportunity to decide if she wants to remain on the maternity unit or to move to another unit. Many institutions have cross-trained nurses to provide postpartum care on gynecology units for women whose babies have died; some nurses on these units have experience in dealing with death and bereavement as a function of working with gynecologic cancer clients and may provide highly sensitive and expert physical and emotional care.

The physical needs of a bereaved mother are the same as those of any woman who has given birth. Bereaved mothers still

In some communities a volunteer organization of professional photographers (e.g., Now I Lay Me Down to Sleep [www.nowilaymedowntosleep.org]) has a photographer on-call around the clock to take photographs of families and their deceased baby free of charge. Some institutions will take photos with a digital camera and give families the camera's memory card containing their baby's photos for downloading when the parents are ready.

Nurses should be aware of the risk of family members and friends using social media such as Instagram, Twitter, Vine, and Facebook to post photos and videos of this intimate family event. A frank talk with the family about ownership of this occasion may help forestall this behavior.

Addressing Cultural and Spiritual Needs of Parents

Parents who experience perinatal loss can be from widely diverse cultural, ethnic, and spiritual groups. Many of the emotional responses and suggested interventions in this chapter are based on middle-class Euro-American views. Although there are likely no particular differences in the individual, intrapersonal experiences of grief based on culture, ethnicity, or religion, there are complex differences in the meaning of children and parenthood, the role of women and men, the beliefs and knowledge about modern medicine, views about death, mourning rituals and traditions, and behavioral expressions of grief. Thus the nurse must be sensitive to the responses and needs of parents from various cultural backgrounds and religious groups. To do this the nurse needs to be aware of his or her own values and beliefs and acknowledge the importance of understanding and accepting the values and beliefs of others who are different or even in conflict. Furthermore, it is critical to understand that the individual and unique responses of a parent to a perinatal loss cannot be entirely predicted by his or her cultural or spiritual backgrounds. The nurse approaches each partner as an individual needing support during a profoundly difficult and distressing life experience.

It would be impossible to address all of the specific differences and needs of parents from diverse cultural and religious groups because of the complexity of this task and the lack of adequate research in this area of practice. Instead, some key concepts are presented and a few examples of areas of particular concern are given. The cultural meaning of children has a strong effect on the response of parents, extended family, and the community when an infant dies or is stillborn. Cultural and religious beliefs often affect decision making surrounding stillbirth or death of an infant. For example, death of an infant or having a stillborn infant profoundly affects the foundations of a Jewish family and involves many specific cultural and religious traditions, such as naming of the baby, burial, and mourning rituals (Shuzman, 2003). Muslim women have described their husbands or family members as the main decision makers and appreciate being reminded by their husbands, family, or close friends that their loss was a test from God (Sutan & Miskam, 2012). Some religious groups do not allow autopsies and cremation except under unusual circumstances (Chichester, 2007). Making a decision to end life-sustaining measures is less acceptable for some cultural and ethnic groups. African-American parents may be less likely than Caucasians to make a decision to stop life-sustaining treatments in

a terminally ill infant (Moseley, Church, Hempel, et al., 2004). Photographs can conflict with beliefs of some cultures, such as among some Native Americans, Inuit, Amish, Hindus, and Muslims. Families from these cultures should be offered this opportunity sensitively but there should be no insistence on photography. In many cultures decisions do not reside solely with the individual woman or couple but with the extended family. In Hispanic families, the concept of *la familia* is critical. Family decisions are often made together and communicated through someone appointed by the family rather than the parents.

Culture and religious beliefs also influence the customs following death. Many religious groups have rituals that are performed at the time of death. They include prayers, ritualistic washing and shrouding, or anointing with oil. Nurses should ask parents about their needs as they relate to rituals at the time of and following death. For example, baptism is extremely important for Roman Catholics and some, but not all, Protestant groups. Baptism can be performed by a layperson, such as a nurse of the Christian faith, in an emergency situation when a priest cannot be there in a timely fashion. The nurse should inquire about parental beliefs and preferences related to infant baptism. The nurse can offer to contact the hospital chaplain or the family's own clergy who can help sort out theological questions related to rituals of faith.

Expressions of grief vary across cultures from quiet and stoic to dramatic responses. Muslims view death as a part of life and believe a baby's death is God's will. The Muslim mother may cry but loud wailing is not acceptable. The tearing of a garment, *keria*, may be done by Jewish parents at the time of a death. Hispanic parents and family members may be very demonstrative in their grief (Purnell & Paulanka, 2008). Some African-American women use self-healing strategies that reflect inner processes, resources, and remedies (Van, 2001).

Providing Sensitive Discharge and Follow-up Care

When leaving the hospital, mothers are often transported from the nursing unit to their vehicle in a wheelchair. This can be very upsetting for the woman who has experienced a pregnancy loss. It is especially difficult if other women are seen leaving with babies; thus the timing of discharge of couples who have experienced a perinatal loss should be done with great sensitivity. They should not be discharged at a time when other mothers with live babies are leaving. Some institutions give the bereaved mother some token of remembrance such as a teddy bear or a flower to carry as they leave.

The grief of the mother and her family does not end with discharge; rather it begins anew once they return home, attend the funeral, and continue their lives without a new baby. There are numerous models for providing follow-up care to parents after discharge, and, although there is no solid evidence from sound clinical trials regarding the benefit of these programs, nonexperimental studies and clinical evaluations suggest these programs are helpful. Programs include hospital-based bereavement teams who provide support during hospitalization and follow-up contacts. Follow-up phone calls after a loss are helpful to some but not all parents. The calls are made at times that are known to be difficult for

bereaved persons such as the first week at home, 1 month to 6 weeks later, 4 to 6 months after the loss, and at the anniversary of the death. Families who experienced a miscarriage, ectopic pregnancy, or death of a preterm baby may appreciate a phone call on the estimated date of birth. The calls provide an opportunity for parents to ask questions, share their feelings, seek advice, and receive information to help them in processing their grief.

A grief conference can be planned when parents return for an appointment with their physician or midwife, nurses, and other members of the health care team. At the conference, the loss or death of the infant is discussed in detail, parents are given information about the baby's autopsy report and genetic studies, and they have opportunities to ask the questions that have arisen since their baby's death. Parents appreciate the opportunity to review the events of hospitalization, go over the baby's and mother's chart with their primary health care provider, and talk with those who cared for them and their baby while they were in the hospital or birthing facility. This is an important time to help parents understand the cause of the loss or to accept the fact that the cause will forever be unknown. This gives health care professionals the opportunity to assess how the family is coping with their loss and provide additional information and education on grief.

Some parents are very interested in finding a perinatal or parent grief support group. Talking with others who have been through similar experiences, sharing memories of the pregnancy and the baby, and gaining an understanding of the normality of the grief process can be very helpful. Over time it is possibly the only place where bereaved parents can talk about the wished-for child and their grief. However, not all parents find such groups helpful.

When referring to a group, it is important to know something about the group and how it operates. For example, if a group has a religious base for their interventions, a nonreligious parent would not likely find the group to be helpful. If parents experiencing a perinatal loss are referred to a general parental grief group, they might feel overwhelmed with the grief of parents whose older children have died of cancer, suicide, or homicide. In addition, other parents whose older children have died may inadvertently minimize the grief of parents following a perinatal loss. Thus the focus of the group needs to match the parents' needs.

Providing Postmortem Care

Preparing the baby's body and transporting it to the morgue depend on the procedures and protocols developed by individual hospitals. The Joint Commission (www.jointcommission.org) requires that appropriate care be offered to the body after death. A sensitive and respectful approach for taking the fetus or infant to the morgue is the use of a burial cradle, which makes the process more dignified for parents and the nursing staff. A burial cradle is a miniature casket usually made of Styrofoam or wood (Fig. 37-5).

Postmortem care can be an emotional and sometimes difficult task for the nurse. However, nurses can find that providing postmortem care helps them in their own grief related to a perinatal loss. This is particularly true for NICU nurses who have cared for an infant for several hours, days, or weeks.

FIG 37-5 Burial cradle. (Courtesy Shannon Perry, Phoenix, AZ.)

! NURSING ALERT

An important caveat is needed for nurses providing care for newborns that are thought to be deceased: dying neonates may respond reflexively to the stimulation of cleaning and preparing for the morgue, and sometimes will do this for several hours after being pronounced dead. This is extremely startling and upsetting when a baby that has been pronounced dead takes an agonal respiration or an extremity twitches. If this happens, the nurse should notify a physician for confirmation of death.

SPECIAL CIRCUMSTANCES

Prenatal Diagnoses with Poor Prognoses

Early prenatal diagnostic tests such as ultrasonography, chorionic villus sampling, and amniocentesis can determine the well-being of the embryo or fetus (see Chapter 26). Reasons for prenatal testing include history of chromosomal abnormality in the family; three or more miscarriages; maternal age over 35 years; lack of fetal growth, movement, or heartbeat; and diabetes, hypertension, lupus, sickle cell disease, or other chronic illnesses. If the health care provider is certain that the baby has a serious genetic defect that will lead to death in utero or after birth (congenital anomalies incompatible with life or genetic disorders with severe intellectual disability), the choice of interruption of a pregnancy via dilation and evacuation or induction of labor can be offered (Manning, 2009).

Foreknowledge of a congenital diagnosis in conjunction with the possibility of suffering by the baby can intensify parental grief (Hunfeld, Tempels, Passchier, et al., 1999). The decision to terminate a pregnancy is difficult and can lead to feelings such as guilt, despair, sadness, depression, and anger. The woman who decides to continue the pregnancy needs intensive support from the nursing staff. The time of labor and birth can be particularly difficult. The nurse should remember that expectant parents may be grieving for not only the loss of the "perfect child" but also loss of expectations for their child's future. Thus a nurse should assess how these parents feel about the experience, offer options for their memories as appropriate, and be a support person and good listener. Healing can be facilitated when words can be given to feelings. Perinatal palliative care

or hospice care for parents experiencing prenatal diagnoses of lethal birth defects can be effective in helping families both before and after their loss (Calhoun, Napolitano, Terry, et al., 2003). Perinatal palliative care, described in detail earlier, does not have to be a formal program, although many do exist. It is the provision of care for families as they plan for the birth and probable death of their baby and involves support, information, and resources. If the baby lives more than a few minutes or hours after birth, conventional hospice care may be incorporated into care management of the infant and family (Davis & Helzer, 2011).

Death of a Fetus in a Multiple Gestation

The death of a fetus in a multifetal gestation during pregnancy, labor, birth, or after birth requires the mother and partner to both parent their live-born infant and grieve their dead or dying one at the same time. Such a death imposes a confusing and ambivalent transition into parenthood (Swanson, Kane, Pearsall-Jones, et al., 2009). They can experience difficulty parenting their surviving child with all the joy and enthusiasm of new parents because their surviving child reminds them of what they have lost. Yet they can also have difficulty fully grieving their loss because their surviving child demands their attention. These parents can be at risk for altered parenting and complicated bereavement.

It is important to help the parents acknowledge the birth of all their babies, although one or more may be stillborn. The nurse should plan the care of these families as they do all bereaved families, offering all the options previously noted. With the parents' consent, photographs should be taken of the babies and parents should be offered the opportunity to hold their babies and have time to say goodbye to the baby who has died.

It is helpful to alert bereaved parents that well-meaning family members or friends may say, "Well, at least you have the other baby," implying that there should be no grief because they are lucky to have one living baby. Parents can anticipate insensitivity to their loss and may find it helpful to respond, "That is not how I feel." By simply setting a boundary on what their feelings are, they are able to acknowledge the baby who died and then have an opportunity to share more about their feelings if they so choose. When there is a loss of one or more babies in a multiple gestation, bereaved parents face specific issues in telling their surviving child about his or her twin, dealing with the possibility of that child's feelings of survivor guilt, and deciding on how to celebrate birthdays, special holidays, or anniversaries of the baby's death.

Adolescent Grief

Adolescents grieve the loss that occurs with miscarriage, stillbirth, or newborn death and have significant emotional, social, and cognitive responses that can differ from those of older women. Teens need a great deal of emotional support from the nurses who care for them.

Nurses and other health care professionals, as well as family members, may believe that the adolescent's loss of her baby, although sad, may open the opportunity for the young woman to complete her education and experience life without the demands of motherhood. Adolescent girls, then, may not receive the support they need from staff and family. In addition, adolescent girls often do not have the support from the father of

the baby as compared with older women who have a perinatal loss; thus there is a great need to provide sensitive care to all adolescents who experience any type of perinatal loss.

The first step for the nurse in caring for a bereaved adolescent is to develop a trusting relationship with her. Second, the nurse should acknowledge the significance of the loss, regardless of the mother's age. Third, the nurse should offer options for saying goodbye and provide anticipatory guidance, support, and information to meet the adolescent at the point of her need. It can take longer for adolescents to process their grief because of their lack of cognitive and emotional maturity, although this varies. Moreover, adolescents are often highly involved with their friends who may lack maturity and perspective on the loss but at the same time are good sources of social support by simply being present. Encouraging the bereaved teen to seek out friends may be very helpful. Being patient, saving mementos, and giving the adolescent information on how to contact the nurse are interventions that can help the adolescent accept the loss and work through her grief and sadness.

Complicated Grief

Although most parents cope adequately with the pain of their grief and return to some level of their usual functioning, some have extremely intense grief reactions that last for a very long time; this response is **complicated grief**. It is also called complicated bereavement, prolonged grief, pathologic grief, or pathologic mourning (Zhang, El-Jawahri, & Prigerson, 2006). Complicated grief can result when there is sudden or traumatic loss, as occurs with stillbirth or termination of pregnancy due to lethal fetal anomalies (Cacciatore, 2010; Kersting, Kroker, Steinhard, et al., 2007). Complicated grief differs from what is considered normal grief in its duration and the degree to which behavior and emotional state are affected. Risk factors for complicated grief include poor social support, history of mental health problems, and a more neurotic pre-loss personality (Badenhorst & Hughes, 2007). A study by Swanson and colleagues (2007) found that among women still overwhelmed with grief one year later, many had miscarried again or were not yet pregnant again, experienced six or more negative events in their lives, and were distant from their partners.

People experiencing complicated grief seem to be in a state of chronic mourning. Evidence of complicated grief includes intense longing and yearning for the deceased, inability to trust others, excessive bitterness, difficulty moving on with one's life, feeling that life is empty or meaningless, hopelessness, loneliness, intense and continued guilt or anger, and relentless depression or anxiety that interferes with role functioning. Complicated grief can lead to abuse of drugs (including prescription medications) or alcohol, severe relationship difficulties, high levels of depressive symptoms, low self-esteem, feelings of inadequacy, and suicidal thoughts or threats years after the loss (Swanson, 2000; Zhang et al., 2006).

Posttraumatic stress disorder (PTSD) can occur following perinatal loss (Badenhorst & Hughes, 2007; Turton, Evans, & Hughes, 2009). Symptoms of posttraumatic stress include reliving the trauma, avoiding things and places that are reminders, panic attacks, physical symptoms such as chronic pain, feelings of mistrust, problems with relationships and daily activities, substance abuse, and depression.

People showing signs of complicated grief or posttraumatic stress should be referred for counseling. It is the responsibility of a qualified mental health professional to determine whether the parents are experiencing a normal, albeit intense grief response or whether they are also having a serious mental health problem such as depression. However, it is important when referring to a therapist or counselor that the referral is made to one who is experienced in grief counseling. Making an appointment for counseling or therapy is a big step. The highest number of cancellations and missed visits in a therapist's practice are first visits; therefore, anything the nurse can do for a family or individual to help with that major hurdle is helpful. However, it also is important to remember that people can have symptoms but may not, for whatever reason, be ready to deal directly with these symptoms or may not have the energy to make the call. Enlisting a family member to encourage parents to seek such assistance can be helpful.

Posttraumatic Growth

Researchers have noted that women and their partners can experience personal growth in the aftermath of a perinatal

loss (Black & Sandelowski, 2010). Known as *posttraumatic growth* (PTG), this phenomenon is characterized by development along one or more of five dimensions: personal strength, appreciation for life, spirituality, relating to others, and new possibilities (Tedeschi & Calhoun, 1996, 2004, 2008). Growth coexists with grief. In witnessing the grief of women, partners, and families in the aftermath of a perinatal loss, it is important that the nurse recognize that people in fact can and do grow after highly traumatic events. Nurses should be alert for signs of growth in bereaved individuals, for instance, when a woman comes in for a 6-week postpartum check, she may indicate that she and her partner are closer because of this loss or note that she is beginning to look at opportunities to go back to school or change jobs. These are not indications that the woman's grief has gone away but that she has experienced growth from the trauma of her loss. The nurse needs to simply affirm these developments with simple comments such as, "I'm glad for you."

KEY POINTS

- Attachment to the idea of a baby can begin before pregnancy with many hopes and dreams for the future and can become more pronounced over the course of pregnancy.
- Women can feel profound grief regardless of the length of gestation; however, women tend to have higher levels of grief with longer gestations.
- When a fetus or a newborn dies, all members of a family are affected, but no two family members grieve in the same way.
- When birth and death coexist, sensitive care by a nurse is critical in assisting the woman and her family in their grief, regardless of the woman's age or stage of gestation.
- An understanding of the grief process is fundamental to care management of families experiencing perinatal loss.
- Assessment of each family member's perception and experience of the loss is important.
- Cultural and religious beliefs affect a family's response to and coping with perinatal death.
- Therapeutic communication and active listening can help women and their partners and families identify their feelings, feel comfortable in expressing their grief, and understand their bereavement process.
- Follow-up after discharge is important in providing care to families who have experienced a loss because of the evolving nature of grief.
- Nurses need to be aware of their own feelings of grief and loss to provide a nonjudgmental environment of care and support for bereaved families.

akusher-lib.ru

A

abdominal Belonging or relating to the abdomen and its functions and disorders.

ABO incompatibility Hemolytic disease that occurs when the mother's blood type is O and the newborn's is A, B, or AB.

abortion Termination of pregnancy before the fetus is viable and capable of extrauterine existence, usually less than 20 weeks of gestation (or when the fetus weighs less than 500 g); miscarriage.

abruptio placentae (placental abruption) Premature separation of the placenta; the detachment of part or all of a normally implanted placenta from the uterus before the birth of the infant.

acceleration Visually apparent abrupt (onset to peak less than 30 seconds) increase in fetal heart rate (FHR) above the baseline rate. The peak is at least 15 beats/minute above the baseline, and the acceleration lasts 15 seconds or more, with a return to baseline less than 2 minutes from the beginning of the acceleration.

acculturation Changes that occur within one group or among several groups when people from different cultures come into contact with each other.

acquaintance Process used by parents to get to know or become familiar with their new infant; an important step in attachment.

acrocyanosis Peripheral cyanosis; blue color of hands and feet in most infants at birth that may persist for 7 to 10 days.

active phase of labor Phase in first stage of labor from 4 to 7 cm in dilation.

active pushing (descent) phase of labor Period during second stage labor when the woman has strong urges to bear down as the fetal presenting part presses on the pelvic floor.

acute bilirubin encephalopathy Acute manifestations of bilirubin toxicity that occur during the first weeks after birth.

acute respiratory distress syndrome (ARDS) Condition that occurs when the lungs are unable to maintain levels of oxygen and carbon dioxide within normal limits. ARDS is not specific to pregnancy; it can also result from trauma, pneumonia, sepsis, aspiration of gastric contents, fat emboli, acute pancreatitis, and drug overdose. When ARDS is associated with pregnancy, the precipitating factors can also be amniotic fluid embolism, air embolism, tocolytic therapy, asthma, thromboembolism, disseminated intravascular coagulopathy, pyelonephritis, preeclampsia, eclampsia, severe hemorrhage, blood transfusion reactions, or peripartum cardiomyopathy. Also called shock lung.

adjuvant chemotherapy Chemotherapy administered soon after surgical removal of a tumor.

afterbirth pains See afterpains.

afterpains Painful uterine cramps that occur intermittently for approximately 3 to 7 days after birth and that result from contractile efforts of the uterus to return to its normal involuted condition. Also called afterbirth pains.

agonist An agent that activates or stimulates a receptor to act.

alcohol-related birth defects (ARBDs) See alcohol-related neurodevelopmental disorders (ARNDs).

alcohol-related neurodevelopmental disorders (ARNDs) Infants exposed prenatally to alcohol who are affected but do not meet the criteria for fetal alcohol syndrome (FAS); these disorders run the gamut from learning disabilities and behavioral problems to speech or language problems and hyperactivity.

alpha-fetoprotein (AFP) Fetal antigen; elevated levels in amniotic fluid are associated with neural tube and open abdominal wall defects.

amenorrhea Absence or suppression of menstruation or menstrual flow.

amniocentesis Procedure in which a needle is inserted through the abdominal and uterine walls under ultrasound guidance into the amniotic fluid; some fluid is withdrawn; used for assessment of fetal health and maturity.

amnioinfusion Infusion of room-temperature isotonic fluid (usually normal saline or lactated Ringer's solution) into the uterine cavity if the volume of amniotic fluid is low, in an attempt to increase the fluid around the umbilical cord and prevent compression during uterine contractions.

amnion Inner membrane of two fetal membranes that form the sac and contain the fetus and the fluid that surrounds it in utero.

amniotic Pertaining or relating to the amnion.

amniotic fluid Fluid surrounding the fetus derived primarily from maternal serum and fetal urine.

amniotic fluid embolus (AFE) Rare but devastating complication of pregnancy characterized by the sudden, acute onset of hypoxia, hypotension, cardiovascular collapse, and coagulopathy. AFE occurs during labor, during birth, or within 30 minutes after birth. Also known as anaphylactoid syndrome of pregnancy.

amniotic fluid index (AFI) Evaluation of the total amount of amniotic fluid by measuring the vertical depths (in centimeters) of the largest pocket of amniotic fluid in all four quadrants surrounding the maternal umbilicus. A normal AFI is 10 cm or greater.

amniotomy Artificial rupture of the membranes (AROM), using a plastic amnihook or a surgical clamp.

analgesia Alleviating the sensation of pain or raising the threshold for pain perception without loss of consciousness.

anaphylactoid syndrome of pregnancy See amniotic fluid embolus (AFE).

anencephaly Congenital deformity characterized by the absence of both cerebral hemispheres (cerebrum and cerebellum) and the flat bones of the overlying skull.

anesthesia Encompasses analgesia, amnesia, relaxation, and reflex activity. Anesthesia abolishes pain perception by interrupting the nerve impulses to the brain. The loss of sensation may be partial or complete, sometimes with the loss of consciousness.

aneuploidy One of the two types of deviations from the correct number of chromosomes per cell, in which the numerical deviation is not an exact multiple of the haploid set. Having an abnormal number of chromosomes.

antagonist An agent that blocks a receptor or a medication designed to activate a receptor.

antenatal glucocorticoids Medications administered to the mother for the purpose of accelerating fetal lung maturity when an increased risk exists for preterm birth between 24 and 34 weeks of gestation.

anthropometric measurements Body measurements, such as height and weight.

anticipatory grief Grief that predates the loss of a beloved object.

anxiety disorders Mood disorders characterized by prominent symptoms of anxiety that impair functioning. Examples are obsessive-compulsive disorder, posttraumatic stress disorder, generalized anxiety disorder, panic disorder, agoraphobia, and other phobias. Anxiety disorders are the most common psychiatric disorders.

ARNDs See alcohol-related neurodevelopmental disorders (ARNDs).

appropriate for gestational age an infant whose birth weight falls between the 10th and 90th percentile on intrauterine growth curves

APGAR score numeric expression of the condition of a newborn obtained by rapid assessment at 1 and 5 minutes of age; developed by Dr. Virginia Apgar.

ARTs See assisted reproductive therapies (ARTs).

asphyxia Term used when fetal hypoxia results in metabolic acidosis.

assimilation Occurs when a cultural group loses its identity and becomes part of the dominant culture.

assisted reproductive therapies (ARTs) Treatments for infertility, including in vitro fertilization procedures, embryo adoption, embryo hosting, and therapeutic insemination.

asymptomatic bacteriuria Persistent presence of bacteria within the urinary tract of women who have no symptom of infection. A clean-voided urine specimen containing more than 100,000 organisms per milliliter is diagnostic.

atony Absence of muscle tone. See also uterine atony.

attachment (1) The process by which a parent comes to love and accept a child and a child comes to love and accept a parent. (2) A specific and enduring affective tie to another person.

attitude The relation of the fetal body parts to one another. Normally the back of the fetus is rounded so that the chin is flexed on the chest, the thighs are flexed on the abdomen, the legs are flexed at the knees, and the arms are crossed over the thorax. This attitude is called general flexion.

augmentation of labor Stimulation of ineffective uterine contractions after labor has started spontaneously but is not progressing satisfactorily.

autolysis "Self-digestive" process by which the uterus returns to a nonpregnant state after childbirth. The decrease in estrogen and progesterone levels after childbirth results in this destruction of excess hypertrophied uterine tissue.

autosomal dominant inheritance disorder Condition in which only one copy of a variant allele is needed for phenotypic expression.

autosomal recessive inheritance disorder Condition in which both genes of a pair are forms associated with the disorder to be expressed.

autosomes Any of the paired chromosomes other than the sex (X and Y) chromosomes.

B

baby blues See postpartum blues.

balanced translocation Translocation in which parts of the two chromosomes are exchanged equally. The individual is phenotypically normal because there is no extra chromosome material; it is just rearranged.

ballottement (1) Movability of a floating object, such as a fetus. (2) Diagnostic technique using palpation: a floating object, when tapped or pushed, moves away and then returns to touch the examiner's hand. (3) Passive movement of the unengaged fetus.

Bartholin cyst Most common benign lesion of the vulva; arises from obstruction of the Bartholin duct, which causes it to enlarge.

basalis, decidua See decidua basalis.

baseline fetal heart rate See fetal heart rate (FHR), baseline.

Bell palsy Acute idiopathic facial paralysis. The cause is unknown, but it may be related to the reactivation of herpesvirus infection or acute human immunodeficiency virus type 1 (HIV-1) retroviral infection. Bell palsy occurs fairly often, especially in women of reproductive age. Pregnant women are affected four times more often than nonpregnant women.

bereavement The feelings of loss, pain, desolation, and sadness that occur after the death of a loved one.

biophysical profile (BPP) Noninvasive assessment of a fetus using ultrasound and the nonstress test. It includes the following components: fetal breathing movements, gross body movements, fetal tone, reactive fetal heart rate (FHR), and qualitative amniotic fluid volume.

biopsy Removal of a small piece of tissue for microscopic examination and diagnosis.

biorhythmicity Cyclic changes that occur with established regularity, such as sleeping and eating patterns.

biparietal diameter Largest transverse diameter of the fetal head; extends from one parietal bone to the other.

bipolar disorder Mood disorder defined by the presence of one or more episodes of abnormally elevated energy levels, cognition, and mood and one or more depressive episodes. Also called manic-depressive disorder. Postpartum psychosis is most commonly associated with a diagnosis of bipolar disorder. (See postpartum psychosis.)

birth control The device and/or practice used to decrease the risk of conceiving or bearing offspring.

birth injury See birth trauma.

birth plan A tool by which parents can explore their childbirth options and choose those that are most important to them.

birth rate Number of live births per 1000 population per year.

birth trauma Physical injury sustained by a neonate during labor and birth. Also called birth injury.

Bishop score Rating system to evaluate inducibility of the cervix; a higher score increases the rate of successful induction of labor.

blastocyst Stage in the development of a mammalian embryo, occurring after the morula stage, that consists of an outer layer, or trophoblast, and a hollow sphere of cells enclosing a cavity.

bloody show Vaginal discharge that originates in the cervix and consists of blood and mucus; increases as cervix dilates during labor.

BMI See body mass index (BMI).

body mass index (BMI) Method of calculating appropriateness of weight for height (BMI = weight [kilograms]/height² [meters]).

BPD See bronchopulmonary dysplasia (BPD).

brachial plexus injury Paralysis caused by physical injury to the upper brachial plexus, occurring most often in childbirth from forcible traction during birth.

bradycardia Baseline fetal heart rate (FHR) of fewer than 110 beats/minute for 10 minutes or longer. True bradycardia occurs rarely and is not specifically related to fetal oxygenation.

Braxton Hicks contractions Mild, intermittent, painless uterine contractions that occur during pregnancy. These contractions occur more frequently as pregnancy advances but do not represent true labor.

breast milk jaundice Also called late-onset jaundice; hyperbilirubinemia that occurs between days 5 and 10 of life, usually in a healthy, breastfed infant; cause is unknown.

breast self-examination (BSE) Self-palpation of breasts to detect for changes in breast tissue.

breastfeeding-associated jaundice Also called early-onset jaundice; hyperbilirubinemia that begins at 2 to 5 days of life; associated with insufficient breastfeeding and infrequent stooling.

bronchopulmonary dysplasia (BPD) Pulmonary condition affecting preterm infants who have experienced respiratory failure and have been oxygen dependent for more than 28 days.

brown fat Source of heat unique to neonates that is capable of greater thermogenic activity than ordinary fat. Deposits are found around the adrenals, kidneys, and neck; between the scapulas; and behind the sternum for several weeks after birth.

C

cafe-au-lait Patches of skin pigmentation present in neurofibromatosis.

cancer of the cervix See cervical cancer.

caput Occiput of fetal head appearing at the vaginal introitus preceding birth of the head.

caput succedaneum Swelling of the tissue over the presenting part of the fetal head caused by pressure during labor.

carcinoma in situ (CIS) Diagnosed when the full thickness of epithelium is replaced with abnormal cells.

carpal tunnel syndrome Pressure on the median nerve at the point at which it goes through the carpal tunnel of the wrist. It causes soreness, tenderness, and weakness of the muscles of the thumb. Edema involving the peripheral nerves may result in carpal tunnel syndrome during the last trimester of pregnancy.

carrier Individual who carries a gene that does not exhibit itself in physical or chemical characteristics but that can be transmitted to children (e.g., a female carrying the trait for hemophilia, which is expressed in male offspring). Heterozygous individuals have only one variant allele and are unaffected clinically because their normal gene (wild-type allele) overshadows the variant allele. They are known as carriers of the recessive trait.

cell-free deoxyribonucleic acid (DNA) screening Screening method to detect the chromosomal abnormalities trisomy 21, 13, and 18. It also provides noninvasive prenatal genetic diagnosis of fetal Rh status, fetal gender, and certain paternally transmitted single gene disorders.

cephalhematoma NOTE: This is spelled cephalohematoma in some sources. Extravasation of blood from ruptured vessels between a skull bone and its external covering, the periosteum. Swelling is limited by the margins of the cranial bone affected (usually parietals).

cephalocaudal Head-to-rump.

cephalopelvic disproportion (CPD) Condition in which the infant's head is of such a shape, size, or position that it cannot pass through the mother's pelvis; can also be caused by maternal pelvic problems. Also called fetopelvic disproportion (FPD).

cerclage Use of nonabsorbable suture to constrict the internal os of a cervix that is dilating prematurely because of cervical weakness. The suture can be placed vaginally or abdominally. A cerclage can be placed either prophylactically or as a rescue procedure.

cervical cancer The third most common reproductive cancer; begins as neoplastic changes in the cervical epithelium. Also called cancer of the cervix.

cervical conization Excision of a cone-shaped section of tissue from the endocervix.

cervical insufficiency Passive and painless dilation of the cervix leading to recurrent preterm births during the second trimester in the absence of other causes. Measurement of cervical length has been used as a way to diagnose cervical insufficiency.

cervical intraepithelial neoplasia (CIN) Uncontrolled and progressive abnormal growth of cervical epithelial cells; preinvasive lesions.

- cesarean birth** Birth of a fetus by an incision through the abdominal wall and uterus. See also elective cesarean birth.
- Chadwick sign** Violet bluish vaginal mucous membrane and cervix that is visible from about the fourth week of pregnancy; caused by increased vascularity.
- choanal atresia** Complete obstruction of the posterior nares, which open into the nasopharynx, with membranous or bony tissue.
- chorioamnionitis** Bacterial infection of the amniotic cavity; usually diagnosed by the clinical findings of maternal fever, maternal and fetal tachycardia, uterine tenderness, and foul odor of amniotic fluid. Other terms for this condition include clinical chorioamnionitis, amnionitis, intrapartum infection, amniotic fluid infection, and intraamniotic infection.
- chorion** Fetal membrane closest to the intrauterine wall that gives rise to the placenta and continues as the outer membrane surrounding the amnion.
- chorionic villi** Tiny vascular protrusions on the chorionic surface that project into the maternal blood sinuses of the uterus and that help form the placenta and secrete human chorionic gonadotropin.
- chorionic villus sampling (CVS)** Removal of fetal tissue from the placenta for genetic diagnostic studies, which can be performed during either the first or second trimester. When performed after the first trimester, the procedure is better known as late CVS or placental biopsy.
- chronic hypertension** Hypertension that is present before pregnancy or that is initially diagnosed during pregnancy and persists longer than 12 weeks postpartum.
- chronic hypertension with superimposed preeclampsia** Condition that usually presents as elevated blood pressures in a woman whose blood pressure previously has been well controlled. Superimposed preeclampsia also may be diagnosed by the development of severe features of preeclampsia such as thrombocytopenia, impaired liver function, the new development of renal insufficiency, pulmonary edema, or new-onset cerebral or visual disturbances.
- CIN** See cervical intraepithelial neoplasia (CIN).
- circumcision** removal of all or part of the foreskin (prepuce) of the penis.
- CIS** See carcinoma in situ (CIS).
- claiming process** Process by which the parents identify their new baby in terms of likeness to other family members, differences, and uniqueness; the unique newcomer is thus incorporated into the family.
- left lip** Incomplete closure of the lip. Lay term is harelip.
- cleft palate** Incomplete closure of the palate or roof of mouth; a congenital fissure.
- climacteric** The period of a woman's life when she is passing from a reproductive to a non-reproductive state, with regression of ovarian function. The cycle of endocrine, physical, and psychosocial changes that occurs during the termination of the reproductive years. Also called climacterium.
- clonus** Hyperactive reflexes.
- clubfoot** Congenital deformity in which portions of the foot and ankle are twisted out of a normal position.
- Cochrane Pregnancy and Childbirth Database** Database of up-to-date systematic reviews and dissemination of views of randomized controlled trials of health care.
- cohabiting-parent family** Family form in which children live with two unmarried biologic parents or two adoptive parents.
- cold stress** Excessive loss of heat that results in increased respirations and nonshivering thermogenesis to maintain core body temperature.
- colostrum** The creamy white to yellowish to orange premilk fluid that may be expressed from the nipples as early as 16 weeks of gestation; the fluid in the breast from pregnancy into the early postpartal period. It is more concentrated than mature milk and is extremely rich in immunoglobulins; it has higher concentrations of protein and minerals but less fat than mature milk; it is also rich in antibodies, which provide protection from many diseases; high in protein, which binds bilirubin; and laxative-acting, which speeds the elimination of meconium and helps loosen mucus.
- colposcopy** Examination of vagina and cervix with a colposcope (a stereoscopic binocular microscope that magnifies the view of the cervix) to identify neoplastic or other changes.
- combined spinal-epidural (CSE) analgesia** An epidural needle is inserted into the epidural space. Before the epidural catheter is threaded, a smaller-gauge spinal needle is inserted through the bore of the epidural needle into the subarachnoid space and a small amount of an opioid or a combination of an opioid and a local anesthetic is injected to rapidly provide analgesia. Afterward, the epidural catheter is inserted as usual. If pain relief is still needed after the effect of the medication injected into the subarachnoid space wears off, additional medication can be injected through the epidural catheter.
- complicated bereavement** See complicated grief.
- complicated grief** Extremely intense grief reactions that last for a very long time; a state of chronic mourning. Also the persistent feelings of anger, guilt, loss, pain, and sadness over time that lead to feelings of hopelessness, helplessness, and diminishing self-worth that are signs and symptoms of clinical depression, which is different from the normal depression of bereavement. Also called complicated bereavement, prolonged grief, pathologic grief, or pathologic mourning.
- conception** Union of the sperm and a single egg (ovum) resulting in fertilization; formation of the one-celled zygote marks the beginning of a pregnancy.
- congenital anomaly** A defect that is present at birth and can be caused by genetic or environmental factors, or both; defined as a physical, metabolic, anatomic, or behavioral deviation from the normal pattern of development.
- congenital diaphragmatic hernia** Diaphragm malformation that allows displacement of the abdominal organs into the thoracic cavity.
- congenital hypothyroidism** Results from a deficiency of thyroid hormones and can be permanent (requires treatment for life) or transient (spontaneously resolves).
- congenital rubella syndrome** Complex of problems, including hearing defects, cardiovascular abnormalities, and cataracts, caused by maternal rubella in the first trimester of pregnancy.
- conization** See cervical conization.
- conjoined twins** Twins who are physically united; Siamese twins.
- continuous positive airway pressure (CPAP)** Method of infusing oxygen or air under a preset pressure by means of nasal prongs, a face mask, or an endotracheal tube.
- contraception** Intentional prevention of pregnancy (impregnation or conception) during sexual intercourse.
- contraction stress test (CST)** Test to stimulate uterine contractions for the purpose of assessing fetal response to stress; it identifies a fetus that is stable at rest but shows evidence of compromise after stress. This test is also known as the oxytocin challenge test (OCT).
- Coombs' test** Indirect: determination of Rh-positive antibodies in maternal blood. Direct: determination of maternal Rh-positive antibodies in fetal cord blood. A positive test result indicates the presence of antibodies or titer.
- cordocentesis** See percutaneous umbilical blood sampling (PUBS).
- corpus luteum cysts** Occur after ovulation and are possibly caused by an increased secretion of progesterone that results in an increase of fluid in the corpus luteum.
- corrected age** Taking into account the gestational age and the postnatal age of a preterm infant when determining expectations for development.
- counterpressure** Pressure to the sacral area of the back during uterine contractions.
- couplet care** Care provided by one nurse, educated in both mother and infant care, who functions as the primary nurse for mother and infant. Also called mother-baby care or single-room maternity care.
- couvade syndrome** The phenomenon of expectant fathers' experiencing pregnancy-like symptoms.
- couvelaire uterus** Associated with placental abruption; occurs when blood accumulates between the separated placenta and the uterine wall. The uterus appears purple or blue rather than its usual "bubblegum pink" color, and contractility is lost.
- CPAP** See continuous positive airway pressure (CPAP).
- crowning** Stage of birth when the top of the fetal head can be seen at the vaginal orifice as the widest part of the head distends the vulva.
- cultural competence** Awareness, acceptance, and knowledge of cultural differences and adaptation of services to acknowledge and support the client's culture.
- cultural prescriptions** Practices that are expected or acceptable; they tell women what to do.
- cultural proscriptions** Forbidden; taboo practices; they tell women what not to do.
- cultural relativism** Learning about and applying the standards of another's culture to activities within that culture.

cystocele Bladder hernia; injury to the vesicovaginal fascia during labor and birth may allow herniation of the bladder into the vagina. Protrusion of the bladder downward into the vagina; develops when supporting structures in the vesicovaginal septum are injured.

D

daily fetal movement count (DFMC) Maternal assessment of fetal activity; the number of fetal movements within a specific time are counted. Also called kick count.

DDH See developmental dysplasia of the hip (DDH).

decidua Mucous membrane, lining of uterus, or endometrium of pregnancy that is shed after giving birth.

decidua basalis The portion of the endometrium directly under the blastocyst, where the chorionic villi tap into the maternal blood vessels. Maternal aspect of the placenta made up of uterine blood vessels, endometrial stroma, and glands. It is shed in lochial discharge after birth.

deletion Loss of chromosomal material and partial monosomy for the chromosome involved. The resulting clinical phenotype of either a terminal or an interstitial deletion depends on how much of the chromosome has been lost and the number and function of the genes contained in the missing segment.

demand feeding Feeding a newborn every third hour or when the baby cries to be fed, whichever comes first.

deoxyribonucleic acid (DNA) Intracellular complex protein that carries genetic information, consisting of two purines (adenine and guanine) and two pyrimidines (thymine and cytosine).

dermoid cysts Germ cell tumors, usually occurring in childhood. These cysts contain substances such as hair, teeth, sebaceous secretions, and bones.

desquamation Shedding of epithelial cells of the skin and mucous membranes.

developmental dysplasia of the hip (DDH) Abnormal development of the hip joint, resulting in instability of the hip, causing one or both of the femoral heads to be displaced from the acetabulum (hip socket).

diabetes mellitus A group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. The current classification system includes four groups: type 1 diabetes, type 2 diabetes, other specific types (e.g., diabetes caused by genetic defects in beta cell function or insulin action, disease or injury of the pancreas, or drug-induced diabetes), and gestational diabetes mellitus.

diastasis recti abdominis Separation of the two rectus muscles along the median line of the abdominal wall. This is often seen in women with repeated pregnancies or with a multiple gestation

dietary reference intakes (DRIs) Nutritional recommendations consisting of the recommended dietary allowances, adequate intakes, and tolerable upper intake levels, the upper limit of intake associated with low risk in almost all members of a population.

dilation The enlargement or widening of the cervical opening and the cervical canal that occurs once labor has begun. The diameter of the cervix increases from being closed to full dilation (approximately 10 cm) to allow birth of a term fetus.

dilation and curettage (D&C) Surgical procedure in which the cervix is dilated if necessary and a curette is inserted to scrape the uterine walls and remove uterine contents. Uterine contents may also be removed by suction curettage, using a catheter attached to an electric-powered vacuum source.

diploid Containing two complete sets of chromosomes, one from each parent.

disseminated intravascular coagulation (DIC) Pathologic form of clotting that is diffuse and consumes large amounts of clotting factors, causing widespread external bleeding, internal bleeding, or both, and clotting. In obstetrics it is most often associated with placental abruption, amniotic fluid embolism, preeclampsia, HELLP syndrome, and gram-negative sepsis. Also called consumptive coagulopathy.

disenfranchised grief Losses that are not openly acknowledged or mourned publicly

dizygotic twins Twins developed from two separate ova fertilized by two separate sperm at the same time; fraternal twins.

dominant trait A trait or disorder expressed or phenotypically apparent when only one copy of an allele associated with the trait is present. Gene that is expressed whenever it is present in the heterozygous gene state (e.g., brown eyes are dominant over blue).

Doppler blood flow analysis Method for measuring blood flow noninvasively in the fetus and placenta using ultrasound to detect intrauterine growth restriction.

doula A specially trained, experienced female labor attendant. A doula is a professional or lay labor-support person who is present during labor to focus on the laboring woman and provide physical and emotional support.

Down syndrome (DS) Abnormality involving chromosome 21 that characteristically results in a typical picture of intellectual disability and altered physical appearance. This condition was formerly called mongolism.

dual diagnosis Coexistence of substance abuse and another psychiatric disorder. Mood and anxiety disorders are the psychiatric disorders most commonly seen along with substance abuse in women. The psychiatric illness usually occurs before substance use begins.

DUB See dysfunctional uterine bleeding (DUB).

ductus arteriosus In fetal circulation an anatomic shunt between the pulmonary artery and arch of the aorta. It is obliterated after birth by a rising PO₂ and a change in intravascular pressures in the presence of normal pulmonary function. It normally becomes a ligament after birth but in some instances remains patent; this is called patent ductus arteriosus (PDA).

ductus venosus In fetal circulation a blood vessel carrying oxygenated blood between the umbilical vein and the inferior vena cava, bypassing the liver. It is obliterated and becomes a ligament after birth.

duration (of uterine contractions) Time (measured in seconds) from the beginning to the end of a contraction.

dysfunctional labor Long, difficult, or abnormal labor, caused by various conditions associated with the five factors affecting labor; also called dystocia.

dysfunctional uterine bleeding (DUB) Excessive uterine bleeding with no demonstrable organic cause, genital or extragenital; most frequently caused by anovulation. Subset of abnormal uterine bleeding.

dysmenorrhea Pain during or shortly before menstruation.

dysplasia Any abnormal development of tissues or organs; preinvasive lesions in cervical epithelium.

E

early deceleration (of the fetal heart rate)

Visually apparent gradual (onset to lowest point ≥ 30 seconds) decrease in and return to baseline fetal heart rate (FHR) associated with uterine contractions. It is thought to be caused by transient fetal head compression and is considered a normal and benign finding. Generally the onset, nadir (lowest point), and recovery of the deceleration correspond to the beginning, peak, and end of the contraction.

early neonatal death Death of a live-born infant less than 7 days old.

eclampsia Onset of seizure activity or coma in a woman with preeclampsia who has no history of preexisting pathology that can result in seizure activity.

ectopic pregnancy Pregnancy in which the fertilized ovum is implanted outside of its normal place in the uterine cavity. Locations include the abdomen, uterine tubes, and ovaries. Ectopic pregnancies are often called tubal pregnancies because at least 90% are located in the uterine tube.

EDB See estimated date of birth (EDB).

effacement The shortening and thinning of the cervix during the first stage of labor. Effacement generally progresses significantly in first-time term pregnancy before more than slight dilation occurs. In subsequent pregnancies effacement and dilation of the cervix tend to progress together. Degree of effacement is expressed in percentages from 0% to 100%.

effleurage Light stroking, usually of the abdomen, in rhythm with breathing during contractions.

e-health literacy Ability to use information and communications technologies to improve health.

ELBW See extremely low birth weight (ELBW).

elective abortion Termination of pregnancy chosen by the woman that is not required for her physical safety.

elective cesarean birth A primary cesarean birth without medical or obstetric indication; sometimes referred to as cesarean on request or cesarean on demand.

ELSI Ethical, legal, and social implications of genetics research.

embryo Conceptus from the second or third week of development until about the eighth week after conception, when mineralization (ossification) of the skeleton begins. This period is characterized by cellular differentiation and predominantly hyperplastic growth.

embryoblast Inner cell mass in blastocyst that gives rise to the embryo.

en face Face-to-face position in which the parent's and infant's faces are approximately 20 cm apart and on the same plane.

encephalocele A herniation of the brain and meninges through a skull defect.

endometrial cancer Most common malignancy of the reproductive system; slow-growing tumor that usually develops in the fundus of the uterus and can spread directly to the myometrium and cervix, as well as to the reproductive organs.

endometriosis Characterized by the presence and growth of endometrial glands and stroma outside of the uterus. Tissue closely resembling endometrial tissue but located outside the uterus in the pelvic cavity. Symptoms may include pelvic pain or pressure, dysmenorrhea, dyspareunia, abnormal bleeding from the uterus or rectum, and sterility.

endometritis Postpartum uterine infection, often beginning at the site of the placental implantation.

engagement Term used to indicate that the largest transverse diameter of the presenting part (usually the biparietal diameter) has passed through the maternal pelvic brim or inlet into the true pelvis and usually corresponds to station 0.

engorgement Distention or vascular congestion. In obstetrics the process of swelling of the breast tissue brought about by an increase in blood and lymph supply to the breast as the body produces milk, which precedes true lactation. Occurring at about 72 to 96 hours after birth, it lasts about 48 hours and usually reaches a peak between the third and fifth postbirth days.

engrossment A parent's absorption, preoccupation, and interest in his or her infant; term typically used to describe the father's intense involvement with his newborn.

entrainment Phenomenon observed in the microanalysis of sound films in which the speaker moves several parts of the body and the listener responds to the sounds by moving in ways that are coordinated with the rhythm of the sounds. Infants have been observed to move in time to the rhythms of adult speech but not to random noises or disconnected words or vowels. Entrainment is believed to be an essential factor in the process of maternal-infant bonding.

epidural block Type of regional anesthesia produced by injecting a local anesthetic alone or in combination with an opioid agonist analgesic into the epidural (peridural) space.

episiotomy Surgical incision of the perineum at the end of the second stage of labor to enlarge the vaginal outlet, facilitate birth, and avoid laceration of the perineum.

episodic changes Changes from baseline patterns in the fetal heart rate (FHR) that are not associated with uterine contractions.

epispadias Defect in which the urethral canal terminates on the dorsum of the penis or above the clitoris (rare).

epulis Red raised nodule on the gums that bleeds easily; tumor-like benign lesion of the gingiva seen in pregnant women. Also called gingival granuloma gravidarum.

erythema toxicum Innocuous pink papular neonatal rash of unknown cause, with superimposed vesicles appearing within 24 to 48 hours after birth and resolving spontaneously within a few days. Also called erythema neonatorum, newborn rash, or flea bite dermatitis.

erythroblastosis fetalis Hemolytic disease of the newborn usually caused by isoimmunization resulting from Rh incompatibility or ABO incompatibility.

esophageal atresia Congenital anomaly in which the esophagus ends in a blind pouch or narrows into a thin cord, thus failing to form a continuous passageway to the stomach.

estimated date of birth (EDB) Approximate date of birth. Usually determined by calculation using Naegel's rule; "due date."

ethnocentrism Belief in the rightness of one's culture's way of doing things.

euglycemia Normal blood glucose level.

euploid cell Cell with the correct or normal number of chromosomes within the cell.

evidence-based practice Providing care based on evidence gained through research and clinical trials.

exchange transfusion Replacing 75% to 85% of circulating blood by withdrawing the recipient's blood and injecting a donor's blood in equal amounts, the purposes of which are to prevent an accumulation of bilirubin in the blood above a dangerous level, to prevent the accumulation of other byproducts of hemolysis in hemolytic disease, and to correct anemia and acidosis.

exenteration, pelvic See pelvic exenteration.

exstrophy of the bladder Results from the abnormal development of the bladder, abdominal wall, and pubic symphysis that causes the bladder, the urethra, and the ureteral orifices to be exposed; rare and males affected twice as often as females.

extended family Family form that includes the nuclear family and other blood-related persons.

external cephalic version (ECV) Turning the fetus to a vertex position by exertion of pressure on the fetus externally through the maternal abdomen.

extremely low birth weight (ELBW) A newborn birth weight of 1000 g (2.2 lb) or less.

F

FAB See fertility awareness-based (FAB) methods.

family planning See periodic abstinence.

FAS See fetal alcohol syndrome (FAS).

feeding-readiness cues Infant responses that indicate optimal times to begin a feeding. The baby may make mouthing motions, suck a fist, or awaken and cry.

fertility awareness-based (FAB) methods Methods of contraception, also known as periodic abstinence or natural family planning, that depend on identifying the beginning and end of the fertile period of the menstrual cycle. These methods provide contraception by relying on avoidance of intercourse during fertile periods.

fertility rate Births per 1000 women from 15 to 44 years of age.

fertilization Union of an ovum and a sperm.

fetal alcohol syndrome (FAS) Congenital abnormality or anomaly resulting from excessive maternal alcohol intake during pregnancy. It is characterized by typical craniofacial and limb defects, cardiovascular defects, intrauterine growth restriction, and developmental delay.

fetal death Intrauterine death; death of a fetus weighing 500 g or more and 20 weeks of gestation or more.

fetal fibronectin (fFN) Glycoprotein "glue" found in plasma and produced during fetal life. It normally appears in cervical and vaginal secretions early in pregnancy and again in late pregnancy. Assessing for the presence or absence of fFN in vaginal secretions is used as a diagnostic test for preterm labor.

fetal heart rate (FHR) baseline The average rate during a 10-minute segment that excludes periodic or episodic changes, periods of marked variability, and segments of the baseline that differ by more than 25 beats/minute. The normal range at term is 110 to 160 beats/minute. In the preterm fetus the baseline rate is slightly higher.

fetal hydrops The most severe form of erythroblastosis fetalis, in which the fetus has marked anemia, cardiac decompensation, cardiomegaly, hepatosplenomegaly, and hypoxia.

fetus Child in utero from approximately the eighth week after conception until birth.

fibroadenoma Benign condition of the breast; discrete, usually solitary lumps less than 3 cm in diameter.

fibrocystic change Characterized by lumpiness, with or without tenderness, in both breasts. Fibrocystic breast condition involves the glandular breast tissue.

first stage of labor Begins with the onset of regular uterine contractions and ends with full cervical effacement and dilation; consists of three phases: the latent phase (through 3 cm of dilation), the active phase (4 to 7 cm of dilation), and the transition phase (8 to 10 cm of dilation).

fistula Abnormal tubelike passage that forms between two normal cavities, possibly congenital or caused by trauma, abscesses, or inflammatory processes.

follicular cysts Develop most commonly in normal ovaries of young women as a result of the mature graafian follicle failing to rupture or when an immature follicle does not resorb fluid after ovulation.

foramen ovale Septal opening between the atria of the fetal heart. The opening normally closes shortly after birth, but if it remains patent, surgical repair usually is necessary.

forceps-assisted birth Birth in which forceps are used to assist in delivery of the fetal head.

fourth stage of labor Initial period of physical recovery from childbirth and the beginning of parent-infant bonding. It is usually considered to last for the first 1 to 2 hours after birth.

frequency (of uterine contractions) Time (measured in minutes) from the beginning of one contraction to the beginning of the next.

friability Easily broken. May refer to a fragile condition of the cervix, especially during pregnancy, that causes the cervix to bleed easily when touched.

funic souffle Soft, muffled, blowing sound produced by blood rushing through the umbilical vessels and synchronous with the fetal heart sounds.

G

galactorrhea Form of nipple discharge or lactation not associated with childbirth or breastfeeding; a bilaterally spontaneous, milky, sticky discharge. When associated with elevated prolactin levels, may be a symptom of a pituitary gland tumor.

galactogogue Medications or other substances that are believed to increase breast milk production

galactosemia Inherited, autosomal recessive disorder of galactose metabolism, characterized by a deficiency of the enzyme galactose-1-phosphate uridylyltransferase.

gamete Egg and sperm. Mature male or female germ cell; the mature sperm or ovum.

gastroschisis Abdominal wall defect at base of umbilical stalk; herniation of the bowel through a defect in the abdominal wall to the right of the umbilical cord.

gate-control theory of pain Helps explain the way hypnosis and the pain relief techniques taught in childbirth preparation classes work to relieve the pain of labor. According to this theory pain sensations travel along sensory nerve pathways to the brain, but only a limited number of sensations, or messages, can travel through these nerve pathways at one time. Using distraction techniques such as massage or effleurage, stroking, music, focal points, and imagery reduces or completely blocks the capacity of nerve pathways to transmit pain. These distractions are thought to work by closing down a hypothetical gate in the spinal cord, thus preventing pain signals from reaching the brain.

gene Basic physical unit of inheritance passed from parents to offspring; contains the information needed to specify traits.

gene therapy Inserting a healthy copy of the defective gene into the somatic cells (of the affected individual).

general anesthesia Administration of several medications that combine to produce unconsciousness and pain relief (often referred to as being "put to sleep"). The major risks associated with general anesthesia are difficulty with or inability to intubate and aspiration of gastric contents.

genetics Study of individual genes and their effect on relatively rare single gene disorders.

genital self-examination (GSE) See vulvar self-examination (VSE).

genome Entire set of genetic instructions found in each cell.

genomics Study of all the genes in the human genome together, including their interactions with each other, the environment, and the influence of other psychosocial factors and cultural factors.

genotype An individual's collection of genes. Hereditary combinations in an individual determining physical and chemical characteristics. Some genotypes are not expressed until later in life (e.g., Huntington's chorea); some hide recessive genes, which can be expressed in offspring, and others are expressed only under the proper environmental conditions (e.g., diabetes mellitus appearing under the stress of obesity or pregnancy).

germinal matrix hemorrhage-intraventricular hemorrhage most common type of intracranial hemorrhage in neonates; the germinal matrix, a vascular network of cells is beneath the lining of the lateral ventricles; hemorrhage extends from the germinal matrix into the ventricles

gestational diabetes mellitus (GDM) Traditionally defined as carbohydrate intolerance with the onset or first recognition occurring during pregnancy. The American Diabetes Association defines GDM as diabetes diagnosed during pregnancy that is clearly not overt (pre-existing) diabetes.

gestational hypertension Onset of hypertension without proteinuria or other systemic findings diagnostic for preeclampsia after week 20 of pregnancy. Gestational hypertension does not persist longer than 12 weeks postpartum and usually resolves during the first postpartum week.

glycosylated hemoglobin A_{1c} Test done to assess recent glycemic control. Hemoglobin A_{1c} levels greater than 6 indicate elevated glucose levels during the previous 4 to 6 weeks.

Goodell sign Softening of the cervix, a probable sign of pregnancy, occurring during the second month.

gravida A woman who is pregnant.

gravidity Pregnancy.

grief A cluster of painful emotional and related behavioral and physical responses experienced following a major loss or death.

growth spurts Times of increased neonatal growth that usually occur at approximately 6 to 10 days, 6 weeks, 3 months, and 4 to 5 months. The increased caloric needs necessitate more frequent feedings to increase the amount of milk needed.

H

habituation An acquired tolerance from repeated exposure to a particular stimulus. Also called negative adaptation; a decline and eventual elimination of a conditioned response by repetition of the conditioned stimulus.

haploid Cell that contains 23 chromosomes or half the number contained in a somatic cell; most gametes are haploid.

hCG See human chorionic gonadotropin (hCG).

health promotion Motivation to increase well-being and actualize health potential.

Hegar sign Softening of the lower uterine segment that is classified as a probable sign of pregnancy; may be present during the second and third months of pregnancy and is palpated during bimanual examination.

HELLP syndrome A laboratory diagnosis for a variant of severe preeclampsia that involves hepatic dysfunction, characterized by hemolysis (H), elevated liver enzymes (EL), and low platelet count (LP); it is not a separate illness.

hematopoiesis Production of blood cells; formation of blood.

hemorrhage, subconjunctival See subconjunctival hemorrhage.

hemorrhage, subgaleal See subgaleal hemorrhage.

hemorrhagic shock Clinical condition in which the peripheral blood flow is inadequate to return sufficient blood to the heart for normal function, particularly oxygen transport to the organs or tissue. Also called hypovolemic shock.

heterozygous Having two dissimilar genes at the same site, or locus, on paired chromosomes (e.g., at the site for eye color, one chromosome carrying the gene for brown, the other for blue).

home birth Planned birth of the child at home, usually done under the supervision of a midwife.

homologous Similar in structure or origin but not necessarily in function.

homosexual family Family in which parents form a homosexual union (lesbian, gay, bisexual, and transgender [LGBT]), who may live together with or without children. Children may be the offspring of a previous heterosexual union, adopted, or conceived by one or both members of an LGBT couple through artificial insemination.

homozygous Having two similar genes at the same locus, or site, on paired chromosomes.

hot flash Transient, sudden sensation of warmth in neck, head, and chest experienced by some women during or after menopause, resulting from autonomic vasomotor disturbances that accompany changes in the neurohormonal activity of the ovaries, hypothalamus, and pituitary gland.

hot flush Visible red flush of skin and perspiration experienced by some women during or after menopause; see also hot flash.

human chorionic gonadotropin (hCG) Hormone that is produced by chorionic villi; the biologic marker in pregnancy tests.

hydatidiform mole Benign proliferative growth of the placental trophoblast in which the chorionic villi develop into edematous, cystic, avascular transparent vesicles that hang in a grapelike cluster. Hydatidiform mole is caused by abnormal fertilization, so there is no viable fetus. Also called a molar pregnancy.

hydramnios See polyhydramnios.

hydrocele Collection of fluid in a scrotal cavity, especially in the sac that surrounds the testis, causing the scrotum to swell.

hydrocephalus Accumulation of cerebrospinal fluid (CSF) in the subdural or subarachnoid spaces; caused by overproduction (rare) of CSF or a decrease in reabsorption.

hydrops fetalis See fetal hydrops.

hyperbilirubinemia Condition in which the total unconjugated serum bilirubin concentration in the blood is elevated. Values are abnormal based on gestational age, days of life, and the baby's general physical condition. Hyperbilirubinemia is characterized by a yellow discoloration of the skin, mucous membranes, sclera, and various organs; caused by bilirubin levels that rise steadily over the first 3 to 4 days, peak around day 5, and decrease thereafter. See also jaundice.

hyperemesis gravidarum Abnormal condition of pregnancy characterized by vomiting excessive enough to cause weight loss, electrolyte imbalance, nutritional deficiencies, and ketonuria.

hyperglycemia Excess glucose in the blood.

hypermenorrhea See menorrhagia.

hyperthermia Body temperature greater than 37.5° C.

hyperthyroidism Excessive functional activity of the thyroid gland.

hypoglycemia Less than normal amount of glucose in the blood.

hypospadias Anomalous positioning of urinary meatus on undersurface of penis or close to or just inside the vagina.

hypothermia Temperature that falls below normal range, usually caused by exposure to cold.

hypothyroidism Deficiency of thyroid gland activity with underproduction of thyroxine.

hypovolemic shock See hemorrhagic shock.

hypoxemia Deficiency of oxygen in the arterial blood.

hypoxia Inadequate supply of oxygen at the cellular level that can cause metabolic acidosis.

hysterectomy Surgical removal of the entire uterus.

I

icterus See jaundice.

idiopathic thrombocytopenic purpura (ITP)

An autoimmune disorder in which antiplatelet antibodies decrease the life span of the platelets. Thrombocytopenia, capillary fragility, and increased bleeding time are diagnostic findings. Also called immune thrombocytopenic purpura (ITP).

illness prevention Desire to avoid illness, detect it early, or maintain optimal functioning when illness is present.

immune thrombocytopenic purpura (ITP) See idiopathic thrombocytopenic purpura (ITP).

imperforate anus A term used to describe a wide range of congenital disorders involving the anus and rectum and genitourinary system.

implantation Embedding of the fertilized ovum in the uterine mucosa; nidation.

inborn error of metabolism Hereditary deficiency of a specific enzyme needed for normal metabolism of specific chemicals (e.g., deficiency of phenylalanine hydroxylase results in phenylketonuria [PKU]; a deficiency of hexosaminidase results in Tay-Sachs disease).

induced abortion Purposeful interruption of a pregnancy before 20 weeks of gestation.

induction of labor Chemical or mechanical initiation of uterine contractions before their spontaneous onset for the purpose of bringing about birth.

infant death Death during the first year of life.

infant mortality rate Number of deaths per 1000 children 1 year of age or younger.

infertility Decreased capacity to conceive. A serious medical concern that affects quality of life and is a problem for 10% to 15% of reproductive-age couples. The term *infertility* implies subfertility, a prolonged time to conceive, as opposed to *sterility*, which means inability to conceive.

insensible water loss (IWL) Evaporative water loss that occurs mainly through the skin and respiratory tract.

intensity (of uterine contractions) Strength of a contraction at its peak.

intermittent auscultation Involves listening to fetal heart sounds at periodic intervals to assess the fetal heart rate (FHR).

interstitial deletion Deletion anywhere else in the chromosome except at the end.

intimate partner violence (IPV) The actual or threatened physical, sexual, psychologic, or emotional abuse by a spouse, ex-spouse, boyfriend, girlfriend, ex-boyfriend, ex-girlfriend, date, or cohabiting partner.

intraductal papilloma A benign tumor that grows within the duct of the breast.

intrahepatic cholestasis of pregnancy (ICP)

Disorder unique to pregnancy that is characterized by generalized pruritus caused by elevated serum bile acids. The itching commonly affects the palms and soles but can occur on any part of the body and is usually worse at night. No skin lesions are present.

intrauterine growth restriction (IUGR) Fetal undergrowth of any cause, such as deficient nutrient supply or intrauterine infection, or associated with congenital malformation; birth weight below population 10th percentile corrected for gestational age.

intrauterine pressure catheter (IUPC)

Catheter inserted into uterine cavity to assess uterine activity and pressure by electronic means.

inversion of the uterus (1) Turning end for end, upside down, or inside out. (2) Deviation in which a portion of the chromosome has been rearranged in reverse order.

involution (1) Rolling or turning inward. (2) Reduction in size of the uterus after birth and its return to its nonpregnant condition.

isoimmunization Production of antibodies by one member of a species against something that is commonly found within that species (e.g., development of anti-Rh antibodies in an Rh-negative person; also called Rh incompatibility).

ITP See idiopathic thrombocytopenic purpura (ITP). Note: The acronym ITP is also known as immune thrombocytopenic purpura.

IWL See insensible water loss (IWL).

J

jaundice Yellow discoloration of the body tissues caused by the deposit of bile pigments (unconjugated bilirubin); also called icterus. See also hyperbilirubinemia.

K

karyotype Pictorial analysis of the number, form, and size of an individual's chromosomes. Schematic arrangement of the chromosomes within a cell to demonstrate their numbers and morphology.

Kegel exercises Pelvic muscle exercises developed to strengthen the pubococcygeal muscles (supportive pelvic floor muscles) to control or reduce incontinent urine loss and to provide support for the pelvic organs and control of the muscles surrounding the vagina and urethra. Also beneficial during pregnancy and postpartum.

kernicterus Bilirubin encephalopathy involving the deposit of unconjugated bilirubin in brain cells, resulting in death or impaired intellectual, perceptive, or motor function and adaptive behavior.

ketoacidosis The accumulation of ketone bodies in the blood as a consequence of hyperglycemia; leads to metabolic acidosis.

key informants Individuals in positions of leadership who can provide information about a situation.

L

L/S ratio See lecithin/sphingomyelin ratio.

labor Series of processes by which the fetus is expelled from the uterus; parturition; childbirth.

Lactogenesis initiation of breast milk production. Stage I: Initial synthesis of milk components beginning at approximately 16 to 18 weeks of pregnancy until approximately day 3 postpartum; the breasts prepare for milk production by producing colostrum. Stage II: begins with delivery of the placenta; progesterone levels drop and prolactin levels increase; onset of copious milk production on day 2 to 4 postpartum. Stage III: begins at approximately 10 days postpartum when mature milk is established and supply is maintained through autocrine control.

lactose intolerance Inability to digest milk sugar (lactose) because of an inherited absence of the enzyme lactase in the small intestine.

lanugo Downy, fine hair characteristic of the fetus between 20 weeks of gestation and birth that is most noticeable over the shoulder, forehead and eyebrows.

large for gestational age (LGA) Exhibiting excessive growth for gestational age; an infant whose birth weight falls above the 90th percentile on intrauterine growth curves.

laryngeal web Results from the incomplete separation of the two sides of the larynx and is most often between the vocal cords.

latch (1) Placement of the infant's mouth over the nipple, areola, and breast, making a seal between the mouth and breast to create adequate suction for milk removal. (2) Attachment of the infant to the breast for feeding.

late deceleration (of the fetal heart rate)

Visually apparent gradual decrease in and return to baseline fetal heart rate (FHR) associated with uterine contractions. It is thought to be caused by a disruption in oxygen transfer from the environment to the fetus. The deceleration begins after the contraction has started, and the nadir (lowest point) of the deceleration occurs after the peak of the contraction. The deceleration usually does not return to baseline until after the contraction is over.

late neonatal death Death of a newborn between 7 and 28 days after birth.

latent (early) phase of labor Phase in first stage of labor up through 3 cm dilation.

latent ("laboring down") phase of labor

Period of rest and relative calm at the beginning of second stage labor. During this phase the fetus continues to descend passively through the birth canal and rotate to an anterior position as a result of ongoing uterine contractions. The woman is quiet and often relaxes with her eyes closed between contractions. The urge to bear down is not strong, and some women do not experience it at all or only during the acme (peak) of a contraction.

LBW See low birth weight (LBW).

lecithin/sphingomyelin ratio Ratio of lecithin to sphingomyelin in the amniotic fluid. It is used to assess maturity of the fetal lung.

leiomyoma Slow-growing benign tumor arising from the muscle tissue of the uterus. Also known as fibroid tumor, fibroma, myoma, or fibromyoma.

letdown or let-down reflex See milk ejection reflex (MER).

leukorrhea White or slightly gray mucoid discharge from the cervical canal or the vagina with a faint musty odor, which may be normal physiologically or caused by pathologic states of the vagina and endocervix (e.g., *Trichomonas vaginalis* infections).

LGA See large for gestational age (LGA).

lie Relationship between the long axis (spine) of the fetus and the long axis (spine) of the mother. In a longitudinal lie, the fetus is lying lengthwise or vertically, whereas in a transverse lie, the fetus is lying crosswise or horizontally in the uterus.

lightening Sensation of decreased abdominal distention produced by uterine descent into the pelvic cavity as the fetal presenting part settles into the pelvis. It usually occurs 2 weeks before the onset of labor in nulliparas.

linea nigra Pigmented line that appears on the middle of the abdomen and extends from the symphysis pubis toward the umbilicus, extending to the top of the fundus in the midline; seen in some women during the latter part of pregnancy.

lithotomy position Position in which the woman lies on her back with her knees flexed and with abducted thighs drawn up toward her chest.

local perineal infiltration anesthesia Process by which a local anesthetic medication is injected into the skin and then subcutaneously to anesthetize a limited region of the body.

lochia Uterine/vaginal discharge after childbirth (during the puerperium) consisting of blood, tissue, and mucus.

lochia alba Thin, yellowish to white, vaginal discharge that follows lochia serosa on about the tenth day after birth and that may last from 2 to 6 weeks postpartum; consists primarily of leukocytes and decidual cells but also contains epithelial cells, mucus, serum, and bacteria.

lochia rubra Red, distinctly blood-tinged vaginal flow that follows birth and lasts 2 to 4 days; consists mainly of blood and decidual and trophoblastic debris.

lochia serosa Serous, pinkish brown, watery vaginal discharge that follows lochia rubra until about the tenth day after birth; consists of old blood, serum, leukocytes, and tissue debris.

low birth weight (LBW) A newborn birth weight less than 2500 g (5.5 lb).

lumpectomy Removal of a small breast tumor and a small amount of surrounding healthy tissue to ensure there are clean margins.

M

macrosomia Birth weight more than 4000 to 4500 g or greater than the 90th percentile.

magnetic resonance imaging (MRI) Noninvasive nuclear procedure for imaging tissues with high fat and water content; in obstetrics, uses include evaluation of fetal structures, placenta, and amniotic fluid volume.

major depressive episode Disorder diagnosed in a person who has at least five of the following signs or symptoms nearly every day: depressed mood, often with spontaneous crying; markedly diminished interest in all activities; insomnia or hypersomnia; weight changes (increases or decreases); psychomotor retardation or agitation; fatigue or loss of energy; feelings of worthlessness or inappropriate guilt; diminished ability to concentrate; and suicidal ideation with or without a suicidal plan.

mammary duct ectasia An inflammation of the ducts behind the nipple.

mammography X-ray filming of the breast; examination technique used to screen for and evaluate breast lesions.

married-blended family Family formed as a result of divorce and remarriage, consisting of unrelated family members (stepparents, stepchildren, stepsiblings).

MAS See meconium aspiration syndrome (MAS).

mastectomy Removal of the breast including the nipple and areola; also called a simple or total mastectomy.

mastitis Infection in a breast, usually confined to a milk duct, characterized by influenza-like symptoms and redness and tenderness in the affected breast.

maternal mortality rate Number of maternal deaths per 100,000 births.

mechanical ventilation Technique used to provide predetermined amount of oxygen; requires intubation.

meconium First stools of infant: viscid, sticky; dark greenish brown, almost black; sterile; odorless.

meconium aspiration syndrome (MAS) Function of fetal hypoxia: with hypoxia, the anal sphincter relaxes and meconium is released; reflex gasping movements draw meconium and other particulate matter in the amniotic fluid into the infant's bronchial tree, obstructing the airflow after birth.

meconium-stained amniotic fluid Presence of green amniotic fluid that is either thin (light) or thick (heavy) in consistency; indicates that the fetus has passed meconium (first stool) before birth.

meiosis Process by which germ cells divide and decrease their chromosomal number by one half; produces gametes (eggs and sperm).

melasma Blotchy, brownish hyperpigmentation of the skin over the cheeks, nose, and forehead, especially in dark-complexioned pregnant women and some women taking oral contraceptives; also known as the mask of pregnancy.

MEN See minimal enteral nutrition (MEN).

menarche Onset, or beginning, of menstrual function; first menstruation.

menopausal hormone therapy (MHT) Hormonal therapy for menopausal symptoms; either as estrogen replacement therapy (ERT) or estrogen therapy (ET), in which a woman takes only estrogen, or hormonal replacement therapy (HRT) or hormonal therapy (HT), in which she takes both estrogen and progestins.

menopause From the Latin *mensis* (month) and Greek *pausis* (to cease); refers only to the last menstrual period; unlike menarche, however, menopause can be dated with certainty only 1 year after menstruation ceases.

metrorrhagia Excessive menstrual bleeding, in either duration or amount. Also known as hypermenorrhea.

menses (menstruation) (Latin plural of *mensis* [month].) Periodic uterine bleeding and vaginal discharge of bloody fluid from the nonpregnant uterus that occurs from the age of puberty to menopause, which begins approximately 14 days after ovulation.

menstruation See menses (menstruation).

MER See milk ejection reflex (MER).

metastasis Spread of cancer from its original site to distant parts of the body. Results from seeding of cancer cells into the blood and lymph systems.

metrorrhagia Intermenstrual bleeding; refers to any episode of bleeding, whether spotting, menses, or hemorrhage, that occurs at a time other than the normal menses.

MHT See menopausal hormone therapy (MHT).

microcephaly Congenital anomaly characterized by abnormal smallness of the head in relation to the rest of the body and by underdevelopment of the brain, resulting in some degree of mental retardation.

microdeletion Deletion too small to be detected by standard cytogenetic techniques.

milia Unopened sebaceous glands appearing as tiny, white, pinpoint papules on forehead, nose, cheeks, and chin of a neonate that disappear spontaneously in a few days or weeks.

milk ejection reflex (MER) Release of milk caused by the contraction of the myoepithelial cells within the milk glands in response to oxytocin; also called letdown or let-down reflex.

minimal enteral nutrition (MEN) Feeding small volumes of food to stimulate or prime the development of the immature gastrointestinal tract of the preterm infant, to achieve better absorption of nutrients when bolus or regular intermittent gavage feedings can be given. Also called trophic feeding.

miscarriage See spontaneous abortion.

mitosis Process of somatic cell division in which a single cell divides, but both of the new cells have the same number of chromosomes as the first; body cells replicate to yield two cells with the same genetic makeup as the parent cell.

modified biophysical profile (mBPP) Combines the nonstress test with measurement of the quantity of amniotic fluid using ultrasound.

modified radical mastectomy Removal of breast tissue, skin, and axillary nodes.

molar pregnancy See hydatidiform mole.

mongolian spot Bluish gray or dark nonelevated pigmented area usually found over the lower back and buttocks; present at birth in some infants, primarily nonwhite. The spot usually fades by school age.

monosomy Chromosomal aberration characterized by the absence of one chromosome from the normal diploid complement. Product of the union between a normal gamete and a gamete that is missing a chromosome.

monozygotic twins Twins developed from a single fertilized ovum; identical twins.

Montevideo units (MVUs) A method for evaluating the adequacy of uterine activity for achieving progress in labor. MVUs are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction that occurs in a 10-minute window, and then adding together the pressures generated by each contraction that occurs during that period of time. MVUs can only be calculated using an intrauterine pressure catheter (IUPC).

Montgomery glands Small, nodular prominences on the areolas around the nipples of the breasts that enlarge during pregnancy and lactation; hypertrophy of the sebaceous (oil) glands embedded in the primary areolae sebaceous glands. Also called Montgomery tubercles or tubercles of Montgomery.

morbidity (1) Condition of being diseased. (2) Number of cases of disease or of sick persons in relationship to a specific population; incidence.

morning sickness Nausea and vomiting that affect some women during the first few months of their pregnancy; can occur at any time of day.

morula Developmental stage of the fertilized ovum in which there is a solid mass of cells resembling a mulberry.

mosaicism Mixture of cells, some with a normal number of chromosomes and others entirely missing or having an extra chromosome.

mourning The process of finding the answers to the questions surrounding the loss, coping with grief responses, and determining how to live again.

multifactorial inheritance Inheritance of phenotypic characteristics resulting from two or more genes on different chromosomes acting together. See also unifactorial inheritance.

multifetal pregnancy Pregnancy in which there is more than one fetus in the uterus at the same time; multiple pregnancy.

multigenerational family Family form consisting of three or more generations of relatives (grandparents, children, and grandchildren).

multigravida A woman who has had two or more pregnancies

multipara A woman who has completed two or more pregnancies to 20 weeks of gestation or more

mutation Spontaneous and permanent change in the normal gene structure in a gene or chromosome in gametes that may be transmitted to offspring.

mutuality Component of parent-infant attachment; the infant's behaviors and characteristics elicit a corresponding set of parental behaviors and characteristics.

myelomeningocele External sac containing meninges, spinal fluid, and nerves that protrudes through defect in vertebral column.

myomectomy Removal of a tumor; specifically removal of a benign tumor of the uterus leaving the uterine walls relatively intact.

N

Naegle's rule Method for calculating the estimated date of birth (EDB) or "due date."

NEC See necrotizing enterocolitis (NEC).

necrotizing enterocolitis (NEC) Acute inflammatory bowel disorder that occurs primarily in preterm or low-birth-weight neonates. It is characterized by ischemic necrosis (death) of the gastrointestinal mucosa, which may lead to perforation and peritonitis; formula-fed infants are at higher risk for this disease.

neonatal abstinence syndrome Signs and symptoms associated with drug withdrawal in the neonate.

neonatal mortality rate (1) Number of neonatal deaths per 1000 births (or per live births). (2) Statistical rate of infant death during the first 28 days after live birth, expressed as the number of such deaths per 1000 live births in a specific geographic area or institution in a given period of time.

neural tube defect (NTD) Improper development of tube resulting in malformation of brain or spinal cord; see alpha-fetoprotein.

neurofibroma Benign, soft tumor.

neutral thermal environment (NTE) Environment that enables the neonate to maintain a body temperature of at least 36.5° C with minimum use of oxygen and energy.

nevus flammeus Port-wine stain; reddish, usually flat, discoloration of the face or neck. Because of its large size and color, it is considered a serious deformity.

nevus vascularis Elevated lesion of immature capillaries and endothelial cells that regresses over a period of years. Also called a strawberry hemangioma.

nitrazine A pH indicator dye.

nondirectiveness According to the principle of nondirectiveness, the individual who is providing genetic counseling respects the right of the individual or family being counseled to make autonomous decisions. Counselors using a nondirective approach avoid making recommendations and try to communicate genetic information in an unbiased manner.

nondisjunction Failure of two homologous chromosomes to separate during reduction division. One resulting cell contains both chromosomes, and the other contains none.

nonnutritive sucking Use of a pacifier by infants.

nonphysiologic jaundice See jaundice, pathologic.

nonshivering thermogenesis Infant's method of producing heat from brown fat by increasing metabolic rate.

nonstress test (NST) Evaluation of fetal response (fetal heart rate) to fetal movement, uterine contractions, or stimulation.

no-parent family Family form in which children live independently in foster or kinship care, such as living with a grandparent.

NTD See neural tube defect.

NTE See neutral thermal environment (NTE).

nuchal cord Encircling of fetal neck by one or more loops of umbilical cord.

nuclear family Traditional family in which male and female partners and their children live as an independent unit, sharing roles, responsibilities, and economic resources.

nullipara A woman who has not completed a pregnancy beyond 20 weeks of gestation.

nulligravida A woman who has never been pregnant and is not currently pregnant.

O

occurrence risk Estimated risk given to a couple who has not yet had children, but are known to be at risk for having children with a genetic disease. See also recurrence risk.

oligohydramnios Decreased amount of amniotic fluid; usually objectively diagnosed when the deepest vertical pocket of fluid measured in two perpendicular planes is less than 2 cm.

oligomenorrhea Infrequent menstrual periods characterized by intervals of 40 to 45 days or longer.

omphalocele Congenital defect resulting from failure of closure of the abdominal wall or muscles and leading to hernia of abdominal contents through the navel.

oogenesis Process of egg (ovum) formation; begins during fetal life in the female.

operculum Plug of mucus that fills the cervical canal during pregnancy; acts as a barrier against bacterial invasion.

ophthalmia neonatorum Infection in the neonate's eyes usually resulting from gonorrheal or other infection contracted when the fetus passes through the birth canal (vagina).

opioid (narcotic) agonist analgesics Medications that stimulate major opioid receptors, mu and kappa. They have no amnesic effect but create a feeling of well-being or euphoria and enhance a woman's ability to rest between contractions. Examples are meperidine (Demerol) and fentanyl (Sublimaze).

opioid (narcotic) agonist-antagonist analgesics Medications that are agonists at kappa opioid receptors and either antagonists or weak agonists at mu opioid receptors. In the doses used during labor, these mixed opioids provide adequate analgesia without causing significant respiratory depression in the mother or neonate. Examples are butorphanol (Stadol) and nalbuphine (Nubain).

opioid (narcotic) antagonist Medication that promptly reverses the central nervous system (CNS) depressant effects, especially respiratory depression, of narcotics. An example is naloxone (Narcan).

osteoporosis Deossification of bone tissue resulting in structural weakness; generalized, metabolic disease characterized by decreased bone mass and increased incidence of bone fractures, especially after menopause.

outcomes-oriented care Measures effectiveness of care against benchmarks or standards.

ovarian cancer The second most frequently occurring reproductive cancer, which causes more deaths than any other female genital tract cancer. Also called cancer of the ovary.

ovulation Periodic ripening and discharge of the ovum from the ovary, usually 14 days before the onset of menstrual flow; the release of a mature ovum from the ovary at intervals (usually monthly).

oxytocin Hormone produced by the posterior pituitary that stimulates uterine contractions and the release of milk in the mammary gland (let-down reflex). Synthetic oxytocin (Pitocin) may be used to either induce or augment labor.

P

paced breathing techniques Various breathing methods used to control pain during labor. They include slow-paced, modified-paced, and pattern-paced breathing patterns.

palmar erythema Pinkish red, diffuse mottling or well-defined blotches seen over the palmar surfaces of the hands in about 60% of Caucasian women and 35% of African-American women during pregnancy; related primarily to increased estrogen levels.

parity The number of pregnancies in which the fetus or fetuses have reached 20 weeks of gestation.

participant observation Assessment method in which the nurse actively participates in the community to understand the community more fully and to validate observations.

patent ductus arteriosus (PDA) Condition that occurs when the fetal ductus arteriosus fails to close after birth. Also see ductus arteriosus.

pathologic grief See complicated grief.

pathologic jaundice Jaundice usually first noticeable within 24 hours after birth; caused by some abnormal condition such as an Rh or ABO incompatibility and resulting in bilirubin toxicity (e.g., kernicterus); unconjugated hyperbilirubinemia that is either pathologic in origin or severe enough to warrant further evaluation and treatment. Also called nonphysiologic jaundice.

pathologic mourning See complicated grief.

PCOS See polycystic ovary syndrome (PCOS).

PDA See patent ductus arteriosus (PDA).

pelvic Pertaining or relating to the pelvis.

pelvic exenteration A total exenteration involves removal of the perineum, the pelvic floor, the levator muscles, and all reproductive organs. Additionally, pelvic lymph nodes, rectum, sigmoid colon, urinary bladder, and distal ureters are removed, and a colostomy and ileal conduit are constructed.

pelvic inflammatory disease (PID) Infectious process that most commonly involves the uterine (fallopian) tubes (salpingitis), uterus (endometritis), and more rarely, the ovaries and peritoneal surfaces. Usually secondary to sexually transmitted infections.

pelvic relaxation Refers to the lengthening and weakening of the fascial supports of pelvic structures. Congenital or acquired weakness of the pelvic support structures.

percutaneous umbilical blood sampling (PUBS) Procedure during which a fetal umbilical vessel is accessed for blood sampling or for transfusions. Also called cordocentesis.

perimenopause Period of transition of changing ovarian activity before menopause and through first few years of amenorrhea; precedes menopause and lasts about 4 years. During this time ovarian function declines. Ova slowly diminish, and menstrual cycles may be anovulatory, resulting in irregular bleeding. The ovary stops producing estrogen and eventually menses no longer occur.

perinatal bereavement the complex emotional responses experienced by women and men beginning immediately after the death of an expected child through miscarriage, stillbirth, neonatal death, or termination of pregnancy for fetal anomalies.

perinatal loss Loss associated with childbearing; death of a fetus or infant through the twenty-eighth day after birth.

perinatal mood disorders Set of disorders that can occur any time during pregnancy as well as in the first year postpartum and can include depression, anxiety, obsessive-compulsive disorder, posttraumatic stress disorder, and postpartum psychosis.

perinatal mortality rate Combined fetal and neonatal mortality. See also death, perinatal.

perinatal palliative care A formalized end-of-life (EOL) interdisciplinary care model specifically aimed at intervening when pregnancy is expected to end in stillbirth or neonatal death.

perineum A skin-covered muscular area that covers the pelvic structures. The perineum forms the base of the perineal body, a wedge-shaped mass that serves as an anchor for the muscles, fascia, and ligaments of the pelvis. Area between the vagina and rectum in the female and between the scrotum and rectum in the male.

periodic abstinence Contraceptive method in which a woman abstains from sexual intercourse during the fertile period of her menstrual cycle; also referred to as natural family planning (NFP) because no other form of birth control is used during this period.

periodic changes Changes from baseline of the fetal heart rate that occur with uterine contractions.

persistent pulmonary hypertension of the newborn (PPHN) Combined findings of pulmonary hypertension, right-to-left shunting, and a structurally normal heart.

phenotype An individual's observable traits. Refers to the observable expression of an individual's genotype, such as physical features, a biochemical or molecular trait, and even a psychologic trait. Expression of certain physical or chemical characteristics in an individual resulting from interaction between genotype and environmental factors.

phenylketonuria (PKU) Inborn error of metabolism caused by a deficiency in the enzyme phenylalanine hydrolase. Absence of this enzyme impairs the body's ability to metabolize the amino acid phenylalanine found in all protein foods. Consequently, toxic accumulation of phenylalanine in the blood occurs, which interferes with brain development and function.

phototherapy Using lights to reduce serum bilirubin levels by oxidating bilirubin into water-soluble compounds that are then processed in the liver and excreted into bile and urine.

physiologic anemia A modest decrease in the hemoglobin concentration and hematocrit in pregnancy, caused by the relative excess of plasma.

physiologic jaundice Yellow tinge to skin and mucous membranes in response to increased serum levels of unconjugated bilirubin; not usually apparent until after 24 hours; also called neonatal jaundice, physiologic hyperbilirubinemia, or nonpathologic unconjugated hyperbilirubinemia.

phytoestrogens Plant compounds that have a weak estrogenic effect in the human body; used in managing menopause as an alternative or complement to conventional hormone replacement therapy. Also known as isoflavones.

pica Unusual craving during pregnancy; the practice of consuming nonfood substances (e.g., clay, soil, and laundry starch) or excessive amounts of foodstuffs low in nutritional value (e.g., ice or freezer frost, baking powder or soda, and cornstarch), is often influenced by the woman's cultural background.

PID See pelvic inflammatory disease (PID).

placenta Latin, "flat cake"; afterbirth, specialized vascular disk-shaped organ for maternal-fetal gas and nutrient exchange. Normally it implants in the thick muscular wall of the upper uterine segment.

placenta accreta Unusual placental adherence; accreta is a slight penetration of the myometrium.

placenta increta Unusual placental adherence; increta is deep penetration of the myometrium.

placenta percreta unusual placental adherence; percreta is perforation of the myometrium.

placenta previa Placenta is implanted in the lower uterine segment such that it completely or partially covers the cervix or is close enough to the cervix to cause bleeding when the cervix dilates or the lower uterine segment effaces. Placenta previa can be further classified as complete, marginal, or low-lying.

placental abruption See abruptio placentae.

plugged milk ducts Milk ducts blocked by small curds of dried milk.

PMDD See premenstrual dysphoric disorder (PMDD).

PMS See premenstrual syndrome (PMS).

polycystic ovary syndrome (PCOS) Occurs when an endocrine imbalance results in high levels of estrogen, testosterone, and luteinizing hormone (LH) and decreased secretion of follicle-stimulating hormone.

polyhydramnios Increased amount of amniotic fluid; usually objectively defined as pockets of amniotic fluid measuring more than 8 cm.

polyp Small tumor-like growth that projects from a mucous membrane surface.

polyploidy One of the two types of deviations from the correct number of chromosomes per cell, in which the deviation is an exact multiple of the haploid number of chromosomes or one chromosome set (23 chromosomes).

position Relationship of a reference point on the presenting part of the fetus to the front, back, or sides of the mother's pelvis.

positional plagiocephaly Asymmetry of an infant's skull; abnormally flattened shape and appearance, usually in the occipital region (the back of the head) as a result of lying consistently on the back.

positive signs of pregnancy Those signs attributed only to the presence of the fetus (e.g., hearing fetal heart tones, visualizing the fetus with ultrasound, palpating fetal movements).

postmenopause The time after menopause.

postpartum Happening or occurring after birth (mother).

postpartum blues A let-down feeling, accompanied by irritability and anxiety, which usually begins 2 to 3 days after giving birth and disappears within a week or two. Sometimes called the baby blues.

postpartum depression (PPD) Major depressive episode with an onset in pregnancy or within 4 weeks of childbirth. (See major depressive episode.)

postpartum hemorrhage (PPH) Excessive bleeding after childbirth; traditionally defined as a loss of 500 ml or more after a vaginal birth and 1000 ml after a cesarean birth.

postpartum infection Any clinical infection of the genital canal that occurs within 28 days after miscarriage, induced abortion, or childbirth; in the United States, the presence of a fever of 38°C or more on 2 successive days of the first 10 postpartum days (not counting the first 24 hours after birth). Also called puerperal infection.

postpartum psychosis Postpartum depression with psychotic features, including auditory or visual hallucinations, paranoid or grandiose delusions, elements of delirium or disorientation, and extreme deficits in judgment accompanied by high levels of impulsivity that can contribute to increased risks of suicide or infanticide.

postterm pregnancy Pregnancy that extends past 42 completed weeks of gestation (294 days or more from the first day of the last menstrual period). Sometimes also referred to as a postdates or prolonged pregnancy.

PPH See postpartum hemorrhage (PPH).

PPHN See persistent pulmonary hypertension of the newborn (PPHN).

precipitous labor Labor that lasts less than 3 hours from the onset of contractions to the time of birth.

preconception care Care designed for health maintenance before pregnancy. Suggested components of preconception care are health promotion, risk assessment, and interventions.

predictive testing Genetic testing used to clarify the genetic status of asymptomatic family members.

pre-dispositional testing Testing for a gene mutation that indicates susceptibility for developing a condition; a positive result does not indicate a 100% risk of developing the condition.

preeclampsia Pregnancy-specific condition in which hypertension and proteinuria develop after 20 weeks of gestation in a woman who previously had neither condition. In the absence of proteinuria preeclampsia may be defined as hypertension along with either thrombocytopenia, impaired liver function, the new development of renal insufficiency, pulmonary edema, or new-onset cerebral or visual disturbances.

pregestational diabetes Type 1 or type 2 diabetes that existed before pregnancy.

premature rupture of membranes (PROM) Spontaneous rupture of the amniotic sac and leakage of amniotic fluid beginning before the onset of labor at any gestational age.

premenstrual dysphoric disorder (PMDD) A more severe variant of premenstrual syndrome (PMS) in which 3% to 8% of women have marked irritability, dysphoria, mood lability, anxiety, fatigue, appetite changes, and a sense of feeling overwhelmed. The most common symptoms are those associated with mood disturbances.

premenstrual syndrome (PMS) Complex, poorly understood condition that includes one or more of a large number (more than 100) of physical and psychologic symptoms beginning in the luteal phase of the menstrual cycle, occurring to such a degree that lifestyle or work is affected, and followed by a symptom-free period.

presentation The part of the fetus that enters the pelvic inlet first and leads through the birth canal during labor. The three main presentations are cephalic presentation, breech presentation, and shoulder presentation.

presenting part That part of the fetus that lies closest to the internal os of the cervix.

presumptive signs of pregnancy Those changes felt by the woman (e.g., amenorrhea, fatigue, breast changes)

presymptomatic testing Mutation analysis for a disorder in which symptoms are certain to appear if the individual lives long enough.

preterm birth Birth that occurs between 20 0/7 and 36 6/7 weeks of gestation. Preterm births are categorized as very preterm (<32 weeks of gestation), moderately preterm (32 to 34 weeks of gestation), and late preterm (34 to 36 weeks of gestation).

preterm labor Regular contractions along with a change in cervical effacement or dilation or both, or presentation with regular uterine contractions and cervical dilation of at least 2 cm before 37 0/7 weeks of gestation.

preterm premature rupture of membranes (preterm PROM) Premature rupture of membranes that occurs before 37 0/7 weeks of gestation.

primigravida A woman who is pregnant for the first time.

primipara A woman who has completed one pregnancy with a fetus or fetuses who have reached at least 20 weeks of gestation.

primary dysmenorrhea Painful menstruation beginning 2 to 6 months after menarche, related to ovulation. Condition associated with abnormally increased uterine activity, due to myometrial contractions induced by prostaglandins in the second half of the menstrual cycle.

probable signs of pregnancy Those changes observed by an examiner (e.g., Hegar sign, ballottement, pregnancy tests)

prolapse of the umbilical cord Umbilical cord lies below the presenting part of the fetus; may be frank (visible) or occult (hidden, rather than visible).

prolonged deceleration (of the fetal heart rate) Visually apparent decrease (may be either gradual or abrupt) in fetal heart rate (FHR) of at least 15 beats/minute below the baseline and lasting more than 2 minutes but less than 10 minutes.

prolonged grief See complicated grief.

PROM See premature rupture of membranes (PROM).

pruritic urticarial papules and plaques of pregnancy (PUPPP) The most common specific dermatosis in pregnancy. Lesions usually appear first on the abdomen but can spread to the arms, thighs, back, and buttocks. PUPPP classically appears in primigravidas during the third trimester. It almost always causes severe itching but is not associated with poor maternal or fetal outcomes.

pruritus Itching.

pruritus gravidarum itching that occurs during pregnancy; usually occurs over the abdomen.

ptyalism Excessive salivation.

puberty Period in life in which the reproductive organs mature and one becomes functionally capable of reproduction; the entire transitional stage between childhood and sexual maturity.

puddendal nerve block Injection of a local anesthetic at the pudendal nerve root to produce numbness of the genital and perianal region.

puerperium The interval between the birth of the newborn and the return of the reproductive organs to their normal nonpregnant state; also called the fourth trimester of pregnancy or the postpartum period. Period after the third stage of labor and lasting until involution of the uterus takes place, usually about 3 to 6 weeks.

pyrosis A burning sensation in the epigastric and sternal region from stomach acid. Also called heartburn or acid indigestion.

Q

quickenings Maternal perception of fetal movement ("feeling life"); usually occurs between weeks 16 and 20 of gestation but may be felt earlier by multiparous woman.

R

radical hysterectomy Involves removal of the uterus, the tubes, the ovaries, the upper third of the vagina, the entire uterosacral and uterovesical ligaments, and all of the parametrium on each side, along with pelvic node dissection encompassing the four major pelvic lymph node chains: ureteral, obturator, hypogastric, and iliac.

rape Legal term that is defined differently by each state. Usually refers to forced sexual intercourse or penetration of the mouth, anus, or vagina by a body part or object without consent; it may or may not include the use of a weapon.

RDS See respiratory distress syndrome (RDS).

recessive trait A trait or disorder expressed or phenotypically, apparent only when two copies of the alleles associated with the trait are present. Genetically determined characteristic that is expressed only when present in the homozygotic state.

reciprocity Type of body movement or behavior that provides the observer with cues, such as the behavioral cues infants provide to parents and parents' responses to cues.

rectocele Herniation or protrusion of the anterior rectal wall through the relaxed or ruptured vaginal fascia and rectovaginal septum; it appears as a large bulge that may be seen through the relaxed introitus.

recurrence risk Estimated risk of a couple having a child with a specific genetic disease once they have produced one or more children with the same genetic disease.

regional analgesia Partial pain relief and motor block produced by a variety of local anesthetic agents.

regional anesthesia Complete pain relief and motor block produced by a variety of local anesthetic agents.

reproductive tract infection Encompasses both sexually transmitted infections and other common genital tract infections.

respiratory distress syndrome (RDS) Condition resulting from decreased pulmonary gas exchange, leading to retention of carbon dioxide (increase in arterial PCO₂). Most common neonatal causes are prematurity, perinatal asphyxia, and maternal diabetes mellitus; hyaline membrane disease (HMD).

retinopathy of prematurity (ROP) Associated with hyperoxemia, resulting in eye injury and blindness in premature infants.

Rh immune globulin a solution of gamma globulin that contains Rh antibodies; administered to prevent sensitization in an Rh negative woman who has had a fetomaternal transfusion of Rh positive fetal red blood cells.

ribonucleic acid (RNA) Element responsible for transferring genetic information within a cell; a template, or pattern.

rooting reflex Normal response of the newborn to move toward whatever touches the area around the mouth and to attempt to suck. This reflex usually disappears by 3 to 4 months of age.

ROP See retinopathy of prematurity (ROP).

S

second stage of labor Begins with full cervical dilation (10 cm) and complete effacement (100%) and ends with the baby's birth. It is composed of two phases: the latent ("laboring down") phase and the active pushing (descent) phase.

secondary dysmenorrhea Acquired menstrual pain that develops later in life than primary dysmenorrhea, typically after age 25 years. This condition is associated with pelvic pathology, such as adenomyosis, endometriosis, pelvic inflammatory disease, endometrial polyps, or submucous or interstitial myomas (fibroids).

segmental mastectomy Includes tylectomy, wide excision, and quadrantectomy or segmental mastectomy and involves removal of the tumor, which may be larger, along with a rim of healthy tissue around it, to ensure clear margins.

- selective reduction** A procedure done during multifetal pregnancies to reduce the number of developing embryos to a number (usually one to three) that can be safely carried to near term.
- semen analysis** Basic test for male infertility; examination of semen specimen to determine liquefaction, volume, pH, sperm density, and normal morphology. Complete semen analysis includes the study of the effects of cervical mucus on sperm forward motility and survival and evaluation of the sperm's ability to penetrate an ovum.
- sentinel event** An unexpected occurrence involving death or serious physical or psychologic injury or the risk thereof. Serious injury specifically includes loss of limb or function.
- sepsis** Bacterial infections of the bloodstream.
- septic shock** Caused by the toxins released into the bloodstream in septicemia. The most common sign is a decrease in blood pressure, a vital sign often not assessed in the care of the neonate. The infant often appears gray or mottled and can be noted to have cool extremities. Other signs are rapid, irregular respirations and pulse (similar to septicemia in general).
- septicemia** Generalized infection in the bloodstream.
- sex chromosome** Chromosome associated with determination of gender: the X (female) and Y (male) chromosomes. The normal female has two X chromosomes, and the normal male has one X and one Y chromosome.
- sexual assault** Intentional unwanted completed or attempted touching of the victim's genitals, anus, groin, or breasts, directly or through clothing as well as by voyeurism.
- sexual response cycle** The phases of physical changes that occur in response to sexual stimulation and sexual tension release. Divided into four phases: excitement phase, plateau phase, orgasmic phase, and resolution phase. The four phases occur progressively, with no sharp dividing line between any two phases. Specific body changes take place in sequence. The time, intensity, and duration for cyclic completion also vary for individuals and situations.
- sexual violence** Broad term that encompasses a wide range of sexual victimization including sexual harassment, sexual assault, and rape.
- sexually transmitted infections (STIs)** Infections transmitted as a result of sexual activity with an infected individual; also called sexually transmitted diseases (STDs). Include more than 25 organisms that cause infections or infectious disease syndromes primarily transmitted by intimate contact.
- SGA** See small for gestational age (SGA).
- shoulder dystocia** Condition in which the head is born but the anterior shoulder cannot pass under the pubic arch to complete the birth of the entire fetus.
- sibling rivalry** Jealousy and other negative behaviors exhibited by siblings in response to the addition of a new baby in the family.
- SIL** See squamous intraepithelial lesion (SIL).
- single-parent family** Family form characterized by one parent (male or female) in the household. This may result from loss of spouse by death, divorce, separation, desertion, or birth of a child to a single woman.
- sleep-wake states** Variations in the state of consciousness of infants.
- small for gestational age (SGA)** Inadequate growth for gestational age; an infant whose rate of intrauterine growth was restricted and whose birth weight falls below the 10th percentile on intrauterine growth curves
- somatic cell** Cell of the body of an individual that becomes differentiated and composes the tissues, organs, and parts of that individual. Diploid cell; not a gamete.
- souffle** Soft, blowing sound or murmur heard by auscultation.
- spermatogenesis** Process by which mature spermatozoa are formed, during which the diploid chromosome number (46) is reduced by half (haploid, 23).
- spina bifida** The most common defect of the central nervous system (CNS); results from failure of the neural tube to close at some point.
- spinal anesthesia (block)** Regional anesthesia induced by injection of a local anesthetic medication alone or in combination with an opioid agonist analgesic into the subarachnoid space at the level of the third, fourth, or fifth lumbar interspace.
- spiral electrode** A small electrode attached to the presenting fetal part (usually the head) to assess the fetal heart rate using the internal mode of monitoring.
- spontaneous abortion** Pregnancy that ends as a result of natural causes before 20 weeks of gestation. A fetal weight less than 500 g also may be used to define an abortion. Miscarriage is the lay term for a spontaneous abortion.
- spontaneous rupture of membranes (SROM)** Rupture of membranes by natural means.
- squamocolumnar junction** Site in the endocervical canal where columnar epithelium and squamous epithelium meet, usually located just inside the cervical os; also called the transformation zone, the most common site for neoplastic changes; cells from this site are scraped for the Pap test.
- squamous intraepithelial lesion (SIL)** Term used to describe neoplastic changes of the cervix in abnormal cervical cytology reports.
- standard of care** Level of practice that a reasonable, prudent nurse would provide.
- station** Relationship of the presenting fetal part to an imaginary line drawn between the ischial spines of the pelvis. It is a measure of the degree of descent of the presenting part of the fetus through the birth canal.
- sterilization** Surgical procedure intended to render a person infertile or unable to produce children.
- stillbirth** The birth of a baby after 20 weeks of gestation and 1 day or weighing 350 g (depending on the state code) that does not show any signs of life.
- strawberry hemangioma** See nevus vascularis.
- striae gravidarum** Shining, slightly depressed reddish lines caused by stretching of the skin, often found on the abdomen, thighs, and breasts during pregnancy. These streaks turn to a fine pinkish white or silver tone in time in fair-skinned women and brownish in darker-skinned women. Also called stretch marks.
- subconjunctival hemorrhage** Injuries resulting from rupture of subconjunctival capillaries, caused by increased intracranial pressure (ICP) during birth.
- subculture** Group existing within a larger cultural system that retains its own characteristics.
- subgaleal hemorrhage** Bleeding into the subgaleal compartment, which is a potential space that contains loosely arranged connective tissue, located beneath the galea aponeurosis, the tendinous sheath that connects the frontal and occipital muscles and forms the inner surface of the scalp.
- subinvolution** Failure of a part (e.g., the uterus) to reduce to its normal size and condition after enlargement from functional activity (e.g., pregnancy).
- substance abuse** The continued use of substances despite related problems in physical, social, or interpersonal areas. Any use of alcohol or illicit drugs during pregnancy is considered abuse.
- supine hypotension** Fall in blood pressure caused by impaired venous return when gravid uterus presses on ascending vena cava, when woman is lying flat on her back; vena cava syndrome.
- supply-meets-demand** Physiologic basis for determining milk production. The volume of milk produced equals the amount of milk removed from the breast.
- surfactant** Phosphoprotein necessary for normal respiratory function that prevents the alveolar collapse (atelectasis). See also lecithin and L/S ratio.
- surgical menopause** Occurs with hysterectomy and bilateral oophorectomy.
- synchony** Fit between an infant's cues and the parent's response.

T

- tachycardia** Baseline fetal heart rate greater than 160 beats/minute for 10 minutes or longer.
- tandem nursing** The practice of breastfeeding a newborn and an older child.
- telephonic nursing** Services such as warm lines, nurse advice lines, and telephonic nursing assessments using telephones, the Internet, and Skype.
- teratogens** Nongenetic factors that cause malformations and disorders in utero.
- term** Birth after 37 weeks gestation; early term—37 0/7 through 38 6/7 weeks; full term—39 0/7 through 40 6/7 weeks; late term—41 0/7 through 41 6/7 weeks; postterm (postmature)—after 42 weeks.
- terminal deletion** Deletion at the end of a chromosome.
- tetraploid** Cell that has four times the normal number of chromosomes (4N); example of a polyploidy.
- theca-lutein cysts** Develop as a result of prolonged stimulation of the ovaries by human chorionic gonadotropin (hCG).
- therapeutic abortion** Pregnancy that has been intentionally terminated for medical reasons.
- thermogenesis** Creation or production of heat, especially in the body.
- thermoregulation** Control of temperature.
- third stage of labor** Stage of labor from the birth of the baby to the expulsion of the placenta.
- thrombophlebitis** Inflammation of a vein with secondary clot formation.
- thrush** Fungal infection of the mouth or throat that is characterized by the formation of white patches on a red, moist, inflamed mucous membrane and is caused by *Candida albicans*. Also called mycotic stomatitis.

tocolytics Medications given to arrest labor after uterine contractions and cervical change have occurred. Also used to treat uterine tachysystole.

tocotransducer Electronic device for measuring uterine contractions using the external mode of monitoring. Also called a tocodynamometer.

TORCH infections Collective name for *toxoplasmosis*, other infections (e.g., hepatitis), rubella virus, cytomegalovirus (CMV), and herpes simplex virus, a group of organisms capable of crossing the placenta; these infections can affect a pregnant woman and her fetus.

tracheoesophageal fistula An abnormal connection between the esophagus and the trachea; often occurs with esophageal atresia.

transformation zone See squamocolumnar junction.

transition phase of labor Phase in first stage of labor from 8 to 10 cm in dilation.

transition to parenthood Period of time from the preconception decision to conceive through the first months of having a child, during which parents define their parental roles and adjust to parenthood.

translocation Condition in which a chromosome breaks and there is an exchange of chromosomal material between two chromosomes; all or part of the broken chromosome is transferred to a different part of the same chromosome or to another chromosome.

trial of labor (TOL) Period of observation to determine if a laboring woman is likely to be successful in progressing to a vaginal birth.

trimester One of three periods of about 13 weeks each into which pregnancy is divided.

triploid Cell that has three times the normal number of chromosomes (3N); example of a polyploidy.

trisomy Product of the union of a normal gamete with a gamete containing an extra chromosome. Condition whereby any given chromosome exists in triplicate instead of the normal duplicate pattern.

trophoblast Outer layer of cells of the developing blastodermic vesicle (blastocyst) that develops the trophoderm or feeding layer, which will establish the nutrient relationships with the uterine endometrium.

tubercles of Montgomery See Montgomery glands.

twins Two neonates from the same impregnation developed within the same uterus at the same time.

U

UAE See uterine artery embolization (UAE).

UI See urinary incontinence (UI).

ultrasound transducer External signal source for monitoring fetal heart rate electronically.

unbalanced translocation Translocation in which part of a chromosome is transferred to a different chromosome; there is extra chromosomal material—extra of one chromosome but correct amount or deficient amount of other chromosome. The individual will be both genotypically and phenotypically abnormal.

unifactorial inheritance Inheritance of phenotypic characteristics controlled by a single gene. See also multifactorial inheritance.

urinary incontinence (UI) Disturbance in urinary control.

uterine Referring or pertaining to the uterus.

uterine artery embolization (UAE) Treatment during which polyvinyl alcohol (PVA) pellets are injected into selected blood vessels to block the blood supply to the fibroid and cause shrinkage and resolution of symptoms.

uterine atony Relaxation of uterus; leads to postpartum hemorrhage. Failure of the uterine muscle to contract firmly.

uterine dehiscence Separation of a prior uterine scar. The potential for maternal or fetal complications as a result of uterine dehiscence is negligible because separation of a prior scar does not result in hemorrhage. Sometimes called incomplete uterine rupture.

uterine displacement Variation of the normal placement of the uterus, which is normally held in anteversion by the round ligaments, with the cervix pulled backward and upward by the uterosacral ligaments.

uterine polyps Tumors that are on pedicles (stalks) arising from the uterine mucosa; may be endometrial or cervical in origin.

uterine prolapse Falling, sinking, or sliding of the uterus from its normal location in the body. The degree of prolapse can vary from mild to complete. In complete prolapse the cervix and body of the uterus protrude through the vagina, and the vagina is inverted.

uterine resting tone Degree of tension in the uterine muscle between contractions; relaxation of the uterus between contractions.

uterine rupture Rare but life-threatening obstetric injury in which there is complete non-surgical disruption of all uterine layers. The major risk factor for uterine rupture is a scarred uterus as a result of previous cesarean birth or other uterine surgery.

uterine souffle A rushing or blowing sound of maternal blood flowing through uterine arteries; synchronous with the maternal pulse.

uterine tachysystole More than five contractions in 10 minutes, averaged over a 30-minute window, regardless of the presence of an abnormal fetal heart rate or pattern or the woman's perception of pain. The term tachysystole applies to both spontaneous and stimulated labor.

uteroplacental insufficiency (UPI) Decline in placental function—exchange of gases, nutrients, and wastes—leading to fetal hypoxia and acidosis; evidenced by late fetal heart rate decelerations in response to uterine contractions.

V

vacuum-assisted birth Birth involving attachment of vacuum cup to fetal head and using negative pressure to assist in birth of the fetus. Also called vacuum extraction.

vaginal birth after cesarean (VBAC) Giving birth vaginally after having had a previous cesarean birth.

Valsalva maneuver Any forced expiratory effort against a closed airway such as holding one's breath and tightening the abdominal muscles (e.g., pushing during the second stage of labor).

variability (of the fetal heart rate) Irregular waves or fluctuations in the baseline fetal heart rate (FHR) of two cycles per minute or greater. It is a characteristic of the baseline FHR and does not include accelerations or decelerations of the FHR. Four possible categories of variability have been identified: absent, minimal, moderate, and marked.

variable deceleration (of the fetal heart rate) Visually abrupt (onset to nadir [lowest point] less than 30 seconds) decrease in fetal heart rate (FHR) below the baseline. The decrease is at least 15 beats/minute or more below the baseline, lasts at least 15 seconds, and returns to baseline in less than 2 minutes from the time of onset. Variable decelerations are caused by compression of the umbilical cord.

vasa previa Occurs when fetal vessels lie over the cervical os and are implanted into the fetal membranes rather than into the placenta. There are two variations of vasa previa: velamentous insertion of the cord and succenturiate placenta.

vernix caseosa Protective gray-white fatty substance of cheesy consistency covering the fetal skin.

very low birth weight an infant whose birth weight is less than 1500 g (3.3 lb)

vestibular schwannoma Tumor on the eighth cranial nerves, the hearing and balance nerves.

viability the capacity to live outside the uterus; infants born at 22 to 25 weeks of gestation are considered to be on the threshold of viability.

vibroacoustic stimulation One of the methods of testing antepartum fetal heart rate response. Generally performed in conjunction with the nonstress test. Uses a combination of sound and vibration to stimulate the fetus. Also called the fetal acoustic stimulation test (FAST).

von Willebrand disease (vWD) A type of hemophilia; probably the most common of all hereditary bleeding disorders.

VSE See vulvar self-examination (VSE).

vulvar self-examination (VSE) Systematic examination of the vulva by the woman.

vulvectomy Surgical removal of all or parts of the vulva.

vulvodynia Complex condition thought to be a chronic pain disorder of the vulvar area; this term is used if pain is present with no visible abnormality or no identified neurologic diagnosis.

vWD See von Willebrand disease (vWD).

W

walking survey Using one's senses while traveling through a community to obtain information about sociocultural characteristics and the environment, housing, transportation, and local community agencies.

warm lines Telephone lines that are offered as a community service to provide new parents with support, encouragement, and basic parenting education.

X

X-linked dominant inheritance Mode of genetic inheritance by which a dominant gene is carried on the X chromosome.

X-linked recessive inheritance disorder Disorder for which the abnormal genes are carried on the X chromosome.

Z

zygote Cell formed by the union of two reproductive cells or gametes; the fertilized ovum resulting from the union of a sperm and an ovum (egg).
