Central endotracheal intubation is used in most cases with the exception of older children where single lung anesthesia is possible. The patient is placed in the lateral position, with the affected side uppermost. The optical port is generally inserted just anterior to the angle of the scapula in the mid-axillary line. Two or three additional ports are inserted under thoracoscopic vision for the best possible manipulation. The lung is collapsed and retracted with creation of a pneumothorax with minimal pressures (5–7 mmHg of CO_2, flow rates of 1.5–2 L/min) to expose the posterior mediastinal cyst.

The pleura at the base of the cyst is incised either with scissors or diathermy hook. Two types of duplications are encountered, requiring slightly different techniques during their resection. The commonly encountered duplication has a separate muscle wall and is attached to the native esophagus by connective tissue adhesions. The dissection can be completed using either diathermy scissiors, harmonic scalpel, or LigaSure™ (ValleyLab, Boulder, CO, USA). The vagus, phrenic nerve, and thoracic duct are at risk of injury during the resection of the thoracic inlet duplication. Esophageal duplications sharing a common muscle wall with the native esophagus are relatively rare and a technical challenge to resect thoracoscopically. A nasogastric tube or an endoscope placed *in situ* during resection can help avoid resection of a major portion of wall and mucosa of the native esophagus. The cyst should be completely excised with the esophageal mucosa left intact if possible. Marsupialization should be avoided as leaving residual cyst wall tends to result in recurrence.[8] Once the cyst is removed, the defect in the esophageal musculature and mucosa can be sutured with absorbable sutures. The specimen is decompressed by aspiration and delivered by expanding one of the anterior ports.

In the presence of a thoraco-abdominal duplication cyst, complete resection is achieved by an additional laparoscopic approach. A separate intra-abdominal cyst can be successfully resected either at the same time or at a subsequent laparoscopic resection.[5]

Most esophageal duplications following resection do not require postoperative chest drains. We recommend a chest drain only if the esophageal mucosa is breached during the resection.[16] Postoperative pain is managed by i.v. paracetamol and oral anti-inflammatory drugs. The majority of thoracoscopically resected cases can be discharged the following day.

Thoracotomy and resection

A lateral thoracotomy through the bed of the fifth rib is recommended for an open resection. Adhesions, either

(d) Duplication cyst specimen following thoracoscopic excision.

inflammatory or as a result of a previous operation, are the cause of complications in open operations. Bleeding and air leaks, either from the lung parenchyma or from fistulation, should be managed intraoperatively in order to avoid postoperative complications. The above-mentioned nerves and thoracic duct are also at risk of injury as bleeding or adhesions may obscure their presence near the duplication.

Cervical and suprasternal cysts

Cervical excision can be achieved by placing the patient supine with a roll under the shoulders. Once the cyst wall is identified, the dissection is continued staying close to its surface. The recurrent laryngeal nerve is particularly at risk of injury as it can travel on the surface of the esophageal duplication.

SURGICAL COMPLICATIONS

Surgical complications are related to the site and mode of surgery. Incomplete excision is associated with recurrence and the need for further surgery.[8] Esophageal leak is a possibility with both the open and thoracoscopic approach. A minor leak can be managed conservatively with a period of

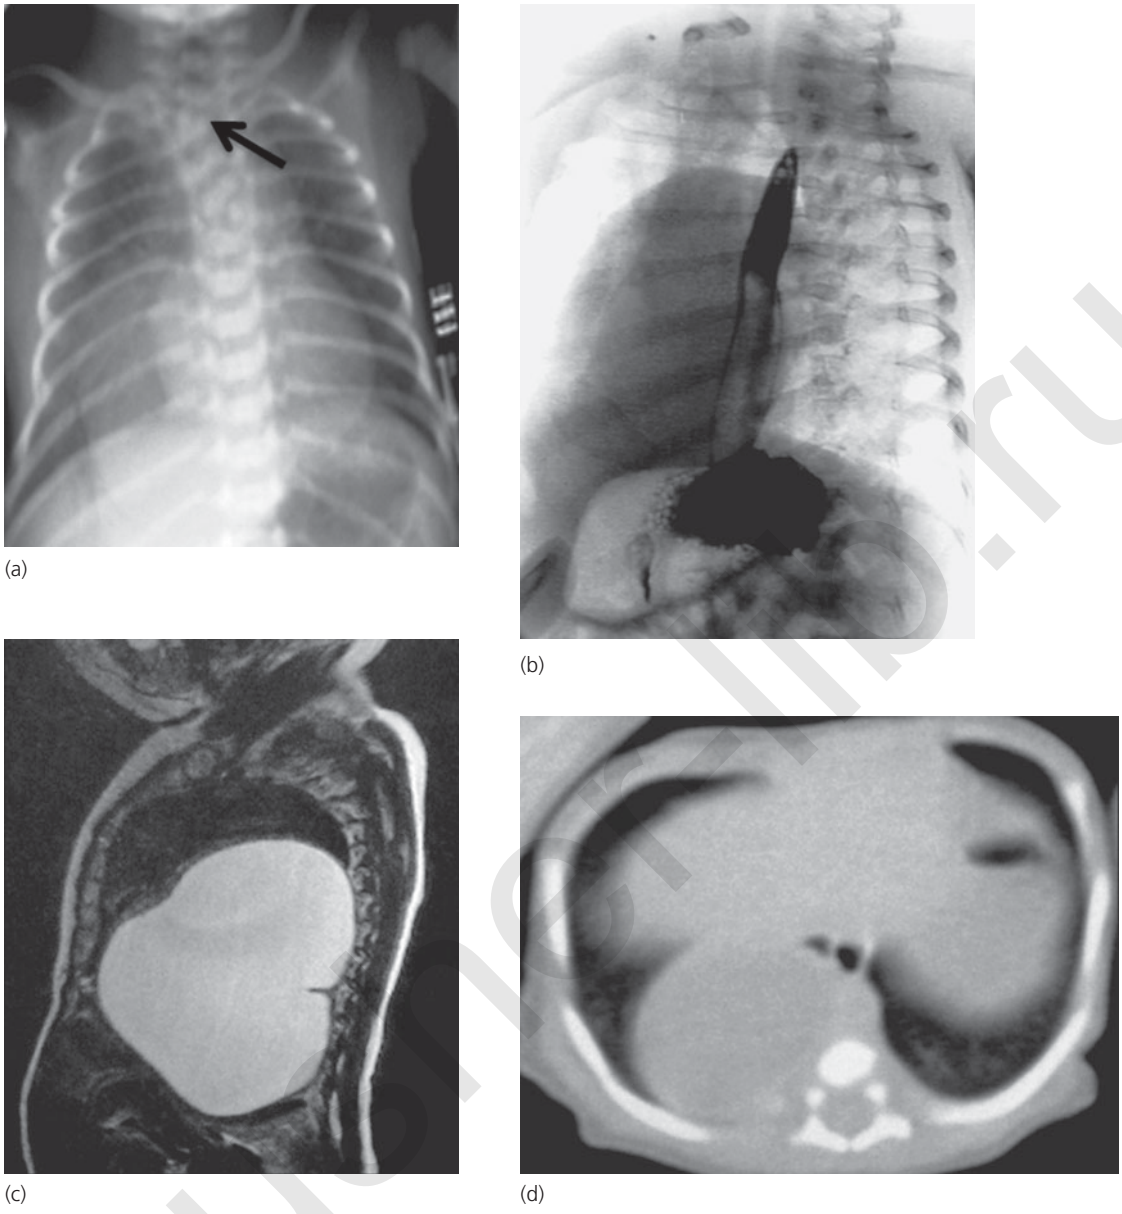

Figure 41.5 (a) Chest x-ray showing vertebral anomalies in an antenatally detected foregut duplication cyst. (b) Contrast study demonstrating a large posterior mediastinal duplication cyst. (c) Magnetic resonance imaging was done to rule out neuroenteric component in the presence of vertebral anomalies. (d) Computed tomography confirmed a smooth low attenuation posterior mediastinal duplication cyst.

nil by mouth with parenteral nutrition, antibiotics, and chest drainage. However, major leaks may require thoracotomy, esophageal repair, and chest drainage.[7,13] This group of patients are at risk of esophageal stricture long term, that may respond to dilation. Esophageal pseudodiverticulum is a long-term risk if the esophageal musculature is not approximated.[15] A persistent air leak will require thoracotomy and formal repair of the bronchus or trachea.[13] In a retrospective series, two postoperative deaths have been reported secondary to septic complications – one from an esophageal leak and the other from cyst-related sepsis.[8]

Injury to the vagus, recurrent laryngeal nerve, and phrenic nerve in the cervical and the superior mediastinial duplication can be avoided by careful dissection and staying close to the cyst wall. Judicious use of the monopolar diathermy in dissecting close to the nerves is recommended. There is a higher risk of nerve or thoracic duct injury during surgery for an infected cyst because of adhesions and bleeding.

LONG-TERM OUTCOME

All esophageal duplications should be excised because of the potential for life-threatening complications: peptic ulceration and bleeding or perforation, acute airway obstruction, recurrent infection, mediastinitis, meningitis, and the long-term risk of cancer. Thoracoscopic excision in the asymptomatic patient has a lower complication rate than surgery for a cyst-related complication. Patients who are known to have

incomplete excision should be monitored for recurrence. The patients with vertebral anomalies should be monitored for scoliosis. Rarely, a motility disorder of the esophagus is noted in some cases after resection as a result of damage to the pharyngeal plexus. After resection of the cervical duplication, a pharyngeal pouch can be a long-term consequence.

Esophageal perforation in the newborn

DAVID S FOLEY AND HIRIKATI S NAGARAJ

INTRODUCTION

Iatrogenic esophageal perforation occurs rarely in neonates given the repeated orotracheal and oro-esophageal instrumentation of these patients, and was first reported in the literature by Eklof and colleagues.[1] In the past two decades, perforation of the esophagus in extremely premature neonates has become increasingly recognized and reported. Spontaneous perforation of the esophagus (neonatal Boerhaave syndrome) is extremely rare, and Fryfogle[2] performed the first successful repair. Despite the favorable results of non-operative management in cases of neonatal esophageal perforation, this condition may be fatal without early diagnosis and treatment, and aggressive surgical therapy is occasionally warranted.[3–5] Surgeons must continue to play a central role in the individualization of care in these patients.

CLASSIFICATION AND ETIOLOGY

Esophageal perforation in newborns can be classified as iatrogenic or non-iatrogenic. Non-iatrogenic perforations are extremely rare, and are usually seen in full-term infants when they occur. The most common site of perforation is the lower third of the esophagus. Etiological hypotheses for spontaneous perforation include increased intra-abdominal pressure at delivery, perinatal hypoxemia, and reflux-associated peptic esophagitis.[6]

Iatrogenic perforation of the esophagus is most commonly seen in premature, small for gestational age (SGA) infants,[7] and usually occurs in the cervical esophagus or hypopharynx. Pharyngeal suctioning with a stiff catheter, traumatic laryngoscopy, esophageal intubation, and digital manipulation of the neonatal head during breech delivery have all been described as causative.[8–11]

During instrumentation, when the neck is hyperextended, perforation of the esophagus may occur at the level of the cricopharyngeus muscle, where the posterior esophageal wall is compressed by the sixth or seventh cervical vertebra. Submucosal injury by a laryngoscope blade or endotracheal tube may be the initial injury to the hypopharynx, resulting in cricopharyngeal spasm.[12] Endotracheal intubation, especially in premature, SGA neonates, may further compromise the esophageal introitus. Subsequent oropharyngeal suctioning or insertion of a nasogastric tube may extend the submucosal injury into a full-thickness perforation.

Perforation of the middle esophagus is usually associated with dilatation of a stricture, or a postoperative anastamotic leak following esophageal atresia repair.[13,14] An improperly placed chest tube may cause disruption of a fresh esophageal anastamosis, or may penetrate a proximal myotomy site.[15] Direct pressure necrosis of an otherwise normal esophagus has been reported in a premature neonate.[16]

Distal esophageal perforation may be associated with dilatation of an esophageal stricture secondary to esophagitis, a technical error during antireflux surgery, or a misplaced gastrostomy balloon.[17]

DIAGNOSIS AND CLINICAL MANIFESTATIONS

Newborns with iatrogenic esophageal injury may demonstrate excessive salivation and mucoid secretions due to difficulty swallowing, and many will have overt respiratory distress. The examiner will have difficulty passing a nasogastric tube, either as the inciting event, or as a result of swelling or a false tract created by prior instrumentation. In neonates, an abnormal position of the nasogastric tube on post-placement chest x-ray is commonly the first indication of esophageal perforation.[7]

In premature infants, the presence of blood-tinged oral secretions after endotracheal intubation warrants serial x-ray examinations of the chest. The proper diagnosis often will be missed in the absence of such an examination. The symptoms of perforation may not be recognized until the child develops esophageal obstruction, and may be mistaken for esophageal atresia.[7,11] Esophageal perforation may be differentiated from atresia of the esophagus by an asymptomatic interval after birth, a premorbid history of repeated attempts at intubation or vigorous suctioning, absence of prenatal polyhydramnios,

and the position and course of the nasogastric tube on chest x-ray.[7] Some perforations of the esophagus create respiratory distress secondary to the development of hydropneumothorax. In these cases, the right pleural space is most commonly affected.[3,5,9,11] Thoracentesis or tube thoracostomy should yield serosanguinous fluid or the contents of the previous feeding. Chylopneumothorax has also been reported in association with neonatal esophageal perforation.[18]

Anteroposterior and lateral x-rays of the chest and neck should be obtained in any suspected case of perforation. The abnormalities seen in these cases depend on the site of injury. Hypopharyngeal and cervical perforations frequently demonstrate extraluminal air in the neck, without pneumomediastinum initially. Mid-esophageal perforations may demonstrate pneumomediastinum, pneumothorax, or hydrothorax. An unusual course of the nasogastric tube (right pleural cavity, pericardial cavity (Fig. 42.1) or right side of the mediastinum) supports the diagnosis, and may be confirmatory. Widening of the mediastinum and blurring of the mediastinal margin may occur secondary to the development of mediastinitis, but are later and more subtle findings. These changes should prompt esophagography. Mollit *et al.*[19] described three types of injuries that are seen in premature neonates: (1) a pharyngeal diverticulum created by a local cervical leak; (2) a mucosal perforation extending posteriorly in parallel to the esophagus; and (3) a free intrapleural perforation where there is obvious leakage of air and esophageal contents into the pleural cavity.

In cases where chest x-ray demonstrates the nasogastric tube to be located in the pleural cavity or pericardium, the diagnosis of esophageal perforation can be confirmed (Fig. 42.2). In this situation, precise localization of the site of perforation may be unnecessary, unless the patient's clinical condition deteriorates after removal of the nasogastric tube and tube thoracostomy drainage. If symptoms suggest esophageal obstruction, esophagography should be performed by administering a small quantity of diatrizoate meglumine (Hypaque™), diatrizoate sodium (Renografin) or metrizamide into the proximal esophagus; gastografin and barium should be avoided due to the risk of worsening mediastinitis or inducing significant pulmonary inflammation with aspiration. In cases of pharyngeal–esophageal perforation, cricopharyngeal spasm may be so severe that no contrast material will enter the native esophagus. In these cases, several clues may help to differentiate submucosal perforation or peudodiverticular formation from congenital esophageal atresia.[20] These include:

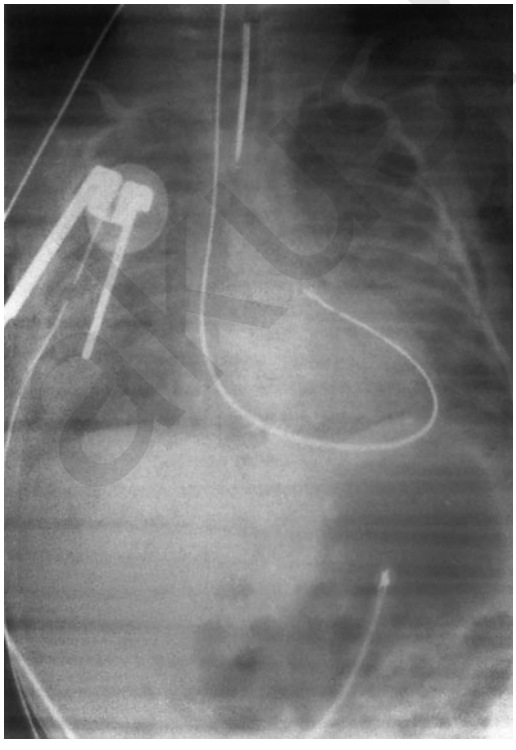

Figure 42.1 Chest x-ray shows displacement of the nasogastric tube to the pericardial sac.

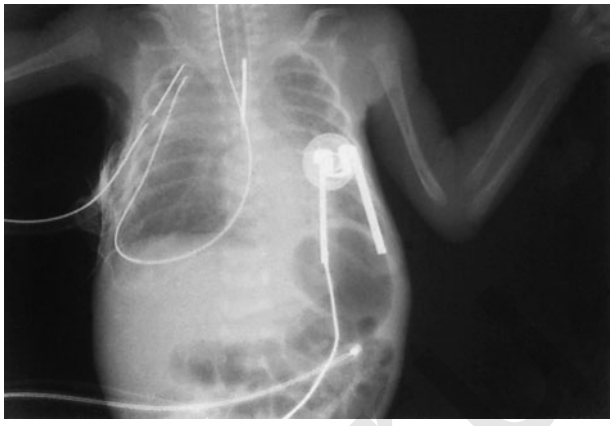

Figure 42.2 Anteroposterior view demonstrates coiled nasogastric tube in right pleural cavity and chest tube placed for tension pneumothorax.

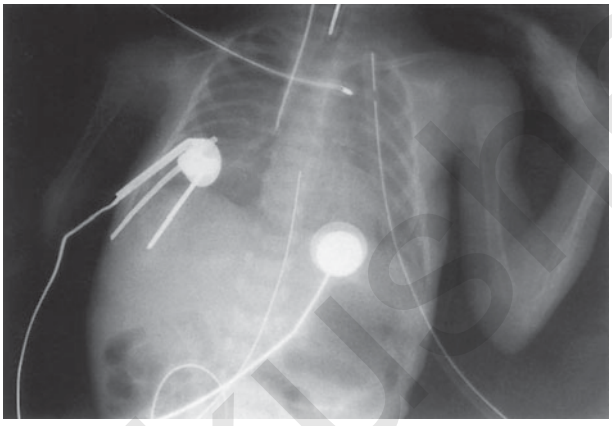
- the distance between the trachea and opacified tract on lateral x-ray is greater than that of the pouch in a congenital esophageal atresia, which is closely associated with the trachea;
- the opacified tract in perforation cases is longer, narrower, and more irregular than in esophageal atresia;
- the trachea is slightly compressed on lateral x-ray by the upper pouch in esophageal atresia, but this is not so in esophageal perforation.

Esophagoscopy is usually not indicated at the time of diagnosis, and may actually enlarge the perforation.

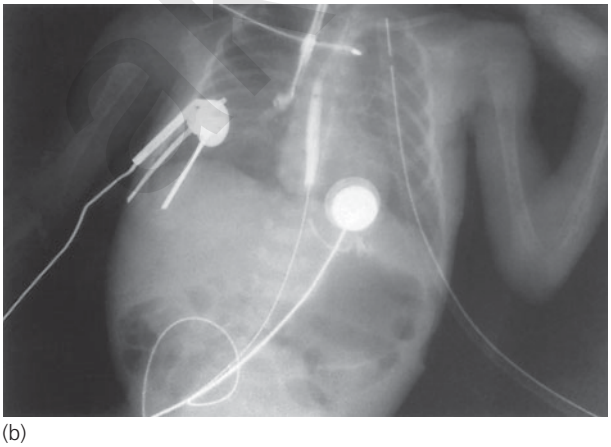
Spontaneous perforation of the neonatal esophagus usually presents with respiratory distress, which may be immediate or delayed for several hours after the event. There is a greater predilection for right-sided pneumothorax in neonatal Boerhaave syndrome, in contrast to the left-sided pneumothorax typically seen in adults.[6,16] This may be explained by the close adherence of the aorta to the left side of the esophagus in neonates, which provides an additional mediastinal barrier on the left side. If the perforation remains undiagnosed, respiratory distress will worsen with subsequent feedings. Esophagography must be performed in all suspected cases of free perforation, to evaluate the extent of the damage and to localize it.

MANAGEMENT

The management of neonatal esophageal perforations has favored a selective approach in recent years.[5,19,21,22] Esophageal perforation can be a rapidly fatal condition that requires immediate recognition and aggressive management for a successful outcome. However, the treatment of esophageal perforation must be individualized according to the site and size of injury, the systemic response of the neonate, and the time interval between the injury and initiation of treatment. Small submucosal perforations of the hypopharynx and esophagus, limited to the mediastinum and without systemic symptoms, may be managed by non-operative methods (Fig. 42.3). Actual localization of the peforation is not essential in these infants. If the nasogastric tube is noted in the mediastinum or pericardial cavity, the tube can be withdrawn and a new tube placed under fluoroscopic control. A broad-spectrum antibiotic must be given for 7–14 days. Intravenous fluids and hyperalimentation should be administered, as oral feedings must be withheld. Esophagography should be performed 7–10 days after the injury. If the perforation is completely healed, oral feeding may be resumed. If the perforation has not healed during this interval, conservative treatment for another week will usually allow complete healing.



(a)



(b)

Figure 42.3 Contrast study demonstrating contained, submucosal perforation of the proximal esophagus.

In general, routine surgical intervention does not appear to improve the rate of survival in these newborns. Tube thoracostomy should be placed when the chest x-ray indicates pneumomediastimun, pneumothorax, or hydrothorax (Fig. 42.4). All newborn infants with esophageal perforation must be carefully monitored during treatment, including the use of white blood cell counts or C-reactive protein levels, platelet counts, blood gas analyses, and chest x-ray evaluation. If there is clinical deterioration or respiratory compromise, and closed chest drainage does not handle the leak, direct repair of the perforation is indicated.

In cases where direct repair of the perforation is not technically feasible because of scarring, inflammation and tissue friability, diverting cervical esophagostomy with closure of the perforated area and concomitant gastrostomy is indicated. If at all possible, efforts should be made to avoid future esophageal replacement. Long, linear perforations to the lower end of the esophagus require an immediate thoracotomy, debridement of the necrotic edges and primary repair of the defect with pleural flap coverage. A gastrostomy tube may be inserted in these situations to minimize the risk of gastroesophageal reflux during healing.

If there is a delay of more than 24 hours in the diagnosis of a spontaneous perforation of the esophagus, unprotected primary repair cannot be safely accomplished. After adequate debridement, the treatment should be local esophagectomy with closure of the proximal and distal esophagus, proximal esophagostomy, and gastrostomy tube placement. Critically ill newborns should be managed with chest tube drainage, cervical esophagostomy (with or without ligation of the cardio-esophageal junction), and gastrostomy.[23] Broad-spectrum antibiotics, i.v. fluids, and hyperalimaentation should be continued until clinical signs of sepsis improve. Gastrostomy feedings may be attempted after 48 hours. In cases where extensive debridement or resection is necessary, esophageal substitution is indicated after an interval of at least six months, when the mediastinal inflammation has resolved.

Perforations that occur following dilation of esophageal anastamotic strictures are usually managed non-operatively, as long as the leak is contained or can be adequately drained by tube thoracostomy. These perforations may take some

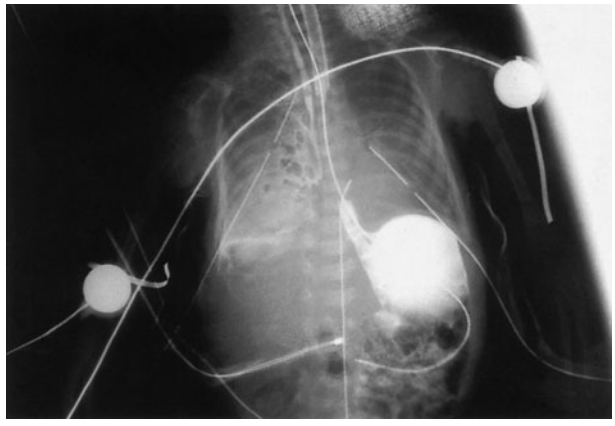


Figure 42.4 Free spillage of contrast material into right pleural cavity, indicating a free perforation in this infant. Clinical deterioration warranted direct repair.

time to heal due to obstruction at the stricture site. Recently, endoscopic stenting has been reported as a means of containing leakage and promoting healing in these cases.[24]

CONCLUSION

Iatrogenic perforation of the esophagus is more common than reported in the literature, and may be fatal without early diagnosis. The incidence of recognized pharyngeal and esophageal perforations is low, however, considering the large number of pharyngeal instrumentations that are performed on premature infants in modern neonatal intensive care units.[19] Gentle laryngoscopy with proper visualization of the vocal cords during intubation, avoidance of protruding stylets, careful suctioning of the pharynx, and avoidance of forceful nasogastric tube placement are all essential factors in the prevention of these injuries.

It is generally accepted that most iatrogenic perforations of the esophagus in newborns are cervical, and made when inexperienced personnel attempt to intubate the trachea. With early diagnosis, most of these perforations can be managed non-operatively with successful outcomes.[25] However, these infants should be monitored closely. If they develop systemic illness, appropriate operative intervention is often required. Early diagnosis of this condition allows for more treatment options, which include non-operative therapy, closed chest drainage, and primary repair. The mortality rate in neonates with esophageal perforation (4%) is significantly less than that in older children and adults (25–50%).[5,26] Delayed diagnosis may result in the inability to repair the injury primarily, a significant increase in mortality, and the eventual need for esophageal replacement among survivors. Surgical consultation is warranted in all cases of esophageal perforation to allow timely and selective management, thereby limiting both mortality and long-term morbidity.

Gastro-esophageal reflux in the neonate and small infant

MICHAEL E HÖLLWARTH

INTRODUCTION

Gastro-esophageal reflux (GER) is the term that describes the back flow of gastric content into the esophagus, sometimes reaching even the mouth. It is a common phenomenon and occurs in otherwise normal individuals several times during day and night, especially after ingestion of fluids, e.g. soup, tea, coffee, or milk. Therefore, reflux episodes are more common in neonates and infants as long as they are nourished mainly with milk. The typical reflux symptoms in this age group are regurgitation, spitting up and flaccid leak out of milk after meals and when asleep. Pathological reflux defines a situation when the reflux causes symptoms in the neonate, such as failure to thrive, sleep disturbance, and obviously pain. The aim of this chapter is to discuss the normal esophagus in newborns and its function, the typical symptoms of reflux in this age group, the investigating procedures, and the conservative and operative therapy.

ANATOMY

The esophagus is a muscular tubular organ responsible for the transport of food from the mouth to the stomach. The upper half is composed of striated muscles and its lower half consists of smooth muscle. The lumen is covered by a non-keratinizing, stratified squamous epithelium. At the esophageal–gastric junction the epithelial layer changes to a monolayer columnar epithelium, the so-called cardia epithelium.

The diaphragmatic hiatus of the esophagus is fixed by the phrenico-esophageal membrane, which is incompetent in the case of a hiatal hernia. The medial wall of the esophagus directly continues into the lesser curvature of the stomach while the lateral wall forms a kind of incisure – the so-called His angle. Within the lumen at the His angle is a mucosal fold (flutter valve), which is passively pressed against the lower esophageal sphincter (LES) when the gastric fundus is filled, thus preventing reflux (Fig. 43.1).[1] The flatter the angle of His, the less developed is the flutter valve, and the more readily a reflux occurs by anatomical reasons.

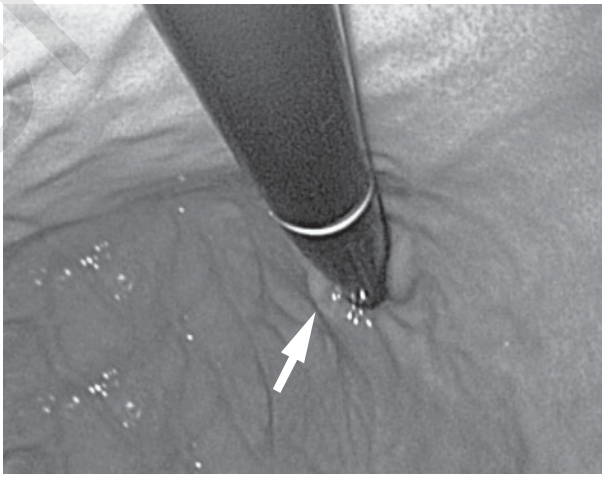

Figure 43.1 Typical mucosal 'flutter valve' at the site of the His angle within the stomach.

INNERVATION

The esophagus has a parasympathetic innervation through the vagus nerve which runs along the esophagus. Sympathetic innervation arises from post-ganglionic neurons of the sympathetic chain. The myenteric plexus and the submucosal plexus contain also non-adrenergic and non-cholinergic nerves, and execute the complex activity of the esophagus through a number of neurotransmitters. Most important is a central regulation by consecutively activated nuclei in the brainstem responsible for the peristalsis and relaxations of the esophageal sphincters.

THE SPHINCTERS

There are two sphincter systems at the upper and lower end of the esophagus. In adults, the tone in the upper esophageal sphincter (UES) is markedly higher (between 40 and 80 mmHg) than in the LES (between 15 and 25 mmHg). The UES relaxes during propulsion of food from the oral cavity, but also when refluxed volume reaches the upper esophagus from below; then, refluxed material can reach the hypopharynx and eventually the oral cavity.

Reflux of the contents of the stomach into the esophagus is prevented by the LES. The pressure ranges between 15 and 25 mmHg in adults. On manometry, the pressure zone permits easy identification of the exact position of the sphincter. The pressure transition of the LES lies exactly within the diaphragm. The upper half of the sphincter can be assigned to the chest cavity while the lower portion of the pressure zone is assigned to the abdominal cavity (Fig. 43.2).

PERISTALSIS

Once food enters the esophagus, it is transported by a propulsive peristaltic wave into the stomach (primary peristalsis). In any local distension of the esophagus, as in cases of reflux, a propulsive peristaltic wave arises locally and transports the contents of the esophagus back into the stomach (secondary peristalsis). Isolated and disorderly contractions are defined as tertiary peristalsis or pathological contractions.

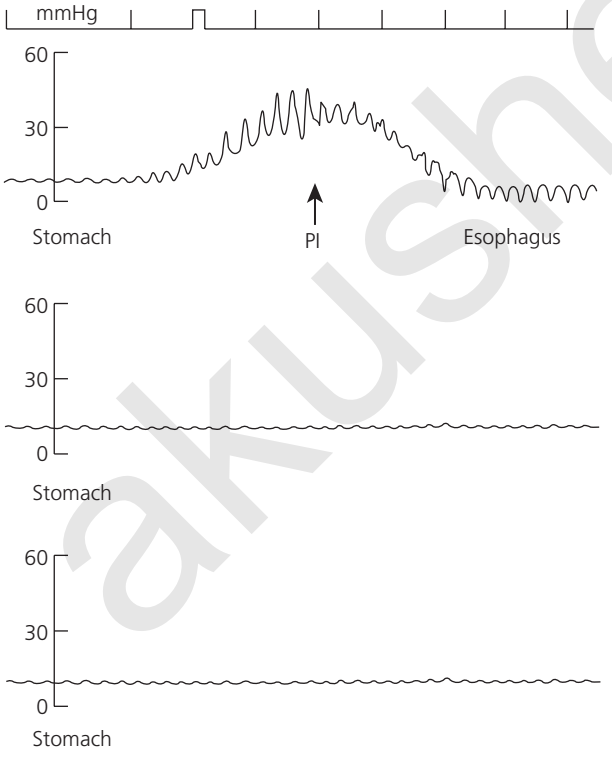

Figure 43.2 Slow pull-through manometry through the lower esophageal sphincter (LES) in a newborn child. PI indicates the pressure inversion from a typical stomach tracing to a typical esophageal tracing. Thus, the PI is located within the diaphragmatic hiatus and one part of the LES belongs to the abdomen and the other part to the thorax. Except for the sphincter, there is no intra-abdominal esophagus.

CAUSES OF REFLUX

One of the specific characteristics of the LES is that its tonus not only relaxes when food enters the esophagus through a propulsive peristaltic wave, but regular spontaneous relaxations of 5–10 seconds' duration (spontaneous transient LES relaxation (STLESR)) occur even in the absence of any other esophageal activity in healthy individuals. Thereby, a common space is opened between the stomach and the esophagus and can be demonstrated on manometry as a sudden change of the typical esophageal tracing into an abdominal pressure curve, the 'common cavity phenomenon' (CCP) (Fig. 43.3). Usually, these relaxations remain unrecognized because in

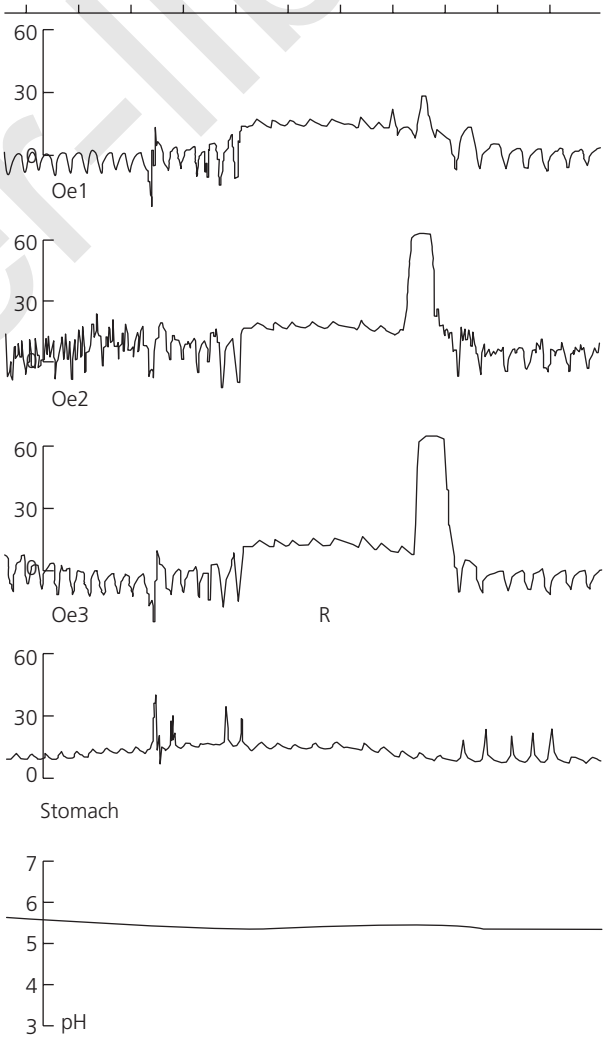

Figure 43.3 Spontaneous pressure inversion of the esophageal tracing to an abdominal tracing indicates the opening of the lower esophageal sphincter due to a transient relaxation. This is the manometric sign of reflux – the common cavity phenomenon. It is always terminated by a secondary propulsive peristalsis.

most events the reflux reaches only the lower esophagus. The volume is immediately returned to the stomach by a secondary peristalsis (volume clearance). Any drop of the pH, however, is neutralized in a stepwise manner by saliva during subsequent acts of deglutition (acid clearance). In patients with pathological reflux or reflux disease, STLESRs occur significantly more often and for longer.

THE DEVELOPMENT OF THE ESOPHAGUS IN THE NEONATE AND SMALL INFANT

The best way to investigate the esophageal function in this age group is manometry combined with pH monitoring. Studies in premature and newborn babies have shown that the length of the LES is 10.7 mm. The tone of the LES in these groups of babies was in the range 18.0–23.0 mmHg. Thus, the tone in the LES is identical to the tone in older age groups and in adults (Table 43.1).[2]

Manometric studies have shown that there is a physiological delay in the development of propulsive esophageal peristalsis. Induced swallows in the youngest group of patients have been followed in only 59% by a propulsive peristalsis and in 41% by simultaneous contractions of the esophagus. However, already at the age of 4 weeks nearly all investigated babies had a normal peristaltic response in eight of ten induced swallows.

Table 43.1 Results of esophageal manometry: the LES pressure values in newborn babies and infants are already normal.

	n	Age (days)	LES tone (mmHg) x ± s.d.	LES length (mm) x ± s.d.	PS ($n = 10$)
Premature (GA 30–36)	7	7–28	23.0 ± 3.6	1.0 ± 1.1	–
Newborns	24	1–10	20.4 ± 8.0	10.7 ± 0.8	5.2[a]
Newborns	19	11–28	21.8 ± 10.0	11.0 ± 0.5	7.3
Infants	20	>28	18.0 ± 7.0	11.3 ± 1.1	7.9

[a] $p < 0.05$.
LES, lower esophageal sphincter.
PS is the response of propulsive peristaltic waves in the esophagus after ten induced swallows. The results show that the response is significantly lower within the first 10 days of life, but thereafter it is normal with nearly eight propulsive responses out of ten induced swallows.

REFLUX IN THE NEWBORN

Mild spitting, a flaccid leak out, or vomiting of milk as a sign of a pronounced GER is observed in approximately half of all newborns and young infants. The subsequent development shows that these symptoms become less frequent after the first four to six months of the infant's life and are no longer observed at 12 months in most cases. Previously, it was believed that frequent reflux in these young age groups was caused by a physiologic absence of tone in the LES. However, our former studies using adequate manometric techniques have clearly shown that the incidence of GER in newborns and infants is not caused by a low or even absent pressure of an immature LES nor by a deficient esophageal peristalsis, but it is the consequence of other factors (Table 43.1).

What is immature in this age group and what might cause the higher incidence of reflux? Three factors have to be considered:

1. **Spontaneous LES relaxation**: we were able to show that GER in newborn and infants is caused by STLESRs. Babies with pathological reflux have significantly more frequent and more prolonged STLESRs, but a normal LES tone (Table 43.2).[2,3] These findings were later confirmed by Omari *et al.*[4] Further investigations showed that pathological STLESRs are associated with immaturity of the normal propulsive peristalsis of the esophagus. Thus, we can conclude that reflux in this age group is not caused by an absent LES tone, but must be regarded as delay in the central motor coordination in the esophagus and its sphincters. The particularly high prevalence of reflux in infants with sleep apnea is an additional indicator in the conclusion that immature central regulatory structures are responsible for the frequent STLESRs.[5] In most cases, a spontaneous maturation of this functional instability occurs within the first year of life and thereafter the reflux pattern is identical to that of adults. However, it has been shown that the disappearance of the clinical signs of reflux around the age of 12 months does not necessarily mean that the esophageal function is normalized.[6] Despite persistent reflux, the clinical signs may be mild or even absent but years later sequelae of a chronic pathological reflux may become evident. Recent investigations in adults have shown that approximately half of young adults with reflux disease had marked symptoms in their childhood.[7]
2. **The His angle** may have a significant impact on the function of the LES and the incidence of spontaneous relaxations in this age group. In contrast to older children, the His angle in newborns and infants is not sharp but flat and no mucosal valve can be seen during endoscopy (Fig. 43.4). Any increased intragastric pressure after meals is then exerted directly towards the sphincter due to the lack of the mucosal valve mechanism.

Table 43.2 CCP occur significantly more often and longer in babies with GER when compared to normal controls. However, the LES tone is not different between groups.

	Seconds	With reflux (*n*)	Controls (*n*)
CCP episodes	<7	12.4 ± 2.6[a]	3.3 ± 0.5
	7–15	9.6 ± 1.1[a]	3.4 ± 0.4
	>15	3.0 ± 0.8[a]	0.7 ± 0.2
Total CCP time (%)		2.0 ± 0.3[a]	0.5 ± 0.05
LES tone (mmHg)		25.3 ± 2.6	30.2 ± 1.4

[a] $p < 0.05$.
CCP, common cavity phenomenon; GER, gastro-esophageal reflux; LES, lower esophageal sphincter.

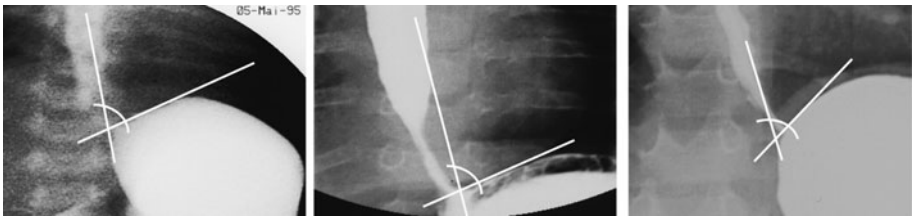

Figure 43.4 Development of the His angle: the diaphragm moves upward with age and the His angle becomes markedly sharp angled in this child with a primary gastro-esophageal problem.

3. Finally, it is well known that any **ingested fluid causes reflux** episodes. The largely liquid nutrition (milk) given in infancy causes frequent refluxes. The number of reflux events is significantly reduced towards the end of the first year as soon as nutrition is more solid.

SYMPTOMS OF PATHOLOGICAL REFLUX IN NEWBORNS AND INFANTS

Pathological reflux in this age group may be characterized by different symptoms. The most typical reported signs are regurgitation, effortless leak out of milk or food after meals, between meals, and when asleep. A moist pillow is another sign of reflux. Further symptoms of pathological reflux are restless sleep with sudden wake up and crying periods. If recurrent vomiting of food is significant, the child may develop malnutrition and failure to thrive.[8–10] Rarely one may observe even rickets despite seemingly adequate vitamin D supplementation as a consequence of the recurrent vomiting. Further suspicious symptoms are developmental disorders, recurrent respiratory tract infections due to microaspirations, greater irritability and agitation. Quite often the reflux-related problems in feeding the baby may significantly disturb the interaction between mother and child. However, the clinical symptoms are not reliable indicators of a GER disease and often demonstrate poor correlation with the results of 24-hour pH monitoring or histology.[11]

The most significant complication of GER is esophagitis, which is caused by too frequent and prolonged relaxations of the LES and chronic acid exposure of the esophagus. The resulting inflammation of the mucosa may cause microbleeding and result in chronic anemia. If the inflammation spreads to deeper layers of the esophageal wall, it may eventually cause stenosis due to simultaneous formation of scars. However, in newborns and infants, as long as the babies are largely fed with milk, the acidic gastric juice is largely buffered during the first 2 hours after feeding (Fig. 43.5). Thus, esophagitis is a very rare occurrence in this age group.

DIAGNOSIS OF REFLUX

There are several diagnostic tests to determine a pathological reflux. However, in most cases only a few of them are needed in the newborn age group. It depends on the underlying problem whether or not an extensive diagnosis is needed.

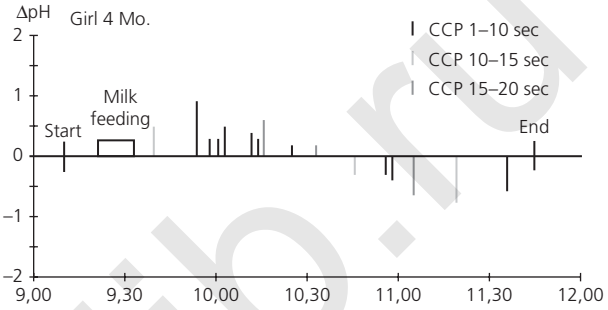

Figure 43.5 Combined manometric study and pH monitoring after a typical milk meal in a four-month-old child. The lines indicate reflux episodes with a common cavity phenomenon of different duration. The results show that refluxes are accompanied by a slight pH decrease only 1 hour after feeding.

In this section, the principal diagnostic tests to determine a pathological gastro-esophageal reflux are described.

Radiological investigation of esophageal passage

The primary purpose of x-ray diagnosis is to investigate the morphology and peristaltic function of the esophagus. Visualization of the gastro-esophageal junction, demonstration of a gliding or fixed hiatus hernia, assessment of the angle of His, the finding of smooth or pathological pharyngo-esophageal deglutition, the course of esophageal peristalsis, and any remarkable features in the epithelium as signs of inflammation constitute the most important information that needs to be obtained from a radiological investigation. A further finding is evidence of aspiration of contrast medium during the investigation. In contrast, the actual evidence of reflux is of less importance because radiological exposure time is short and the true extent of reflux may be overestimated or underestimated. Indirect signs of a pathological reflux include air reflux during the investigation, a positive water siphon test (reflux after taking a large sip of water as a reflux provocation), and the height of the reflux events must be documented.[12] This may yield an evaluation scheme which however, should be used only if it concurs with a 24-hour pH-metry.

Twenty-four-hour pH monitoring

This investigation is the gold standard to evaluate the function of the esophagus. The thinnest possible glass or

antimony electrodes are introduced by the nasal route and the ongoing pH values are recorded on a battery-driven recorder. Ideally, multichannel probes are used and pH values in the stomach, the lower esophagus, and the upper esophagus are registered. Thus, a pH drop in the esophagus can be correlated with the pH in the stomach, and the number of acidic refluxes that reach the upper esophagus can also be determined.

All pH drops below 4 of at least 15 seconds' duration (number of refluxes), the time required for normalization of pH and/or the increase of pH to 4 (reflux clearance), the number of refluxes with a clearance time of more than 5 minutes and the longest reflux are evaluated. Intake of food and the time in lying or upright position are also registered. Different institutions use different cut-off values which are partly influenced by values in adults. We use the threshold values shown in Table 43.3. The low threshold value of 3% used in infants fed largely on milk takes into account the fewer number of acidic refluxes during which the pH drops below 4 (Fig. 43.5).

The weakness of the method is the fact that it does not demonstrate refluxes with a neutral pH or mildly alkaline refluxes with an increase in pH.

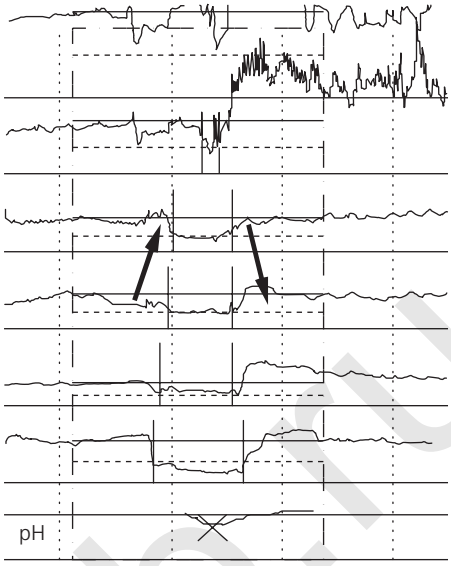

Figure 43.6 Combined impedance and pH monitoring: it shows a short reflux episode with a not significant decrease of the pH in the esophagus which would not be detected by pH monitoring alone.

Table 43.3 Cut-off values in our GI laboratory: the lower pH-% value in children under one year of age is the result of the fact the gastric acidity is neutralized in infants who are mainly fed with milk products (see also Figure 43.5).

Age (year)	pH < 4 in%	No. of refluxes	Refluxes >5 min	Reflux number	Clearance
<1	<3	<30	<5	<50	<1
>1	<5	<35	<5	<50	<1

Combined impedance/pH monitoring

Combining the impedance technique with pH monitoring allows determination of all refluxes and the direction of bolus movements. Thus, even all neutral and alkaline refluxes can be recorded over 24 hours (Fig. 43.6). This provides a much more informative and valuable assessment of a true reflux compared to simple pH-metry.[13–15] As microaspirations of non-acid refluxes may play an important role in recurrent respiratory tract infection, combined impedance/pH monitoring may well replace simple pH monitoring in the near future as the new gold standard of investigation.

Manometry

Manometric investigations of esophageal function were introduced as a diagnostic procedure in the late 1960s, primarily to measure pressure in the LES. It was presumed at the time that low pressures are responsible for the reflux. Initial manometric investigations in newborns and infants appeared to confirm this fact.[16] However, only with the use of low-perfusion, low-compliance pumps has it been possible to obtain relevant pressure data.

As mentioned earlier under Reflux in the newborn (p. 418), our investigations performed in the 1970s showed that even at this age, normal pressure values are registered in the LES.[2] Furthermore, manometry is an excellent method to demonstrate the motor function and peristalsis of the esophagus. It shows that reflux of the contents of the stomach occurs during spontaneous transient relaxations of the LES. The manometric sign of these relaxations is the CCP, which is characterized by an increase of the esophageal pressure tracings up to abdominal pressure values and the typical reversal to abdominal pressure fluctuations with the respiration (Fig. 43.3). Secondary peristalsis causes the refluxed volume to be conveyed back to the stomach. Normalization of the drop in pH is achieved in a stepwise manner by swallowing saliva. In combination with pH-metry, the CCP also allows the investigator to analyze non-acid, neutral, or alkaline refluxes and thus draw conclusions such as those derived from impedance measurement. However, the disadvantage of manometry is that it is a motion-dependent investigation and requires a quiet child; therefore, it is not suitable as a routine method, but is indispensable for scientific questions.

Endoscopy and histology

Investigations with flexible fiberoptic endoscopes and biopsies are invasive investigations but the only way to diagnose esophagitis. As such, they are a part of the standard procedure in older patients with GER but are rarely needed as a routine procedure for reflux in newborn infants.

Briefly, the endoscope is introduced into the esophagus under visual control and is usually extended down to the duodenum. Biopsies from the duodenum and antrum of the stomach are taken routinely. The tip of the device is inverted in the stomach in order to inspect the gastro-esophageal junction from below. Under normal circumstances, the esophagus encloses the device tightly and the above-mentioned flutter valve (see Anatomy, p. 416) can be seen at the lateral circumference. In contrast, in a hiatus hernia the cardia is slightly opened and the investigator is able to see into the herniated stomach, whereas the LES encircles the device higher up.

By withdrawing the endoscope further, the gastro-esophageal junction and the Z-line are inspected precisely. In normal cases, the esophageal epithelium is smooth and milky-red in color (grade 0). In the presence of esophagitis, one may find reddening, swelling (grades 1 and 2), striated erosion (grade 3), deep ulceration (grade 4), or stenosis (grade 5). Mild reddening of the mucosa at the distal esophagus is a normal condition. Grades 0–2 are largely prone to subjective assessment and often do not concur with the histological outcome. Therefore, it is essential to take several biopsy specimens, starting 1–2 cm proximal to the Z-line, upward into the upper esophagus. The quality of the biopsied material is of decisive importance for an accurate histological diagnosis. Therefore, an endoscope with the largest possible external diameter should be used to obtain the best possible material with the largest biopsy forceps. The biopsy specimens should be placed on a piece of cork, correctly oriented immediately after the specimen is taken, and then inserted in formalin. An optimal biopsy specimen should include the entire epithelium, as well as the basal-cell layer. Thickening of the basal-cell layer and relative elongation of the papilla (due to a thinner epithelial zone) are signs of increased cell turnover and pathological reflux. Evidence of intraepithelial eosinophils then confirms the presence of obvious esophagitis even in the absence of corresponding symptoms. Erosions and ulcerations are, by nature, signs of severe chronic esophagitis. However, in children, this condition is not always associated with unequivocal symptoms. On the other hand, the presence of more than 20 eosinophils per 'high-power' field is a sign of non-reflux-related allergic/atopic disease, which is also known as eosinophilic esophagitis.

Nuclear medicine investigations

Scintigraphic investigations permit the investigator to observe migration of the bolus through the esophagus, any reflux-related aspiration of nuclear medicine tracer material in the lungs, and the measurement of the time taken to empty the stomach after standardized meals. This consists of a solid and a liquid portion, e.g. an egg dish and water. ^{99m}Tc-labeled sulfur colloid is used as tracer. The act of swallowing is visualized in dynamic sequences. After setting the regions of interest (ROI), on the one hand refluxes are registered and on the other hand the mean time taken to empty the stomach is measured as a time/activity curve. Investigations after 24 hours permit the investigator to establish the presence of tracer in the lung, provided aspiration has occurred.

CONSERVATIVE THERAPY OF THE REFLUX DISEASE

A pathological reflux may be considered to exist when the infant has a history of significant regurgitation and flaccid vomiting, suffers from recurrent respiratory tract infections and/or pain, is restless at night, or has other typical symptoms. As the risk of esophagitis is very low at this age, an endoscopic investigation does not need to be performed if no other indications are present. In addition to a 24-hour pH monitoring or impedance pH monitoring, a contrast swallow of the esophagus and an ultrasound investigation of the pylorus are usually needed to exclude any pathologies that would hinder spontaneous healing of the reflux disease, such as hiatal hernia, chronic organo-axial gastric volvulus, gastric stenosis, pylorus hypertrophy, or other anatomic problems.

Since esophageal dysfunction with pathological reflux matures spontaneously in 90% of the otherwise normal infants, conservative measurements are the therapy of choice. Former investigations have shown that the prone position with the trunk raised most effectively prevents reflux, because the hiatus is in the highest position.[17] However, the risk of sudden infant death is markedly increased in this position because vomiting during sleep may result in an obstruction of the nose and mouth and cause prolonged apneic spells and sudden infant death syndrome (SIDS). Today, the supine position with an elevated trunk or left side positioning during sleep and elevation of the head of the bed is recommended.[18,19]

Frequent small volume meals and thickening of food with rice gruel are recommended. There is no clear evidence from the literature that any of these measurements and/or special manufactured milk formulas are effective in reducing the reflux index scores but they do reduce the vomiting episodes.[8,19–21] In most cases, the symptoms abate within the next few months. Prokinetic therapy has not proved to be effective and is no longer used in children.[10]

As mentioned above, the disappearance of the symptoms does not necessarily mean that there is no more reflux, it might just not reach the mouth. Therefore, at the end of the first year a control 24-hour impedance/pH monitoring should be performed to exclude definitively persistent reflux.[22,23]

About 10% of these children still have pathological results and need further treatment and controls. In these patients, addition of acid suppressive therapy is usually indicated, e.g. proton pump inhibitors (PPI). However, more studies are needed to determine which symptoms in infants and children should be treated with PPI.[24] When administering any form of medication for the treatment of reflux, one should be aware of the fact that the production of gastric acid is largely reduced, but the number of non-acidic refluxes will not necessarily be reduced. They may cause recurrent aspiration especially during sleep and chronic respiratory tract infections.

Our experience has shown that spontaneous normalization of the esophageal function may still occur until the age of three to four years and conservative treatment can be continued if the symptoms are minimal and the parents want

to avoid surgery. However, after this time, a spontaneous maturation of the function cannot be expected and surgical therapy is indicated. It has been shown that in these patients pathological reflux pattern continues until adulthood.[7]

SURGICAL THERAPY

As mentioned above, surgery of reflux is not indicated in most of the newborns and infants due to the spontaneous maturation of the esophageal function within the first year of life. However, there is a small group of patients in which any trials of conservative therapy are ineffective, even when treated under in-hospital supervision. Additionally, the process of spontaneous normalization of a pathological reflux cannot be expected in babies after correction of an esophageal atresia, diaphragmatic hernia, congenital hiatal hernia or even upside down stomach, organo-axial gastric volvulus and some other congenital anomalies. In these children, surgical procedures are indicated because the long-term sequelae of unphysiologic neutralization of gastric acid with PPI are problematic.

The strategic principles of reflux surgery consist of creating an intra-abdominal portion of the esophagus and a complete (Nissen) or partial plication (dorsal Toupet, ventral Thal) of the gastric fundus around the esophagus.[25] The standard approach today is by laparoscopy. The choice of the method depends on the surgeon and good results are achieved with all three methods. However, long-term follow-up controls after fundoplication show a relatively high failure rate, especially in cerebrally handicapped patients, in prematures, and when the procedure has been performed in early childhood.[26] The most common complication is recurrent reflux, which has been observed with all three surgical methods (Table 43.2).[27–29] It is related to the natural agitation in this region due to the movement of the diaphragm during respiration and to the significant shortening of the esophagus that occurs during swallowing.[30] Further risk factors for recurrence are severe rumination and regurgitation which occur in some cerebrally handicapped children.[31] Rare complications after a Nissen procedure may occur in patients with a rather tight fundoplication and the inability to vomit, a gas bloat syndrome, or dumping.

A rarely used method which might be useful in a patient with a very small stomach is the Collis gastroplasty, for which the His angle is deepened parallel to the esophagus with a stapler. The lengthened fundus is then used for a Nissen, Toupet, or Thal plication around the elongated esophagus.

The gastro-esophageal dissection is another method which is useful in rare cases of severely cerebrally handicapped infants with massive rumination and recurrent GER.[32] The esophagus is detached from the stomach and anastomosed to a Roux-en Y jejunal loop. Orally ingested food is thus diverted directly into the jejunum and recurrent reflux or rumination is rendered impossible.[33]

In the last few years, a number of new technical methods have been introduced for the treatment of reflux in adults, such as creation of a mucosal fold by an intraluminal stapler, radiowave damage of the cardia (Stretta procedure), or endoscopic submucosal injection of foreign material (Enteryx®). Experiences in children are rare and long-term results are lacking.[34–37]

SPECIAL PROBLEMS OF REFLUX IN THE NEWBORN AND INFANT

Laryngopharyngeal reflux

Chronic microaspiration of acidic reflux during the day and/or night may causes laryngeal symptoms, such as hoarseness, the urge to cough, and dysphagia. Each endoscopic investigation is incomplete if the larynx is not inspected. Reddening, ulcerations, or pseudopolyps on the vocal cords are typical signs of laryngeal reflux. However, these findings are very rare in this age group as long the babies are mainly fed with milk. As regards therapy, medication with PPI is recommended.

Reflux-associated infections of the respiratory tract

Aspiration of acidic or even non-acidic reflux is the cause of recurrent respiratory tract infections and pneumonia. Other causes, such as cystic fibrosis, aspirated foreign bodies, H-type fistulas, or other malformations of the respiratory tract must be excluded. In cerebrally handicapped children, disruption of the pharyngo-esophageal transport – disturbed swallowing – is also a well-known cause of recurrent aspiration.

Diagnosis is not simple, except when the radiological investigation shows aspiration of the contrast material during reflux phases. Neither bronchioalveolar lavage nor nuclear medicine investigations are unequivocal. pH monitoring with one recording point in the upper and one in the lower esophagus provides only indirect signs, when a large number of refluxes extend into the upper esophagus. If evidence of recurrent reflux-associated aspiration is obtained, surgery is indicated.

Reflux and apnea syndrome

Apnea and SIDS are the most common causes of death between the ages of two and six months. The association of reflux and apneic spells has been investigated with unequivocal results.[38] Some studies have not proved a temporal relationship between GER and apnea.[8,39,40] Although an increased rate of GER was observed after feeding in preterm infants, a corresponding increase of apneic spells was not found. Our investigations with manometry and pH-metry in infants with pathological sleep apnea have not shown that acidic refluxes are directly causing apneic spells. However, we did register a markedly delayed maturation of motor function of the esophagus in babies with sleep apnea or apparent life-threatening events (ALTE).[5] Further studies have shown that infants investigated due to a pathologic sleep apneic pattern frequently have also pathological reflux, whereas infants with a primary history of pathological reflux have no remarkable

apneic spells.[41] These investigations support the hypothesis that infants with sleep apnea syndrome or ALTE suffer from a deeper localized underlying immaturity of regulation centers in the brainstem, while the causes for a delay in the maturation of the esophageal motor function are localized in higher brainstem regions and therefore not necessarily associated with disorders of the respiratory regulation.[2]

Hiatal hernia

Any upward gliding of portions of the stomach into or above the esophageal hiatus are called hiatal hernia (HH). A gliding HH is rare in newborns and infants, but one cannot expect a spontaneous normalization of this anatomic malformation. The previously used term 'forme mineure' for minimal HH in infants is no longer considered a pathology, but is known as a normal finding of the special anatomy of the gastro-esophageal junction in this age group.

Para-esophageal hernias are not so rare findings after fundoplication. A part of the stomach slips through the hiatus into the chest, lateral to the gastro-esophageal junction. If a small postoperative para-esophageal hernia is combined with reflux or any other symptoms, surgical correction is indicated. A congenital form of para-esophageal hernia is the upside-down stomach in the newborn, which is a more or less complete displacement of the stomach into the chest while the gastro-esophageal junction remains in the normal position.

Esophageal atresia and diaphragmatic hernia

The lower segment of the esophagus in patients with esophageal atresia is characterized by an abnormal or absent propulsive peristalsis, even after uneventful surgery. Due to the absent peristalsis refluxed material remains for a prolonged time in the esophagus and volume as well as acid clearance are significantly prolonged. In this age group, the long acid clearance time may already cause a chronic esophagitis. A spontaneous normalization of the pathology cannot be expected; therefore, surgical correction is usually necessary.

Children with congenital diaphragmatic hernia frequently suffer from a pathological reflux due to the abnormal anatomy of the gastro-esophageal-diaphragmatic anatomy.[42] Early fundoplication is indicated because a spontaneous normalization of the disturbed function cannot be expected.

REFLUX IN NEUROLOGICALLY IMPAIRED CHILDREN

In patients with severe neurological impairment gastro-esophageal reflux disease is a common disorder that may lead to a number of complications, such as esophagitis, esophageal stenosis, anemia, and/or Barrett esophagus. Although these symptoms usually become clinically evident only in later childhood, vomiting, recurrent respiratory tract infections as well as failure to thrive are, in small babies, strong indicators that the underlying pathology is accompanied by a significant reflux problem.[43] Manometric studies show that these children suffer not from a sphincter insufficiency but from too many spontaneous LES relaxations. These findings again support the hypothesis that pathological reflux is strongly connected to a dysfunction of the regulation centers in the brain. Whether a conservative therapy including PPI, a fundoplication (with or without a button gastrostomy), or an esophagogastric dissection is needed has to be decided on an individual basis considering the quality of life and circumstances of the child.

CONCLUSION

Gastro-esophageal reflux is common in neonates and small infants. It is caused in most cases not by an insufficient LES but by a delay in the development of the esophageal function characterized by many spontaneous relaxations of the LES. In more than 90% of the babies, a spontaneous maturation of the esophageal function can be expected until the end of the first year of life and, therefore, unspecific conservative measurements are usually sufficient. In contrast, babies with severe and recurrent complications of reflux, e.g. recurrent respiratory tract infections and/or congenital malformations, usually need a surgical therapy by a semi-circular or complete fundoplication.

Pyloric atresia and prepyloric antral diaphragm

VINCENZO JASONNI, ALESSIO PINI PRATO, GIOVANNI RAPUZZI, AND GIROLAMO MATTIOLI

PYLORIC ATRESIA

Introduction

Gastric outlet obstruction in the newborn may be due to pyloric atresia, antral web, or hypertrophic pyloric stenosis. The most common cause of gastric outlet obstruction is hypertrophic pyloric stenosis.

Pyloric atresia is a rare congenital malformation representing less than 1% of all atresias and diaphragms of the gastrointestinal tract.[1–3] Up to 50% of these patients have associated abnormalities, of which epidermolysis bullosa is the most common.[1,4–6] Familial occurrence of pyloric atresia has been reported.[5,7] Puri *et al.*[8] described pyloric atresia in three consecutive siblings in a family.

Etiology

Although certain etiology is still unknown, mucosal desquamation has been suggested to play a role, mainly in patients with associated epidermolysis bullosa.[9] Junctional epidermolysis bullosa associated with pyloric atresia (EB-PA (congenital disorders and malformations) OMIN 226730) is a rare autosomal recessive inherited disease in which mucocutaneous fragility is associated with this type of gastrointestinal atresia.[9] This association is usually fatal during the first few weeks or months of life, even following surgical correction of intestinal obstruction. Recently, mutations in the genes encoding the subunit polypeptides integrin alpha 6 beta 4 (ITGA6 and ITGB4) have been identified in several patients with epidermolysis bullosa and pyloric atresia.[9–11] Regardless of association or not with epidermolysis, Bar-Maor *et al.*[12] and El Shafie *et al.*[13] concluded that there is strong evidence to support a genetic determination of pyloric atresia with an autosomal recessive mode of inheritance.

Pathology

There are three main different types of pyloric obstruction: type A, membranous pyloric obstruction; type B, longitudinal segmental atresia; and type C, pyloric aplasia (Fig. 44.1). Table 44.1 shows the incidence of different types of pyloric obstruction.[2,3]

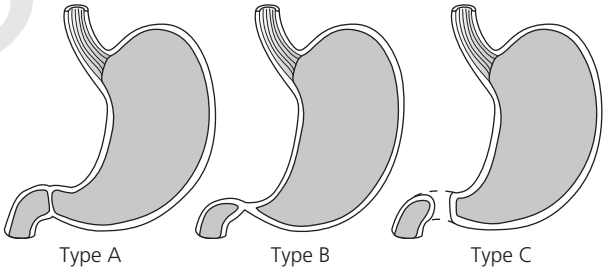

Figure 44.1 Anatomical varieties of congenital pyloric obstruction: type A, membranous pyloric obstruction; type B, longitudinal segmental atresia; type C, pyloric aplasia.

Table 44.1 Incidence of the different pyloric atresia types ($n = 140$).

Type of atresia	No. of cases	%
Membranous (type A)	77	57
Atresia (type B)	46	34
Aplasia (type C)	12	9
No data	5	3.5

Data from Muller *et al.*[2] and Lorenzet and Morger.[3]

History and physical examination

Prenatal diagnosis of pyloric atresia can be suspected when polyhydramnios is present and associated with a dilated stomach. Prenatal diagnosis of pyloric atresia and epidermolysis bullosa can be performed in pregnancies at risk for recurrence of this syndrome. However, some sonographic signs suggest the possibility of significant cutaneous desquamation and blister formation in a fetus, especially when there is positive amniotic acetylcholinesterase coupled with elevated alphafetoprotein.[14] Recently, prenatal magnetic resonance imaging has been used to confirm the diagnosis but its utility remains unclear.[15]

Presentation

The newborn with complete pyloric obstruction presents shortly after birth with persistent non-bilious vomiting and epigastric distension.[16] There is no significant gender predominance and there are a high proportion of infants with low birth weight.[17,18] Respiratory problems are common, and dyspnea, tachypnea, cyanosis, and/or excessive salivation may suggest esophageal atresia.[19] Very rarely, congenital gastric outlet obstruction can be associated with esophageal atresia.[20]

Delayed diagnosis of pyloric atresia can determine gastric perforation, although this complication has also been reported as early as 12 hours post-delivery.[21] See Table 44.2 for clinical features.[2,3]

Table 44.2 Clinical features of pyloric atresia ($n = 140$ patients).

Symptoms and signs	Occurrence (%)
Bile-free vomiting	100
Single stomach bubble (one bubble) on x-ray	98
Distended epigastrium	68
Polyhydramnios	63
Birth weight <2500 g	53
Prematurity	45
Jaundice	21
Peristaltic movements in the epigastrium	18
Hemorrhagic vomiting	12

Data from Muller *et al.*[2] and Lorenzet and Morger.[3]

Diagnosis

A plain x-ray of the abdomen will usually confirm the clinical diagnosis. X-ray (Fig. 44.2) will show severely dilated stomach without air below. Contrast study, although unnecessary, can confirm complete obstruction at the pyloric region. The radiological diagnosis is based on the identification of three radiological signs: the single gas bubble sign, the absence of beak sign (typical of hypertrophic pyloric stenosis), and the presence of the pyloric dimple sign on a contrast study.[22] The single gas bubble sign is not specific for the diagnosis of pyloric atresia, but it is an indicator of a gastric outlet obstruction. The ultrasonographic examination can be helpful and demonstrates the absence of normal pyloric muscle and canal, which is specific for the diagnosis of this entity.[22]

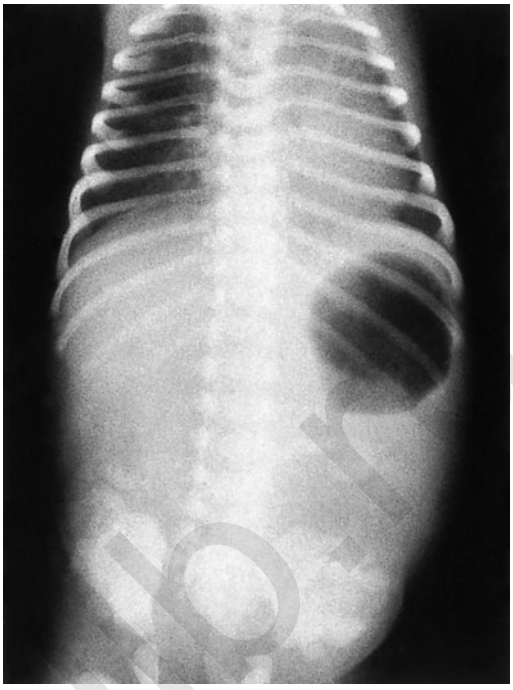

Figure 44.2 Abdominal x-ray showing absence of air beyond the stomach.

Management

Depending on the type of pyloric obstruction, different operative procedures are used. The best results from operative treatment of membranous obstruction are obtained by excision of the membrane associated with pyloroplasty according to Heineke-Mikulicz or Finney.[1–4] Transgastric excision of the pyloric membrane without pyloroplasty has also been reported.[23] In the case of longitudinal segmental atresia, the operative method depends on the length of the atresia. When the atresia is short, a Finney pyloroplasty can be carried out. For longer atresias, the procedure of choice is excision and end-to-end gastroduodenostomy.[4] Gastrojejunostomy is not recommended, due to the high mortality rate[4] and because of the risk of marginal ulcer and blind loop syndrome.

Preoperative management

Usually newborns are referred to the hospital and admitted within the first 2 days of life. They are generally in good physical condition, except those with epidermolysis bullosa. Preoperative preparation should consist of gastric decompression by nasogastric tube insertion. An i.v. infusion should be started to correct dehydration, electrolyte imbalance, and metabolic alkalosis in most cases. A central line should be

inserted to administer parenteral nutrition and long-term medical treatment specifically in those newborns with associated epidermolysis bullosa.

Operative technique

LAPAROTOMY

A transverse abdominal incision is made 2 cm above the umbilicus, starting 2 cm to the left of the midline and running laterally in a skin crease for about 5 cm (Fig. 44.3a). The abdominal cavity is opened in the line of the incision. Careful exploration and search for other intestinal atresias are performed at this site.[13]

IDENTIFICATION OF THE SITE OF OBSTRUCTION

During the procedure, it may prove difficult to identify the exact disease, therefore a gastrotomy can be helpful in this regard.[16] Another way to find the exact location of the web and prevent the gastrotomy can be achieved by placing a firm 12–14 Ch nasogastric tube, to be advanced up to the region of the obstruction.[24]

PYLOROPLASTY

This procedure is indicated for membranous pyloric obstruction (type A) and short atresia (type B).[4,8,12]

After identification of the pylorus, a longitudinal incision is made with cutting diathermy or scissors, starting on the gastric side of the pylorus to the duodenum (Fig. 44.3b). A blunt dissecting forceps, which is inserted into the lumen, is useful at this stage. Care must be taken that no inadvertent damage is done to the posterior wall of the stomach or duodenum. The total length of the incision should be 1.5–2 cm, extending approximately 1 cm on the gastric side and 1.5–1 cm on the duodenal side of the pylorus; it should be performed on the midline between the greater and lesser curvatures of the stomach and superior and inferior borders of the duodenum. The greater length on the gastric side is necessary because of the thicker gastric wall and in order to properly align both margins of the incision in the transverse direction. The membrane is excised circumferentially and the mucosa approximately with 5-0 readsorbable sutures (Fig. 44.3c). The duodenal lumen is inspected and a catheter is pushed down to exclude further distal atresias. The longitudinal incision is then closed transversely in two layers after meticulous hemostasis (Fig. 44.3d).

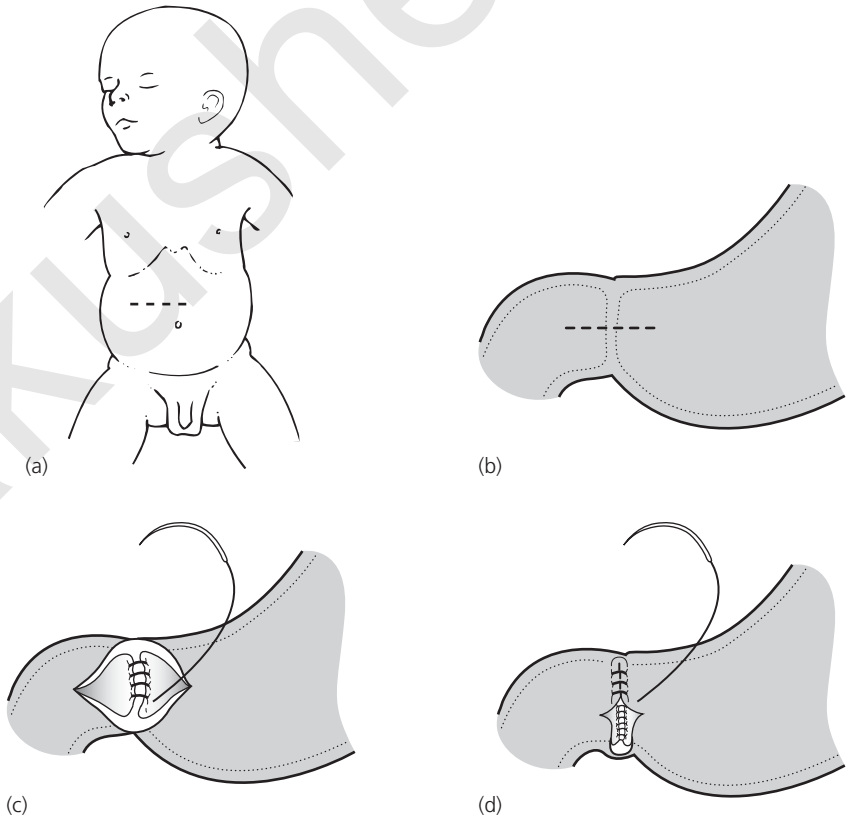

Figure 44.3 Operative technique of pyloroplasty: (a) skin incision; (b) pyloric longitudinal incision; (c) incision of the membrane and suture; (d) longitudinal incision closed transversely.

CLOSURE OF ABDOMEN

Gastrostomy is generally not necessary. The abdomen is closed in two layers and the nasogastric tube is left in the stomach for decompression.

LAPAROSCOPY

Although literature reports are still lacking, laparoscopic approach to pyloric atresia is an alternative option to the conventional open procedure. Although newborns have high sensitivity to insufflation, pneumoperitoneum is usually well tolerated if CO_2 pressure is maintained below 8 mmHg.[25] If achieved laparoscopically, the procedure should not significantly differ from that performed with the conventional laparotomic approach.

Postoperative management

Parenteral nutrition should be discontinued when the patient can be fed predominantly by mouth. The nasogastric tube should be kept *in situ* for 2–3 days to maintain gastric decompression or even longer if there are signs of delayed gastric emptying. Intravenous broad-spectrum antibiotics are administered intraoperatively and should be discontinued after 3–5 days, according to the patient's condition.

Complications

Complications are uncommon but include strictures, leakage, adhesions, infections, and bleeding as for any other abdominal surgery. Wound dehiscence and/or infection can occur, particularly in patients with epidermolysis bullosa.

Long-term results

Early diagnosis and surgical intervention with adequate neonatal supportive care has significantly improved the survival of pure pyloric atresia. Mortality has been associated with delayed diagnosis,[12,13] but it is mainly due to the associated malformation. Survival and long-term results are excellent in isolated forms of pyloric atresia. The overall mortality rate is about 45% and the majority of these fatal cases are those with epidermolysis bullosa and other multiple intestinal atresias.[6,26] On the basis of these considerations, Rosenbloom and Ranter[27] suggested the non-operative management of pyloric atresia, unless the skin disease is responsive to treatment. On the other hand, Hayashi *et al.*[7] reported long-term survival in four of five patients with pyloric atresia and epidermolysis bullosa. A comprehensive review from Dank and coworkers,[28] in 1999, reported that 51 of 70 patients with pyloric atresia associated with epidermolysis bullosa had been operated upon worldwide, with a long-term survival of roughly 31%. It was not surprising that survival was mainly observed in patients with mild forms of epidermolysis.

PREPYLORIC ANTRAL DIAPHRAGM

Introduction and etiology

Prepyloric antral diaphragm is a rare anomaly involving a submucosal web of gastric tissue covered by gastric mucosa and found in the distal gastric antrum. A total of about 150 cases has been reported, divided between pediatric and adult age ranges.[29] Reports have suggested both acquired and congenital forms, citing epidemiological and histological evidence.[30]

Pathology

There are three groups of patients: a neonatal group with complete or partial obstruction; a group presenting later in childhood; and a group not diagnosed until later in life.[31] Significant associated abnormalities are noted in about 30% of children with antral web, including mainly the gastrointestinal tract and cardiovascular system.[30]

History, presentation, and diagnosis

In the neonatal group, non-bilious vomiting is the predominant presenting symptom. Other symptoms include apnea, cyanosis, and no weight gain.[30] The older children complain of abdominal pain, vomiting, fullness after eating, and bloating. In the adult group, the clinical history consists of episodic cramping, epigastric pain or fullness following meals, and intermittent vomiting. There is one report describing a case in the eighth decade of life.[32]

The diagnosis of antral web with a central aperture is with a barium meal in 90% of cases.[30] The typical appearance of a web in an infant is a thin, membranous septum, projecting into the antral lumen, perpendicular to its longitudinal axis 1–2 cm proximal to the pylorus (Fig. 44.4a).

Gastroscopy has recently been noted to be of use in confirming clinical and radiological evidence of the web in older infants and in children.[33] Features of the web include:

- a small fixed central aperture surrounded by gastric mucosa that is smooth and devoid of folds;

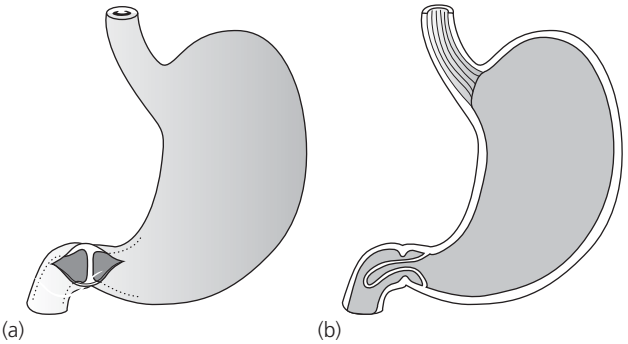

Figure 44.4 (a) Prepyloric antral web; (b) windsock antral membrane protruding into the duodenum.

- no change in the opening size of the web with peristalsis;
- that the gastric wall proximal and distal to the web is seen to contract normally.[34]

Management

Preoperative and postoperative management does not significantly differ from that of pyloric atresia. Surgery for partially obstructing antral web consists of excision of the web, combined with pyloroplasty if the web is very close to the pylorus (same as pyloric atresia). Furthermore, at operation, it is important to pass a Foley catheter distally to the stomach, and then to inflate the balloon and withdraw the catheter.[24] Windsock pyloric and antral membranes protruding into the duodenum have been reported (Fig. 44.4b) and would be missed at laparotomy by simple inspection of the gastric lumen.[35] Other methods have been reported. Most noticeably, some reports described successful endoscopic transection using a standard papillotome[36] and forceful dilatation of antral membrane without pyloroplasty.[37]

Medical treatment has been reported with success in infants without pronounced obstruction.[38] While this concept of conservative management is supported by some surgeons, the majority of the reports preferred the surgical correction of this entity, which reduces and prevents morbidity and unnecessary counseling in this group of babies and children.[4,29]

Complications and long-term results

Complications do not significantly differ from those of pyloric atresia.

Hypertrophic pyloric stenosis

PREM PURI, BALAZS KUTASY, AND GANAPATHY LAKSHMANADASS

INTRODUCTION

Hypertrophic pyloric stenosis (HPS) is the most common condition requiring surgery in the first few months of life. It is characterized by hypertrophy of the circular muscle of the pylorus, causing pyloric channel narrowing and elongation. The incidence of pyloric stenosis varies widely with geographic location, season, and ethnic origin.[1] The incidence has been reported to be approximately three per 1000 live births.[2] There is some evidence that in recent years the incidence of pyloric stenosis has increased significantly in some parts of the UK.[3–5] Boys are affected four times more often than girls.[6] Recently, a dramatic rise in incidence among male infants but not for females was reported, so that rates for the two sexes were 6.2 and 0.9 per 1000 infants per year.[7,8]

ETIOLOGY

Although earlier diagnosis, advances in fluid and electrolyte therapy, and pediatric anesthesia have reduced the mortality to practically zero, the exact etiology of pyloric stenosis is unknown.[9] This condition is usually classified as a congenital disorder. It is almost unknown in stillbirths, associated anomalies are very uncommon, and the patient usually presents with vomiting after the second week of life. For these reasons, it has been suggested that it may be an acquired condition. Rollins *et al.*[10] measured pyloric muscle dimensions on ultrasonography in 1400 consecutive newborn infants. Nine of these infants subsequently developed pyloric stenosis and were operated upon. Their pyloric muscle measurements at birth were all within the normal range. This study clearly showed that congenital pyloric muscular hypertrophy is not present in babies who later develop pyloric stenosis.

The occurrence of infantile hypertrophic pyloric stenosis (IHPS) has been associated with several variables such as genetic, environmental, and mechanical factors. The pyloric sphincter, a zone of intermittently increased pressure, is able to contract tonically and phasically and produce an effect on gastric emptying. Pyloric sphincter function and motility is under a complex control system which involves the enteric nervous system, gastrointestinal hormones, and interstitial cells of Cajal (ICC); these pathways have been investigated in IHPS and abnormalities in hormonal control, extracellular matrix, smooth muscle fibers, growth factors, and ICC have been implicated in the pathogenesis of the disease.

EXTRINSIC FACTORS

Various environmental and mechanical factors have been proposed as potential causes of IHPS. Maternal smoking has been shown to double the risk for IHPS.[11] Recently, the significantly higher prevalence of breast milk feeding in early pyloric stenosis (in the first 2 weeks of life) has been found.[12] Another risk factor, maternal age, has been related to IHPS: significantly increased risk for IHPS with young maternal age (<20 years) and significantly decreased risk with maternal age 30 years and older.[8]

Neonates treated with erythromycin for different types of infection in the first 2 weeks of life have been found to carry an up to ten-fold risk of IHPS.[13] Erythromycin has been associated with an increased risk of IHPS as it acts as a motilin agonist and induces strong gastric and pyloric contractions that may lead to pyloric hypertrophy. Infants of mothers exposed to erythromycin during lactation have been reported to be at higher risk of IHPS while prenatal exposure has not been found to be associated with increased risk.[14]

In a small number of cases, IHPS has been believed to develop as secondary effect to a primary gastric outlet obstruction by mechanical factors. A transpyloric feeding tube, an antral polyp, and a pyloric cyst have been associated with IHPS.[15]

GENETICS

As IHPS tends to run in families, genetic factors have been implicated in its etiology. IHPS is relatively rare in babies of

African, Indian, and Chinese extraction.[16,17] Boys are affected four times more often than girls,[10] and IHPS has been reported in multiple siblings and multiple births.[18–20] Siblings of patients with IHPS are 15 times more likely to suffer the condition than children who have no family history of IHPS.[21] In a follow-up study extending over 45 years, Carter and Evans found that 5–20% of the sons and 2.5–7% of the daughters of affected patients developed IHPS.[22] Sons and daughters of affected female patients had three to four times the incidence of IHPS than sons and daughters of affected male patients.[21]

IHPS has been associated with a number of inherited genetic syndromes, such as Smith-Lemli-Opitz and Cornelia de Lange, as well as chromosomal abnormalities including partial trisomy of chromosome 9, partial trisomy of chromosome 13, and partial monosomy of chromosome 8 and 17.[23]

Although a specific gene responsible for IHPS has not yet been discovered, several susceptible loci have been identified, such as 16p12-q13, 16q14, 11q14-q22, and Xq23.[24,25] In view of the implication of the enzyme neuronal nitric oxide synthase (nNOS) in the pathogenesis of IHPS, NOS1, the gene encoding nNOS on chromosome 12q has been investigated by linkage analysis and evaluation of nNOS mRNA expression[26] and suggested as a susceptibility locus.

ABNORMALITIES OF HORMONAL CONTROL

The human pylorus is characterized by a zone of elevated pressure that relaxes with antral peristalsis, contracts in response to intraduodenal stimulation, and prevents the retrograde movement of duodenal contents into the stomach.[27] The hormonal control of the pyloric sphincter function by mediators such as gastrin, cholecystokinin, and secretin, has been reported to be the same as in other gastrointestinal (GI) sphincters.[4] Since Dodge successfully induced pyloric stenosis by prolonged perinatal maternal stimulation with pentagastrin in approximately one-half of a litter,[28] together with the finding of elevated serum gastrin levels in infants with IHPS,[29] much attention has been paid to the role of gastrin in the pathogenesis of IHPS. It has been suggested that repeated hyperacid stimulation of the duodenum induced by gastrin evokes repeated pyloric sphincter contractions with work hypertrophy of the pylorus.[30] However, Janik *et al.*[31] failed to induce pyloric stenosis in other species by prenatal administration of pentagastrin. Some investigators found significantly high plasma gastrin levels in affected infants compared to healthy controls,[29,32] whereas others failed to confirm this finding.[33,34] Since raised serum gastrin levels return to normal following pyloromyotomy, it is believed that they are secondary to antral stasis.[33]

Prostaglandins are produced in response to acid secretion and have a role in gastrointestinal motility, as well as cytoprotective and trophic effects. Prostaglandins PGE2 and PGE2a in the gastric juice have been found to be elevated in IHPS as compared with controls and based on the belief that they influence pyloric contraction, it has been suggested that these substances may be responsible for pylorospasm and pyloric hypertrophy.[35] Although the finding of elevated PGE2 in IHPS has been confirmed, evidence on prostaglandins causing relaxation of circular smooth muscle has challenged the hypothesis that prostaglandins cause pyloric hypertrophy.[36] However, prostaglandin treatment for cyanotic congenital heart disease has been shown to induce antral hyperplasia and gastric outlet obstruction that mimics IHPS.[37]

ABNORMALITIES OF PYLORIC INNERVATION

Although the smooth-muscle sphincter tone is myogenic, contraction and relaxation are under neural control via activation of excitatory and inhibitory pathways, respectively. Sympathetic stimulation is believed to exert an excitatory effect on the pyloric sphincter, while parasympathetic stimulation has either an excitatory effect via cholinergic neurons or an inhibitory effect via non-adrenergic non-cholinergic neurons.[38]

The innervations of the musculature regulating motility is particularly dense at the level of the smooth-muscle sphincters of the GI tract.[39] Relaxation of the sphincter is accomplished by activation of inhibitory motor neurons.[40] As a defect in pyloric relaxation has been thought to be responsible for the gastric-outlet obstruction and development of pyloric muscle hypertrophy, many investigators have sought evidence for a neural abnormality in specimens of IHPS, that may explain the failure of pyloric muscle relaxation.[9] Earlier studies concentrated on abnormalities in the myenteric plexus,[41–48] and more recent studies with advances in laboratory techniques and equipment have focused on the glial cells, the synaptic function, and the neurotransmitter status in both the myenteric plexus and pyloric muscle layers.[26,48–59]

Ganglion cells

Many investigators have reported conflicting morphologic findings as regards ganglion cells in the myenteric plexus in IHPS. A number of early authors found decreased numbers of ganglion cells, which were attributed either to degenerative changes related to vagal overstimulation[41,42,45] or to immaturity.[43,44] On the other hand, Rintoul and Kirkman[46] suggested that Dogiel type I ganglion cells (primarily motor) were selectively absent in IHPS. Belding and Kernohan[42] and Spitz and Kaufmann[47] found that the majority of myenteric ganglion cells in the hypertrophic pylorus showed degenerative changes. However, Tam,[48] using immunohistochemical stains for neuron-specific enolase, stated that neurons were neither immature nor severely degenerated. Langer *et al.*[60] demonstrated using electron microscopy that there were fewer nerve cell bodies in the myenteric plexus in IHPS and the total number of ganglia was lower than that in control samples.

Cholinergic and adrenergic innervations

Cholinergic nerve distribution has been studied using acetylcholinesterase (AChE) histochemical staining. Strong AChE staining was observed in the myenteric plexus and the

muscle layers in controls, whereas in IHPS specimens AChE staining was markedly decreased in the muscular layers but strong in the myenteric plexus.[52]

The studies from our laboratory have reported that adrenergic immunoreactivity is absent in the muscular layers and markedly decreased in the myenteric plexus in IHPS in comparison to controls.[9]

Nitrergic innervation

Nitric oxide (NO) is a gaseous free radical, synthesized from L-arginine in a reaction catalyzed by nNOS. NO has a well-described role as a major NANC inhibitory neurotransmitter that mediates pyloric relaxation in the enteric nervous system.[61] Vanderwinden *et al.*[57] and Kobayashi *et al.*[51] have reported that enzyme NADPH diaphorase, which is identical to NO synthase (NOS), is absent or markedly reduced in hypertrophic pyloric muscle while it is preserved in the myenteric plexus in IHPS. Furthermore, a NOS gene-deleted knockout mouse model is described in which the only abnormality is gastric-outlet obstruction due to pyloric hypertrophy.[62] Barbosa *et al.*[63] administered nitro-L-arginine methyl ester hydrochloride (L-NAME), a known NOS inhibitor, to pregnant rats and their newborns then noted that the L-NAME rats had larger stomaches and pyloric hypertrophy. Kusafuka and Puri,[26] using RT-PCR technique, demonstrated low levels of nNOS mRNA in pyloric muscle of IHPS patients compared to normal controls. Since a low level of nNOS mRNA may lead to impaired local production of NO, it is suggested that the excessively contracted hypertrophied circular muscle in IHPS is a result of reduced expression of the nNOS gene at the mRNA level.[26]

Synapse formation

Synapses provide the final neuronal control of the GI tract by regulating neurotransmission at the neuromuscular terminals. The reduction of synaptic vesicles and presynaptic terminals in hypertrophied pyloric muscle layers have been demonstrated.[49,55] Furthermore, a study from our laboratory reported markedly reduced neural-cell adhesion molecule (NCAM) expression on nerve fibers within circular and longitudinal muscles in patients with IHPS compared with normal pylorus.[51] NCAM plays an important role in the formation of initial contacts between nerve and muscle cells and affects tissue formation during embryogenesis.[64,65] These reports suggest that there is impairment of neurotransmission between nerves and muscle in IHPS.

Nerve-supporting cells

The nerve-supporting cells permit cell bodies and processes of neurons to be ordered and maintained in a proper spatial arrangement, and are essential in the maintenance of basic physiological functions of neurons.[66] The nerve-supporting cells of the intrinsic enteric nervous system are often referred to as enteric glia.[9] Enteric glia have been reported to express various markers for both astrocytes and Schwann cells, such as: (1) glial fibrillary acidic protein (GFAP), a specific marker for astrocytes within the central nervous system; and (2) S-100, a marker for astrocytes and Schwann cells. A study from our laboratory demonstrated that in IHPS cases S-100 and GFAP-immunoreactive fibers were either absent or markedly reduced within the hypertrophied circular and longitudinal muscles.[50] The absence or marked reduction of nerve-supporting cells in IHPS corresponds to the absence or reduction of peptidergic, nitrergic, cholinergic, and adrenergic nerve fibers, and is additional evidence that a defect of intramuscular innervation exists in IHPS.

ABNORMALITIES OF THE INTESTINAL PACEMAKER SYSTEM (ICC)

Interstitial cells of Cajal are small fusiform or stellate cells with prominent nuclei and varicose processes that form networks in the GI tissues. They express C-KIT, a transmembrane protein kinase receptor, essential for their development and maintenance. Morphologic studies have suggested three major functions of ICC: (1) they are pacemaker cells in GI smooth muscle; (2) they facilitate active propagation of electrical events; and (3) they mediate neurotransmission.[67,68] A number of investigators have reported a lack of ICC in hypertrophic pyloric muscle from patients with IHPS using C-KIT antibody and electron microscopy.[69,70] The lack of ICC in IHPS suggests the disruption of their network and the interruption of the generation of slow waves may contribute to the motility disturbances of the pyloric sphincter.[69]

Carbon monoxide (CO) acts as a neurotransmitter in the gastrointestinal tract and has been shown to cause smooth muscle relaxation. The main source of endogenous CO is through degradation of heme, catalyzed by heme oxygenase (HO). Heme-oxygenase-2 (HO-2), an isoform of HO, is present in the enteric neurons and in intramuscular ICC, suggesting that CO may serve as an intercellular messenger between enteric neurons, ICC, and smooth muscle cells.[71] Our laboratory has investigated immunocolocalization of HO-2 and ICC in IHPS and reported that although intramuscular ICC were HO-2 positive in controls, HO-2 and ICC were not detected in IHPS. It is suggested that impaired intercellular communication between ICC and smooth muscle cells may contribute to motility dysfunction in infants with IHPS.[72]

ABNORMALITIES OF EXTRACELLULAR MATRIX PROTEINS

Previous studies have reported an increase in connective tissue in IHPS, particularly in the septa that run between the circular muscle bundles.[41,42] Extracellular matrix (ECM) proteins, particularly collagen, are important microenvironmental factors of the neuronal processing pathway in the early embryonal stage and an important matrix for cell adhesion and movement.[9] Cass and Zhang[73] reported an increase in ECM proteins such as chondroitin sulfate,

fibronectin, and laminin in specimens of pyloric muscle in IHPS. Another study reported abnormal amounts of elastin fibers and elastin in the pyloric muscle in IHPS.[74] Using M-57 antibody, which can distinguish newly synthesized type I procollagen from fully processed mature collagen, it was reported that type I procollagen was markedly increased in not only the connective tissue septa between circular muscle bundles, but also among the circular muscle fibers in patients with IHPS, suggesting that the hypertrophied circular muscle in IHPS is actively synthesizing collagen.[74,75] These studies suggested that increased ECM proteins may be responsible for the characteristic 'firm' nature of the pyloric tumor.

Desmin is the main protein of intermediate filaments and is important for the organization and function of muscle fibers. A strong expression of desmin was observed in pyloric muscle biopsies from infants with IHPS, in contrast to absent or weak expression in controls. A similar pattern of strong desmin expression has been demonstrated in the fetal pylorus, suggesting that the organization of intermediate filaments in IHPS is in a fetal state of development.[76]

ABNORMALITIES OF SMOOTH-MUSCLE CELLS

The ongoing contractile tone in the smooth-muscle sphincters is generated by myogenic mechanisms. Langer *et al.*[60] found smooth-muscle cells (SMC) in IHPS to be morphologically normal, containing contractile filaments, intermediate filaments, dense bodies, and caveolae. They found, however, that SMC in IHPS were frequently in a proliferative phase, with large amounts of dilated rough endoplasmic reticulum with a lower proportion of contractile filaments, and very few gap junctions exhibited between SMC compared with control specimens. In contrast, they demonstrated significant ultrastructural abnormalities of the inhibitory enteric nervous system in IHPS. We performed quantitative evaluation of proliferative activity in pyloric muscle in IHPS and showed that proliferative activity is markedly increased in SMC in IHPS.[77]

Gentile *et al.*[78] studied cytoskeletal elements of pyloric SMC in IHPS using immunohistochemical staining and confocal laser microscopy. Talin, a protein responsible for SMC–ECM interaction, and dystrophin, a protein with adhesion properties, were present in controls but absent in IHPS patients, suggesting that the membrane–cytoskeleton interactions and the cell–matrix communications are altered.

Romeo *et al.*[79] investigated dystroglycans and sacroglycans, two proteins that, along with dystrophin, form the dystrophin–glycoprotein complex which is important for maintaining the structural integrity and function of muscle fibers. They reported that although dystroglycans showed similar expressions in IHPS and controls, sacroglycans were present in controls but absent in IHPS. It is suggested that lack of sacroglycans can alter the physiology of SMC and predispose to IHPS.

ABNORMALITIES OF GROWTH FACTORS

Growth factors are peptides that control cell proliferation and modulate cellular functions by binding to specific high-affinity cell membrane receptors. Although the mechanisms responsible for smooth-muscle hypertrophy are unknown, with progress in molecular biology, there is increasing evidence to suggest that the growth of SMC is regulated by several growth factors.[80–82] IGF-I and PDGF-BB are potent SMC mitogens *in vitro* and act synergistically to stimulate SMC proliferation. IGF-I mediates the growth-promoting effects of PDGF in mesenchymal cells.[83] IGF-I and PDGF have been shown to be produced by SMC, and their effects are mediated via their receptors.[84,85] Transforming growth factor alpha (TGF-α) is a growth regulatory peptide found in a wide range of embryonic and adult tissues. It has been recognized that TGF-α has a growth-promoting effect on vascular and visceral SMC.[86] EGF is best known as a potent growth stimulator. It appears to play a critical role early in growth of cultured smooth muscle, in which its production is highest and its growth-promoting effects are greatest.[86] The studies from our laboratory have reported increased expression of IGF-I, PDGF-BB, TGF, and EGF, in hypertrophic pyloric muscle in IHPS,[87–90] suggesting that the increased local synthesis of peptide growth factors in SMC may play a critical role in the development of pyloric muscle hypertrophy in IHPS.

PATHOLOGY

In IHPS, the mean appearance of the pylorus is that of an enlarged muscle mass usually measuring 2–2.5 cm in length and 1–1.5 cm in diameter. On histological examination, marked muscle hypertrophy and hypoplasia[77] primarily involving the circular layer and hypertrophy of the underlying mucosa is described.[91] Increased fibroblast, fibronectin, proteoglycan chondroitin sulfate, desmin, elastin, and collagen have been found on the immunohistochemical analysis of the hypertrophic muscle.[73,74] Abnormally contorted and thickened nerve fibers have been shown with confocal microscopy.[92] These changes are causing either partial or complete obstruction of the pyloric canal.

CLINICAL FEATURES

The usual onset of symptoms occurs between 3 and 6 weeks of age. It may present earlier and has been rarely reported in premature infants.[93] Demian *et al.*[12] investigated 278 patients with IHPS and only 16 (5.8%) presented during the first 14 days of life. Presentation of HPS in infants older than 12 weeks of age is considered rare and reports in the literature are few and far between.[94,95]

Vomiting is the most common presenting symptom. Initially there is only regurgitation of feeds, but soon it is characteristically projectile and free of bile. In 17–18% of cases, the vomitus may contain fresh or altered blood, usually attributed to irritative gastritis or esophagitis.[96]

Owing to inadequate fluid and calorie intake, dehydration and weight loss soon become apparent. In patients who present late, there is disappearance of subcutaneous fat and wrinkled skin. Stools become infrequent, dry, firm, and scanty. However, some infants have diarrhea (starvation diarrhea).

Jaundice occurs in about 2% of cases and has been shown to be related to decrease in glucoronyl transferase, which occurs as a consequence of starvation.[97]

Pylorospasm and gastro-esophageal reflux give similar clinical findings and it may be difficult to differentiate them from IHPS without further evaluation. Other surgical causes of non-bilious vomiting include gastric volvolus, antral web, preampullar duodenal stenosis, duplication cyst of the antropyloric lesion, and ectopic pancreatic tissue within an antropyloric muscle, which are all far less common than IHPS. Common medical causes of non-bilious vomiting are gastroenteritis, increased intracranial pressure, and metabolic disorders (Box 45.1).[23]

Associated anomalies are found in 6–20% of patients.[6,18] These include esophageal atresia, malrotation of bowel, Hirschsprung's disease, anorectal anomalies, cleft lip and palate, and urological anomalies.

Box 45.1 Differential diagnosis of IHPS

Surgical conditions
- Gastric volvolus
- Antral web
- Preampullar duodenal stenosis
- Duplication cyst
- Ectopic pancreas within the pyloric muscle

Medical conditions
- Pylorospasm
- Gastro-esophageal reflux
- Gastroenteritis
- Increased intracranial pressure
- Metabolic disease

DIAGNOSIS

It should be possible to diagnose HPS on clinical features alone in 80–90% of infants.[98–100] The important diagnostic features of pyloric stenosis are visible gastric peristalsis and a palpable pyloric tumor. Physical examination of the infant is best carried out during a test feed which relaxes the abdominal wall and makes the detection of pyloric tumor easier. The abdomen is completely exposed and observation made for gastric peristalsis, which is often visible in this condition as a bulge appearing in the left upper quadrant and moving slowly to the right across the epigastrium. On palpation of the abdomen, an olive-shaped pyloric tumor is palpable in most cases just above the umbilicus at the lateral border of the rectus muscle below the liver edge.

In general, the diagnosis of pyloric stenosis can be made with confidence on the basis of the history and clinical examination alone. When the clinical findings are equivocal, the diagnosis can be confirmed by sonography or barium meal.

The diagnosis by ultrasonography relies on the measurement of the pyloric diameter, pyloric length, and muscle thickness. Of the three parameters, muscular wall thickness is considered to be the most precise on sonography. Blumhagen and Coombs[101] were the first to point out that pyloric muscle thickness of the hypoechoic ring is the most important sonographic parameter in the diagnosis of pyloric stenosis (Fig. 45.1). They considered a thickness of 4 mm or more to be pathological. Other investigators believe that muscle thickness of 5 mm or more is most reliable for the diagnosis of pyloric stenosis.[102] False-positive results are rare, but false-negative rates range from 0 to 19% and largely depend upon the skill of the ultrasonographer.[6,102] In recent years, ultrasound has been used by surgeons to diagnose pyloric stenosis and leaving only problematic or equivocal cases for the radiologist. With this method, IHPS is diagnosed immediately from the emergency room decreasing hospital stay.[103]

Barium meal study is still a highly sensitive examination for the diagnosis of IHPS. In patients in whom the pyloric tumor cannot be palpated and ultrasound is not definitive, usually it confirms the diagnosis and it may also detect gastro-esophageal reflux or intestinal malrotation. Before barium study, the stomach should be emptied with a nasogastric tube, then 30–60 mL of barium is instilled under fluoroscopic control. The characteristic radiological feature of pyloric stenosis is a narrowed elongated pyloric canal giving a 'string' or 'double track' sign caused by compressed invaginated folds of mucosa in the pyloric canal (Fig. 45.2). However, barium meal study provides indirect information about the antropyloric canal status. Failure of the relaxation of the antropyloric lesion, known as pylorospasm, demonstrates the same findings as those of IHPS. The emptying speed of the barium meal to the distal bowel will be important to differentiate these two conditions.[104]

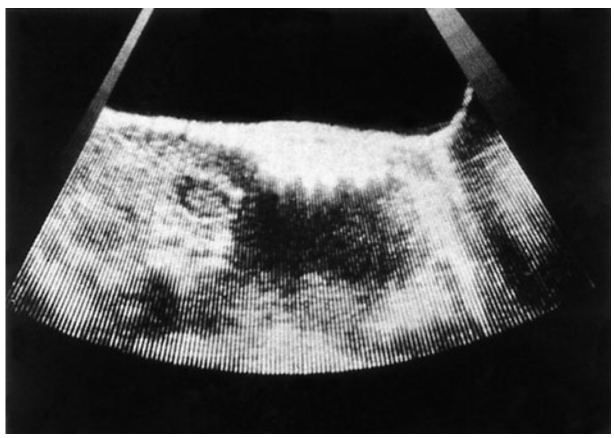

Figure 45.1 Longitudinal real-time sonogram section reveals hypoechoic ring with echogenic center typical of pyloric tumor.

MANAGEMENT

Preoperative management

Persistent vomiting in these patients results in chloride depletion and metabolic alkalosis. Estimation of serum electrolyte level, urea nitrogen level, hematocrit, and blood gases

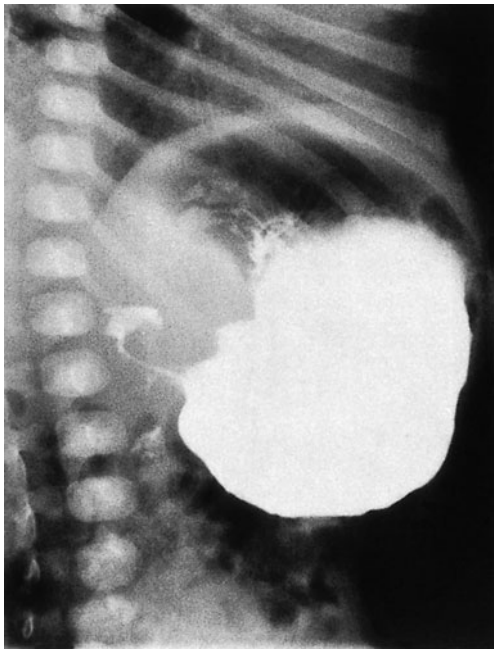

Figure 45.2 Pyloric stenosis. Severe narrowing of pyloric region giving the 'string sign' in this 3-week-old infant who presented with projectile vomiting.

should be done to determine the state of dehydration and acid–base abnormalities. A nasogastric tube is passed to keep the stomach empty. Saline irrigation through the nasogastric tube may help in removing mucus and milk curd. If the barium meal study has been carried out prior to surgery, it may be necessary to remove the residual barium meal by gastric aspiration.

Nowadays, many babies with pyloric stenosis do not show any clinical evidence of dehydration on admission and their serum electrolyte levels are usually normal. They are given their maintenance requirements of fluid as half-straight saline, and are operated on as soon as feasible.

If the infant is mildly dehydrated and has hypochloremic alkalosis, maintenance fluids can be given as 0.45% saline with 5% dextrose containing 10 mmol of potassium chloride per 500 mL, together with adequate volumes of isotonic saline to correct for continuing nasogastric losses. If the infant is more severely dehydrated (>5%), sodium and chloride ions must be replaced with isotonic saline to enable the kidney to excrete bicarbonate, thereby correcting the acid–base status.[6,17] The operation for pyloric stenosis is not an emergency and should never be undertaken until serum electrolyte levels have returned to normal.

Operation

The Ramstedt's pyloromyotomy is the universally accepted operation for pyloric stenosis.

INCISION

A 3 cm transverse right upper quadrant incision provides excellent exposure and direct access to the pylorus with minimal retraction (Fig. 45.3). Another incision which is commonly used is an umbilical fold incision.[105–108]

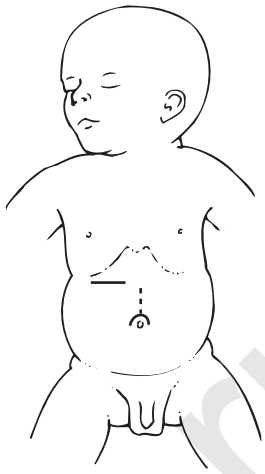

Figure 45.3 Skin incision for pyloromyotomy.

PROCEDURE

The transverse incision lateral to the rectus muscle is cut through all layers of muscle and peritoneum. The pyloric tumor is delivered by gentle traction on the stomach (Fig. 45.4). The surgeon applies an index finger to the duodenal end of the pylorus and stabilizes the pyloric tumor. An incision is then made over the anterosuperior part of the pylorus, beginning at the clearly demarcated pyloroduodenal junction about 2 mm proximal to the pyloric vein and extending onto the gastric antrum, where muscle is thin (Fig. 45.5). The pyloric muscle is then widely split down to the mucosa using mosquito forceps (Fig. 45.6). Some surgeons prefer a Denis Browne pyloric spreader. When the pyloric muscle has been adequately split, the mucosa can be seen to be bulging (Fig. 45.7). To test the mucosal injury, the stomach is inflated through the nasogastric tube and passage of air through the pylorus to duodenum is confirmed. Then the pylorus is dropped back into the abdomen. The peritoneum is closed with 4-0 polyglactin (Vicryl) and muscles approximated using 3-0 polyglactin (Vicryl). 5-0 Vicryl is used for subcuticular stitches.

Tan and Bianchi described the supraumbilical fold approach for pyloromyotomy. Circumumbilical incision is made through about two-thirds of the circumference of the umbilicus. The skin is undermined in a cephalad direction above the umbilical ring and linea alba is exposed. The linea alba is divided longitudinally in the midline from the umbilical ring to as far cephaled as necessary to allow easy delivery of the pyloric tumor.[105–108]

Although supraumbilical skin fold incision for pyloromyotomy certainly gives a superior cosmetic result, this incision does not offer any advantage as regards postoperative feeding tolerance or duration of hospital stay. The problem with the supraumbilical incision is that it does not always allow easy access to the hypertrophic pyloric muscle. Delivery of a large pyloric tumor can be fairly difficult and

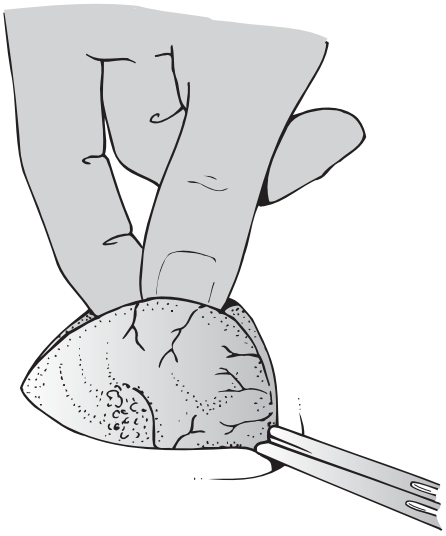

Figure 45.4 Delivery of pyloric tumor.

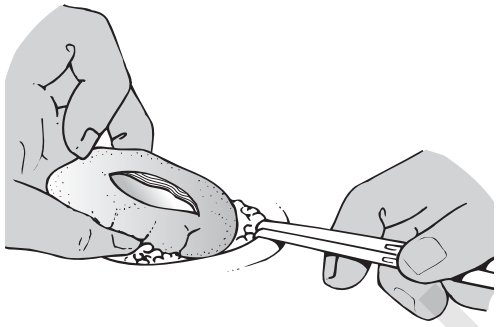

Figure 45.7 Bulging mucosa seen after complete splitting of pyloric muscle.

time consuming and may damage the serosa of the stomach or duodenum by tearing.[105] Moreover, in comparison with the transverse incision approach, some studies observed that the supraumbilical approach led to an increase in the rate of wound infection.[109]

LAPAROSCOPIC PYLOROMYOTOMY

Since 1991,[110] when the first laparoscopic pyloromyotomy was reported, there have been numerous publications supporting this approach,[104,111] and recently, single incision laparoscopic pyloromyotomy has also been reported.[112] For the laparoscopic procedure, the patient is placed in the supine position at the end of the table. A 5 mm port is placed in the umbilical fold after an open technique under direct vision. Pneumoperitoneum is established with CO_2 at maximum pressure of 6–8 mmHg. Two additional access sites are placed in the left and right mid-clavicular line just below the costal margin under direct vision with the camera. The duodenum is grasped with atraumatic forceps just distal to the pylorus olive to stabilize it. An endotome or diathermy hook is placed through the right incision and the pylorus is incised in its avascular plane from the prepyloric vein well into the gastric antrum (Fig. 45.8). The muscular layer is then separated with an endoscopic spreader (Fig. 45.9). A satisfactory pyloromyotomy is evidenced by ballooning of the intact mucosa. The absence of mucosal perforation is checked by insufflations of air in the nasogastric tube; if none is seen, the instruments and ports are removed. The umbilical fascia is closed with 4-0 absorbable suture and the skin of all the wound is reapproximated with 5-0 subcuticular absorbable sutures.[23]

Compared to open pyloromyotomy, laparoscopic pyloromyotomy is associated with significantly shorter postoperative recovery, decreased analgesia requirements, and superior cosmetic results in prospective, randomized controlled trials.[113–115] However, there is not much cosmetic advantage when compared with the umbilical approach. Moreover, laparoscopy is associated with higher frequency of incomplete pyloromyotomy: the reported incidence of incomplete myotomy is 2–8%, whereas this complication is extremely uncommon with open surgery.[113]

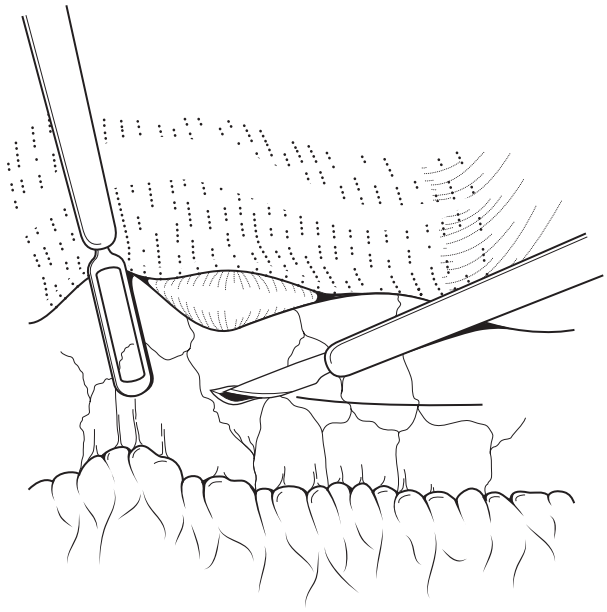

Figure 45.8 Laparoscopic incision.

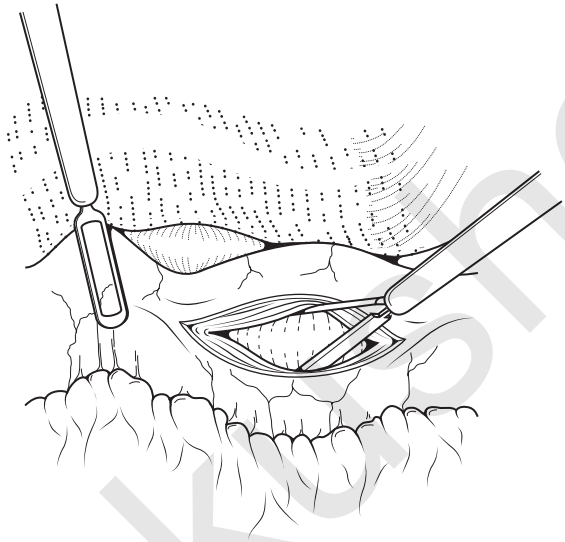

Figure 45.9 The muscular layer is separated with an endoscopic spreader.

Postoperative care

Maintenance i.v. fluids are continued postoperatively until the infant is feeding satisfactorily. The timing of reintroduction of feeds continues to be controversial.[116–119] Several studies have investigated postoperative feeding regimens for IHPS patients with respect to time of reintroduction of feeding and speed of advancement in an attempt to discover the safest and most cost-effective method. Some surgeons recommend starting oral feeds 4–6 hours after operation and gradually increasing the volume and concentration so as to resume normal feeds by the third or fourth day. Others have shown that postoperative vomiting is reduced if feeds are not started until 24 hours postoperatively. The vomiting following pyloromyotomy is usually self-limiting and independent of the timetable or composition of the postoperative dietary regimen.[119] A previous study showed that a postoperative standardized feeding regimen for patients with IHPS, where feeding was begun in the immediate postoperative period or 2–6 hours postoperatively decreased the length of hospitalization and hospital costs without adverse effects.[118]

COMPLICATIONS

Duodenal perforation is usually the result of excessive separation of fibers at the distal end of the pylorus. It is not serious provided that it is recognized and closed with one or two sutures. A patch of omentum should be brought up and tied over the wound. The need for reoperation after pyloromyotomy because of recurrent vomiting is reported with an incidence of up to 8%. Other complications included hemorrhage, wound infection, and wound dehiscence. With improvements in techniques, the incidence of complications after pyloromytomy is very low.

Gastric volvulus

ALAN E MORTELL

INTRODUCTION

Gastric volvulus is a rare, potentially life-threatening condition first described by Berti in 1866.[1] A review of the world literature in 1980 identified only 51 cases in children under 12 years of age.[2] Of these, 26 (52%) were infants and half of these were younger than one month of age. In a recent series, neonates have accounted for only 21% of cases of gastric volvulus.[3,4] In older children, gastric volvulus may be associated with neurodevelopmental handicap and splenic abnormalities but in neonates there is a strong link with diaphragmatic defects. In the last two decades, numerous descriptions of acute and chronic gastric volvulus in children have been published, bringing the total number of reported cases to more than 580.[3–8]

ETIOLOGY

Gastric volvulus may be defined as an abnormal rotation of one part of the stomach around another;[9] the degree of twist varies from 180 to 360° and is associated with closed loop obstruction and the risk of strangulation. Lesser degrees of gastric torsion are probably common, frequently asymptomatic, and are not diagnostic of volvulus. Such cases may be associated with transient vomiting in infants but spontaneous resolution is the rule.[7,10] Gastric volvulus may be either organoaxial, occurring around an axis joining the esophageal hiatus and the pyloroduodenal junction, or mesenteroaxial, around an axis joining the midpoint of the greater and lesser curves of the stomach (Fig. 46.1). The majority of patients present with organoaxial volvulus (54%) compared to mesenteroaxial volvulus in 41% and combined volvulus in only approximately 2% of cases.[3] A mixed or combined picture occurs if the stomach rotates around both axes simultaneously. The usual direction of rotation is anterior, i.e. in organoaxial volvulus the greater curve moves upwards and forwards above the lesser curve, causing the posterior gastric wall to face anteriorly. The gastro-esophageal junction and the pylorus may both become obstructed. In anterior mesenteroaxial rotation, the antrum comes to lie anterosuperior to the fundus and obstruction is usually in the antropyloric region.

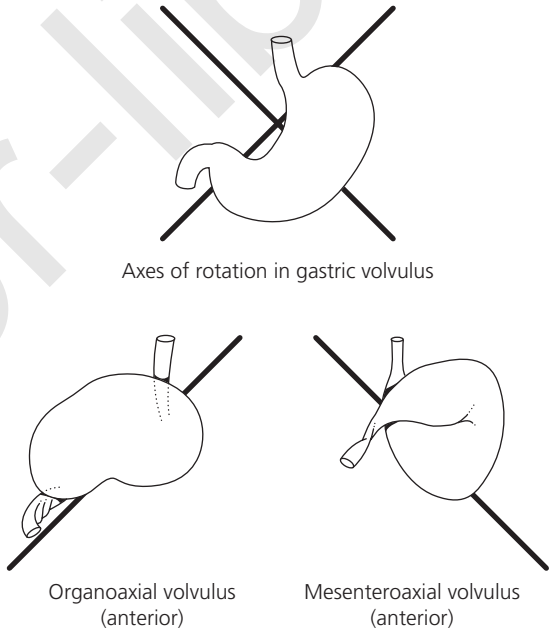

Figure 46.1 Diagrammatic representation of the main types of gastric volvulus.

Acute, complete volvulus is most often seen in infancy in contrast to chronic and partial varieties, which more often occur in older children and adults. More complex patterns of gastric volvulus have been described in neonates and infants with abnormal gastric bands or adhesions (see below under Pathogenesis), and in older children after gastrostomy[11,12] or Nissen fundoplication, performed either open[13–15] or laparoscopically.[16]

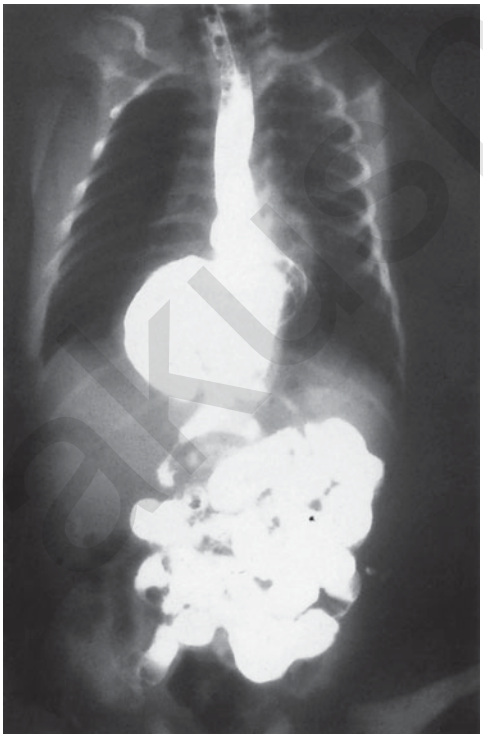
CLINICAL CASES

The following three cases illustrate different aspects of the presentation and management of gastric volvulus in infancy.

Case 1

A full-term male infant presented soon after birth with cyanotic attacks during feeding. A tracheo-esophageal fistula was initially suspected, but a plain chest x-ray (Fig. 46.2a) showed a gastric shadow lying in front of the heart and a barium swallow (Fig. 46.2b) demonstrated an organoaxial gastric volvulus within the chest. Via a left thoracotomy, the stomach was derotated and reduced into the abdomen with repair of the esophageal hiatus. A gastropexy was not performed and subsequent progress was uneventful.

(a)



(b)

Figure 46.2 (a) Plain chest radiograph showing an air-filled viscus in the chest (case 1). (b) Barium study showing the stomach lying above the diaphragm with the greater curvature uppermost (case 1).

Case 2

A full-term male infant presented at 4 days of age with intermittent vomiting. This was initially attributed to a urinary infection, but the vomiting continued and a barium meal showed that there was delayed passage of contrast into the stomach from the esophagus. When the barium was injected via a nasogastric tube, the stomach was seen to lie horizontally and to empty very slowly. At laparotomy, the pylorus was hypertrophied and the stomach was distended. The gastrocolic omentum was deficient along most of the greater curve, allowing free organoaxial rotation of the stomach. A pyloromyotomy and anterior gastropexy were performed, after which the child became symptom-free.

Case 3

A female infant presented at the age of three months with a history of loud borborygmi, inability to bring up wind after feeding, and occasional vomiting. On examination, bowel sounds were heard in the chest. Barium meal showed an organoaxially rotated intrathoracic stomach. Via an abdominal approach, a large paraesophageal hernia was reduced, followed by a crural repair and Nissen fundoplication. The child remained asymptomatic four years later.

PATHOGENESIS

The stomach is relatively fixed at the esophageal hiatus and at the pyloroduodenal junction and is also stabilized by four 'ligamentous' attachments – the gastrohepatic, gastrosplenic, gastrocolic. and gastrophrenic ligaments (Fig. 46.3). Despite these attachments, considerable changes in shape and position of the normal stomach are possible. This is highlighted by the gastric rotation that can sometimes be observed during air insufflation of the stomach at the time of laparoscopically assisted percutaneous endoscopic gastrostomy insertion.[17] Absence or attenuation of the normal anatomical anchors results in abnormal gastric mobility, which may be encouraged still further by a coexistent diaphragmatic defect. Most

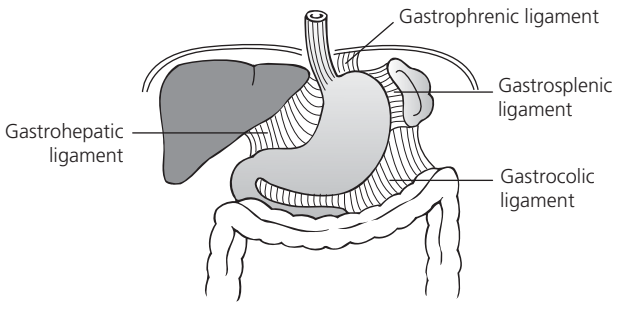


Figure 46.3 Diagrammatic view of the stabilizing gastric ligaments.

cases of gastric volvulus in the newborn are secondary to diaphragmatic defects with or without deficient ligamentous attachments.[18–24] The contribution of the gastrocolic and gastrosplenic ligaments to fixation of the stomach is demonstrated by the observation in the cadaver that their division allows 180° rotation of the normal stomach.[2,5,25]

Eventration or herniation of the diaphragm is present in about two-thirds of all children presenting with gastric volvulus.[3] However, this proportion is as high as 80% in some series of infants.[2,19] Diaphragmatic hernias are typically paraesophageal or posterolateral defects but gastric volvulus within a Morgagni hernia is also possible.[3,26] The presumed mechanism of gastric volvulus in this situation is upward displacement of the transverse colon, which pulls up the greater curve of the stomach into the expanded left upper quadrant. Acute gastric volvulus may therefore present as an early complication of diaphragmatic defects.

Gastric distension may encourage the development of gastric volvulus.[25] Infantile hypertrophic pyloric stenosis may rarely be a predisposing factor, as described in case 2 above. Two similar cases have been reported but those infants also had diaphragmatic defects.[27,28] Air swallowing can also cause gastric distension, and intermittent gastric volvulus has been reported in an aerophagic neurologically impaired child.[23]

Other rare causes of gastric volvulus in the neonate and infant include: abnormal bands or adhesions producing an axis of rotation for the stomach;[6,19,29] rectal atresia with consequent overdistension of the transverse colon;[30] congenital absence or resection of the left lobe of the liver which may promote abnormal gastric mobility;[31,32] and congenital deficiency of the gastrocolic omentum.[5,33] The asplenic syndrome (asplenia, congenital heart disease, with or without intestinal malrotation and deficiency of the gastric ligaments) is increasingly recognized as a predisposing condition.[34,35] Nakada *et al.*[36] reported gastric volvulus as a complication in three of 25 patients with asplenia, the youngest of whom was one month of age. Anchoring gastric ligaments were deficient in all cases. Because of the potentially fatal outcome of acute gastric volvulus in this situation, Okoye *et al.*[37] have recommended prophylactic gastropexy. Defective fixation and ligamentous laxity also account for the association between gastric volvulus and a wandering spleen.[38–40] Intestinal malrotation is associated with gastric volvulus, even in the absence of asplenia.[6,29,36,41]

Gastric volvulus in children may rarely arise as a postoperative complication. It has been described after Nissen fundoplication, presumably because the stomach has been extensively mobilized by division of gastrosplenic and gastrocolic attachments.[13–15,42] There is one recorded case of gastric volvulus developing after repair of a diaphragmatic hernia[19] and another as an iatrogenic complication of gastric transposition in infancy.[43]

CLINICAL FEATURES

The clinical features depend on the degree of rotation and obstruction. In adults, the triad of Borchardt is diagnostic of acute volvulus: (1) unproductive retching; (2) acute localized epigastric distension; and (3) inability to pass a nasogastric tube.[44] These features are difficult to assess in the infant and may be absent. Persistent regurgitation and vomiting (sometimes unproductive) are common, although nonspecific, presenting symptoms in the newborn. The vomitus may or may not contain bile, depending on the degree of pyloric obstruction. Hematemesis and anemia are well described and occasionally the vomiting is described as projectile. Failure to thrive and chest infections are sometimes evident.[41] Upper abdominal pain and distension may be noted in older infants and children. However, abdominal signs may be minimal if the stomach is intrathoracic, when respiratory distress and tachypnea are the dominant features.[2,20,22,45,46] Failure to pass a nasogastric tube may have several causes in the newborn and the successful passage of a tube does not exclude the diagnosis.[15,19] In neonates, confusion with esophageal atresia is possible but arrest of the nasogastric tube in the distal esophagus and radiographic abnormalities on routine films should raise suspicion and prompt investigation by contrast studies.[47] In older children, presenting symptoms may be intermittent, chronic and also non-specific.[15]

DIAGNOSIS

Plain abdominal and chest x-rays are essential. A distended stomach in an abnormal position should suggest the possibility of gastric volvulus. In mesenteroaxial volvulus, the stomach is spherical on the plain film taken with the patient in the supine position, and two fluid levels are often visible on the erect film – one in the fundus (the lower) and the other in the antrum (upper) (Fig. 46.4a); these findings may be absent if the stomach has been decompressed by a nasogastric tube. A paucity of distal bowel gas in acute volvulus can indicate gastric outlet obstruction.[48] Contrast studies clarify the anatomy (Fig. 46.4b) and the site(s) of obstruction, which is usually at the pylorus, giving a so-called 'beak' deformity.[18] Organoaxial volvulus is more difficult to diagnose on plain films (especially if there is no associated diaphragmatic defect) and may indeed be missed during a contrast study. The distended stomach lies rather horizontally on the plain film, with a single fluid level. On contrast examination, the esophagogastric junction is lower than normal, the greater and lesser curves are inverted, and the antrum and duodenum are distorted (Fig. 46.5). In the presence of a diaphragmatic defect, such as a paraesophageal hernia, the antrum may herniate into the retrocardiac position, producing a fluid level in the chest above the gastric fundus, and thus organoaxial volvulus can also rarely give rise to two fluid levels.[49] Computed tomography (CT) has been used in cases where gastric volvulus was not diagnosed on plain films; however, it should not be necessary if an upper gastrointestinal contrast study is performed and may only serve to delay treatment.[48] A CT scan can yield further information about structural abnormalities, such as splenic position or absence.

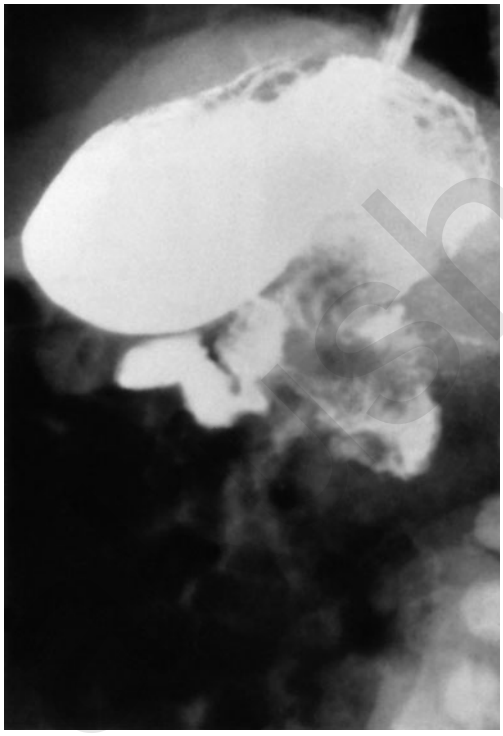

Figure 46.5 Oblique view of barium meal demonstrating an organoaxial gastric volvulus in a neonate who presented with intermittent vomiting (case 2).

TREATMENT

Acute gastric volvulus requires appropriate resuscitation and urgent surgery if ischemic necrosis and gastric perforation are to be avoided. If possible, the stomach should be decompressed preoperatively by nasogastric suction but vigorous attempts to pass a tube must be avoided because of a risk of gastric perforation.[19] An abdominal approach is recommended, even when the stomach lies in the chest, since this allows identification of any associated gastrointestinal anomalies and accurate diaphragmatic repair if required. Occasionally, preliminary needle aspiration of the stomach may be warranted before manipulating a tensely dilated stomach and reducing the volvulus.[50] Any associated diaphragmatic defect should be repaired and the stomach fixed to the anterior abdominal wall (Box 46.1).

Gastrostomy alone may be used for gastric fixation in neonates, since it provides adequate fixation, postoperative decompression, and a route for postoperative feeding. A Stamm gastrostomy using a 10 or 12 French gauge Malecot catheter secured by a double purse-string absorbable suture is appropriate (Fig. 46.6a). In infants with no predisposing diaphragmatic defect, an anterior gastropexy should be added (Fig. 46.6b). This involves suturing the greater curve of the stomach to the parietal peritoneum of the anterior abdominal wall and the under surface of the diaphragm by a series of non-absorbable sutures. There are three recorded cases of recurrence following this approach.[51,52] Fundoplication may be necessary if there is evidence of gross gastro-esophageal reflux, but several authors have achieved good results in such cases

with a crural repair alone and a more conservative approach is warranted provided the tendency to volvulus is prevented.[41,42] Diaphragmatic crural repair must be performed meticulously, as there is often a common hiatus for the esophagus and aorta in these patients.[42] There is no justification for gastrectomy, gastroenterostomy, or the colonic displacement operation described by Tanner[9] in this age group.

In older children with isolated gastric volvulus preliminary nasogastric decompression followed by a laparoscopic anterior gastropexy is an option[33] and this technique has also been reported in a neonate.[53] In gastric volvulus due to a wandering spleen, splenopexy alone may be sufficient.[54]

COMPLICATIONS

A number of complications can result from gastric volvulus including prolonged gastric ileus, pyloric ischemia, gastric outlet obstruction, gastric necrosis, and perforation.[6]

The mortality from gastric volvulus is difficult to assess with recent series reporting mortality rates of 7.1% in acute gastric volvulus compared to 2.7% in chronic cases.[6] Untreated, gastric volvulus has a mortality rate of up to 80%, highlighting the importance of prompt recognition and treatment. Deaths have been reported due to missed or delayed diagnosis, with subsequent gastric necrosis and perforation, or inadequate gastric fixation.[4,8,19,21,24]

Most recent series report uncomplicated early outcomes after surgery. One long-term follow-up study of nine infants demonstrated no recurrences or late complications.[4]

Gastric perforation

ROBERT K MINKES

INTRODUCTION

Gastric perforation in the neonatal period is rare, however it continues to be associated with significant morbidity and mortality. Spontaneous neonatal gastric perforation is estimated to occur in one in 2900 live births[1] and accounts for approximately 10–15% of all gastrointestinal perforations in neonates and children (Table 47.1). Gastrointestinal perforations occur more commonly in males, however there appears to be no sex predilection for those occurring in the stomach.[2–4] Recent series may suggest a male predominance, but this remains inconclusive.[5–7] The terminology used to describe neonatal gastric perforation has been inconsistent and its etiology remains a topic of debate. Spontaneous or idiopathic gastric perforations refer to those with no identifiable underlying cause and account for the majority of gastric perforations in most reported series.[1,3,5–13] Nevertheless, many pediatric surgeons believe that an underlying cause can be found in most cases of neonatal gastric perforation.[14]

Siebold, in 1926, is credited with the first description of a gastrointestinal perforation with no demonstrable cause, the so-named spontaneous perforation.[15] In 1929, Stern *et al.*[16] reported attempts at surgical repair. Agerty *et al.*[17] reported the first successful repair of a neonatal intestinal (ileum) perforation in 1943 and Leger *et al.*,[18] in 1950, described the first successful repair of a neonatal gastric perforation. Survival following a neonatal gastric perforation was rare prior to the 1960s. While mortality has improved since that time it remains significant and ranges from 25 to over 50% in most series.[1,2,4–7,14,19,20]

ETIOLOGY

Gastric perforations in neonates can be broadly categorized as spontaneous (idiopathic), ischemic, or traumatic; however, in many instances, the etiology may be multifactorial. Ischemia, necrosis, and perforation may occur with no obvious inciting factors.[21] Box 47.1 lists several possible causes and associations with gastric perforations. Spontaneous gastric perforations most often occur on the greater curvature.[1,21,22] Neonatal gastric perforation can occur in full-term, premature, and small for gestational age neonates. Some infants appear to have been healthy and medically stable prior to the development of the perforation, whereas others have underlying medical conditions or congenital anomalies. There are reports of intrauterine gastric perforation with no known underlying cause.[23] Unrecognized overdistension or ischemic insult may result in a perforation that is thought to be spontaneous. Ischemic perforations occur in the setting of physiologic stress such as prematurity, asphyxia, sepsis, and necrotizinig enterocolitis. The perforations are often associated with ulcerations and ischemic tissue. Traumatic perforation results from pneumatic distention during mask ventilation, positive pressure ventilation, or iatrogenic injury during gastric intubation. Several specific causes of neonatal gastric perforation have been reported including intestinal atresias, prenatal stress, trauma, exposure to corticosteroids and non-steroidal anti-inflammatory agents (Box 47.1). Several theories on the etiology of spontaneous (idiopathic) gastric perforations have been suggested but no single theory is universally accepted. Theories include congenital absence of the gastric muscle,[8,10] forces exerted during vaginal delivery,[24] and pneumatic distention.[25,26] Studies in dogs and human neonatal cadavers suggest that rupture is caused by overdistention and is in keeping with the law of Laplace.[11] With gastric distention the greatest wall tension is exerted on the fundus, the site of most spontaneous perforations. In addition, overdistension can cause ischemic changes, a finding present in many cases of perforation.[4] Recent studies suggest a deficiency of the tyrosine kinase receptor C-KIT$^+$ mast cells and a lack of C-KIT$^+$ intersitial cells of Cajal may contribute to idiopathic gastric perforation.[27,28] Mice lacking C-KIT$^+$ mast cells develop spontaneous gastric ulceration or perforation. In addition, postmortem examination of stomachs of neonates who died of idiopathic gastric perforation, revealed a deficiency in both C-KIT$^+$ mast cells and interstitial cells of Cajal when

  - indomethacin[38,54]
  - corticosteroids[39]

compared to controls. The authors suggest that these abnormalities could result in impaired immunity and abnormal motility predisposing to gastric perforation.

CLINICAL PRESENTATION

The clinical presentation of gastric perforation is variable. The majority of cases present within the first 7 days of life, however later presentations are reported.[2,6,7,12,21,22,29] The neonates are often premature or have a history of asphyxia or hypoxia.[3,4,12,20–22] Neonates may present with feeding intolerance or emesis that may contain blood. Many develop abrupt onset of rapidly progressive abdominal distension from pneumo- or hydroperitoneum.[30] These infants progress to respiratory distress, hemodynamic instability, and signs of shock, such as hypothermia, cyanosis, poor peripheral perfusion, and low urine output. The abdomen may rapidly become tense and tender with signs of peritoneal irritation. Ventilation may be impaired or ineffective until the abdomen is decompressed. Subcutaneous emphysema in the abdominal wall or pneumoscrotum may be perceived.[31,32] Infants with posterior perforations into the lesser sac may present with a more insidious course, making the diagnosis difficult.

Infants with perforation secondary to an underlying process often have evidence of the predisposing condition, such as findings of tracheo-esophageal fistula, duodenal atresia, malrotation, or diaphragmatic hernia.[3,25,33,34] In some instances, a secondary cause is found at the time of operation. In cases of iatrogenic perforation, a history of traumatic naso- or orogastric intubation, prior surgery, corticosteroid or nonsteroidal administration, and aggressive ventilation or cardiopulmonary resuscitation may be obtained.[29,35–39]

DIAGNOSIS

The diagnosis of gastric perforation is made from the clinical history, physical examination, and radiographic studies. In infants with massive pneumoperitoneum, a plain abdominal x-ray will demonstrate air under the diaphragm that extends laterally, trapping the abdominal viscera medially and producing a saddlebag appearance.[40] The stomach is not visualized by plain x-ray in 90% of cases.[41] Other plain x-ray findings include subcutaneous emphysema, pneumoscrotum, ascites, or an oro- or nasogastric tube outside the confines of the stomach. Pneumatosis intestinalis and portal venous air are signs of necrotizing enterocolitis, which may coexist with gastric perforation. Calcification and dilated loops of bowel are common findings of more distal perforation and a gasless abdomen is seen in cases of neonatal volvulus. A definitive diagnosis may not be made prior to laparotomy. A water-soluble contrast study will reveal extravasation from the stomach into the peritoneal cavity (Fig. 47.1). Ultrasound may show ascites or fluid collections. In premature infants with known lung disease, pneumoperitoneum can result from air tracking from the mediastinum. A chest film demonstrating pneumomediastinum, an air–fluid level in the stomach, a negative peritoneal aspirate, and an intra-peritoneal drain that bubbles with the ventilator cycle can help to exclude an intra-abdominal process.

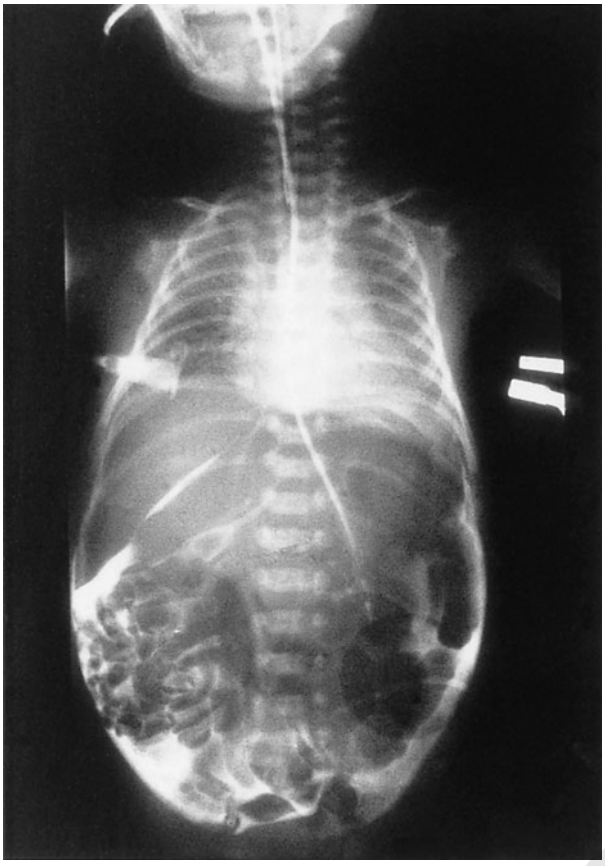

Figure 47.1 Diagnosis. Contrast study demonstrating gastric perforation. Abdominal distention, pneumoperitoneum, and contrast extravasation into the peritoneal cavity are seen. There is no evidence of lung disease and no findings suggestive of enterocolitis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis is broad and includes conditions that cause sudden deterioration in the newborn and conditions that produce vomiting and abdominal distention. Conditions causing cardiovascular collapse include sepsis, pneumothorax, cardiac dysfunction, intraventricular hemorrhage, electrolyte abnormalities, hypoglycemia, necrotizing enterocolitis, perforated viscus, and malrotation with midgut volvulus. Conditions associated with vomiting and abdominal distention include Hirschsprung's disease, intestinal atresia, meconium ileus, meconium plug syndrome, imperforate anus, perforated viscus, necrotizing enterocolitis, and midgut volvulus.

PERIOPERATIVE CARE

Infants with gastric perforation develop septic parameters and need to be resuscitated accordingly. Neonates may become unstable prior to the development of free intra-abdominal air. Infants who develop respiratory distress require intubation and increased ventilator support is needed as the abdomen becomes more distended. Appropriate laboratory investigations include blood cultures, white blood cell count, hemoglobin, hematocrit, platelet count, electrolyte profile, and blood gas analysis. Broad-spectrum antibiotics should be initiated. Fluid boluses and blood transfusions are given to achieve hemodynamic stability and adequate urine output. An oro- or nasogastric tube should be carefully passed and placed on low intermittent suction. Once free intra-abdominal air is identified, the patient is stabilized and a laparotomy should be performed. Aspiration of the peritoneum with an i.v. cannula when an overly distended abdomen is impeding ventilation can be a life-saving measure.[4]

SURGICAL TECHNIQUE

Traditionally, open exploration and repair is required. Recently, successful laparoscopic repair of neonatal gastric perforation has been reported.[42] For an open repair an upper abdominal transverse skin incision (Fig. 47.2) is made and dissection carried through the rectus muscle until the peritoneum is entered. The umbilical vein is divided. The incision can be extended as needed. Peritoneal fluid and debris are evacuated. The abdomen is explored for the site of perforation. When a perforation of the stomach is not found, careful exploration of the gastro-esophageal junction, duodenum, small bowel, and colon should be performed. The lesser sac should be opened and inspected for contamination and integrity of the posterior surface of the stomach.

The most common site of a spontaneous perforation is near the greater curvature. The perforation can be small or extensive and extend high on the stomach. For isolated perforations, the devitalized edges of the perforation are debrided back to viable tissue (Fig. 47.3). The defect is closed in one or two layers and may be reinforced with an omental patch (Fig. 47.4). Stapled closure of a perforation, as well as repair around a gastromy tube have also been successful. A variety of techniques have been used to manage extensive perforations or necrosis that requires subtotal or total gastrectomy. In a stable infant, subtotal gastrectomy can be performed with reconstruction with an esophagogastric

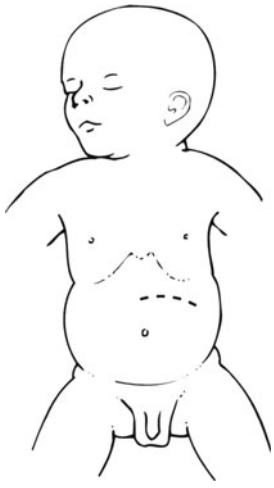

Figure 47.2 Incision. Upper abdominal transverse skin incision. The incision can be enlarged to gain access to the entire abdomen.

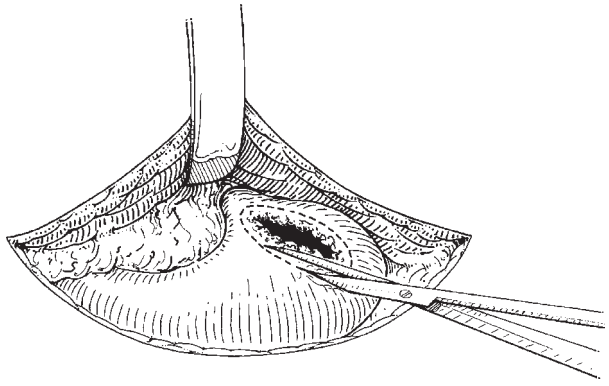

Figure 47.3 Exposure and resection. The entire perforation is exposed. A variable area of the stomach is found to be devitalized or necrotic. The edges of the perforation are resected back to bleeding viable tissue. On rare occasions, extensive resection, subtotal, or total gastrectomy are required.

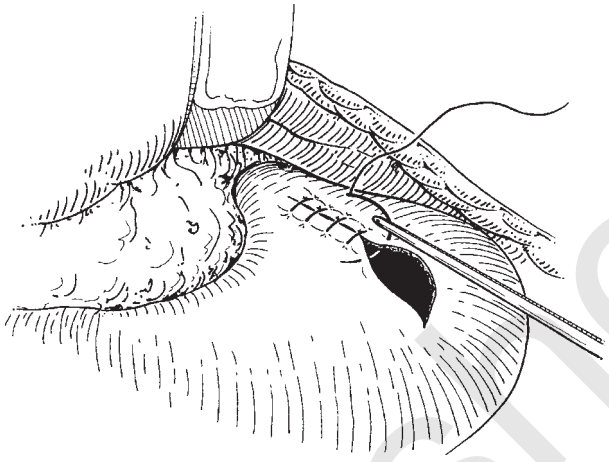

Figure 47.4 Closure. The free edges of healthy tissue are closed in one (depicted) or two layers. An omental patch may be used. Careful inspection of the posterior wall of the stomach and the entire small and large bowel should be performed to exclude additional areas of necrosis.

anastamosis.[43] Several techniques for reconstruction after total gastrectomy have been reported including transverse colon interposition, Roux-en-Y esophago-jejunal anastomosis and Hunt–Lawrence pouch reconstruction.[5,29,44] Reconstruction following total gastrectomy in an unstable neonate can be delayed and performed in stages. In the initial surgery, the esophagus is closed and a feeding tube placed distally through the distal gastric remnant or separate jejunostomy. The esophagus is decompressed and the child supported with parenteral nutrition until tube feedings can be initiated through the feeding tube. Reconstruction can be considered several weeks later when the clinical condition and nutritional status have improved.

Following repair of the perforation, the abdomen is lavaged with warm saline. Peritoneal drainage is not needed for most primary repairs but is used routinely by some surgeons. The fascia and skin are closed in standard fashion. Postoperatively, supportive and resuscitative care is continued. The child is maintained on broad-spectrum antibiotics, gastric acid suppression therapy, and total parenteral nutrition. The stomach should be decompressed. Feedings are held until the infant has stabilized. Many surgeons obtain a contrast study prior to initiating enteral feeds.

Gastrostomy

MICHAEL WL GAUDERER

INTRODUCTION

Gastrostomy, one of the oldest abdominal operations in continuous use,[1] has played an important role in the management of various surgical conditions of the neonate.[1–7] The procedure was frequently employed for feeding as well as intestinal decompression. Additionally, a combination of gastric drainage with post-pyloric feeding via a jejunal tube was most helpful in the pre-parenteral nutrition era. In the past four decades, however, improvement in surgical techniques and postoperative care has led to a more selective use of gastrostomies in patients with major congenital anomalies of the gastrointestinal tract and abdominal wall. On the other hand, there has been an increased utilization of gastrostomies in infants and children without surgical pathology. In most of these, the indication is an inability to swallow, usually secondary to central nervous system impairment. Ironically, these are often patients who have survived because of aggressive neonatal resuscitation and technological advances.

INDICATIONS

In infants, the three main indications are long-term feeding, decompression, or a combination of both modalities. Additional indications include gastric access for esophageal bougienage and administration of medications.

Nasogastric feeding tube versus gastrostomy

Because the newer 5F and 8F infant feeding tubes are highly biocompatible and remain smooth and soft for prolonged periods of time, they are usually well tolerated, even by the smallest premature infants. In general, feeding tubes should be preferred if the expected length of enteral access is up to one to two months. Beyond this arbitrary time frame, complications such as naso-otopharyngeal infections and gastro-esophageal reflux tend to increase. Gastrostomies should be considered when direct gastric access for feeding or the administration of medication is expected to last more than several months.

Nasogastric decompression tube versus gastrostomy

With careful attention to appropriate intragastric position and regular flushing, naso- or orogastric tubes generally decompress more effectively than do gastrostomy tubes. The newer 8 or 10F tubes are well tolerated for up to several weeks. The author's preference when performing gastric decompression lasting up to 3–4 weeks in newborns is a 10–20 inch (38–51 cm) long, 8F single-lumen tube. Longer tubes are prone to plugging, thus becoming ineffective. It should be remembered that most commercially available 8F tubes are designed for feeding and have only two holes. Additional holes of appropriate size should therefore be added. However, care must be taken not to make the holes too big in order to avoid kinking. These 8F tubes should be attached directly or via a short connecting tube to a spill-resistant open container and irrigated regularly. No suction should be applied to single-lumen tubes. Double-lumen (vented) catheters, such as the 10F Replogle tube, originally designed for the aspiration of saliva in patients with esophageal atresia, tend to be much stiffer and are therefore more likely to cause problems. Additionally, if the venting lumen is obstructed and suction is applied, mucosa is sucked into the holes, leading to trauma and rendering the tube ineffective.

GASTROSTOMY IN SELECT NEONATAL SURGICAL PATHOLOGY

Esophageal abnormalities

Once considered essential in the management of patients with esophageal atresia, gastrostomies are no longer employed routinely. Analysis of large series demonstrates that esophago-esophagostomy without the use of a gastrostomy is

safe[8] and may in fact be beneficial for decreasing the incidence of gastro-esophageal reflux.[9] A gastrostomy is indicated in esophageal atresia without fistula, when a difficult repair or a stormy course is anticipated, in staging procedures, and when the child has associated anomalies that may interfere with feeding. The stoma, employed for the decompression or feeding, can also be used to provide access for the management of anastomotic complications such as leakage or strictures.

Duodenal obstruction

Congenital duodenal obstruction is usually associated with proximal duodenal dilatation and atony, as well as gastric dilatation. Total parenteral nutrition and nasogastric decompression are generally effective in postoperative management. However, if the need for prolonged gastric decompression is anticipated, a valuable alternative in this setting is the placement of a fine silicone rubber catheter alongside a gastrostomy catheter, across the anastomosis and into the proximal jejunum[1,10] (Fig. 48.1). Although these tubes are at times difficult to place and maintain, this simple and time-honored technique can decrease or eliminate the need for parenteral nutrition.

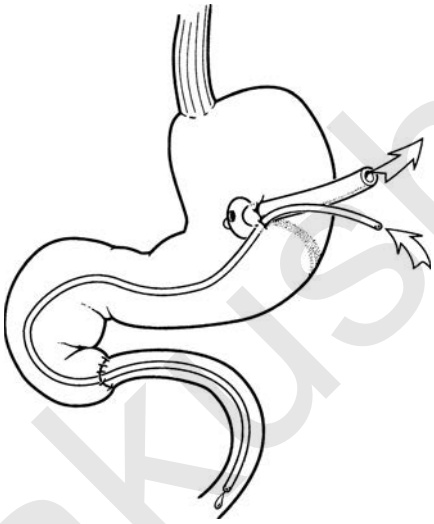

Figure 48.1 Combination gastric decompression and intrajejunal feeding, demonstrated diagrammatically in a newborn with repaired duodenal atresia.

Major abdominal wall defects

Prolonged ileus typically follows the repair of gastroschisis and occasionally other major wall defects. Although decompressive gastrostomies are not routinely employed, they can be helpful in patients with gastroschisis and associated atresia, particularly those requiring long-term continuous feeding.

Short-gut syndrome

Infants who have lost over 50% of their small bowel have profound alteration of gastrointestinal physiology. Initial gastric hypersecretion may require prolonged drainage. As the remaining intestine undergoes adaptive changes, continuous enteral feedings become necessary. As this latter process can be fairly lengthy, direct gastric access via gastrostomy is desirable.

Other surgical pathology

In any neonatal or infant condition in which a prolonged ileus or partial luminal occlusion (e.g. recurrent adhesive bowel obstruction, complicated meconium ileus, small bowel Hirschsprung's disease) is anticipated or in whom a complex feeding regimen is likely (e.g. those with intestinal lymphangiectasia), a gastrostomy can facilitate management. Gastrostomies are also helpful in some children with extra-abdominal surgical pathologies (Fig. 48.2).

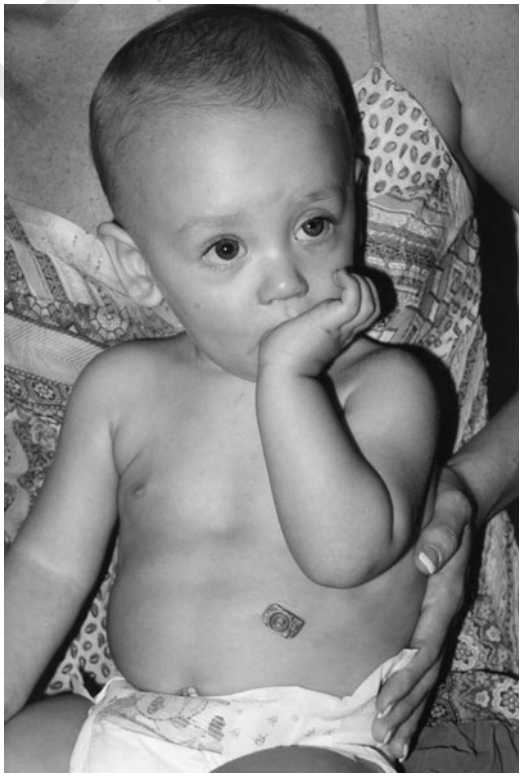

Figure 48.2 Ten-month-old child who presented with respiratory distress shortly after birth because of a large left cervical neuroblastoma. The lesion was fully resected on the 2nd day of life. However, the extensive dissection resulted in difficulty swallowing. A percutaneous endoscopic gastrostomy was placed at age 4 weeks and swallowing therapy initiated. Normal feeding gradually returned, and a few weeks after this picture was taken the gastrostomy could be removed. The only residual side effect is a left-sided Horner's syndrome.

'Non-surgical' pathology

The number of pediatric patients with an inability to swallow referred to the surgeon for the placement of a gastrostomy continues to increase. The main indications in infants are swallowing difficulty secondary to central nervous system lesions as well as other abnormalities of deglutition, feeding supplementation, large volume medications, and chronic malabsorption syndromes. Because the neurologically impaired children frequently have foregut dysmotility and gastro-esophageal reflux in addition to swallowing difficulties, anti-reflux procedures are at times added to gastrostomies. The question of whether to use gastrostomy only or gastrostomy plus an anti-reflux procedure continues to be a subject of considerable debate.[11,12]

ADVANTAGES AND DISADVANTAGES OF GASTROSTOMIES

Direct access to the stomach provides the surgeon with valuable perioperative access for drainage of air or fluids, a reliable long-term source of intermittent or continuous administration of nutrients, or a combination of both. As stated, nasogastric tubes tend to drain better than gastrostomies in the immediate postoperative period. However, a gastrostomy can eliminate the need for long-term naso- or orogastric intubation and the complications associated with placement and maintenance of these tubes. Gastrostomies interfere less with oral feedings than do nasogastric tubes, although the newer, smaller catheters are better tolerated. Gastrostomies are preferred over jejunostomies because the latter are less physiological and more prone to mechanical complications.[1]

The disadvantages of gastrostomies in the neonatal period include: the need for an operative intervention with or without laparotomy; the observation that the procedure is not always simple, particularly if the child has associated anomalies; and the observation that gastrostomy placement may interfere with gastric emptying and increase the incidence of gastro-esophageal reflux.[1,9] It has also been recognized that both nasogastric tubes and gastrostomies may promote gastric colonization with bacteria. Gastrostomies, as well as any other enteral tubes placed in infants, are associated with a long list of potential early and late complications.[1,13–18]

TECHNIQUE

There are multiple approaches to construct a gastrostomy. These techniques and their many variations are based on three fundamental principles:

1. Formation of a serosa-lined channel from the anterior gastric wall around a catheter. This catheter is placed in the stomach and exits either parallel to the serosa as in the Witzel technique, or vertically as in the Stamm or Kader approaches.[1,19]
2. Construction of a tube or conduit from a full-thickness gastric wall flap, leading to the skin surface. A catheter is then introduced intermittently for feeding. Several different configurations of the gastric wall flap have been described.[1,19]
3. Percutaneous techniques, i.e. without laparotomy, in which the introduced catheter holds the gastric and abdominal walls in apposition, with or without the aid of special fasteners.[1,19]

The Stamm technique, illustrated here, is the most widely employed gastrostomy with laparotomy in the neonatal setting, either as an isolated intervention, or when employed in conjunction with another intra-abdominal procedure. It can be used in children of any size and even on the smallest stomach (e.g. in newborns with esophageal atresia without fistula). A standard gastrostomy tube or a skin-level device can be placed under local anesthesia, although general anesthesia is preferred because abdominal wall relaxation is required. The procedure is usually short. After the tract is well healed, this stoma is suitable for the passage of dilators or guide wires.

The construction of a gastric wall tube is difficult in very young children. For a variety of reasons, this approach is not appropriate for newborns.

The first of the gastrostomies without laparotomy was the percutaneous endoscopic gastrostomy (PEG), initially developed for high-risk pediatric patients. The diagrams represented follow the initial description of the 'pull' PEG.[20] It has been employed in neonates weighing as little as 2.5 kg, usually for the purpose of long-term enteral feeding.[13–21] Although there is no need for abdominal wall relaxation, general endotracheal anesthesia is employed in this age group so that the airway is protected from compression during endoscopy. The procedure is very short and there is no postoperative ileus, no potential for bleeding or wound disruption and only minimal interference with subsequent interventions on the stomach, such as a fundoplication. The main disadvantage of this and other pure endoscopic techniques is that the virtual space between the stomach and the abdominal wall cannot be visualized. This shortcoming can be overcome by the addition of laparoscopic control.[22,23] Although in the typical PEG a long tube is initially employed, a primary insertion of a skin-level device is also possible.[24,25]

Several other methods of gastrostomy without laparotomy have been introduced and most are suitable for newborns. One of these is the percutaneous endoscopic 'push' technique which is performed with the aid of needle-deployed gastric anchors or 'T' fasteners, and the Seldinger method of guidewire introduction followed by progressive tract dilatations. A long tube or skin-level gastrostomy device is then inserted.[26] A similar approach is used by interventional radiologists and found to be suitable for even very small stomachs.[27–30]

In the last couple of decades, minimally invasive, laparoscopically aided approaches have been introduced. These are essentially expansions of the above methods, significantly increasing the choices of gastric access techniques available to surgeons managing infants.[31–36] Studies

comparing various techniques have been recently published.[37] One of the most widely employed laparoscopically aided gastrostomies is illustrated below. For infants with an abnormal epigastric anatomy, in whom the above techniques are difficult or impossible to perform, a hybrid procedure employing a mini-laparotomy and the PEG principle was developed.[38]

Stamm gastrostomy

The child is placed on the table with a small roll behind the back. When possible, a nasogastric tube is inserted for decompression and to help identify the stomach, if necessary. A small transverse incision is made over the left upper rectus abdominis muscle (Fig. 48.3). This incision should be neither too high, because it would bring the catheter too close to the costal margin, nor too low, avoiding the colon and the small bowel. A short vertical incision is an alternative. However, this approach is less desirable because the linea alba is the thinnest area of the abdominal wall. Bleeders are simply clamped. Fascial layers are incised transversely and the rectus muscle retracted or transected. When identification of the stomach is not immediate, downward traction of the flimsy greater omentum readily allows visualization of the transverse colon and stomach.

The site of gastrotomy placement on the anterior gastric wall is critical in infants. A position midway between the pylorus and the esophagus is chosen (Fig. 48.4). The site should be neither too high, because this would interfere with a fundoplication should one be needed in the future, nor too low, because stomas at the level of the antrum are prone to leakage and pyloric obstruction by the catheter. The surgeon must not place the catheter too close to the greater curvature, to avoid the so-called gastric pacemaker and to minimize the potential for gastrocolic fistula.[1]

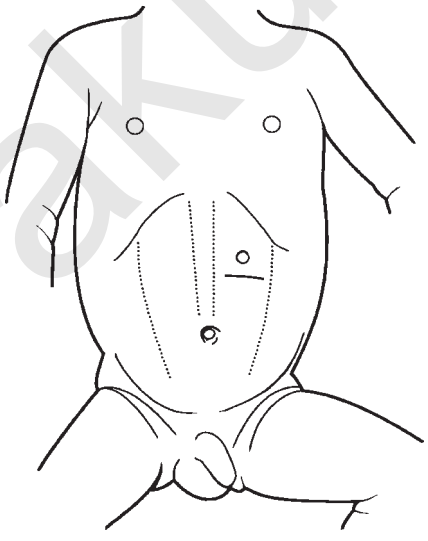

Figure 48.3 Gastrostomy incision and catheter exit site. An alternative is a short vertical midline incision.

The anterior gastric wall is lifted with two guy sutures (4-0 silk) at the site of the stoma, ensuring that the posterior wall is not included (Figs 48.4–48.7). A concentric purse-string suture (4-0 synthetic, absorbable material) is placed (Figs 48.4–48.6). The gastrotomy, at the center of the purse string, is made sharply through the serosa and muscular wall of the stomach.

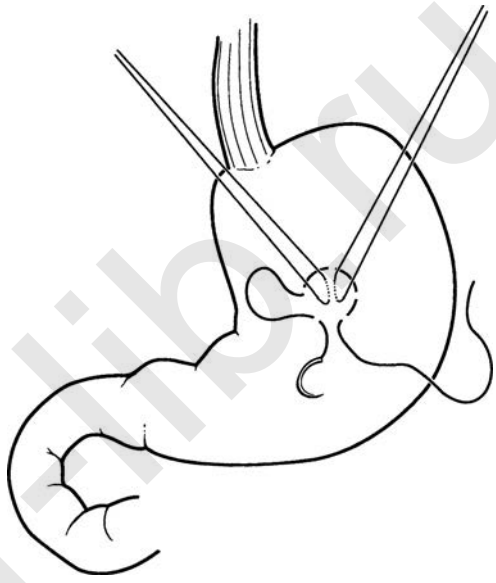

Figure 48.4 Gastrotomy site on the anterior gastric wall. The traction guy sutures and the purse-string suture are shown.

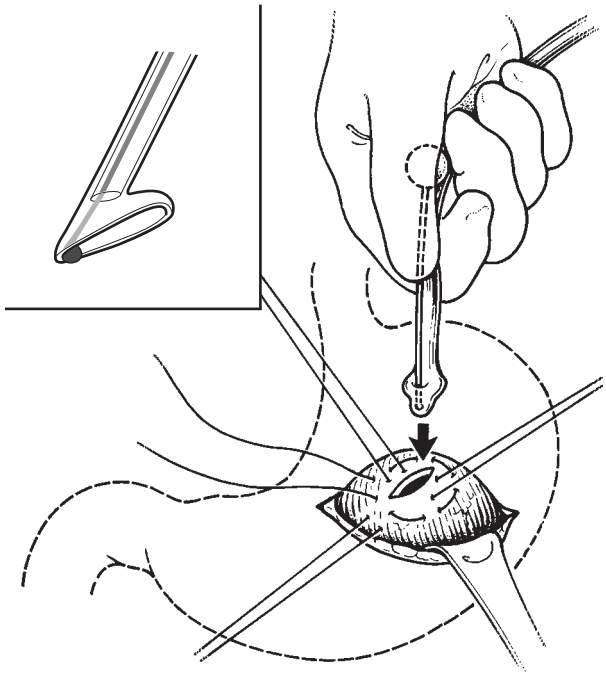

Figure 48.5 Introduction of a de Pezzer catheter using a simple stylet. The inset shows insertion of a percutaneous endoscopic gastrostomy-type catheter. Reproduced with permission from Ref. 19.

A small hemostat is introduced to confirm access into the gastric lumen. We prefer a mushroom-type catheter (de Pezzer), sizes 12–14 Fr gauge, for neonates. The mushroom head of the catheter is stretched with a short stylet to allow atraumatic introduction into the stomach (Fig. 48.5). The purse string is tied to invert the seromuscular gastric wall around the tube (Fig. 48.6). Other suitable catheters are the Malecot or the 'T' tube, but both have the disadvantage of becoming more easily dislodged. However, a short 'T' tube is useful if the stomach is very small. It is also our preferred tube for infant jejunostomies. We avoid the Foley or balloon-type catheters because the main lumen is proportionately smaller and the balloon occupies more intragastric space. Long balloon-type catheters, which may rupture, also have a greater propensity for distal migration into the small bowel. Skin-level devices (buttons or balloon-type) may be inserted during the operation, instead of the traditional long tubes.[19] The exit site for the catheter should be through the mid-portion of the rectus muscle about 1–2 cm above or below the laparotomy incision (Figs 48.3, 48.7, and 48.8). Although some surgeons bring the catheter out by way of the primary abdominal incision, wound complications that may occur in this setting tend to be more complex.[1] Once the exit site is chosen, the anterior gastric wall is secured to the posterior aspect of the anterior abdominal wall with four equidistant sutures or, as illustrated, with a continuous suture of double-ended 4-0 synthetic monofilament thread (Figs 48.6 and 48.7).[21] The catheter position is tested by injecting and aspirating saline. Gentle traction on the catheter ensures that its intragastric position is maintained.

The posterior rectus sheath is closed with a running suture of 4-0 absorbable, synthetic material. The anterior rectus sheath is approximated with interrupted sutures of the same material. The subcutaneous layer is closed with a couple of 5-0 or 6-0 synthetic, absorbable sutures. The skin can be approximated with either interrupted or continuous 5-0 or 6-0 subcuticular sutures. Adhesive strips cover the incision (Fig. 48.8). The catheter is firmly secured with two sutures of 3-0 or 4-0 synthetic, monofilament thread. These sutures are removed after 1 week and a small cross-bar is placed loosely to prevent distal catheter migration. Occlusive dressings are not used after the first couple of postoperative days. Conversion of a long tube to a 'button' can be performed after a firm adherence between gastric and abdominal wall is established.

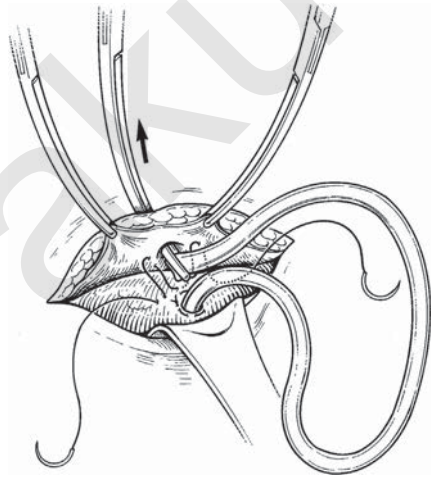

Figure 48.6 The purse-string suture is tied. The continuous monofilament suture, used to anchor the stomach to the anterior abdominal wall, has been partially placed. The catheter is brought out through the counter-incision. Reproduced with permission from Ref. 19.

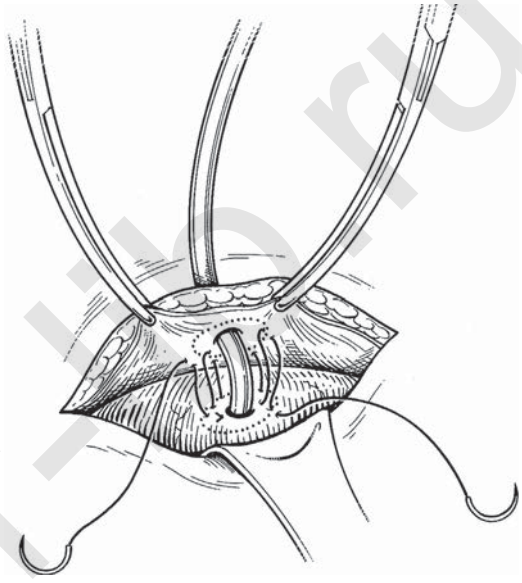

Figure 48.7 The continuous monofilament suture placement is continued anteriorly and then tied. This provides a 360° fixation of the stomach to the anterior abdominal wall with a watertight seal. Reproduced with permission from Ref. 19.

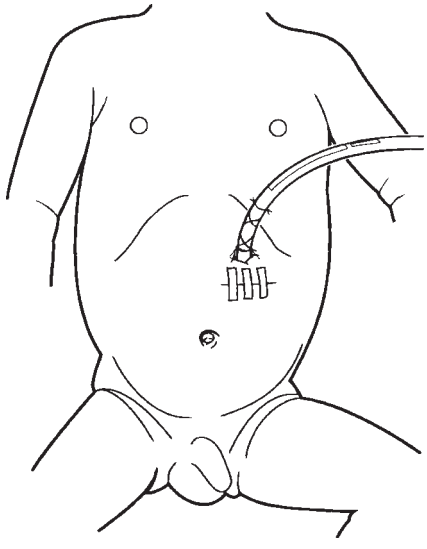

Figure 48.8 Completed procedure. The subcuticular closure, adhesive strips, and secured gastrostomy catheter are shown. The immobilizing sutures are removed after several days and a small cross-bar is placed to prevent distal catheter migration. An alternative is the placement of a 'button' or a balloon-type skin-level device, instead of a long tube, at the initial procedure.[19]

Percutaneous endoscopic gastrostomy

The PEG technique, as initially described,[20] is applicable to neonates and small infants.[21] The procedure must, however, be done with great precision and endoscopic skill. PEG incorporates four basic elements:

1. Gastroscopic insufflation brings the stomach into apposition to the anterior abdominal wall (Fig. 48.9).
2. With the stomach apposed to the abdominal wall, a cannula is introduced percutaneously into the gastric lumen under direct endoscopic guidance (Fig. 48.10).
3. This cannula serves as access to introduce a guide-wire, which is then withdrawn out of the patient's mouth with the gastroscope (Fig. 48.11). A tract is thus established.
4. A PEG catheter with a tapered end is attached to the oral end of the guide-wire and pulled in a retrograde fashion until it assumes its final position, keeping the stomach firmly apposed to the abdominal wall (Fig. 48.12).

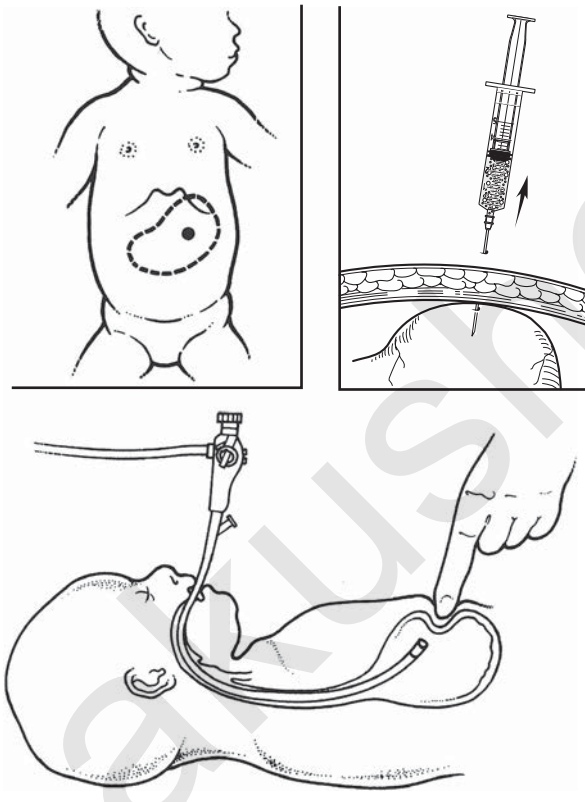

Figure 48.9 Percutaneous endoscopic gastrostomy (PEG). The air insufflated through the endoscope approximates the stomach to the abdominal wall and displaces the colon caudally. Digital pressure is applied to the proposed gastrostomy site, which usually corresponds to the area where transillumination is brightest. Transillumination and clear visualization of an anterior gastric wall indentation are key points. Without these, an open or laparoscopic technique should be employed. Long-lasting local anesthetic is drawn into a syringe and the proposed PEG site injected. The needle is advanced further and continuous aspirating pressure is applied to the plunger. Air aspiration should only occur when the tip of the needle enters the gastric lumen. Reproduced with permission from Ref. 19.

Although there are multiple variations of the original PEG technique[1,20,22–26] and several types of catheters, one must be cautious, because most of these are not suitable for use in infants. We employ a 16 Fr gauge (or smaller) commercially available silicone rubber pediatric PEG catheter. Larger, stiffer catheters, or those with a stiff, non-collapsible inner retainer, can easily tear the infant's esophagus.

A single dose of an i.v. broad-spectrum antibiotic is administered at the outset. The child remains in the supine position throughout the procedure. The abdomen is cleansed and sterilely draped. Gastroscopy is performed with the smallest pediatric gastroscope available. The scope is inserted and advanced slowly into the stomach, at which point the light is seen through the left upper quadrant abdominal wall. With the gastroscope in place, insufflation distends the stomach, apposes it against the anterior abdominal wall, and displaces the colon downward. When the room lights are dimmed, the gastric contour is clearly visible, particularly in small children.

The preferred gastrostomy site is over the mid-portion of the left rectus muscle, as depicted in the inset of Figure 48.9. Digital pressure is exerted at this site, and this is seen by the endoscopist as a 'polypoid lesion' or 'mound' on the anterior gastric wall. (Gastric transillumination and endoscopically visualized digital indentation of the stomach are the most important factors in safe PEG placement.) The endoscopist

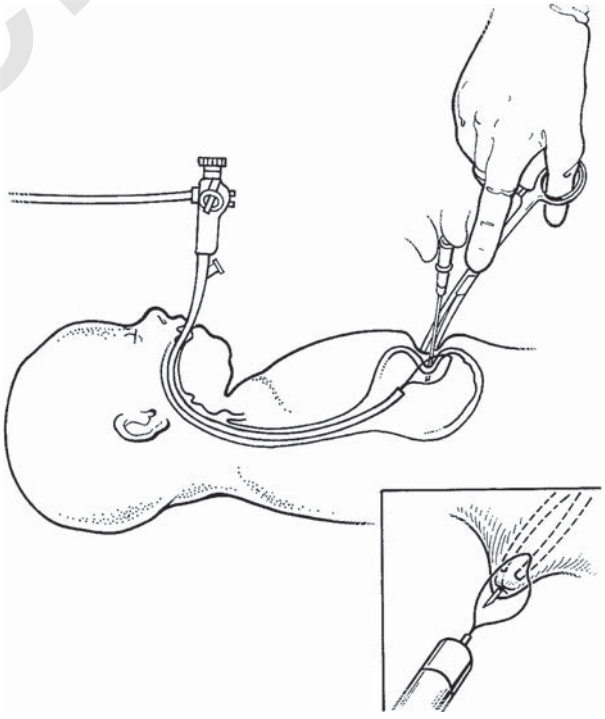

Figure 48.10 A small skin incision is made and a Kelly-type hemostat applied to maintain the intragastric indentation. The endoscopist places the polypectomy snare around the 'mound', the cannula is introduced between the slightly spread prongs of the hemostat and then thrust through the abdominal and gastric walls into the open snare. The snare is partially closed, but not tightened around the cannula. Reproduced with permission from Ref. 19.

then places an endoscopic polypectomy snare around this invagination of the anterior gastric wall. Digital pressure is released and a 0.5–0.7 cm skin incision is made. A hemostat with slightly opened prongs is placed in the incision, recreating and maintaining the intragastric 'mound' (Fig. 48.10). Through this incision and through the prongs of the hemostat, a 16-gauge, smoothly tapered, i.v. cannula and needle are thrust through abdominal and gastric walls under endoscopic visualization. This should be performed quickly to avoid displacing the stomach from the abdominal wall. The snare, if properly positioned initially, will be around the advancing cannula. If not, it can be maneuvered to encircle the cannula. A long, monofilament synthetic suture or a plastic-covered steel guide-wire is then advanced through the cannula and grasped by the snare (Fig. 48.11). If there is difficulty with the snare, a biopsy or alligator-type forceps may be used. As the gastroscope and snare are withdrawn, the suture is brought out of the patient's mouth (Fig. 48.11, inset). The previously selected PEG catheter is then connected to the suture outside the patient's mouth and both suture and catheter are coated with a water-soluble lubricant. Traction on the abdominal portion of the suture or guide-wire pulls the catheter in a retrograde fashion, through the mouth, esophagus, and stomach, and across the abdominal wall (Fig. 48.12). The gastroscope is reintroduced to verify the catheter position under direct vision. While re-endoscopy might theoretically be unnecessary, we believe it adds safety to the procedure.

Traction on the catheter is continued until the inner catheter retainer or 'dome' loosely touches the gastric mucosa (Fig. 48.12). Markings on the commercially available catheters, or markings added to tubes without marks, are helpful in indicating the final position of the tube. The external cross-bar is then placed (Fig. 48.12). Excessive pressure by the external cross-bar on the abdominal wall will produce pressure necrosis and eventual catheter extrusion, and should be avoided. The tapered catheter end is cut off and a connector attached. Tape is used for temporary catheter immobilization. Although the tube can be used immediately, we have arbitrarily placed it to gravity drainage for the first 24 hours and instituted tube feedings the day after the procedure. The catheter may be converted to a skin-level device by using the external port valve at any time. To replace the PEG catheter with a 'button' or balloon-type skin-level device, we find it is prudent to wait until firm adhesions between the stomach and abdominal wall are established. This may take one to two months or longer.

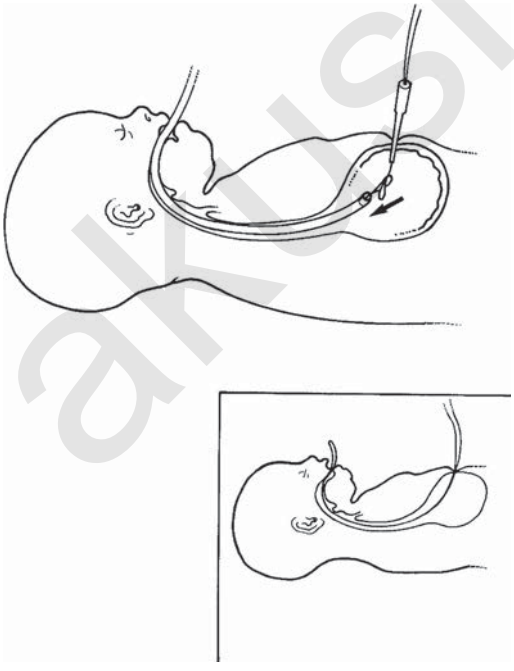

Figure 48.11 The needle is removed and the guide-wire inserted. The polypectomy snare grasps the guide and exits it through the mouth. An alternative to the polypectomy snare is an alligator or biopsy forceps. Reproduced with permission from Ref. 19.

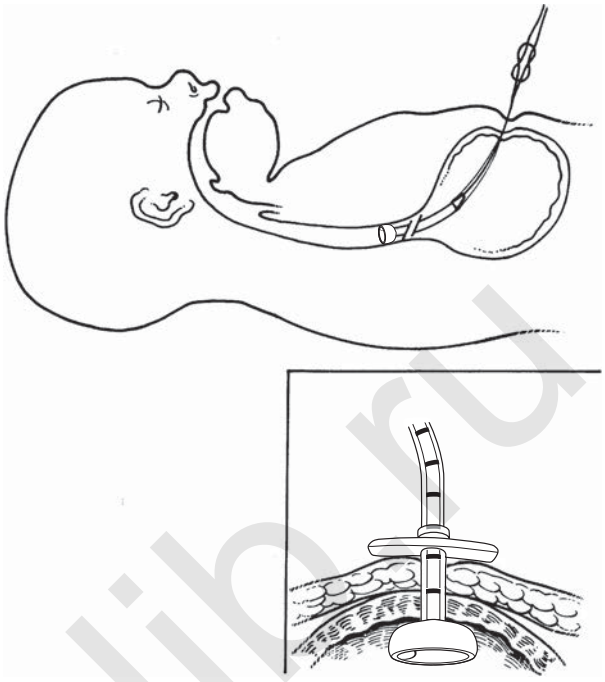

Figure 48.12 The appropriate size percutaneous endoscopic gastrostomy catheter is attached to the oral end of the guide-wire and pulled in a retrograde manner through the infant's esophagus and stomach, then across gastric and abdominal walls. The inset shows the position of the catheter at the end of the procedure. Reproduced with permission from Ref. 19.

Laparoscopically assisted gastrostomies

Direct visualization by a laparoscope expands the options for constructing a gastrostomy.[31–36] Several approaches have been described. In addition to the videoscopically controlled PEG, the two most common methods are adaptations of the Stamm technique and modifications of the 'push' PEG. Our preference is for the latter because, in order to place a purse-string suture through the exposed segment of the anterior gastric wall, the trocar site must be sufficiently enlarged. This may predispose the site to leakage. In order to

temporarily anchor the stomach to the abdominal wall, different approaches may be employed, notably T-fasteners and U-stitches. The most suitable site for the gastrostomy is selected in the left upper quadrant and marked. A nasogastric tube is inserted. Pneumoperitoneum is established in the child's size-appropriate manner, a trocar is placed at the umbilicus and the laparoscope is introduced. A needle is pushed through the previously marked abdominal wall site and the appropriate relation between the anterior gastric wall and the stoma site established. A small skin incision is made and a 5 mm trocar inserted. A grasper is introduced and the gastrotomy site on the anterior gastric wall is lifted toward the parietal peritoneum (Fig. 48.13). A U-stitch is passed through the abdominal wall, through the anterior gastric wall, and back out through the abdominal wall. A second U-stitch is passed parallel to the first one, 1–2 cm apart (Fig. 48.13). The sutures are lifted, maintaining the stomach in contact with the abdominal wall. The grasper and the trocar are removed. The stomach is insufflated with air through the nasogastric tube and a needle is inserted through the trocar site into the gastric lumen, between the two U-stitches. A Seldinger-type guide-wire is passed through the needle into the stomach (Fig. 48.14). The tract is dilated over the guide-wire to the size required to insert either a Foley-type catheter or a balloon-type skin-level device. These are placed over the same guide-wire. Stiffening of the catheter shaft with a thin metallic dilator is helpful. The previously placed U-stitches are tied over the wings of the 'button' (Fig. 48.15). If a long tube is placed, a pair of bolsters is employed. Care must be taken to avoid excessive tension. In a recently described technique, the U-stitches are replaced by a continuous suture.[39]

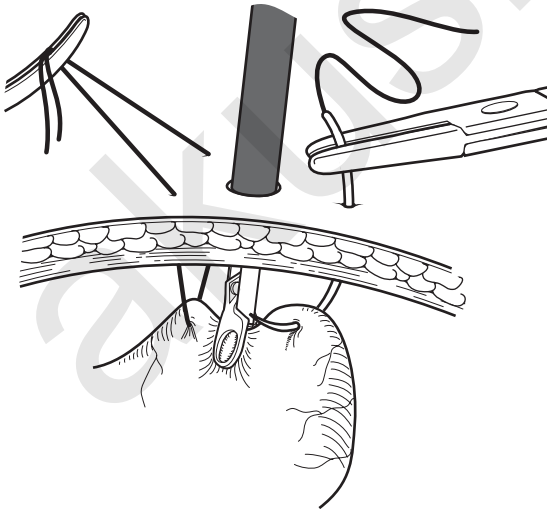

Figure 48.13 Laparoscopically assisted gastrostomy. Following the establishment of pneumoperitoneum and insertion of a trocar at the gastrostomy site, a grasper is introduced and the appropriate portion of the anterior gastric wall is lifted. Two sutures are placed in the manner shown. Reproduced with permission from Ref. 19.

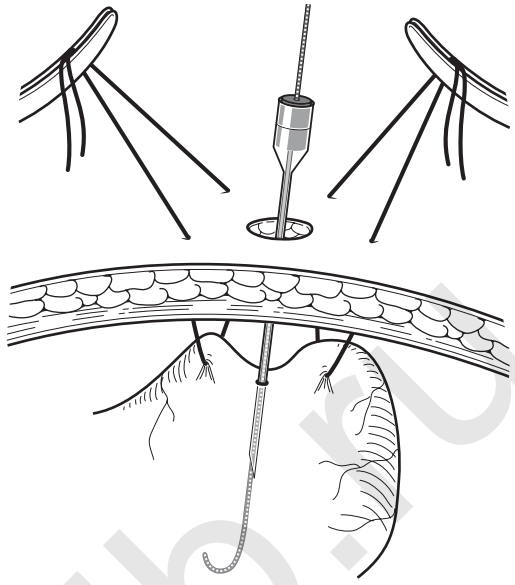

Figure 48.14 The stomach is insufflated with air through the nasogastric tube and a needle is inserted through the trocar site into the gastric lumen, between the two U-stitches. A Seldinger-type guide-wire is passed through the needle into the stomach. The tract is dilated over the guide-wire to the size required to insert either a Foley-type catheter, a balloon-type skin-level device, or other low-profile access device. These are placed over the same guide-wire. Reproduced with permission from Ref. 19.

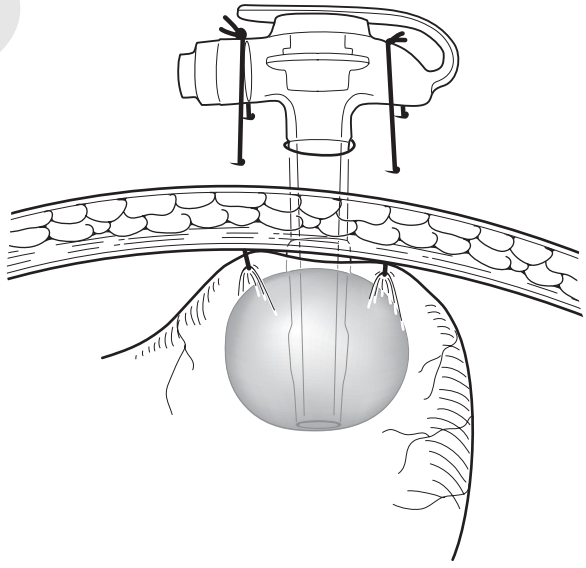

Figure 48.15 A balloon-type 'button' has been placed. The previously placed U-stitches are tied over the 'wings' of the skin-level device. Reproduced with permission from Ref. 19.

SELECT COMPLICATIONS OF GASTROSTOMIES

Although frequently considered a simple procedure and often delegated to a junior member of the surgical team, a

gastrostomy has a considerable potential for early and late morbidity, particularly among neonates.

Complications related to operative technique

SEPARATION OF STOMACH FROM ABDOMINAL WALL

This serious mishap most commonly occurs after early gastrostomy tube reinsertion, before a firm adhesion between gastric and abdominal walls has occurred. However, it can also occur at any time thereafter. During the attempt to replace a dislodged catheter, the stomach is pushed away from the abdominal wall; that displacement leads to a partial or complete separation of the stoma. If recognition of the problem is delayed, severe peritonitis and death may result.[1,2,5,6,13–16] To avoid this and other mechanical problems, the stomach must be firmly anchored to the anterior abdominal wall and the catheter well secured to the skin, particularly with the open, Stamm-type techniques. In the event of early removal or dislodgement of the tube, the tract can be gently probed and a thin Foley catheter inserted. This must be followed by injection of a radio-opaque contrast material under fluoroscopy to ensure an intragastric position of the tube and absence of intraperitoneal leakage. If there is any question about the position of the catheter, prompt exploration is necessary.

WOUND SEPARATION, DEHISCENCE, AND VENTRAL HERNIA

These are usually the result of technical problems and carry high morbidity and mortality rates.[1,3,5,6] Leakage from an enlarged incision can be life threatening.[3] Such mishaps can be minimized by the use of appropriate, small incisions and by bringing the tube out through a counter-incision. These complications will not occur after a PEG, or a laparoscopic gastrostomy, because there is no laparotomy.

HEMORRHAGE

Major bleeding is described in pediatric series[4,6] and is usually related to inadequate hemostasis at the time of catheter insertion. Gentle traction on the catheter can control the bleeding, but reoperation may become necessary.

INFECTION

This complication can occur with any type of gastrostomy.[1,3–5,13–18] Although usually limited to the skin and subcutaneous tissue, it can lead to full-thickness abdominal wall loss. Infections are less common following PEG placement[8] or laparoscopic gastrostomy and can usually be avoided through the use of prophylactic antibiotic administration and a skin incision only slightly larger than the diameter of the tube.

INJURY TO THE POSTERIOR WALL OF STOMACH

The posterior gastric wall can be damaged or perforated not only during the initial procedure,[33] but also later during catheter change.[1] Once the tube is introduced, air or saline should be injected to test the tube's position and function.

INJURY TO OTHER ORGANS

During open procedures, damage to the liver and spleen can occur through the improper use of retractors or other instruments. The distended colon may be mistaken for the stomach, particularly in patients with intra-abdominal adhesions in whom mobility of intestinal loops is limited.

GASTROCOLIC FISTULA

Although it can occur with any gastrostomy, this complication is more likely with the percutaneous endoscopic techniques.[1,13] With proper technique however, this problem should be rare. During the PEG procedure, the importance of appropriate gastric insufflation with downward colonic displacement, transillumination, and the indentation on the anterior abdominal wall cannot be overemphasized. On the other hand, overinflation must be avoided because it can distort the local anatomy, including the position of the colon. Additionally, air-filled small bowel loops will displace the colon cranially and move it between the stomach and the abdominal wall.

Complications related to care of stoma

SKIN IRRITATION AND MONILIASIS

Next to granulation tissue, these are the most frequent problems encountered. Usually related to leakage, and compounded by occlusive dressings, irritation is best prevented by avoiding any occlusive devices, including nipples, tape, or gauze pads.[1] The site should be kept open and dry at all times. Ointments and other solutions, except for the treatment of moniliasis, should be avoided. Catheters, if kept long, can be immobilized with a small external cross-bar.

TUBE PLUGGING

Catheters must be flushed with water after each feeding to prevent blockage. In neonates, the amount should be small and added to the fluid intake.

ADMINISTRATION OF IMPROPER FEEDINGS

Careful and slow administration of the appropriate nutrient prevents metabolic abnormalities, as well as diarrhea and excessive reflux.

DELAY IN THE REINTRODUCTION OF A DISLODGED CATHETER

Accidental dislodgement of long gastrostomy catheter is fairly common. The catheter must be replaced before the tract closes, which can be in a few hours unless it is well matured and epithelium lined. Careful dilation of the tract is usually successful.

TRAUMA DURING REINSERTION OF CATHETER

Improper catheter reintroduction can lead to damage to the pancreas, liver, or spleen, particularly if long stylets or other traumatic instruments are used to elongate a mushroom-type tip. Small children are more prone to this complication, given the short distance of these organs from the abdominal wall. Gentle insertion and aiming toward the gastric cardia or fundus is the method least likely to project injury.

Complications related to catheters

GRANULATION TISSUE

This is by far the most frequent problem associated with gastrostomies. Usually, granulation tissue formation is mild, and a few applications of silver nitrate are curative. If this condition is neglected, however, granulation tissue will predispose to leakage, bleeding, and chronic discharge. With excessive growth, excision and cauterization become necessary. Granulation tissue formation will cease once epithelialization of the tract has occurred. We have found that a cream combining an antifungal and a steroid preparation helps to minimize the formation of this abnormal tissue.

LEAKAGE

Severe continuous leakage is uncommon in properly constructed gastrostomies.[1,3] However, severe widening of the stoma can lead to skin excoriation, dislodgment of the tube, metabolic imbalance, and even death.[1,3] The main cause of leakage in most children is enlargement of the stoma by the pivoting motion of the gastrostomy tube, which is often too large or too stiff.[1] Catheters brought through the incision or the thinner midline are more prone to this problem. Management of leakage begins with control of granulation tissue and placement of a smaller, softer catheter to avoid pivoting motion. A variety of other methods have been tried with varying degrees of success.[1] In extreme cases, reoperation or stoma relocation becomes necessary.

INTERNAL MIGRATION

Distal migration of a long catheter producing high intestinal obstruction is a well-known problem.[1,3,5] It can occur with any gastric tube, but is particularly common with long, balloon-type catheters.

EXTERNAL MIGRATION

Overzealous approximation of external immobilizing devices, such as the bumper, can lead to embedding of the inner cross-bar of a PEG catheter, mushroom tip, or balloon in the gastric and abdominal wall.[1] The usual presentations are malfunction with limited flow, leakage, lack of to-and-fro motion of the catheter, or the formation of an abscess. The catheter should be removed and replaced. This problem can be avoided by giving the catheter enough 'play', i.e. a little to-and-fro motion.

PERFORATION OF ESOPHAGUS AND SMALL BOWEL

The balloon of a Foley-type catheter can be accidentally inflated in the esophagus[40] or small bowel,[41] leading to wall disruption.

PERSISTENT GASTROCUTANEOUS FISTULA

In the longstanding gastrostomy, an epithelium-lined channel will form. Although most stomas close spontaneously after a few days, excision of the tract with simple closure is indicated if drainage persists after several weeks.[1]

Prevention

A long list of additional complications is recorded, and these can be particularly dangerous in the newborn age group.[1,3–7,13–18] Most of the common gastrostomy care-related problems can be prevented with meticulous attention to detail during placement and subsequent follow up.[15] The use of skin-level devices such as the original gastrostomy button,[1,42] the balloon-type versions, or the externally placed port-valve[43] has dramatically decreased the most common problems associated with older, long tubes. Many techniques, whether open, endoscopic, or laparoscopically aided, now permit the initial placement of one of these well-tolerated skin-level devices (Figs 48.16 and 48.17).

CONCLUSION

Although gastrostomy is a basic and fairly simple procedure, the surgeon must carefully consider the advantages versus disadvantages when using it in conjunction with another major intervention in the newborn. If the gastrostomy is used for long-term enteral feeding, careful consideration must be given not only to the often difficult ethical problems encountered in some neonatal patients, but also to the duration of these enteral feedings, potential complications, and the problem of gastro-esophageal reflux. These children benefit from a team approach, including the neonatologist, pediatric surgeon, pediatric gastroenterologist, primary nurse, and nutritionist. It is also paramount that the parents or caregivers be an integral part of the decision-making process at the different stages of management. Long-term

Figure 48.16 Completed percutaneous endoscopic gastrostomy and tracheostomy in a four-month-old child, weighing 3.5 kg, with poor swallowing and severe bronchopulmonary dysplasia. The child was born prematurely at 29 weeks' gestation and was hospitalized following an eventful neonatal course. Sutures are not used after the percutaneous endoscopic gastrostomy and the catheter is connected to a small clear plastic trap. After 24 hours, the external cross-bar is checked and loosened, if necessary, to accommodate for wound edema. Feedings are then started.[30] Notice the tracheal traction sutures used as safety measures with the child's tracheostomy and the scar of a previously repaired inguinal hernia.

Figure 48.17 Two former premature infants with complex neonatal courses. Both receive supplemental feedings and medication via the gastrostomy. The child on the left has a balloon-type skin-level device and the one on the right has an original, low-profile gastrostomy button.

follow up is essential, and its importance cannot be overemphasized. Whether the gastrostomy is placed as an adjunct, or for the prime purpose of feeding, every effort should be directed towards resuming oral feeding whenever possible.

Duodenal obstruction

YECHIEL SWEED

INTRODUCTION

Congenital duodenal obstruction is the most common cause of intestinal obstruction in the newborn period, occurring in 1 in 5000–10 000 live births.[1–3]

Duodenal obstruction is the result of intrinsic lesion, extrinsic lesion, or a combination of both. Intrinsic duodenal obstruction may be caused by duodenal atresia, stenosis, diaphragm, a perforated diaphragm, or a 'windsock' web. The windsock web is a duodenal membrane which is ballooned distally as a result of peristalsis from above.[4,5] Extrinsic duodenal obstruction may be caused by annular pancreas, malrotation, or preduodenal portal vein. Although the annular pancreas forms a constricting ring around the second part of the duodenum (Fig. 49.1), it is not believed to be the cause of duodenal obstruction[6,7] and there is usually an associated atresia or stenosis in patients with an annular pancreas.[8–10] Similarly, preduodenal portal vein has also seldom been reported to be the cause of duodenal obstruction and it is often associated with other causes of intestinal obstruction, such as malrotation or duodenal atresia.[11,12]

Duodenal atresias have been traditionally classified by Gray and Skandalakis[13] into three types (Fig. 49.2). Type I defect, the most common (Fig. 49.2a), is represented by a mucosal and submucosal diaphragmatic membrane with an intact muscle wall. The opening of the bile duct at the ampulla of Vater is almost always located proximal to the duodenal web. Type II defect has a short fibrous cord that connects the two atretic ends of the duodenum (Fig. 49.2b). In type III defect, there is a complete separation of the atretic ends with a mesenteric defect (Fig. 49.2c). The reported prevalence of type I is about 92%, type 2 is 2%, and type 3 is 7%.[7] Duodenal stenosis is approximately half as prevalent as atresia.[14]

Figure 49.3 shows the wide spectrum of various types of duodenal obstruction. The proximal and distal segments of the duodenum may be separated by a gap (Fig. 49.3a), be in apposition (Fig. 49.3b), or be joined by a fibrous cord (Fig. 49.3c). Other types include duodenal stenosis (Fig. 49.3d), complete diaphragm (Fig. 49.3e), a perforated diaphragm (Fig. 49.3f), a windsock web (Fig. 49.3g), and an annular pancreas (Fig. 49.3h).

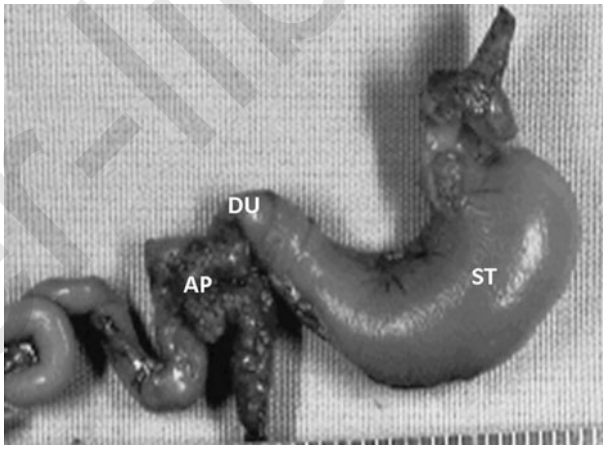

Figure 49.1 Duodenal obstruction caused by an annular pancreas associated with duodenal stenosis in post-mortem of a 14-week-old fetus with a diagnosis of Down syndrome. AP, annular pancreas; DU, duodenum; ST, stomach.

ETIOLOGY

The underlying cause of duodenal atresia remains unknown although its pathophysiology has been well described. Frequent association of duodenal atresia or stenosis with other neonatal malformations suggests that both anomalies are due to a developmental error in the early period of gestation. Duodenal atresia differs from other atresias of the small and large bowel, which are isolated anomalies caused by mesenteric vascular accidents during later stages of development. This theory of vascular disturbance was presented by the classic study of Lauw and Barnard.[15]

No predisposing maternal risk factors are known. Although up to one-third of patients with duodenal atresia have Down

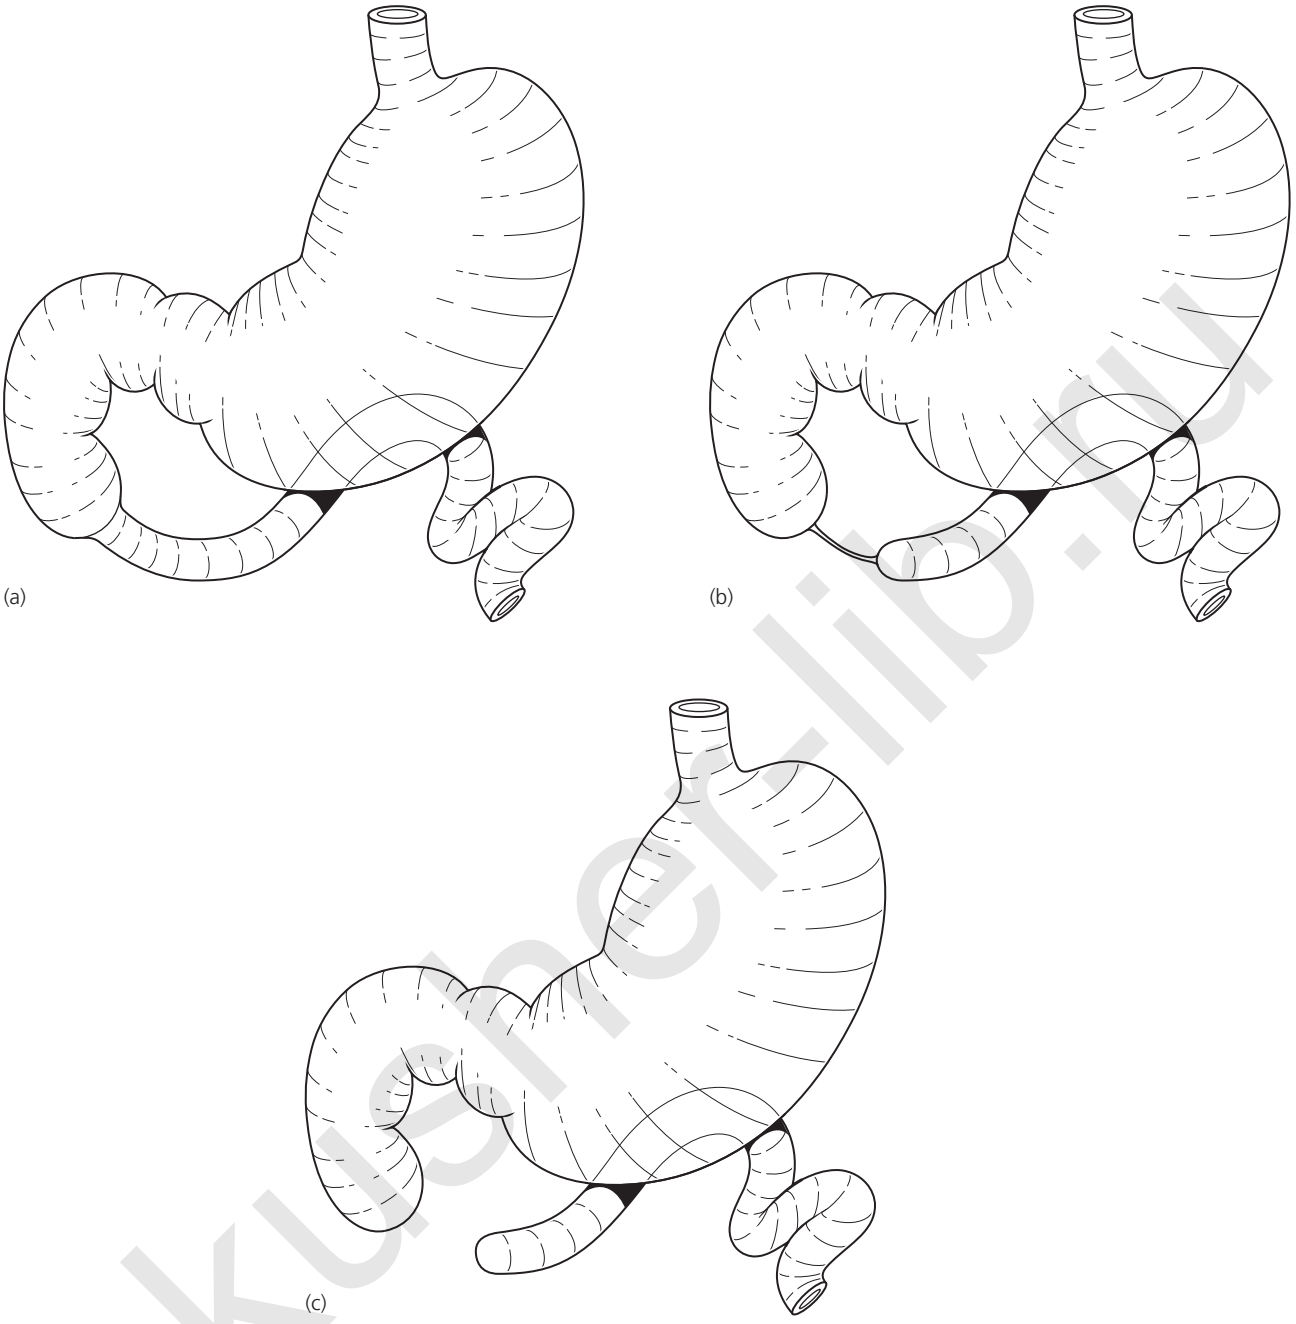

Figure 49.2 Types of duodenal atresia (by Gray and Skandalakis[13]). (a) Type I, mucosal membrane with intact muscle wall. (b) Type II, fibrous cord connecting the two atretic ends of duodenum. (c) Type III, a complete separation of the atretic ends with a mesenteric defect.

syndrome (trisomy 21) it is not an independent risk factor for developing duodenal atresia.[16] In the large California population-based registry of 2.5 million infants, the risk of duodenal atresia was found to be 265 times higher in infants with Down syndrome compared to those without it and the corresponding frequencies were 46 and 0.12 per 1000 births.[17]

Although duodenal obstruction is usually not regarded as a familial condition there have been several reports of familial cases,[18–21] and a very rare group of hereditary multiple intestinal atresias with fatal outcome.[22]

PATHOPHYSIOLOGY

Duodenal atresia, web, and stenosis usually occur in the second part of the duodenum, close to the area of intense embryological activity involved with the development of the biliary and pancreatic structures. These anomalies are believed to result from a developmental error during early fetal life.[23–25]

Duodenal maldevelopment occurs secondary to either inadequate endodermal proliferation (gut elongation outpaces

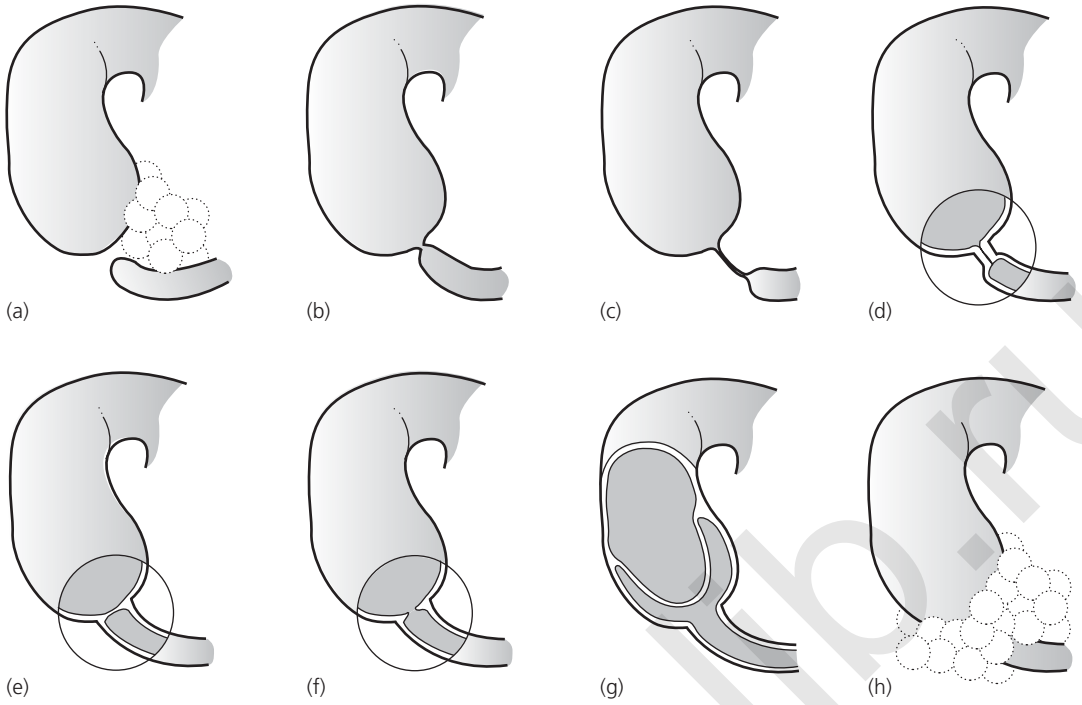

Figure 49.3 Various types of duodenal obstruction. (a) Blind ends separated by a gap. (b) Two ends in apposition. (c) Ends joined by a fibrous cord. (d) Duodenal stenosis. (e) Complete duodenal membrane. (f) Perforated diaphragm. (g) Windsock web. (h) Annular pancreas.

proliferation) which occurs at 5 weeks of embryonic life or failure of the epithelial solid cord to recanalize (failure of vacuolization) which appears at 11 weeks of gestation.

Many investigators have demonstrated that the epithelium of the duodenum proliferates during 30–60 days of gestation, completely plugging the duodenal lumen. A subsequent process termed vacuolation occurs whereby the solid duodenum is recanalized. Vacuolation is believed to occur by way of apoptosis, or programmed cell death, which happens during normal development within the lumen of the duodenum. Occasionally, duodenal atresias are associated with annular pancreas. This is likely due to failure of duodenal development rather than robust and/or abnormal growth of the pancreatic buds.[26]

At the cellular level, the gastrointestinal tract develops from the embryonic gut, which is composed of an epithelium derived from endoderm, surrounded by cells of mesodermal origin. Cell signaling between these two embryonic layers appears to play a critical role in coordinating patterning and organogenesis of the duodenum. Sonic hedgehog genes encode members of the hedgehog family of cell signals. Both are expressed in gut endoderm, whereas target genes are expressed in discrete layers in the mesoderm. Mice with genetically altered sonic hedgehog signaling display duodenal stenosis, suggesting that genetic defects in the sonic hedgehog family of genes may influence the development of duodenal abnormalities.[27]

Recently, fibroblast growth factor-10 was found to be active in the duodenum at a late stage of development, and serves as a regulator in normal duodenal development. Fibroblast growth factor-10(–/–) mutant mice demonstrated duodenal atresia with variable phenotype similar to clinical findings in humans. The phenotype occurred in an autosomal–recessive pattern with incomplete penetrance (38%).[28] This finding suggest a genetic cause of duodenal obstruction although few reports of familial association have been published.[18]

The obstruction of the duodenum usually occurs distal to the ampulla of Vater. Pre-ampullary obstruction is much less common, occurring in about 20% of cases.[29] Occasionally, there may be a bifid termination of the bile duct with one limb of the duct system opening into the duodenum above the atresia and one below.[24,25,30]

ASSOCIATED MALFORMATIONS

There is a high incidence (approximately 50%) of associated anomalies in patients with intrinsic duodenal obstruction, especially Down syndrome which occurs in about 30% of these patients.[3,7,8,31–34]

Table 49.1 presents the overall prevalence and distribution of associated anomalies of duodenal atresia. The data are the collected statistics of 1759 patients with duodenal obstruction from a dozen large series.[32] The associated anomalies in order of frequency are: Down syndrome (28%), annular pancreas (23%), congenital heart disease (22.6%), malrotation (20%), esophageal atresia (8.5%), genitourinary malformations (8%), anorectal anomalies (4.4%), and other bowel atresias (3.5%).

Vertebral anomalies were reported to range between 2%[35] and 37%[36] in these patients. Reports of duodenal atresia have also shown a low incidence of musculoskeletal anomalies.[34]

Other rare anomalies include De Lange syndrome,[35] chromosomal abnormalities,[36–38] multiple intestinal

Table 49.1 The incidence of associated congenital anomalies (%) (collected statistics) ($n = 1759$ patients).

Associated anomaly	%
Down syndrome	28.2
Annular pancreas	23.1
Congenital heart disease	22.6
Malrotation	19.7
Esophageal atresia tracheo-esophageal fistula	8.5
Genitourinary	8.0
Anorectal	4.4
Other bowel atresia	3.5
Others	10.9

abnormalities,[39] choledochal cyst,[40,41] immunodeficiency,[42] tracheomalacia,[34] and situs inversus.[43]

The complex cardiac anomalies among all other associated malformations are the major cause of morbidity and mortality in patients with duodenal atresia.[3,7,14,44,45] Dalla Vecchia *et al.*[14] attributed all the operative mortality (4%) to associated complex congenital heart anomalies in a group of 138 patients with duodenal obstruction in a 25-year survey. Two other important factors affecting higher morbidity and mortality of these patients are prematurity and low birth weight.[7,44,46] The mortality rate is even higher in neonates born with three or more anomalies of the VACTERL association with an overall survival rate of 40–77%.[47–49] Spitz and colleagues reported the combination of esophageal and duodenal atresias as particularly lethal, with mortality rates ranging from 67 to 94% in various series.[50] Jackson *et al.*[51] inferred that the majority of these deaths are caused by failure to recognize the second abnormality preoperatively.

PRENATAL DIAGNOSIS/HISTORY

Maternal polyhydramnios has been reported to be present in 17–75% of cases of duodenal atresia[1,8,14,46,52,53] and is the most common ultrasonographic finding in fetuses with intrinsic duodenal obstruction.[54] Ultrasound is usually performed for suspected fetal or maternal abnormalities when polyhydramnios or a large-for-date pregnancy is established. Although the majority of cases are diagnosed during the seventh or eight month of gestation,[46,55] sonographic detection of duodenal atresia was reported as early as 12 gestational weeks by Tsukerman *et al.*[56] and 19 weeks by Romero.[57]

There has been an increase in prenatal ultrasonographic diagnosis of duodenal atresia during the last three decades, from 14% between the years 1972 and 1991,[58] and 18%[59] to the high rate of 57% for the period 1991–95.[52]

The prenatal sonographic diagnosis relies on the demonstration of the 'double bubble' sign, which is due to simultaneous distension of the stomach and the first part of the duodenum (Fig. 49.4). In many cases, this sonographic sign is observed in the second half of pregnancy, probably due to hydrostatic pressure needed to dilate the duodenum and also to the degree of the duodenal obstruction.[55] Visualization of a fluid-filled double bubble (Fig. 49.4) on prenatal ultrasound scan is associated with duodenal obstruction secondary to intrinsic or extrinsic lesion. This sonographic finding is known to have a low false-positive rate. Zimmer and Bronstein[60] have reported recently that in a few cases it may represent a transient finding in an otherwise healthy fetus. It is possible that intestinal peristalsis in a fetus may show transient dilatation suggesting duodenal obstruction.[55] On the ultrasound examination, it is also important to demonstrate the continuity between the gastric and duodenal bubbles (Fig. 49.4) to exclude other causes, such as choledochal cyst which lacks such communication[61,62] or duodenal duplication.[63]

Often other anomalies can also be diagnosed by ultrasound. Kawana *et al.*[64] and Pameijer *et al.*[65] reported the ultrasonic prenatal diagnosis of a fetus with combined duodenal and esophageal atresias associated with VACTERAL anomalies. Prenatal ultrasonographic diagnosis of annular pancreas has also been reported showing the co-incidence of the double bubble sign together with hyperechogenic bands around the duodenum (corresponding with the tissue of annular pancreas).[66]

Cohen-Overbeek *et al.*[53] investigated the impact of antenatal diagnosis in cases diagnosed with isolated or non-isolated duodenal obstruction. They found that the outcome of prenatally and postnatally diagnosed duodenal obstruction is not essentially different despite the fact that more prematurity and a lower birth weight were observed in the former.

The rapid advancement in imaging technology, including magnetic resonance imaging (MRI) should allow for

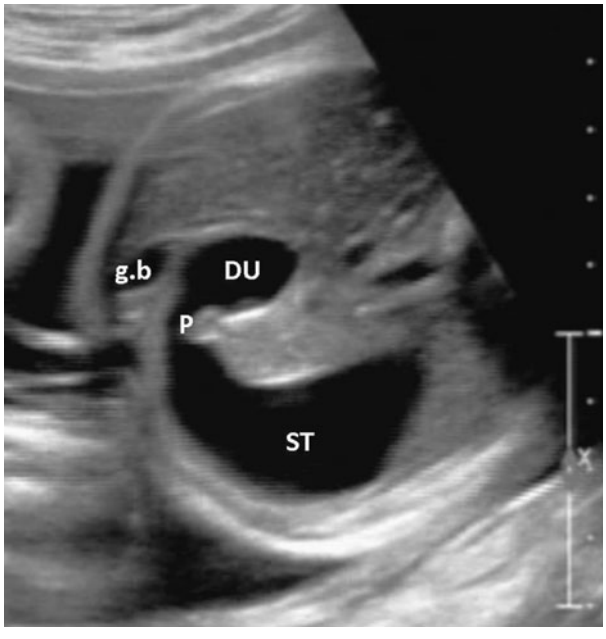

Figure 49.4 Ultrasonography (transverse view) of 24 week gestational age fetus showing the 'double bubble' sign. DU, duodenum; g.b gallbladder; P, pylorus; ST, stomach.

diagnosis during the first and early second trimester, enabling termination.[56] Alternatively, early prenatal diagnosis of duodenal obstruction should lead to karyotype analysis for prenatal screening for trisomy 21 and other associated anomalies.[58,65,67,68]

CLINICAL PRESENTATION AND DIAGNOSIS

About half of these patients are premature and have low birth weight.[7,8,14,44,46,69] Vomiting is the most common symptom and is usually present on the first day of life. Since 80% of the obstructions are located in the post-ampullary region of the duodenum, vomitus in the majority of cases is bile stained. In supra-ampullary atresia it is non-bilous. Orogastric aspiration also yields significant volumes of bile-stained gastric fluid. There is minimal or no abdominal distension because of the high level of obstruction. The infant may pass some meconium in the first 24 hours of life and thereafter constipation may develop. Dehydration with weight loss and electrolyte imbalance (hypokalemic/hypochloremic metabolic alkalosis) soon follows if the diagnosis is done late and if fluid and electrolyte losses have not been adequately replaced.[53,70] Incomplete duodenal obstruction usually leads to the delayed onset of symptoms.[7,44,58]

The diagnosis of duodenal obstruction is confirmed on x-ray examination. An abdominal x-ray will show a dilated stomach and duodenum, giving the characteristic appearance of a double bubble sign (the stomach and the proximal duodenum are air-filled) with no gas beyond the duodenum (Fig. 49.5). In partial duodenal obstruction, a plain film of the duodenum will show a double bubble appearance but there is usually some air in the distal intestine (Fig. 49.6). Occasionally in cases of duodenal atresia, air may be seen distal to the site of obstruction due to associated bile duct bifurcation.[71] X-ray findings in patients with annular pancreas are usually indistinguishable from duodenal atresia or stenosis.

In some cases of partial duodenal obstruction, plain films may be normal. Upper gastrointestinal tract contrast x-ray is indicated in these patients to establish the cause of incomplete duodenal obstruction. This may show a stenotic segment of duodenum with dilatation of the proximal segment, or a sharp termination of the dilated segment, indicating a perforated diaphragm (Fig. 49.7).

Incomplete duodenal obstruction usually leads to delayed onset of symptoms, and the diagnosis of duodenal diaphragm with a central aperture is sometimes delayed for months or even years.[72–74] Mikaelsson *et al.*[75] reported the late diagnosis and treatment of eight out of 16 patients with membranous duodenal stenosis. Their patients were diagnosed and operated at between the ages of one month and four years. Occasionally, a duodenal diaphragm may be stretched and ballooned distally, giving the windsock appearance on contrast study (Fig. 49.8).[72]

The most important differential diagnosis of duodenal obstruction is duodenal obstruction caused by malrotation resulting in extrinsic compression related to Ladd's bands across the duodenum, or volvulus of the midgut loop, although this is rare. Midgut volvulus may result in gangrene of the entire midgut within hours and thus diagnostic investigation is urgently required, though the symptoms may relent because the obstruction may be incomplete or intermittent in malrotation. Part of these extrinsic obstructions exhibit the double bubble sign with distal air on plain film, while the majority can be identified from the coil spring appearance of small bowel volvulus following barium injection.[76] However, Samuel *et al.*[77] observed that volvulus neonatorum was not encountered in neonates with duodenal atresia and stenosis who had associated malrotation. They suggested that duodenal obstruction could perhaps be a flood-gate that prevents volvulus in these children.

Preduodenal portal vein is a rare anomaly and generally asymptomatic. It is a rare cause of duodenal obstruction and often coexists with other anomalies resulting in bowel obstruction.[78–80] In most of these patients, it is impossible to diagnose preduodenal portal vein prior to surgery.

The wide variety of additional congenital anomalies with special emphasis on cardiac malformation, often severe,[7,14,32,44,81] makes preoperative diagnosis imperative. Anterior-posterior and lateral chest and abdominal x-rays ascertaining visualization of the entire spine, should also be performed.

Soon after the x-ray, cardiac and renal ultrasound should be carried out routinely in all these babies. A micturating cystourethrogram should be performed in those babies with abnormal urogenital ultrasound or an associated anorectal anomaly. Rectal biopsy should be taken in babies with constipation and the combination of Down syndrome and duodenal atresia, to exclude Hirschsprung's disease.[34,44]

PREOPERATIVE MANAGEMENT

Although duodenal atresia is a relative emergency, the patient should not be rushed to the operating room until the infant's hemodynamic and fluid and electrolyte status is stable. If the clinical history and findings on physical examination indicate that the baby is in no distress, and the x-rays are consistent with the usual presentation of duodenal atresia with no air beyond the second bubble (excluding malrotation), operation should be performed on an elective basis.

A nasogastric tube decompresses the stomach, and i.v. fluid resuscitation can be initiated. Blood samples for electrolyte determination should be obtained and any derangements should be corrected. Prolonged vomiting can result in a hypokalemic hypochloremic metabolic alkalosis. Passage of the orogastric tube rules out esophageal atresia and careful inspection of anal defect variants of imperforated anus should be obtained.

Care is taken to preserve body heat and avoid hypoglycemia, since many of these newborn patients are premature and small-for-date.[7,14,52] Very low birth weight infants or those with respiratory distress syndrome and associated severe anomalies, e.g. congenital heart disease, may occasionally need special preparation, such as resuscitation and ventilation.

OPERATION

Duodenoduodenostomy is the procedure of choice for patients with duodenal atresia, stenosis, and annular pancreas.[8,14,45,82,83]

Duodenoduodenostomy can be performed in either 'diamond shape' (proximal transverse to distal longitudinal) anastomosis as described by Kimura *et al.*[84,85] (Fig. 49.9), or side-to-side fashion (Fig. 49.10). The 'diamond shape' duodenoduodenostomy has been reported to allow earlier feeding, earlier discharge, and good long-term results.[85,86]

Recently, Bax *et al.*[87] and Rothenberg[88] reported the first case and the first series, respectively, on the laparoscopic management of duodenal obstruction. They indicated that the laparoscopic approach has proven to be safe and effective and represents an alternative to the open procedure. They also emphasized that this minimal invasive surgical technique should be used only if the surgeon has appropriate instruments and suturing and laparoscopic skills (Fig. 49.11).[87–89]

Incision

The baby is placed supine on the table with a small roll under the upper abdomen on a warming blanket. Endotracheal anesthesia is used. The abdominal skin is prepared by cleaning with prewarmed povidone iodine.

A transverse supra-umbilical abdominal incision is made 2 cm above the umbilicus starting in the midline and extending laterally into the right upper quadrant for

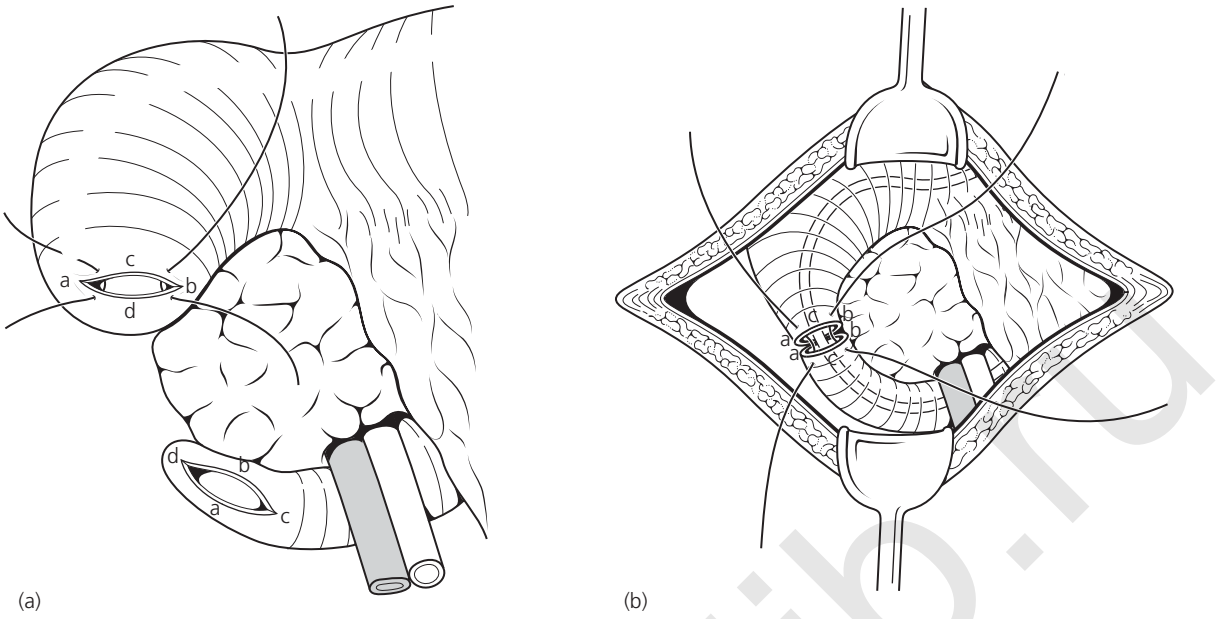

Figure 49.9 Diamond-shaped duodenoduodenostomy. (a) A transverse incision is made in the distal end of the proximal dilated duodenum and a longitudinal incision is made in the smaller limb of the duodenum distal to the occlusion. (b) A single layer anastomosis using interrupted 5/0 Vicryl sutures with posterior knots tied inside the posterior wall of the anastomosis and anterior knots tied outside the anterior wall is performed.

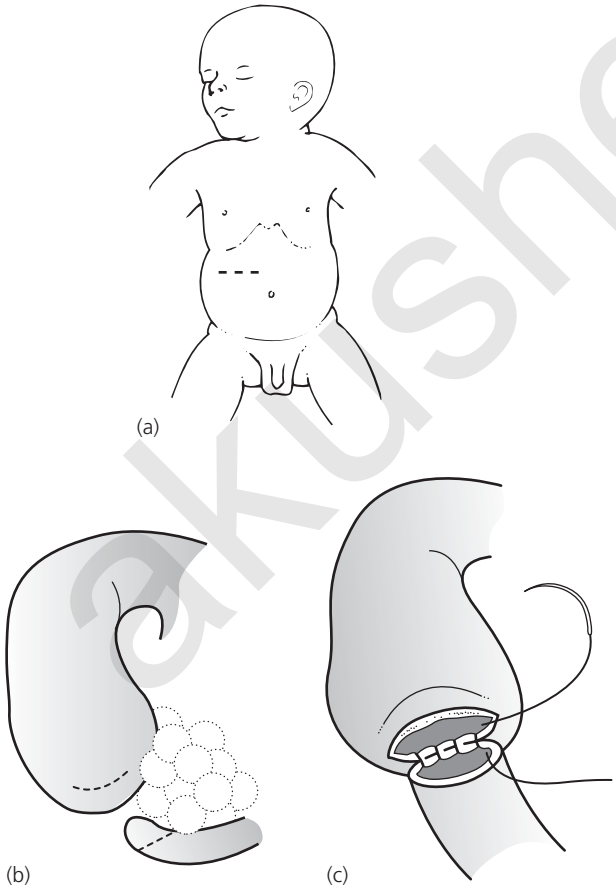

Figure 49.10 (a) Side-to-side duodenoduodenostomy. (b) Parallel incisions of about 1 cm are made in the proximal and distal duodenum. (c) The anastomosis is performed using single-layer interrupted 5/0 Vicryl sutures.

about 5 cm. The abdominal muscles are divided transversely with cutting diathermy and the peritoneal cavity is opened in the line of incision.

Exploration and identification of pathology

After exposing the peritoneal cavity, the surgeon inspects the entire bowel for the presence of other bowel anomalies. There may be an associated annular pancreas, malrotation (in about one-third of the patients), or in rare cases preduodenal portal vein. If the colon is in the normal position, malrotation is probably not a coexisting factor.

The stomach and first portion of the duodenum are usually thickened and dilated. The liver is carefully retracted superiorly. The ascending colon and the hepatic flexure of the colon are mobilized medially and downwards to expose the dilated duodenum.[90]

The duodenum is then adequately mobilized and freed from its retroperitoneal attachments – the Kocher maneuver. Great care must be exercised not to dissect or manipulate either segment of the duodenum medially, to avoid injury to the ampulla of Vater or the common bile duct. The tube in the stomach is then passed distally into the dilated duodenum and helps to locate the point of obstruction and determine if a windsock deformity is present (Fig. 49.3g).

The types of atresia as well as any pancreatic abnormality (e.g. annular pancreas) are noted. In patients with an annular pancreas, the pancreatic tissue should never be divided and should always be bypassed. The duodenum distal to the site of obstruction is small and decompressed. The requirements for distal mobilization vary according to the location of the atresia and to the gap between the two segments (Fig. 49.2). If necessary, the ligament of Treitz is divided and mobilization

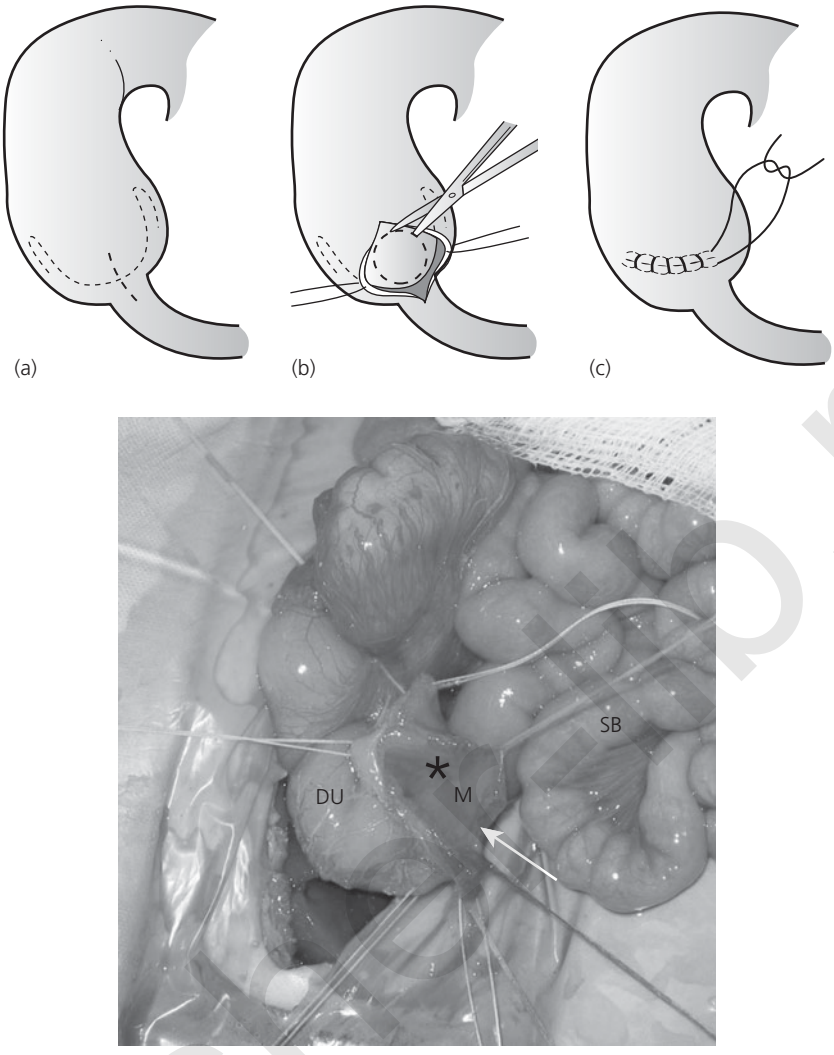

Figure 49.11 Operative technique for duodenal web. (a) Longitudinal incision above the 'tranzitional zone' of the duodenum. (b) Excision of the web leaving the medial third of the membrane intact. (c) The Duodenum is closed transversely. (d) Intraoperative photograph of a 2-week-old infant born with duodenal web with an aperture. DU, opened duodenum; M, membrane, *, papilla of Vater; SB, small bowel. The white arrow points to the excisional line of the membrane.

and displacement of the distal duodenum is performed behind the superior mesenteric vessels, thus allowing a satisfactory anastomosis to be performed without any tension.

'DIAMOND-SHAPED' DUODENODUODENOSTOMY

After abdominal exploration, the duodenum is adequately mobilized. With two traction sutures, the redundant wall of the proximal duodenum is pulled downward to overlie the proximal portion of the distal duodenal segment. A transverse incision is made in the distal end of the proximal duodenum and a longitudinal incision is made in the smaller limb of the duodenum distal to the occlusion.

These are made in such a position as to allow good approximation of the openings without tension.

The papilla of Vater is located by observing bile flow. This is performed by gentle compression of the gallbladder.

The orientation of the sutures in the 'diamond shape' anastomosis and the overlapping between the proximal transverse incision and the distal longitudinal incision are shown in Fig. 49.9.

Additionally, a 10 French Foley catheter should be passed proximally into the stomach and distally into the jejunum and pulled back with the balloon inflated, to ensure that no additional web or a windsock deformity is overlooked. The distal duodenum can be distended to a larger size during this maneuver facilitating the anastomosis. Before pulling back the catheter from the distal duodenum, the surgeon should inject 30–40 mL of warm saline through the catheter to rule out distal atresias of the distal small bowel. The catheter is then removed.

A single layer anastomosis is performed using 5/0 or 6/0 vicryl sutures with posterior knots tied inside the posterior wall of the anastomosis and interrupted sutures with anterior knots tied outside the anterior wall. Before completion of the anterior part of the anastomosis, a 5F silicon nasojejunal transanastomotic feeding tube may be passed down into the upper jejunum for an early postoperative enteral feeding[91] using the same insertion technique as was reported for

patients who underwent surgical repair for esophageal atresia and tracheo-esophageal fistula.[92] Others, however, do not use the nasojejunal tube because they suggest that it may delay the commencement of oral feeding.[14,85]

Then, the right colon is returned to its former position so that the mesocolon covers the anastomosis. The Ladd procedure with inversion appendectomy is performed in patients with malrotation.[58] In these patients, the cecum should be placed in the left lower quadrant to reduce the risk of midgut volvulus.

The wound is closed in layers: the peritoneum and posterior fascia, and the anterior fascia by two layers using continuous 4-0 Vicryl. The skin is closed with running intracuticular suture using 5-0 Vicryl.

SIDE-TO-SIDE DUODENODUODENOSTOMY

The dilated proximal duodenum and the distal collapsed duodenum are approximated using two stay sutures (5-0 Vicryl). Then, parallel incisions with a length of about 1 cm are made in the proximal and distal duodenum (Fig. 49.10). An 8 Fr Foley catheter should be inserted both to the proximal dilated duodenum and to the distal collapsed duodenum in order to rule out windsock membrane and distal atresias, as similarly described in the diamond shape duodenoduodenostomy.

The posterior layer of anastomosis is completed using interrupted 5/0 Vicryl sutures.

At this stage, a transanastomotic 5 Fr gauge silastic nasojejunal tube may be inserted for an early enteral feeding.

The anastomosis is then completed using interrupted 5-0 Vicryl sutures for the anterior layer. The abdomen is closed in the same manner as described in the diamond shape duodenoduodenostomy.

In patients with malrotation, Ladd's procedure and inversion appendectomy should be performed before closure of the abdomen.

In premature infants, some surgeons prefer to perform a gastrostomy and insert the transanastomotic silicon tube via the gastrostomy. The tip of the tube should be well down in the jejunum as to decrease the chance of it becoming displaced.

OPERATIVE TECHNIQUE FOR DUODENAL WEB

A longitudinal incision is performed above the transitional zone between the wide and narrow segments of the duodenum (Fig. 49.11) and the duodenum is opened. The membrane is usually located in the second part and occasionally in the third portion of the duodenum. It can be complete or have a hole. Anatomically, the ampulla of Vater may open directly into the medial part of the membrane, or posteriorly close to it, thus the close relationship of the membrane to the ampulla of Vater makes its identification mandatory, before excision of the web (Fig. 49.11d). Excision of the web should proceed from the lateral duodenal wall, leaving the medial third of the wall intact to avoid damaging the sphincter of Oddi or the ampulla of Vater and continue leaving a circumferential rim of tissue of 1–2 mm (Fig. 49.11b). The resection line is then oversewn using continuous sutures of Vicryl 5/0 and the duodenum is closed transversely in two layers using Vicryl 5/0 (Fig. 49.11c). Because of the pitfalls in cases of the lax membrane that may bulge downwards distally into the distended duodenum (the so-called windsock phenomenon), and in order to avoid missing the anomaly, before closure of the duodenum, the distal patency of the distal duodenum must be verified by inserting a 8 Fr Foley catheter through a duodenotomy.

The experience with fiberoptic duodenoscopy indicates the usefulness of the technique for both the diagnosis and non-operative management of duodenal membrane.[93–95] However, based on reports describing anomalous entry of the pancreatobiliary channels,[96] the delineation of the ducts at endoscopic retrograde cholangiopancreatography may be necessary prior to endoscopic intervention. Most surgeons believe that a duodenotomy is preferable to the potential risk of inadvertent pancreatic or bile duct injury.[96]

LAPAROSCOPIC MANAGEMENT OF DUODENAL OBSTRUCTION

The application of minimally invasive surgical techniques for the correction of congenital anomalies has increased significantly over the last ten years. The ability to perform delicate dissection and intracorporeal anastomosis has broadened the scope of entities that can be approached including neonatal duodenal obstruction. Although most neonatal conditions presenting with bowel obstruction present a difficult problem for laparoscopy because of the dilated bowel and limited abdominal cavity, this is not the case in duodenal atresia. The entire small and large bowel is decompressed, and there is excellent exposure of the proximal duodenum.[87]

For the laparoscopic approach (Fig. 49.12), neonatal laparoscopic instruments (3 mm) and trocars are used. The patient is positioned supine at the end of the operating table. The operating surgeon stands at the patient's feet. The abdomen is insufflated through a 5 mm umbilical port, for a 30° laparoscope. A 3 mm and a 5 mm port are placed in the

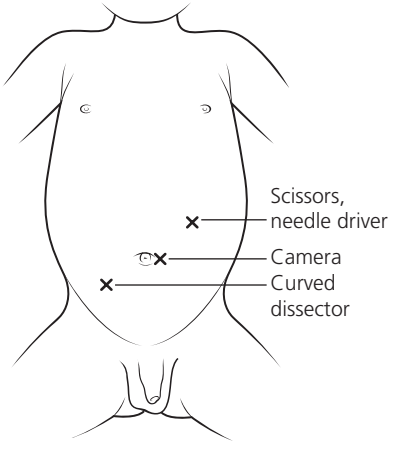

Figure 49.12 Trocar placement and instrumentation for laparoscopic repair of duodenal atresia.

right lower quadrant and left upper quadrant, respectively. The left upper quadrant port is placed for the introduction of suture.

The duodenum is then kocherized, the type of obstruction becomes easily visible, and the dilated proximal and decompressed distal segments are identified.[88,89] A proximal transverse and distal longitudinal duodenotomy is then made. As with the open repair, stay sutures are placed at each corner to facilitate the anastomosis. A diamond-shaped anastomosis is performed with either a separate running suture for the posterior and then anterior wall, or single interrupted stitches of Vicryl. Intracorporeal knot tying is used. An extra port can be placed in the right upper quadrant to help retract the liver and set up the anastomosis. Alternatively, the apical stitch can be tied and brought out through the abdominal wall to assist with retraction and align the enterotomies for the anastomosis. The distal bowel is examined in all cases to ensure that there are no obvious secondary atresias. Once the anastomosis is completed, the ports are removed and the sites are closed with absorbable sutures.

Recently, Spilde *et al.*[97] reported their experience with laparoscopic repair of duodenal obstruction using U-clips for the anastomosis because of the ability of these clips to approximate tissue tightly with little tissue damage.[98] In their report they compared 14 patients who were treated by an open approach and 15 patients who underwent laparoscopic repair of duodenal obstruction. They demonstrated significantly shorter time to initiation of feeds, time to full feeds, and postoperative hospitalization in the laparoscopic group.[97]

The experience with laparoscopic duodenoduodenostomy demonstrates that it can be performed safely and successfully in the neonate with excellent short-term outcomes.[86,87,97] Surgeons with experience in advanced laparoscopic techniques can learn the laparoscopic duoenoduodenostomy and have excellent results.

POSTOPERATIVE CARE

The baby is returned to an incubator (or radiant heat cot) at the thermoneutral temperature for its size and maturity. An i.v. infusion of dextrose/saline is continued in the postoperative period and further fluid and electrolyte management depends on clinical progress, loss by gastroduodenal aspiration, and serum electrolyte levels. Postoperatively, patients may have a prolonged period of bile-stained aspirate through the nasogastric tube, which is mainly due to the inability of the markedly dilated duodenum to produce effective peristalsis, and to a lesser extent, partial mechanical obstruction by the feeding tube (if it was used). Enteral feeding through the transanastomotic feeding tube is generally started within 24–48 hours postoperatively.

The commencement of oral feeding depends on the decrease of the gastric aspirate and may be delayed for several days and occasionally for 1–2 weeks or longer. Once the volume of the gastric aspirate decreases, the feeding tube is withdrawn and the infant can be started on oral feeding.

Spigland and Yazbeck[99] in their follow up of 33 neonates found that bowel transit was established after an average of 13.1 days, 7.5 days after partial web excision, 12.4 days following duodenoduodenostomy, and 15 days after duodenojujenostomy (which is rarely performed today). Spilde *et al.*[97] recently reported that the time to initial feeding was 11.3 days for patients with an open repair of duodenal obstruction compared to 5.4 days for those who were treated by laparoscopic approach. They also found that the average time to full oral intake was 16.9 days for the open group compared to 9 days for the laparoscopic group.

MANAGEMENT OF PERSISTENT MEGADUODENUM BY DUODENOPLASTY

The deformity and dysfunction of the first part of the duodenum – the megaduodenum – are the causes of well-known morbidity[99,100] and occasionally these patients require duodenoplasty.[101] The malfunction of the greatly dilated gut and the absence of effective peristalsis were demonstrated by Nixon in the small bowel,[100,102] but the same phenomenon is thought to occur in the dilated duodenum proximal to the duodenal atresia. Several techniques of duodenoplasty have been described, and it is of the utmost importance to visualize and identify the ampulla of Vater within the duodenal lumen prior to resection and tapering of the duodenum. Hutton and Thomas have reported success by extensive tapering duodenoplasty.[103] Adzick *et al.*[104] and Grosfeld and Rescorla[58] emphasized the merit of tapering duodenoplasty at the primary operation of neonates with dilated duodenum, to improve the immediate postoperative gastrointestinal function and the prevention of further development of megaduodenum. Other techniques include resection and suturing,[105] resection and stapling,[104] and elliptical seromuscular resection.[106]

However, refashioning the anastomosis or bypass techniques usually fail.[100,107,108] Another technique of subtotal duodenal resection with reconstruction of the duodenum by the proximal jejunum as an onlay patch was demonstrated in two children. In this technique, the diseased duodenal wall is completely removed, except for the area of the ampulla of Vater and the duodenum is reconstructed by the jejunum.[109]

OUTCOME AND LONG-TERM RESULTS

The survival of babies with duodenal obstruction has gradually improved over the last 40 years since the first report of surgical correction of intrinsic duodenal obstruction by Ladd in 1931[110] (Table 49.2).[1,3,8,14,46,53,58,59,69,70,82,89,111–113] All agree that the three main factors contributing to the mortality rate in this group of patients are high incidence of associated anomalies, especially severe cardiac malformations, prematurity, and low birth weight.[1,3,7,14,53,58,112] In a recent review covering 45 years (1951–95) of management of duodenal obstruction, Murshed *et al.*[52] found that in the first 15 years, survival reached 51%, in the next 15 years it was 80%, and in

Table 49.2 Survival rates of patients with duodenal atresia and stenosis. Table shows gradual improvement in survival reported over the past 40 years. Most deaths are related to the associated complex cardiac malformations.

[a]Laparoscopic duodenoduodenostomy (years 2004–2008).

the last 15 years 95%. During the latest period, mortality was almost entirely the consequence of associated anomalies.

Dalla Vechia *et al.*[14] reported a relatively low rate of postoperative complications in a series of 138 infants. The early complication rate included anastomotic obstruction in 3%, congestive heart failure in 9%, prolonged adynamic ileus in 4%, pneumonia in 5%, and wound infection in 3%.

Late complications included adhesive bowel obstruction in 9%, megaduodenum and duodenal dysmotility that required tapering duodenoplasty in 4%, and gastro-esophageal reflux requiring surgery in 5%.

Weber *et al.*[83] reported the complication rate and morbidity of three methods of technical repair in a group of 41 newborns with duodenal atresia. The three techniques were: (1) side-to-side duodenoduodenostomy, (2) side-to-side duodenojejunostomy (which is rarely performed today), and (3) diamond-shaped duodenoduodenostomy. There was no difference in the complication rate, but the diamond shape technique was found to be superior for repair, resulting in earlier feeding and discharge. Recently, Kimura *et al.*[85] reported on their experience with 44 patients with the diamond-shaped technique, without the use of gastrostomy or transanastomotic tube, and found a very low rate of complications and good long-term results.

Long-term results of congenital duodenal obstruction were reported by Kokkonen *et al.*,[114] who studied 41 patients aged 15–35 years. They found that growth and development, including body weight, were satisfactory. Although the great majority was symptom-free, on barium meal examination all but two had abnormal findings, including megaduodenum in nine cases. They concluded that some gastrointestinal disturbances are common, even in asymptomatic patients, and careful follow up is important. Salonen and Makinen[115] reported previously on their experience in a small group of nine patients aged 3–21 years and found, in contrast, a normal barium meal in all groups except one. Their result was similar to the ducomentation by Kimura *et al.*[85] with the diamond-shaped technique.

Ein *et al.*[100,108] encountered five patients with late complications of duodenal atresia repair that appeared suddenly between the ages of six months and 24 years. The duodenal repair was functionally obstructed – caused by proximal, dilated duodenal atony. Plication of the dilated atonic proximal duodenum was curative.

The main benefits of laparoscopic approach for the treatment of duodenal atresia are the excellent visualization of the obstruction and the ease of the anastomosis. However, the possible disadvantage of this approach may be that evaluation of the distal bowel for other atretic segments is more difficult to accomplish.[88] The bowel can be inspected visually for distal obstructed segments, but internal webs may be more difficult to see. It is important to emphasize that last-report results of laparoscopic approach for duodenal obstruction are related to short-term follow up. As for the long term, there are no results yet.[88,89,97,116]

Over the last few decades, advances in neonatal intensive care, parenteral nutrition, management of associated anomalies, and improvements in operative technique and postoperative care have improved the outlook for patients born with duodenal atresia and stenosis.[3,7,14,53,58] Mortality today has been reduced to 5–10% and is now related mostly to associated cardiac anomalies.

Malrotation

AGOSTINO PIERRO AND SHIREEN ANNE NAH

INTRODUCTION

Malrotation is the term used to denote an interference with the normal process of orderly return of the fetal intestine from the physiological hernia to the abdominal cavity during which it undergoes systematic rotation and fixation.

EMBRYOLOGY

The intestine initially develops as a tube extending down the midline for the embryo. As the intestine lengthens it protrudes through the umbilical ring into the physiological umbilical hernia where it undergoes further lengthening before returning back into the abdominal cavity. Three stages of development of the midgut are recognized:

Stage I: 4–10 weeks: midgut protrudes and develops in the physiological umbilical hernia.

Stage II: 10–12 weeks: midgut migrates back into the abdomen in an orderly manner, small bowel first and cecocolic loop last. The cecum initially lies on the left but it rotates through 270° to attain its final position in the right iliac fossa. Simultaneously, the duodenum undergoes a 270° anticlockwise rotation.

Stage III: Final phase consisting of fusion of various parts of the mesentery with fixation of cecum and ascending colon and the descending colon.

INCIDENCE

Although it is recognized that malrotation may exist undetected throughout life (0.2%), it is generally accepted that once the diagnosis has been established, surgical correction should be carried out to avoid the occurrence of a volvulus. Fifty-five percent of malrotations present within the first week of life and 80% in the first month. Thereafter, sporadic cases occur throughout life. Malrotations may coexist in association with a number of life-threatening congenital anomalies, e.g. exomphalos and diaphragmatic hernia.

CLINICAL PRESENTATION

Neonatal period

- Recurrent episodes of subacute obstruction with intermittent bilious vomiting.
- Strangulating intestinal obstruction as a consequence of midgut volvulus. The infant presents with bile-stained vomiting which may contain altered blood, abdominal distension and tenderness, the passage of dark blood per rectum, and shock. As the strangulation progresses to gangrene, perforation, and peritonitis, edema and erythema of the anterior abdominal wall becomes evident.

Older infant and child

- Intermittent or cyclical vomiting which often contains bile.
- Failure to thrive.
- Intermittent severe abdominal colicky pain.
- Anorexia as a result of pain associated with eating.
- Malabsorption and/or diarrhea.

RADIOLOGICAL DIAGNOSIS

The plain abdominal x-ray in the infant with midgut volvulus typically shows a 'gasless' appearance with air in the stomach

Figure 50.1 Plain abdominal radiograph showing gas in the stomach and first part of the duodenum with a paucity of gas in the rest of the intestinal tract.

and duodenum and little or no gas in the rest of the intestines (Fig. 50.1).

Contrast studies are diagnostic. The procedure of choice is the upper gastrointestinal contrast study which shows the abnormal configuration of the duodenum, the duodenojejunal junction to the right of the midline, and the small bowel located on the right side of the abdomen. Where volvulus has occurred, the duodenum and upper jejunum show a 'twisted ribbon' or 'corkscrew' appearance (Figs 50.2 and 50.3). The barium enema will show the cecum and appendix in an abnormal position, usually in the right hypochondrium or midabdomen.

Ultrasonography to determine the relationship between the superior mesenteric vein (SMV) and superior mesenteric artery (SMA) has been advocated as a non-invasive method of diagnosing malrotation but this investigation is operator dependent and not reliable in approximately 20% of affected children. Normally, the SMV lies to the right of the SMA whereas in malrotation the position is reversed with the SMV to the left of the SMA. Colour Doppler ultrasound may reveal the ominous 'whirlpool' appearance, which is created when the SMV and mesentery wrap around the SMA in midgut volvulus.

TREATMENT

The operative correction of a malrotation should be regarded as a surgical emergency. Patients presenting with acute strangulating obstruction as a result of midgut volvulus require a brief period (not more than 2–3 hours) of intensive resuscitation in preparation for surgery. An i.v. infusion of crystalloids or 5% human albumin is given at 20 mL/kg administered as rapidly as possible, repeated as required, followed by 0.45% saline in 5–10% dextrose at 10 mL/kg per hour until induction of anesthesia. A nasogastric tube of suitable size is passed and gastric content aspirated and a prophylactic dose of broad-spectrum antibiotics given parenterally. A specimen of blood is taken for crossmatch, hematology and serum electrolyte estimation. Blood for transfusion must be available at the commencement of the laparotomy.

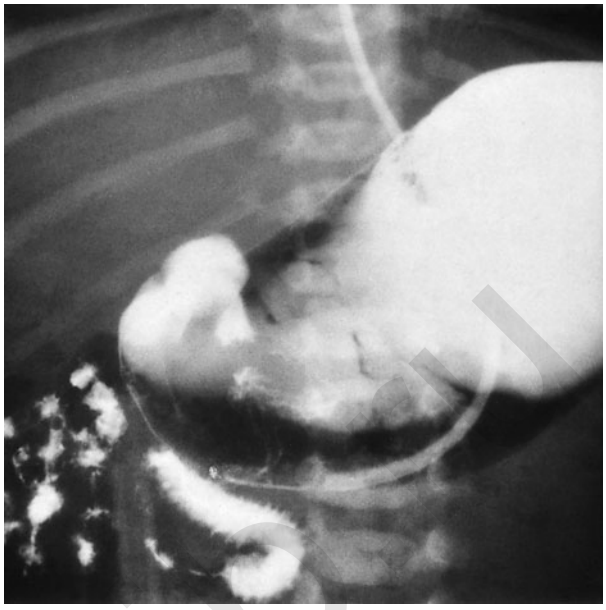

Figure 50.2 Upper gastrointestinal contrast study showing the duodenojejunal flexure to the right of the vertebral column and small intestinal loops in the right upper quadrant of the abdomen.

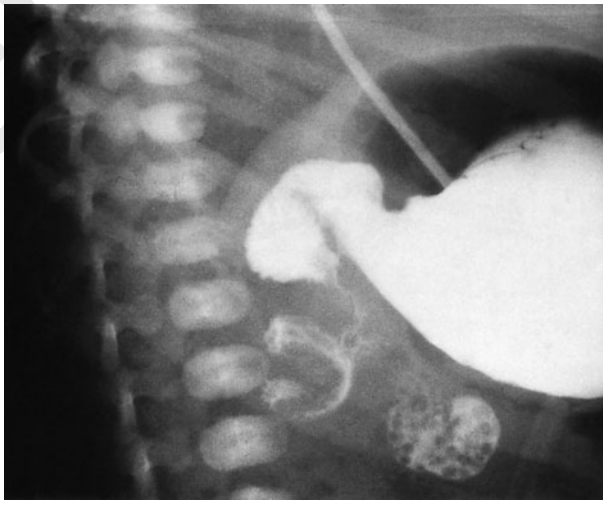

Figure 50.3 Lateral view of an upper gastrointestinal contrast study showing a dilated proximal duodenum with a 'twisted ribbon' appearance of the upper small intestine indicating volvulus of the midgut.

THE OPERATION

Open procedure

INCISION

A laparotomy is performed via a right upper abdominal transverse muscle-cutting incision extending across the rectus abdominis muscle (Fig. 50.4). The obliterated umbilical vein in the free edge of the falciform ligament is ligated and divided. The bowel is delivered into the wound. A small volume of yellowish, free-peritoneal fluid is present in any early intestinal obstruction, but blood-stained fluid is indicative of intestinal necrosis.

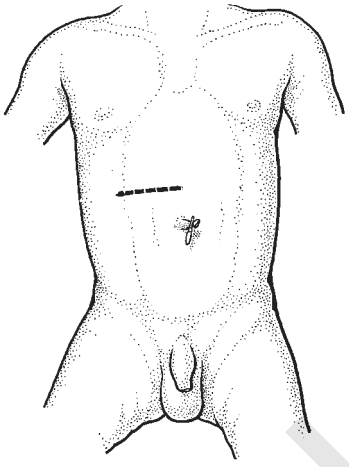

Figure 50.4 Incision to right of midline in the upper abdomen but should be extended across to the left if additional exposure is required.

MANAGEMENT OF MIDGUT VOLVULUS

The volvulus occurs around the base of the narrowed midgut mesentery (Fig. 50.5). The twist usually occurs in a clockwise direction and is untwisted by counter-clockwise rotation of as many 180° rotations as required (Fig. 50.6). Moderately ischemic bowel, which appears congested or dusky, rapidly resumes a normal pinkish color on reduction of the volvulus. Frankly necrotic bowel may be extremely friable and may disintegrate on handling. Bowel of questionable viability should be covered, after untwisting, with moist swabs and left undisturbed for approximately 10 minutes before assessing the extent of ischemic damage. A Ladd's procedure for the malrotation is carried out (see below).

In patients with extensive intestinal gangrene, frankly necrotic bowel should be resected and the bowel ends either tied off or stomas fashioned with a view to a second-look laparotomy in 24–48 hours when a clearer line of demarcation will have established. At this stage, an end-to-end anastomosis may be feasible. In the intervening period, the patient is electively ventilated and resuscitative measures continued.

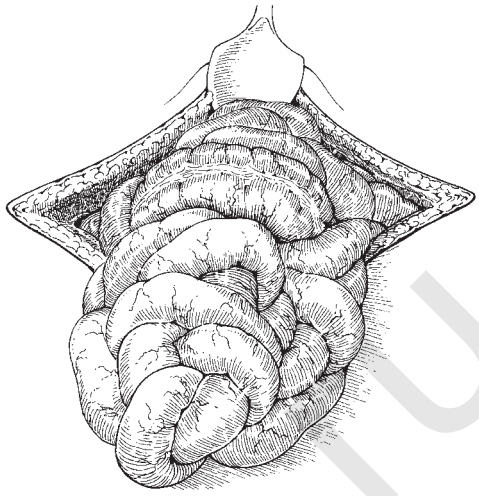

Figure 50.5 Appearance of midgut volvulus which occurs in a clockwise direction.

Figure 50.6 Untwisting of a midgut volvulus in a counter-clockwise direction.

MANAGEMENT OF THE UNCOMPLICATED MALROTATION (LADD'S PROCEDURE)

Having untwisted a volvulus, attention is now directed at the narrow-based mesentery of the midgut and the orientation of the duodenum and colon.

The peritoneal folds which extend from the cecum and ascending colon laterally across the second part of the duodenum and cranially towards the liver and gallbladder are carefully divided (Fig. 50.7). This procedure leaves the right colon freely mobile to allow its displacement to the left side of the peritoneal cavity.

Attention is now directed to the duodenojejunal junction. The ligament of Treitz at the apex of the duodenojejunal flexure is divided and the duodenal loop straightened by mobilizing the third and fourth parts of the duodenum from the head of the pancreas (Fig. 50.8).

The superior mesenteric vessels coursing in the root of the mesentery between the duodenojejunal junction and the

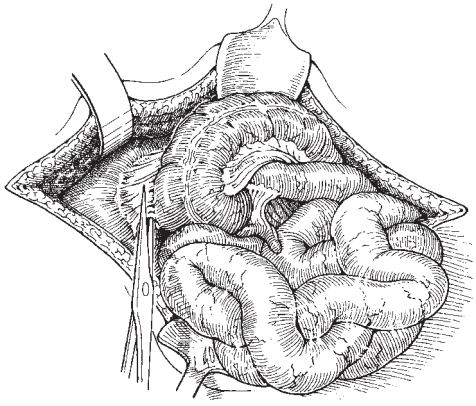

Figure 50.7 Division of peritoneal folds extending from the cecum and ascending colon across the duodenum towards gall bladder and liver (Ladd's bands).

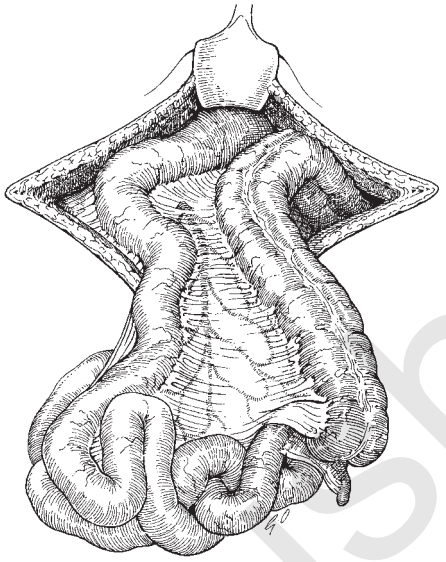

Figure 50.8 The duodenojejunal flexure has been mobilized and the narrow-based mesentery is clearly obvious.

ascending colon are exposed by dividing the anterior layer of the mesentery (Fig. 50.9). The mesentery is often thickened and edematous and care should be taken to avoid trauma to the main vessels. Numerous small lymphatic vessels require electrocoagulation or ligation before division to avoid a chylous leak. There is often quite dense fibrous tissue in the root of the mesentery and this requires careful division in order to achieve adequate widening at the base of the mesentery.

An appendicectomy is usually performed if the viability of the bowel permits, as the cecum will be placed in the left upper quadrant of the abdomen and appendicitis could pose considerable diagnostic difficulty in the future. In infants, the appendix may contribute to the maturation of the intestinal immune system and there may be advantages in preserving it. The parents need to be informed that the appendix is retained and may be in an atypical position.

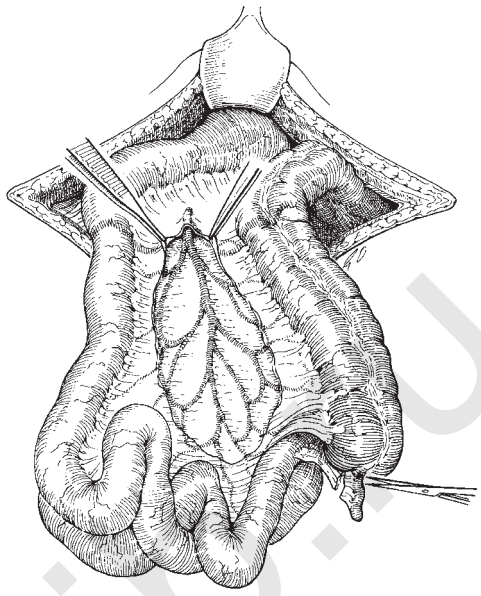

Figure 50.9 Splaying of the root of the mesentery by dividing the anterior layer of the mesentery and dividing fibrous bands crossing over the superior mesenteric vessels.

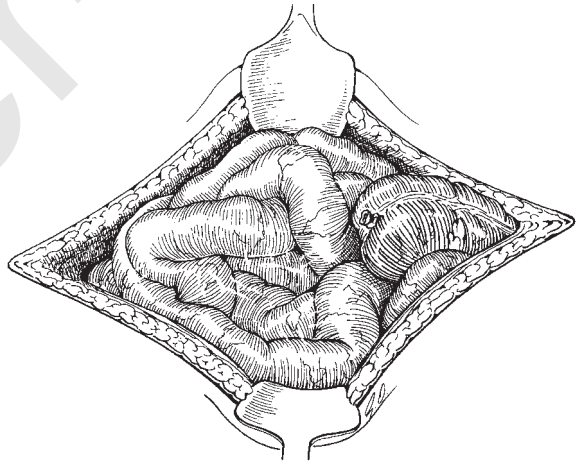

Figure 50.10 Intestine has been replaced into the peritoneal cavity with the small bowel on the right side and the cecum and ascending colon in the left upper quadrant. An appendicectomy has been performed (an alternative is an inversion appendicectomy).

The intestines are now replaced into the peritoneal cavity, commencing with the proximal jejunum which is placed on the right side and ending with the terminal ileum and cecum which are placed in the left upper quadrant (Fig. 50.10). No attempt is made to fix the bowel in this position, although some authors advocate stabilization of the mesentery to prevent recurrent volvulus.

LAPAROSCOPIC CORRECTION OF MALROTATION

A cannula is inserted peri-umbilically using an open technique. Pneumoperitoneum is created (maximum pressure 10 mmHg) and a 5 mm 30° telescope is introduced (Fig. 50.11).

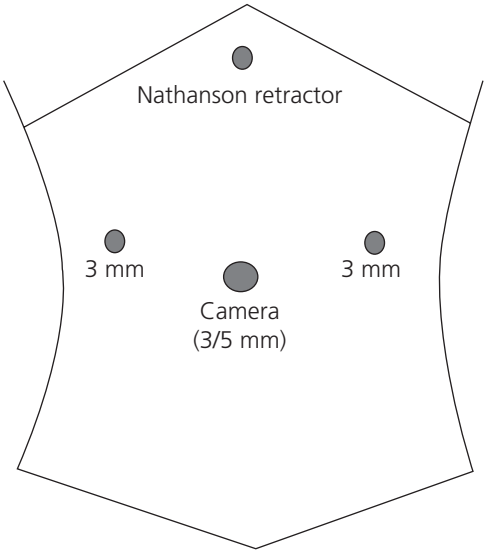

Figure 50.11 Position of ports in laparoscopic Ladd's procedure.

Two 3 or 5 mm instrument ports are inserted in the right and left flanks. A Nathanson retractor may be inserted in the epigastrium for retraction of the liver if needed. The head of the patient is elevated and the right flank may be elevated by rotating the table to help the dissection of the duodenum.

Explorative laparotomy is carried out. Volvulus is not a contraindication to laparoscopy, but presence of strangulation or necrosis may indicate the need for conversion. The ligament of Treitz is identified and the duodenum is straightened using 3 mm hook diathermy and sharp dissection. The thickened fibrous tissue in the root of the mesentery is divided to widen its base, carefully avoiding the superior mesenteric vessels lying in the root of the mesentery. The operation is not different from the description given above in the open procedure.

Volvulus (if present) is untwisted in an anticlockwise direction. The small bowel is placed on the right of the abdomen and the colon on the left.

An appendicectomy may be performed extracorporeally, by delivering the appendix via the instrument port site which usually requires an extension of the incision. Alternatively, with the use of a 5 mm instrument port, the appendix base may be ligated intracorporeally with an endoloop, and the appendix removed.

This operation can be done laparoscopically in children with corrected major exomphalos or congenital diaphragmatic hernia.

POSTOPERATIVE MANAGEMENT

Return of bowel function may be delayed for prolonged periods during which parenteral nutrition may be required but, in general, oral nutrition can be resumed in 5–7 days. Infants who have undergone massive small bowel resection will require parenteral nutrition for many months pending adaptation of the residual intestine.

OUTCOME

Adhesional intestinal obstruction is common after open surgery where up to 50% of patients needs admission to hospital and approximately half may require laparotomy. This risk of adhesional intestinal obstruction is theoretically reduced by the usage of laparoscopy. Published rates of recurrent volvulus range widely from $<0.5\%$ after open surgery to as high as 19% after laparoscopic correction. It is possible that either inadequate widening of the mesenteric base and/or lack of adhesions post-laparoscopy may be associated with an increased risk of recurrent volvulus. Laparoscopy may be difficult in newborn infants due to the small size of the abdominal cavity. More long-term studies are needed to evaluate the effect and suitability of laparoscopic operations for malrotation and volvulus.

Persistent hyperinsulinemic hyperglycemia of infancy

PAUL RV JOHNSON

INTRODUCTION

Persistent hyperinsulinemic hyperglycemia of infancy (PHHI), or congenital hyperinsulinism (CHI) as it is now more broadly termed, is a spectrum of conditions characterized by profound hypoglycemia in the presence of inappropriately high insulin secretion.[1,2] Although rare overall, CHI is a significant cause of hypoglycemic brain injury and mental retardation[3] and therefore, all those involved in the medical and surgical management of neonates need to be familiar with this condition so that the diagnosis can be made promptly, and early treatment implemented. This chapter provides an overview of the etiology, diagnosis, and management of CHI to facilitate this.

ETIOLOGY

Over the past decade, our understanding of the etiology of CHI has increased enormously.[4,5] This has not only led to more focused treatment for certain subforms of the condition, but has also meant that genetic counseling can be offered to some families. CHI can either occur sporadically with an incidence of 1 in 40 000–50 000 or can be familial with an incidence as high as 1 in 2500. Genetically, CHI is a heterogeneous condition, and mutations of seven different genes related to insulin secretion have been reported. Mutations can be sporadic, autosomal recessive, or autosomal dominant.[5] The most common abnormality underlying CHI, is a dysfunction of the ATP-sensitive potassium channel within the pancreatic beta cell (channelopathies).[6] This ion channel is composed of two subunits, each of which is encoded for by a different gene, namely the sulfonylurea receptor gene *SUR1,* and the inward-rectifying potassium channel gene *KIR6.2.* Mutations of the SUR1 gene account for 50–60% of CHI, whereas mutations of the KIR6.2 gene are less common and only responsible for 10–15% of cases.[7] The abnormal potassium channel results in the beta cell being in a constant state of depolarization, and therefore it is constantly secreting insulin despite the cell environment being one of hypoglycemia (Fig. 51.1). A less common group of underlying causes of CHI are the 'metabolopathies', which result from enzyme deficiencies (e.g. glutamate dehydrogenase (GDH), glucokinase (GK), or short-chain L-3-hydroxyacyl-CoA dehydrogenase (SCHAD)), or dysfunction of the insulin receptor. Finally, CHI can be associated with certain specific syndromes such as Beckwith-Wiedemann, Perlman syndrome, and Sotos syndrome, each of which has associated chromosomal abnormalities.

PATHOLOGY

The original term for CHI was nesidioblastosis. This term was created by Laidlaw in 1938, and described the histological finding of islet cells proliferating by budding off the pancreatic ductal tissue within pancreases of infants with severe symptoms of hypoglycemia.[8] However, this term has since been abandoned as it was realized that not only does CHI represent a spectrum of different disorders, but more specifically, that many normal neonatal pancreases also exhibit nesidioblastosis.[9]

However, the most important advance in our understanding of CHI over recent years has been the discovery that there are two distinct histopathological forms, namely a focal form and a diffuse form. Focal CHI is characterized by a focal hyperplasia of the pancreatic beta cells and is to be distinguished from the more discrete adenoma or insulinoma seen in older children or adults. Normal islets are seen outside the focal abnormality (see Fig. 51.2). In the diffuse form of CHI, the islets are abnormal throughout the whole pancreas and exhibit large, pleomorphic, hyperchromatic nuclei (see Fig. 51.3). Distinguishing focal from diffuse CHI is important to ensure that the correct surgical treatment is undertaken.

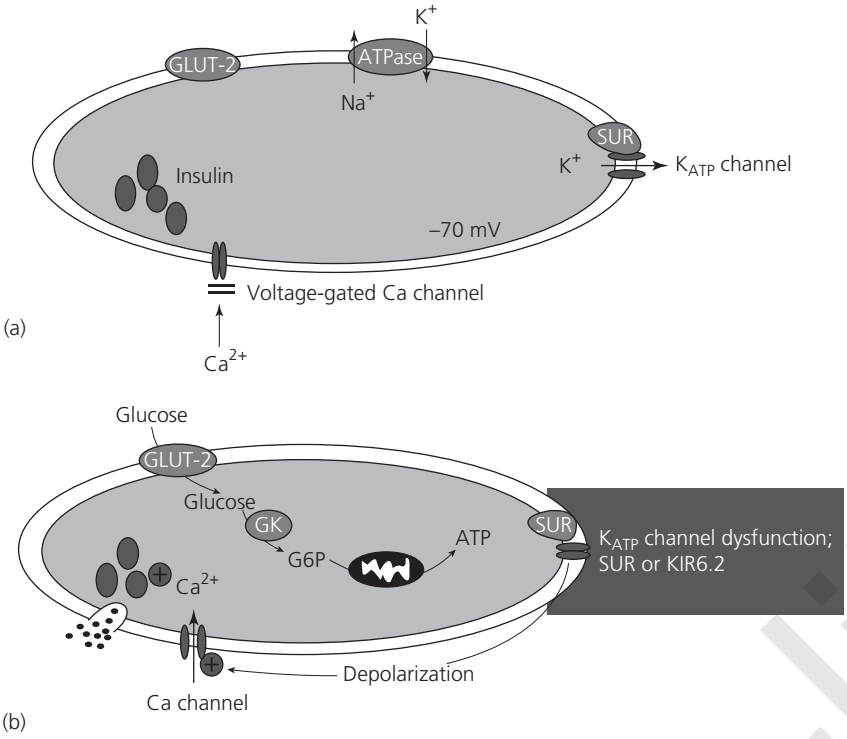

Figure 51.1 (a) Normal resting beta cell. At rest the normal K_{ATP} channel is closed which maintains the membrane potential at −70 mV. This results in the calcium channels remaining closed, preventing any calcium influx or consequent insulin release. (b) Congenital hyperinsulism (CHI) beta cell. The abnormal K_{ATP} channel in the non-stimulated CHI beta cell results in the channel remaining closed even at rest. This causes depolarization of the membrane and opening of the calcium channel. The consequent calcium influx results in insulin degranulation and release.

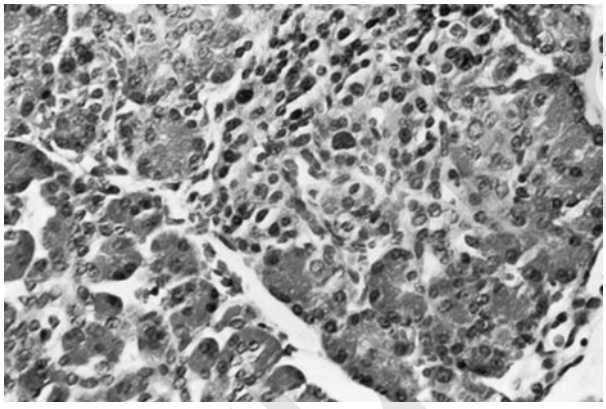

Figure 51.2 Diffuse congenital hyperinsulism: islets have large, pleomorphic, hyperchromatic nuclei present throughout pancreas.

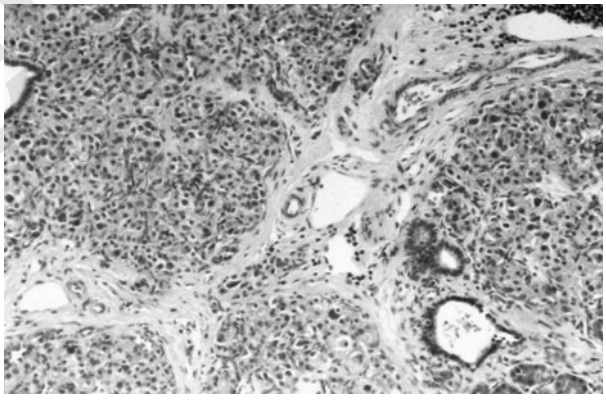

Figure 51.3 Focal congenital hyperinsulism: nodules of adenomatous islet cell hyperplasia with normal islets outside the lesion.

PRESENTATION

Congenital hyperinsulism usually presents within the first few hours or days of life in both premature and term babies, but can occasionally present later in infancy.[7] Babies can present with non-specific symptoms of hypoglycemia such as poor feeding, irritability, or lethargy, or more severe symptoms such as seizures or coma. This explains why ideally all neonates should undergo BM testing shortly after birth. A proportion of babies with CHI are macrosomic, and some have mild facial abnormalities, such as a high forehead, a small nasal tip, and a short columella.[10] CHI is most commonly an isolated condition, but can be associated with certain specific syndromes as described above under Etiology. CHI can sometimes be transient rather than persistent, but it is the persistent forms that are of most relevance to surgeons.

DIAGNOSIS

Congenital hyperinsulism is characterized by hyperinsulinemic, hypoketotic, hypofattyacidemic hypoglycemia.[1] The following diagnostic criteria are used: (1) laboratory blood glucose readings of <2.5–3 mmol/L; (2) a glucose infusion rate of >8 mg/kg/min; (3) unsuppressed insulin

concentrations of >1 mU/L; (4) a positive response to the subcutaneous or intramuscular administration of glucagon (plasma glucose concentrations increasing by 2–3 mmol/L following a 0.5 mg subcutaneous glucagon injection); (5) negative ketone bodies in the plasma and urine.

Until recently, the definitive investigation used to distinguish diffuse and focal forms of the disease was serial venous sampling of insulin. This procedure was invasive, time-consuming, and often resulted in inaccurate localization of focal disease. Over the last few years, the gold standard investigation has become [^{18}F]DOPA positron emission tomography (PET) combined with computed tomography (CT) angiography with 3D reconstruction.[11,12] This test is non-invasive and is both sensitive and specific and gives excellent localization of focal lesions. However, the [^{18}F]fluoro-L-DOPA isotope is only currently available in a few centers.

MANAGEMENT

The main aim of management is to prevent hypoglycemic brain damage and to allow normal psychomotor development. In mild cases, it may be possible to maintain acceptable levels of blood glucose by dietary measures alone. In the majority of cases however, i.v. administration of high concentrations of glucose are required to maintain blood glucose levels above 2.6 mmol/L. Glucose infusion rates in excess of 20 mg/kg/minute, i.e. 15–20% glucose, may be required. In these cases, it is essential to insert a central venous catheter to provide a central route for administration of high concentrations of glucose and to allow frequent monitoring of blood glucose levels.

Medical management

Diazoxide is the first-line medical treatment and is an agonist of the K_{ATP} channel. It is commenced at a dose of 5–20 mg/kg/day in three divided doses. It can be highly effective in the treatment of the transient and syndromic forms of CHI, but in the more severe neonatal forms in which a mutation of the K_{ATP} channel is present, the beta cells may be unresponsive.[7,13] Diazoxide is usually used in conjunction with chlorothiazide at a dose of 7–10 mg/kg/day in two divided doses. These two agents exert a synergistic effect on the K_{ATP} channel with diazoxide. Octreotide is a long-acting analog of the pancreatic hormone somatostatin, and is used in CHI both as a short-term measure to stabilize the baby pending definitive treatment, or sometimes as a long-term treatment combined with frequent feeding, for diffuse disease. Subcutaneous or i.v. glucagon is used in the acute management of hypoglycemia, often in combination with octreotide. Nifedipine has been used successfully in a small number of patients,[14] and is a calcium channel blocker which is aimed at reducing the calcium flux resulting from the constant depolarization of beta cells in CHI. The systemic effect of calcium blockade can be restrictive.

Surgical management

Surgical treatment is indicated when an infant remains dependent on i.v. glucose administration despite maximum medical treatment. Whereas 95% pancreatectomy was until recently the treatment of choice for all cases of CHI that were unresponsive to medical treatment,[15] improvements in our understanding of the histopathology of CHI has enabled more limited and targeted surgical resection treatment to be used for the focal form of the disease.[16,17] Pancreatectomy can be performed using traditional open operative techniques, or can be undertaken using laparoscopic techniques.[18,19] The surgical principles are the same for both techniques.

INCISION

For the open technique, a laparotomy is performed via a generous supra-umbilical transverse muscle-cutting incision, extending through both rectus abdominus muscles (Fig. 51.4). For the laparoscopic approach, a three trocar technique is used with triangulation centered around the umbilicus. Within the peritoneum, a thorough search is made for sites of ectopic pancreatic tissue.

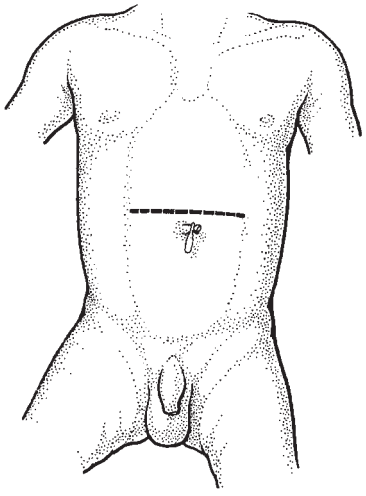

Figure 51.4 Transverse upper abdominal incision extending across both rectus abdominus muscles.

EXPOSURE

The anterior surface of the pancreas is exposed by entering the lesser peritoneal sac via the gastrocolic omentum, ligating and dividing vessels in the greater omentum along the greater curvature of the stomach (Fig. 51.5). The tail of the pancreas lies in the hilum of the spleen. The hepatic flexure is reflected medially and the duodenum kocherized to expose the head of the pancreas. The entire pancreas is carefully examined or inspected.

95% PANCREATECTOMY

In the diffuse form, the dissection of the pancreas proceeds medially from the tail towards the neck of the pancreas that lies just to the right of the superior mesenteric vessels. It is essential for future immunologic competence to preserve the spleen whenever possible. This is accomplished by carefully exposing the short pancreatic vessels passing from the splenic vessels to the pancreas. These vessels, especially the veins, are extremely friable, but meticulous dissection will allow individual ligation, application of metal clips, or electrocoagulation, and division of the vessels without traumatizing the main vessels (Fig. 51.6). Should hemorrhage occur from damage to the splenic vein, direct repair should be attempted. In the event of failure to achieve hemostasis, ligation of the splenic vein with preservation of the splenic function can be expected due to collateral supply from the short gastric vessels. When the dissection has progressed to the right of the superior mesenteric vessels, attention is directed to the head of the pancreas and in particular the uncinate process (Fig. 51.7).

The uncinate process is carefully dissected from behind the superior mesenteric vessels and, after positively defining the course of the common bile duct, the head of the pancreas to the left of the common duct and in the concavity of the duodenal loop is excised, leaving a sliver of pancreatic tissue on the surface of the duodenum and on the left wall of the common duct. The pancreatic duct is identified and ligated with a non-absorbable ligature. Hemostasis is carefully and meticulously achieved. The remaining pancreatic tissue consists of that part of the gland between the duodenum and the common bile duct and the sliver of tissue on the medial wall of the second part of the duodenum (Fig. 51.8). This represents approximately 5% of the total volume of the pancreas, but can vary considerably from patient to

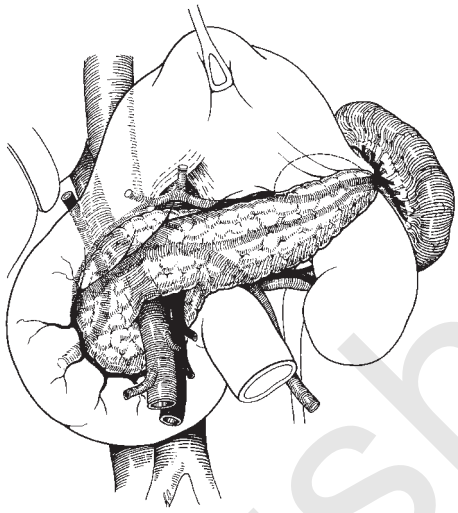

Figure 51.5 Exposure of the head, body, and tail of the pancreas by entering the lesser sac dividing the vessels in the greater omentum along the greater curvature of the stomach.

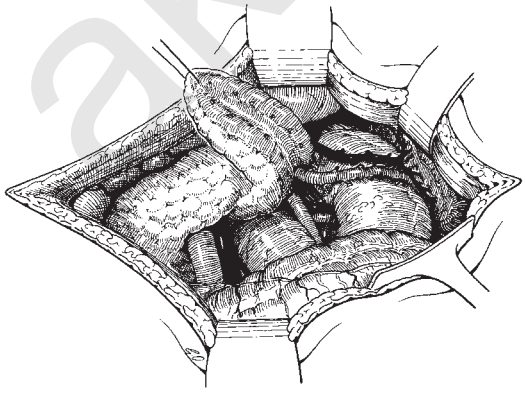

Figure 51.6 The short pancreatic vessels arising from the splenic vessels are divided and the body and tail of the pancreas are gradually dissected towards the head.

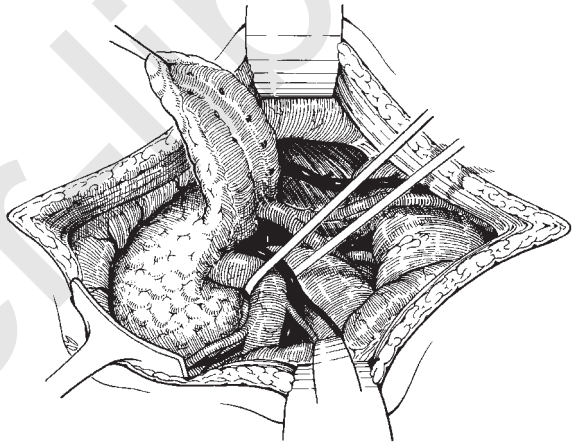

Figure 51.7 The superior mesenteric vessels are displayed and retracted towards the left, exposing the uncinate process of the pancreas.

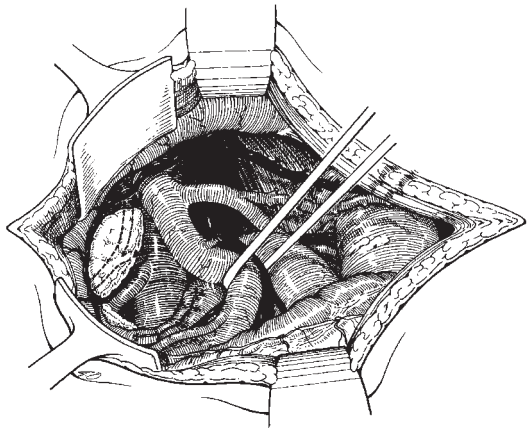

Figure 51.8 Final appearance following 95% pancreatectomy. The only remaining pancreatic tissue lies to the left of the common bile duct and a sliver in the C-curvature of the duodenum. Note splenic vessels and the completer excision of the ucinate process.

patient. A suction drain via a separate stab incision is left in the pancreatic bed.

Laparoscopic resection is performed in a similar manner, but it is easiest to perform the resection using a hook diathermy in a piecemeal manner, using a stay suture at different intervals along the pancreas as dissection proceeds from the pancreatic tail towards the head. For the transection of the pancreas itself, the harmonic scalpel ensures good hemostasis and occlusion of the pancreatic duct and cut parenchyma.

RESECTION OF FOCAL DISEASE

Exactly the same principles as described above apply for resection of focal disease. Based on the preoperative PET scan, the focal lesion is resected leaving the normal pancreas behind.[17] If the focal disease is within the head of the pancreas, occasionally a major Whipple-type resection is required.

POSTOPERATIVE CARE

Postoperatively, glucose infusions and CHI medications are directed by constant monitoring of blood glucose. The infant is kept nil by mouth with a nasogastric tube *in situ* until the postoperative ileus has resolved.

COMPLICATIONS

Each of the medical treatments of CHI can have its side effects.[7] Long-term use of diazoxide is associated with hypertrichosis (excessive growth of hair in areas where hair does not normally grow) and this can limit its long-term use. Octreotide is associated with a wide range of side effects including gastrointestinal upset (abdominal pain, nausea, bloating, and diarrhea), and suppression of growth hormone (GH), thyroid stimulating hormone (TSH), and adrenocorticotropic hormone (ACTH). Recurrent hypoglycemia can occur as a result of insufficient surgical resection of the diffuse form of the disease, or due to failed localization in the focal form, and should be evident within the first 72 hours after the operation. Persistent hypoglycemia may require further surgical resection. Other surgical complications include postoperative infection, bleeding, and operative trauma to the bile duct.[20] If the latter is diagnosed preoperatively, then primary repair and drainage is performed. Delayed diagnosis of bile duct injury can be treated operatively or conservatively depending on the degree of damage and the timing of presentation.

LONG-TERM RESULTS

The neurological outcome of patients with CHI depends on the age of presentation.[3] Neonates with CHI that is unresponsive to medical treatment are at increased risk of brain injury, as are those with a delayed diagnosis and delayed implementation of treatment.[3] The form of CHI per se does not seem to influence outcome. In patients undergoing 95% pancreatectomy, the majority will develop insulin-dependent diabetes by the second decade of life.[21,22] These patients require close monitoring of their glucose homeostasis and a yearly glucose-tolerance test is indicated. For those who do develop diabetes, novel, minimally invasive treatments, such as pancreatic islet transplantation are now achieving excellent results for reversing diabetes in adults.[23] The majority of these patients will require oral pancreatic exocrine replacement. The recent emphasis on limited pancreatic resection for focal CHI means that both exocrine and endocrine insufficiency can be reduced in this group of patients.

Jejuno-ileal atresia and stenosis

ALASTAIR JW MILLAR, ALP NUMANOGLU, AND HEINZ RODE

INTRODUCTION

Jejuno-ileal atresia, defined as a congenital defect in continuity of the bowel, is a common cause of intestinal obstruction in the newborn.[1–3] The incidence of jejuno-ileal atresia varies from 1 in 330 and 1 in 400 live births,[4] to between 1 in 1500 and 1 in 3000 live births.[5] Jejuno-ileal occlusions occur more frequently than duodenal or colonic.[1,6] With improved neonatal and perioperative care, safe anesthesia, refined surgical techniques and management of short bowel syndrome, a survival rate of greater than 90% can be expected in well-resourced centers. At the Red Cross War Memorial Children's Hospital in Cape Town during the 51 years 1959–2009, 333 jejuno-ileal atresias, 251 (75%) jejunum, and 82 (25%) ileum were seen (Table 52.1). Down syndrome is most uncommon in babies with jejuno-ileal atresia (only one baby in the Red Cross Hospital series) compared with duodenal atresias. The first successful surgical repair of an intestinal atresia was in 1911.[7] The mortality rate remained high over the next four decades and it was only in the mid 1950s that an improved understanding of the pathogenesis and pathology of the condition led to innovative surgical techniques which resulted in greatly improved surgical outcome.[5,6]

Table 52.1 Jejunal atresia and stenosis: Red Cross Children's Hospital experience 1959–2009.

Type	Jejunum	Ileum	Total (%)
Stenosis	21	13	10.2
I	61	18	23.7
II	19	13	9.6
IIIa	27	24	15.3
IIIb	60	60	18
IV	63	14	23
Total	251	82	333

ETIOLOGY

In 1889, Bland Sutton postulated that atresia occurred at the site of 'obliterative embryological events' and he quoted atrophy of the vitelline duct.[8] In 1900, Tandler,[9] supported by embryonal studies, suggested that intestinal atresia was related to a lack of recanalization of the solid stage of the intestine, while others have questioned these theories.[10–12] In 1952, Louw published the results of an investigation of 79 patients treated at Great Ormond Street, London, and suggested that jejuno-ileal atresia was probably due to a vascular accident rather than the result of inadequate recanalization.[5] At his instigation, Barnard perfected the experimental model in pregnant mongrel bitches. Mesenteric vascular insults, such as volvulus, intussusception, and interference with the blood supply to a segment of bowel were created in the dog fetus.[13] This not only confirmed the hypothesis but led to a change in the surgical procedure for correcting atresias and stenosis of the jejunum and ileum with a marked improvement in outcome.[14–16] Subsequently, these experimental findings were confirmed by others in several different animal models and in clinical practice.[17–21] Evidence of bowel infarction was present in 42% of 449 cases of jejuno-ileal atresia in a collected series which further supported the vascular hypothesis.[22] Furthermore, the localized nature of the vascular accident occurring late in fetal life would explain the low incidence (less than 10%) of coexisting abnormalities of extra-abdominal organs.

The anomaly is usually not genetically determined although affected monozygotic twins and siblings have been described. A genetic basis however has been established for type IIIb and IV multiple atresias.[23–26]

PATHOLOGY

The classification of jejuno-ileal atresia into three types by Bland Sutton in 1889 has stood the test of time, except for the

subdivision of type III into two categories (a and b) and the addition of type IV (Fig. 52.1).[8,27,28] This subdivision has allowed a better long-term prognostication. In stenosis, the proximal dilated and narrower distal bowel are in continuity with an intact mesentery, but at the point of junction there is a short, narrow, somewhat rigid segment with a narrow but patent lumen. The small intestine is of normal length (Fig. 52.2).

In atresia type I (membrane or web) the dilated proximal and collapsed bowel are in continuity and the mesentery is intact. The intraluminal pressure in the proximal bowel produces bulging of the web into the distal intestine so that the transition from the distended to collapsed bowel is conical in appearance – the 'windsock' effect. The distal bowel is completely collapsed and the small intestine is of normal length (Fig. 52.3).

In atresia type II (blind ends joined by a fibrous band), the proximal bowel terminates in a bulbous blind end which is grossly distended and hypertrophied for several centimeters and is often hypoperistaltic. The bowel proximal to this is usually also considerably distended and hypertrophied for a further 5–10 cm. More proximally, the bowel distension is less marked and the bowel assumes a normal appearance. The distal collapsed bowel commences as a blind end which is sometimes bulbous due to remains of a fetal intussusception. The two blind ends are joined by a thin fibrous band. The corresponding intestinal mesentery is normal but may occasionally be deficient, leaving a V-shaped gap. The small intestine is usually of normal length (Fig. 52.4).

In atresia type IIIa (disconnected blind ends) the appearance is similar to that in type II but the blind ends are completely separate. There is always a V-shaped gap in the mesentery and the total bowel length is reduced (Fig. 52.5).

In atresia type IIIb (apple peel,[17] Christmas tree,[29] or maypole[6] deformity), as in IIIa, the blind ends are disconnected and the mesenteric defect is substantial. This type is the consequence of an extensive infarction of the midgut secondary to a superior mesenteric artery occlusion just distal to the middle colic origin, producing a proximal jejunal atresia with loss of a varying segment of jejunum. The distal ileum remains viable, receiving its blood supply via a precarious collateral from the arterial supply to the right colon, around which the ileum is coiled. Occasionally, additional type I or type II atresias are found along the coiled length of bowel towards the distal blind end. There is always a significant reduction in intestinal length (Fig. 52.6). These babies are usually premature and of low birth weight. In addition, they may have associated anomalies such as malrotation and may develop short bowel syndrome with increased morbidity and mortality.[22] A familial incidence has been reported by Blyth and Dickson[30] and Mishalany and Najjar.[25]

In atresia type IV, multiple atresias are present, which could be a combination of types I–III and often have the appearance of a string of sausages. The bowel length is usually reduced (Fig. 52.7). The site of the most proximal atresia determines whether it is classified as jejunal or ileal.

The intestine proximal to the obstruction becomes dilated and hypertrophied. This dilated bowel frequently has a cyanosed appearance and may have some necrotic areas either from sustained intraluminal pressure or secondary volvulus. Perforation may develop antenatally, leading to

meconium peritonitis or may occur as a postnatal event, especially if diagnosis is delayed. The peristaltic movements in this segment are subnormal and ineffective, and histologic and histochemical abnormalities can be observed up to 20 cm cephalad to the atretic segment (Fig. 52.5).[31,32] In contrast, the distal bowel is unused and worm-like in appearance, but potentially normal in length and function.

Of the 333 patients in our series, there were 34 (10.2%) with stenosis, 79 (24%) with type I, 32 (9.6%) with type II, 51 (15%) with type IIIa, 60 (18%) with type IIIb, and 77 (23%) with type IV atresias (Table 52.1).

CLINICAL FEATURES

A prenatal history of polyhydramnios is frequent and many babies with intestinal atresia are diagnosed by ultrasonographic investigation of the fetus, showing dilated and obstructive fetal intestine.[33] The family history may help to identify hereditary forms and conditions that may predispose to atresia, i.e. cystic fibrosis and anomalies of intestinal rotation.

Atresia or severe stenosis of the small intestine presents clinically as neonatal intestinal obstruction with persistent bile-stained vomiting dated from the first or second day of life. In general, the higher the level of obstruction the earlier and more forceful the vomiting, whereas in low intestinal obstruction the vomiting may be delayed. Abdominal distension is frequently present, more so with the distal ileal intestinal atresias where the distension is generalized compared with the more proximal jejunal atresias where it is confined to the upper abdomen and is relieved by nasogastric tube aspiration. In delayed diagnosis or where perforation has occurred, the distension may be severe and associated with respiratory distress. Constipation is usually not absolute and the meconium passed varies from normal in colour to the more common gray plugs of mucus. Occasionally, if ischemic bowel is present, as in type IIIb atresia, blood may be passed rectally.

Diseases that can mimic jejuno-ileal atresia include midgut volvulus, meconium ileus, duplication cysts, internal hernia, ileus due to sepsis, birth trauma, prematurity, and transplacental crossing of maternal medication.

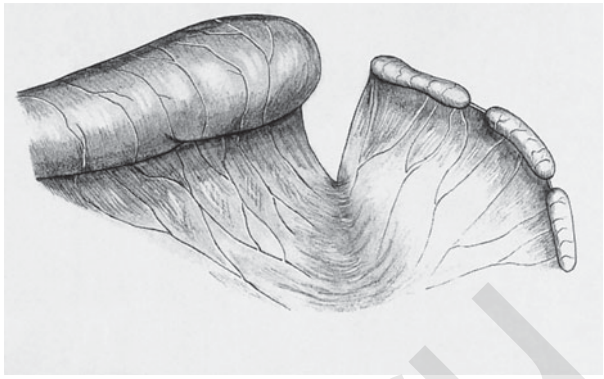
(b)

Figure 52.6 (a) Atresia type IIIb with a gross mesenteric defect and the coiled distal ileum with precarious collateral blood supply, producing the typical 'apple-peel' appearance. (b) Note the classical clinical appearance of the apple-peel atresia. Note the precarious blood supply of the terminal portion of the distal bowel and the grossly dilated proximal jejunum. There is always significant reduction in intestinal length.



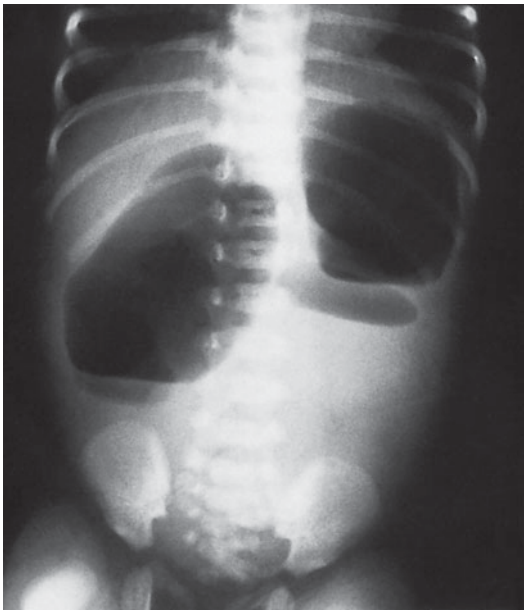
(a)

(b)

Figure 52.7 Multiple atresias with a typical 'string of sausages' seen clinically. The bowel length is usually reduced.

Erect and supine abdominal x-rays will reveal distended small bowel loops and air–fluid levels (Fig. 52.8a). The lower the obstruction, the greater the distended loops of bowel and the more fluid levels will be observed. A single large loop of bowel and air–fluid level would indicate atresia rather than other causes of neonatal intestinal obstruction. A prone lateral view is useful to distinguish between low small bowel and colonic obstruction. In some instances, the first abdominal x-ray may reveal a completely opaque abdomen due to a fluid-filled obstructed bowel. Emptying of the stomach by means of a nasogastric tube and injection of air will demonstrate the level of the obstruction. With intestinal stenosis, the caliber of the proximal obstructed intestine is greater than the distal gut but because the obstruction is incomplete the diagnosis is often delayed. When the abdominal x-ray suggests a complete obstruction, a contrast enema may be performed to exclude colonic atresia, distinguish between small and large bowel distension, determine whether the colon has the typical microcolon appearance, and locate the position of the cecum as an indication of malrotation. It also makes saline injection of the colon at surgery unnecessary, a sometimes tedious maneuver.

The classical appearance of the colon distal to jejuno-ileal atresia is an unused or microcolon (Fig. 52.8). When an incomplete small bowel obstruction is diagnosed, an upper gastrointestinal contrast study is indicated to demonstrate the site and nature of the obstruction. Malrotation may also be observed in 10–30% of babies with jejuno-ileal atresia. Occasionally, dystrophic intraperitoneal calcification of



(a)

(b)

Figure 52.8 (a) Erect abdominal x-ray of a newborn infant showing obstructed upper small bowel loops with fluid levels. No air is visible in the distal bowel. (b) Contrast enema showing the unused or microcolon distal to a jejuno-ileal atresia. In addition, evidence of malrotation is present.

meconium peritonitis may be seen on plain x-ray, signifying intrauterine bowel perforation. If the atresia has formed late in intrauterine life, the bowel distal to the atresia may assume the caliber of a used colon.

GUIDELINES FOR MANAGEMENT

The guidelines for management of jejuno-ileal atresia are as follows:

- Prenatal
  - polyhydramnios, affected family, ultrasonography
- Preoperative preparation
  - gastric decompression
  - fluid management
    - maintenance
    - replacement of deficiency/ongoing losses
  - plain abdominal radiograph (air contrast)
  - contrast enema
  - correction of hematological and biochemical abnormalities
  - prophylactic antibiotics
- Operative
  - identify type of atresia and possible cause
  - establish patency of distal small bowel
  - resection of the proximal bulbous component, ischemic bowel
  - derotation for high jejunal atresia
  - limited distal bowel resection
  - establish patency of distal bowel with saline injection
  - careful measurement of residual bowel length
  - end-to-end, single-layer interrupted suture anastomosis
  - bowel length conservation method – tapering, plication
- Postoperative
  - gastrointestinal decompression
  - antibiotics
  - parenteral nutrition
  - early and graduated enteral feeding with breast milk, special, or polymeric feeds
  - surveillance for gastrointestinal dysfunction
- Special problems
  - anastomotic dysfunction
  - short bowel syndrome
  - associated congenital anomalies.

Adapted from Haller *et al.*[34]

TREATMENT

The newborn baby tolerates operative intervention all the better after a few hours of preoperative preparation, especially if the diagnosis has been delayed. In general, this preparation should pay particular attention to hypothermia, hypoxia, hypovolemia, hypoglycemia, and hypoprothrombinemia. The operation should not be delayed unduly as there is always a danger of further infarction of the bowel, fluid and electrolyte disturbances, and increased risk of infection. In neglected cases with dehydration, more energetic therapy is required.

Operation

STERILIZATION OF SKIN AND DRAPING

The umbilical cord is cleansed with 70% alcohol and is ligated and transected at the level of the abdominal wall. The operative field is sterilized with pre-warmed povidone–iodine 2% in 70% alcohol. Sterile warm Gamgee rolls are placed alongside the baby, who is then draped with towels, and a sterile transparent adhesive drape is applied over the operative field to ensure that they remain dry during the operative procedure, thus preventing heat loss.

INCISION

An adequate incision is required. Exposure is obtained through a supra-umbilical transverse incision transecting the recti muscles 2–3 cm above the umbilicus. The ligamentum teres is subsequently divided and ligated. Alternatively, a small circumumbilical incision may be adequate.[35]

EXPLORATION

If free gas escapes on opening the peritoneum, or if there is contamination of the peritoneal cavity, a pus swab is obtained for Gram stain and culture and the site of the perforation is sought and closed before further exploration is carried out. In the presence of peritoneal contamination, the cavity is irrigated with warm saline or antibiotic-containing fluid – cefoxitin sodium 1 g/L. The entire bowel is exteriorized to determine the site and type of obstruction and to exclude other areas of atresia or stenosis and associated lesions, such as incomplete intestinal rotation or meconium ileus. The appearance of the atretic segment depends upon the type of occlusion, but in all cases the maximal dilatation of the proximal bowel occurs at the point of obstruction; this segment is often aperistaltic and of questionable viability, while the bowel distal to the obstruction is collapsed, tiny and worm-like (Figs 52.5, 52.6, and 52.9).

After the location and type of lesion has been identified, the distal bowel is carefully examined to exclude other atretic segments, which are present in 10–20% of cases. Saline is instilled into the lumen of the distal bowel to confirm patency. Malrotation is corrected if present. The total length of small bowel is measured as this has prognostic significance and may determine the method of reconstruction. The normal length at full-term birth is approximately 250 cm.

After complete patency of the distal small bowel and colon has been established, the next task is to suture the disproportionate proximal and distal blind ends. This is facilitated by applying an atraumatic bowel clamp about 6–8 cm from the distal blind end and distending the intervening segment by injection with half-normal saline, taking care not to split the serosa (Fig. 52.9).

RESECTION

The atretic area and adjacent distended and collapsed bowel are isolated by walling off the rest of the abdominal cavity with moist packs. To ensure adequate postoperative function, the proximal distended and hypertrophied bowel should be liberally resected, even if it appears viable. If the bowel length is adequate (more than 75 cm plus ileocecal valve) the bulbous hypertrophied bowel proximal to the atresia is resected to approximately normal bowel diameter; usually a 10–15 cm section is removed. After milking the intestinal contents into the proximal bulbous end, an atraumatic bowel clamp is applied across the bowel a few centimeters proximal to the site selected for transection. The mesentery adjoining the portion to be resected is divided using bipolar diathermy or ligated up to the proposed lines of section of proximal and distal bowel (Fig. 52.10). The blood supply at this point should be excellent and therefore the bowel is divided at right angles, leaving an opening of about 1.5 cm in width; 2–3 cm of the distal bowel is also removed. This bowel may be transected slightly obliquely and an incision may be continued along the antimesenteric border to create a 'fish-mouth', which renders the opening about equal to that of the proximal bowel (Fig. 52.11). Alternatively, the bowel can be transacted at right angles if an end-to-end anastomosis is planned. In patients with a relatively short segment of severely dilated proximal intestine, de-rotation of the proximal segment, resection to the distal second part of duodenum and establishment of continuity by end-to-end anastomosis with tapering of the duodenum is a good option. However, in patients with long segments of proximal intestine that are significantly dilated, resection of the whole involved segment may result in inadequate remaining intestinal length to allow absorption of enteric nutrients (i.e. short-bowel syndrome). Therefore, these patients frequently are treated by either imbrication or tapering enteroplasty of the proximal dilated segment. In a few cases with extensive congenital short bowel primary serial transverse enteroplasty has been attempted.[36]

Figure 52.9 The proximal atretic bowel is grossly dilated, aperistaltic, and of questionable viability.

ANASTOMOSIS

An inverting mattress of 5-0 or 6-0 polydioxanone sutures unites the mesenteric borders of the divided ends, and temporary stay sutures are inserted at the antimesenteric angles to facilitate accurate approximation. The 'posterior'

(b)

Figure 52.10 (a) The distal bowel distended with saline proximal to the bowel clamp. The extent of the resection is indicated by the dotted line. (b) The extent of resection in the clinical situation is depicted. Note that all grossly dilated bowel is resected.

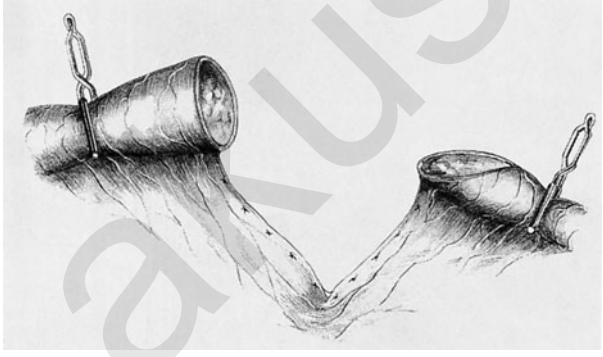

Figure 52.11 The proximal bowel has been transected at right angles and the distal obliquely with continuation of the incision along the antimesenteric border to create a 'fish-mouth'.

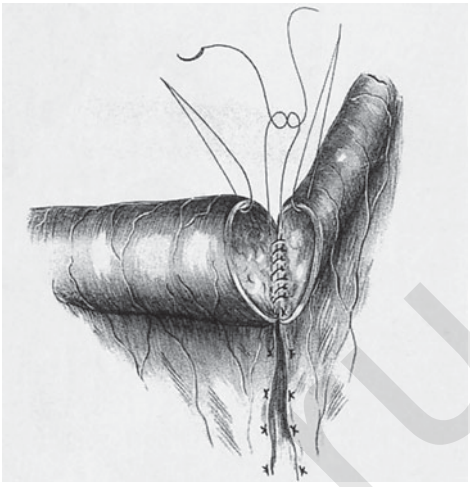
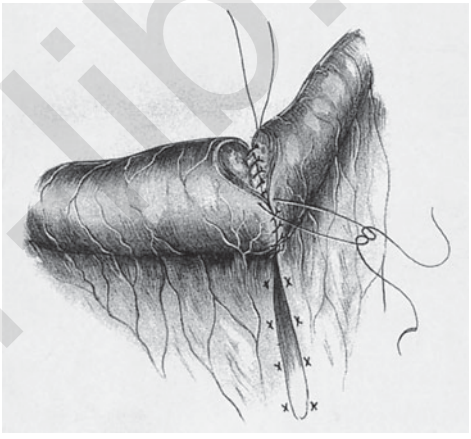
edges of the bowel are united with interrupted through-and-through 5-0 or 6-0 polydioxanone sutures tied on the mucosal aspect (Fig. 52.12a). The 'anterior' edges are joined by similar through-and-through sutures tied on the serosal surface (Fig. 52.12b). The completed anastomosis is not strictly end-to-end but a modification of Denis Browne's



(a)



(b)

Figure 52.12 (a) Anastomosis of the posterior wall with interrupted sutures. (b) The anterior anastomosis.

'end-to-back' method. An alternative suture technique includes extramucosal anastomosis and the use of 5-0 or 6-0 monofilament absorbable sutures and end-to-end sutures taking larger bites on the proximal bowel. Where there is a discrepancy of less than 4:1 between the proximal and distal bowel lumens, an end-to-end extramucosal anastomosis is advised as there is thought to be an earlier return of normal peristalsis. The suture line is tested for leakage and reinforcing sutures are inserted as required. The defect in the mesentery is repaired by approximating (and overlapping if necessary) the divided edges with interrupted sutures (Fig. 52.13). The intestines are returned to the peritoneal cavity. During this procedure, if the mesentery is kept in the configuration of an open fan, kinking or volvulus of the bowel will be avoided.

A similar technique is used for stenosis and intraluminal membranes. Procedures such as enteroplasties, excision of membranes, and bypassing techniques are not recommended because they fail to remove the abnormal segment of bowel; side-to-side anastomosis is avoided due to the risk of creating blind loops.

GASTROSTOMY/ENTERAL DECOMPRESSION AND EARLY ENTERAL FEEDING

It was customary in babies with high jejunal atresias just beyond the duodenojejunal flexure to place a transanastomotic feeding tube for early enteral feeding when parenteral feeding techniques were less sophisticated. The tube was passed into the small bowel distal to the anastomosis before completing the anterior layer of sutures and stabilized at the anastomotic site by a single tethering mucosal stitch, in order to prevent its retrograde displacement into the stomach. The transanastomotic tube was either passed via the nasogastric route or via a Stamm gastrostomy performed on the anterior wall of the stomach. More recently, the value of such transanastomotic tubes has been questioned and the authors have abandoned routine use of these for high jejunal and duodenal atresias.[37] Nutrition is provided by the parenteral route until full enteral feeds are established.

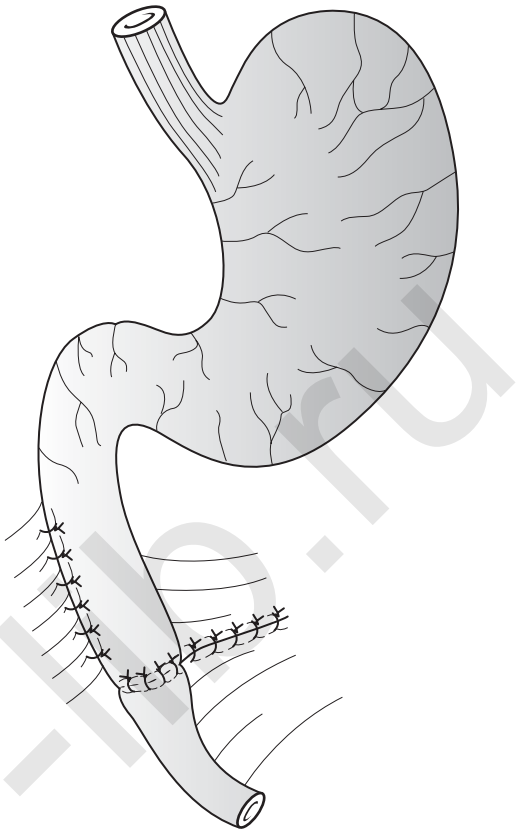

Figure 52.14 The surgical procedure for high jejunal atresia includes derotation of the bowel, back resection into the second part of the duodenum, tapering duodenoplasty or linear seromuscular stripping and inversion plication followed by bowel anastomosis.

CLOSURE OF ABDOMINAL WOUND

Where there has been soiling of the peritoneal cavity from a perforation, the abdominal cavity is again irrigated with saline and all macroscopic debris removed.

The abdominal wound is closed with a single continuous layer of polydioxanone 3-0 or 4-0 sutures to include all layers of the abdominal wall, excluding skin. In fat babies, the adipose layer is approximated with interrupted or continuous 4-0 absorbable sutures. The skin is approximated with continuous subcuticular 5-0 monofilament sutures.

Other surgical maneuvers

In babies in whom the initial insult has resulted in atresias with a markedly reduced length of small intestine or when large resections of multiple atretic segments are required, certain surgical techniques have been advocated in an attempt to preserve maximal intestinal length for survival and growth.[38,39] In addition, disparity in anastamotic size is reduced and prograde duodenal function is facilitated. In high jejunal atresias, the duodenum is fully derotated and the proximal resection extended into the second part of the duodenum with antimesenteric tapering duodenoplasty or inversion plication of the proximal mega duodenum (Figs 52.14 and 52.15).[40,41]

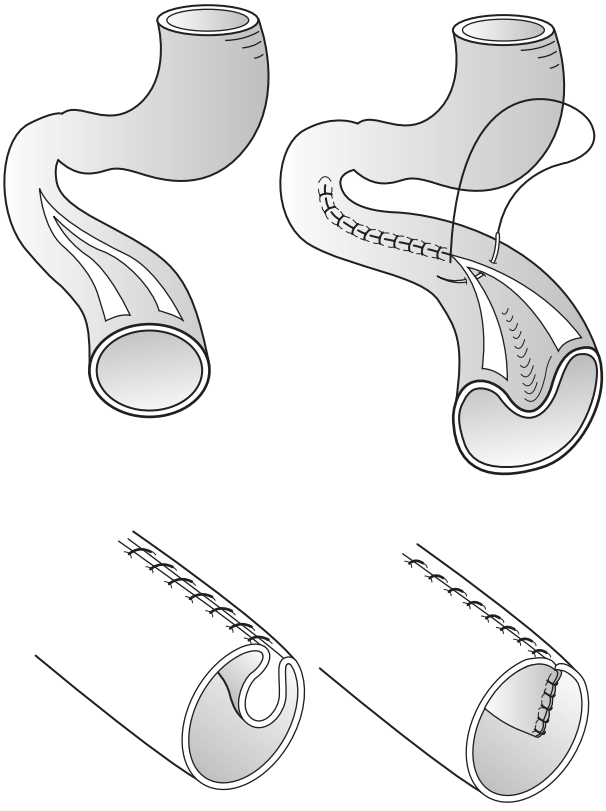

Figure 52.15 The technique of seromuscular stripping and inversion plication. This technique preserves mucosal surface for absorption and prevents unraveling of the placation.

The dilated bowel is trimmed to a lumen size of a 22 Fr gauge catheter. An intestinal autostapling instrument may be used. Inversion plication without excision and tapering has the advantage of preserving valuable mucosa if the bowel length is short. Tapering may have an advantage over plication, as the latter has the tendency to unravel within a few months with subsequent peristaltic dysfunction, especially if the mucosal strip/excision technique has not been utilized. Following this tailoring, the anastomosis is performed as described above and the bowel is returned to the abdomen in the position of nonrotation. In type IIIb, any restricting bands along the free edge of the distal narrow mesentery are released to avoid kinking and interference with the blood supply. The mesentery from any resected bowel is retained and may assist in closure of mesenteric defects. This technique is very helpful and prevents kinking or distortion of the anastomosis. Furthermore, the potential for kinking the single marginal artery and vein requires careful placement of the bowel into the peritoneal cavity at the completion of the anastomosis.

Although isolated type I atresias are best dealt with by primary resection and anastomosis, multiple diaphragms have successfully been perforated and dilated with bougies passed along the length of the bowel. In multiple atresias, multiple resections and anastomosis may be advisable to save as much bowel length as possible. They are, however, often localized, requiring resection and a single anastomosis. A silastic tube passed through the lumen of the entire bowel facilitates these anastomotic procedures.[42]

The fashioning of stomas, e.g. Bishop–Koop,[43] Santulli and Blanc,[17] Rehbein and Halsband,[44] or double barrel,[45] as practiced by some, is not routinely advocated unless there is gross intraperitoneal contamination, making a primary anastomosis unsafe. Jejuno-ileal atresia associated with a gastroschisis is treated by resection and primary anastomosis only if there is no evidence of edema and matting due to amniotic peritonitis. Initial reduction of the eviscerated bowel with the atresia intact and primary closure of the abdominal wall defect, if possible, is preferred. After allowing for disappearance of the edema (10–14 days), a re-laparotomy is performed with resection of the atretic segment and primary anastomosis. Stomas with the potential for fluid and electrolyte loss, wound infection, and other stoma-related complications are thus avoided. There is little place for bowel lengthening procedures at the initial operation. It is advisable to delay such procedures until the neonatal bowel length has grown to its maximum potential length and maximum bowel adaptation has occurred.

POSTOPERATIVE CARE

Postoperative care is conducted according to current standards and guidelines. Nasogastric decompression is usually required for approximately 4 days postoperatively. High jejunal atresias may require a longer period of decompression. Feeding is delayed until the gastric aspirate is no longer bile stained, the abdomen is not distended, and the baby has passed meconium. In babies with a transanastomotic tube, continuous feeding is commenced 24 hours postoperatively. Graduated polymeric feeds are then commenced and increased as tolerated. Oral or gavage feeds are started with return of prograde proximal bowel function.

If at any time there is a suspicion of a leak at the anastomosis as suggested by clinical deterioration, abdominal distension, and vomiting, a plain x-ray of the abdomen may reveal free air in the abdomen. When more than 24 hours have elapsed since surgery, this would indicate a leak or perforation and immediate laparotomy should be performed. Other postoperative complications observed have been ischemia leading to frank necrosis, late onset stenosis, adhesive obstruction, and perforation of the bowel by the transanastomotic tube. Infants with human immunodeficiency virus (HIV) exposure or infection have poor healing with an increased incidence of anastomotic breakdown and wound sepsis with dehiscence.[46]

In babies in whom less than 75 cm of small bowel remains, especially if the ileocecal valve is absent, loose frequent stools and excessive water loss may become problematic. In these patients, and in every instance where normal enteral alimentation cannot be established within 5 postoperative days, parenteral feeding is indicated. Carbohydrate, amino acid, and fat-containing solutions are introduced in a graduated manner over a period of 3 days. Peripheral venous push-in lines are used for short-term total parenteral nutrition (TPN) but for long-term TPN (longer than 10 days), a central line is preferred. Once intestinal function has been re-established, the baby is gradually weaned from a

parenteral to an enteral feeding program. Careful dietary tailoring is required, as each patient may have different tolerance thresholds.

Predictions of the degree of intestinal dysfunction are based upon the known residual length of small intestine. The short bowel syndrome can be contemplated if more than 70% of the bowel length was lost or if the minimal bowel length left after surgery is less than 70 cm. These babies can be divided into four main functional groups: (1) uncorrectable intestinal insufficiency; (2) adequate bowel function for survival after adaptation and/or lengthening and tailoring procedures; (3) adequate alimentary function for growth and development; and (4) normal alimentary function with a degree of intestinal reserve.

When gross intestinal insufficiency is expected the infant is managed as short-bowel syndrome.[47–49] The patient's oral intake is gradually increased in volume and energy content, while the small intestine is allowed to adapt until maximum intake tolerance is reached, which can take months to years.[50] Pharmacological control of intestinal peristaltic activity has been achieved more effectively since the introduction of loperamide hydrochloride. Vitamin B_{12} and folic acid should be administered to patients without the terminal ileum to prevent megaloblastic anemia. The long-term outcome for most of the babies is optimistic, although TPN-associated complications are frequent and sometimes fatal, unless liver and intestinal transplantation is undertaken.[51]

In predicting the ultimate functional outcome, the following factors must be taken into consideration: the ileum adapts to a greater degree than the jejunum; the neonatal small intestine still has a period of maturation and growth ahead of it; and the actual residual small intestinal length is difficult to determine accurately after birth. The proximal obstructed bowel segment is dilated and its functional potential may be overestimated, while that of the distal unused collapsed bowel may be underestimated. Of critical importance is an intact ileocecal valve, which allows for accelerated intestinal adaptation with shorter residual jejuno-ileal length. The absence of the ileocecal valve also leads to an increased transit time, malabsorption, diarrhea, and increased bacterial contamination of the small bowel.

RESULTS

Before 1952, the mortality rate for congenital atresias of the small intestine in Cape Town was 90%. Between 1952 and 1955, 28% of the babies with this condition could be saved. At that stage, most were treated by primary anastomosis without resection. With liberal resection of the blind ends and primary end-to-end anastomosis, the survival rate increased to 78% during 1955–58.[52,53]

During the 20-year period from 1990 to 2010, 130 patients with jejuno-ileal atresias and stenoses were admitted to the pediatric surgical service at the Red Cross War Memorial Children's Hospital. There were nine deaths (93% survival). Factors contributing to the mortality rate were: type of atresia (type III, 32%), proximal bowel infarction with peritonitis, anastomotic leaks, a missed distal atresia, the short-bowel syndrome with parenteral nutrition-associated liver disease, sepsis, and more recently HIV infections. Overall experience is recorded in Table 52.2.

Table 52.2 Mortality related to type of atresia.

Type	Patients	Mortality	%
Stenosis	34	0	0
I	79	4	5.1
II	32	4	12.5
IIIa	51	8	15.7
IIIb	60	10	16.7
IV	77	9	11.7
Total	333	35	10.3

Colonic and rectal atresias

TOMAS WESTER

COLONIC ATRESIA

Introduction

According to Evans,[1] Binninger was the first to describe colonic atresia in 1673. The first survivor was reported in 1922, when Gaub[2] opened a diverting colostomy in a child with an atresia of the sigmoid colon. Potts[3] successfully performed a primary anastomosis in a neonate with an atresia of the transverse colon in 1947.

Atresia of the colon is a rare cause of bowel obstruction in the neonate. The incidence of colonic atresia related to live births has been difficult to ascertain, but an incidence of approximately 1 in 20 000 live births has been considered to be realistic based on the experience in major pediatric surgical centers.[4] In the northwest of England, isolated colonic atresia has been reported to occur in 1 in 66 000 live births.[5] Other investigators have reported that colonic atresias account for 1.8–10.5% of total bowel atresias,[6,7] the incidence of which has been estimated to be 1 in 1500 to 1 in 20 000 live births.[1,8]

Except for stenosis or incomplete occlusion of the colon, three different types of intrinsic occlusion have been distinguished:[9,10]

1. Type I atresia or a membrane (Fig. 53.1a)
2. Type II atresia with blind ends of bowel joined together by a cord-like remnant of bowel, with or without a gap in the mesentery (Fig. 53.1b)
3. Type III atresia with separated blind ends of bowel and a gap in the mesentery (Fig. 53.1c).

Furthermore, a hereditary form with multiple atresias of the gastrointestinal tract has been described, suggested to be of non-vascular origin.[11,12] Type III atresia appears to be most common in atresias proximal to the splenic flexure, whereas types I and II are more common in atresias distal to the splenic flexure.[13,14] In a literature survey it was reported that type III occurred in 60.4% of the cases.[15] Most series

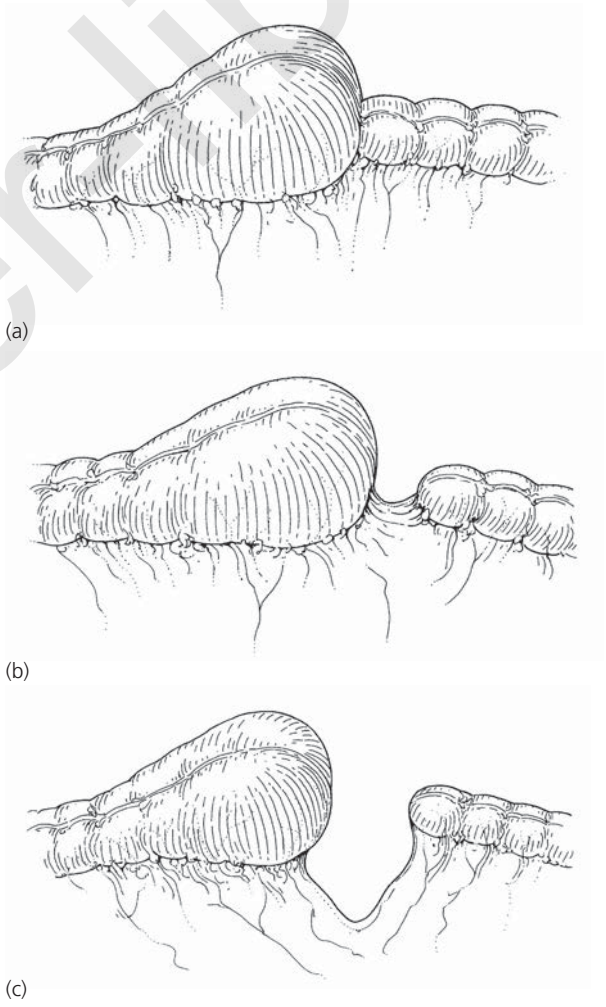

Figure 53.1 (a) Type 1: there is continuity of the outer layers of the bowel wall; the lumen is obstructed by a membrane covered with two layers of mucosa. (b) Type II: the bowel ends are connected by a fibrous band and the mesentery is intact. (c) Type III: a defect in the mesentery is accompanied by a gap between the bowel ends.

show an even distribution between atresias proximal and distal to the splenic flexure.[6,7,16,17]

Etiology

Colonic atresia is probably the result of intrauterine vascular insufficiency. The finding of bile, squamous epithelium, and hair in the bowel distal to the atresia supports the hypothesis that the vascular accident occurs late in development.[9] Several pathological conditions may result in compromised blood supply to the bowel, such as intussusception, volvulus, herniation, tight gastroschisis, and embolic or thrombotic events. It appears likely that focal resorption of the sterile gut occurs after ischemic necrosis. Animal experiments have been performed in which the blood supply was interrupted to different parts of the small intestine or colon, thus inducing various types of atresias. These experiments confirm the etiologic role of *in utero* vascular occlusion.[9,18,19]

Colonic atresia has been reported in monozygotic twins and genetic causes of colonic atresia have been discussed, although their role is not clear.[20]

Presentation

Neonates with colonic atresia present with symptoms indicating distal bowel obstruction. Abdominal distension is usually present at birth, but otherwise develops over the first 24–48 hours of life. Vomiting of bile is very common, but this is not always an early symptom. Failure to pass meconium is the rule and neonates that do not pass meconium within the first 24 hours of life should be considered for further investigations. On examination, the abdomen is distended and often slightly tender, sometimes with visible bowel loops. In those who have an abdominal wall defect, associated atresias should always be suspected.

Colonic atresia is associated with abdominal wall defects, such as omphalocele, gastroschisis, and vesicointestinal fissure, which complicate the management of the patient.[4,14] Boles *et al.*[14] found that four of their 11 patients had gastroschisis. In the series reported by Philippart,[4] 22 of 36 patients with colonic atresia had no associated anomalies, whereas six had vesicointestinal fissures, and three had other abdominal wall defects. Five of the 36 patients had jejunal atresia associated with the colonic atresia. Rarely, colonic atresia has been reported to occur concomitantly with imperforate anus.[7] Malrotation has also been reported to be a common associated anomaly.[15] One important associated anomaly is Hirschsprung's disease, which has been reported in a few cases. Although the colonic atresia was diagnosed at birth in these patients, there was a considerable delay in diagnosing the associated aganglionosis. It is therefore recommended that resected bowel is examined for Hirschsprung's disease.[21] Rectal suction biopsies are suggested in patients who do not gain normal bowel function postoperatively.[22] Some authors recommend that rectal suction biopsies are routinely taken in all patients with colonic atresia.[20,23] Isolated colonic atresia is sometimes associated with skeletal anomalies such as syndactyly, polydactyly, absent radius, and clubfoot.[4] Furthermore, colonic atresia has been reported in association with eye anomalies, such as exophthalmos and optic nerve hypoplasia.[13] In the series reported by Davenport *et al.*,[5] one patient had trisomy 18 and esophageal atresia. The fact that chromosomal abnormalities do occur in patients with colonic atresia makes it reasonable to recommend chromosomal analysis, at least in those patients who have other associated anomalies.

Diagnosis

Prenatal diagnosis of colonic atresia has been reported. However, prenatally detected colonic dilatation may also be the result of Hirschsprung's disease or anorectal malformations.[24]

Plain x-rays show a distal bowel obstruction with multiple dilated loops with air–fluid levels (Fig. 53.2a). A large right-sided loop, corresponding to the proximal dilated colon, has been considered characteristic in patients with colonic atresia.[5] The level of obstruction is confirmed by a contrast enema, which reveals the distal microcolon and incomplete colonic filling (Fig. 53.2b). Pneumoperitoneum, indicating colonic perforation, is not rare and has been reported in about 10% of the cases.[4]

Management

PREOPERATIVE

Correction of fluid and electrolyte abnormalities is started as soon as bowel obstruction is suspected. The gastrointestinal tract is decompressed with a nasogastric tube. Prophylactic antibiotics are administered. The neonate should be in a stable condition before general anesthesia and operation are started.

OPERATIVE

The two therapeutic options available are primary resection with anastomosis and colostomy with anastomosis at a later stage. Traditionally, many authors distinguished between the management of colonis atresias distal and proximal to the splenic flexure. Atresias proximal to the splenic flexure were treated with primary resection and anastomosis, whereas the distal atresias were treated with primary colostomy and delayed establishment of the gastrointestinal continuity.[4,7,13,17,25] More recently, it has been suggested that staged repair should be undertaken in complex cases with, for instance, questionable bowel viability, colonic perforation, and peritonitis, and in patients with concomitant abdominal wall defects. On the other hand, in uncomplicated cases, resection and primary anastomosis was proposed to be the method of choice for atresias at all levels of the colon.[25] There is no evidence that this later approach increases the mortality or complication rate.[5]

The abdomen is opened through a transverse incision a finger diameter above the umbilicus and to the right. The

incision may be extended as required. Cautery is used to divide the muscle layers of the abdominal wall and the umbilical vein is ligated and divided. The site and type of atresia are assessed. It is extremely important that additional atresias are excluded. The patency of the distal colon must always be tested by, for instance, injection of saline. In cases with colonic stenosis, a longitudinal incision, closed transversely is an alternative option for treatment. Some authors have considered the experience with this approach to be limited and therefore recommended resection and primary anastomosis as a more reliable method.[26] In those with type I atresias the bowel adjacent to the atresia is resected and a primary anastomosis is performed. In patients with type II and III atresias, with adequate bowel length, the excessively dilated proximal bowel should also be resected (Fig. 53.3a). A few centimeters of the distal narrow bowel are resected. The mesenteric vessels are divided close to the bowel wall to preserve the blood supply to the adjacent bowel. The distal bowel is incised along the antimesenteric border to achieve lumina of a similar size (Fig. 53.3b). A single-layer anastomosis is performed using interrupted 5-0 absorbable sutures (Fig. 53.4). The wound is closed in layers with absorbable sutures.

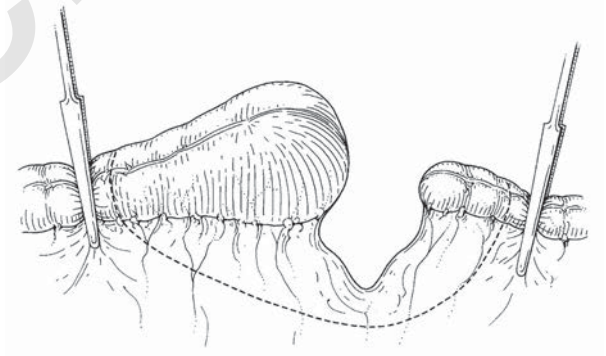
(b)

Figure 53.2 (a) Plain abdominal x-rays often show the hugely dilated bowel segment proximal to the atresia. (b) A contrast enema is diagnostic of a colonic atresia, as demonstrated in this infant with an isolated hepatic flexure defect.

POSTOPERATIVE

During the first postoperative days, parenteral nutrition is administered. Feeding can be started when the baby is well and the gastric aspirates have decreased. In cases with a primary anastomosis, it usually takes a few days before the neonate starts to pass stools. If a colostomy has been



(a)

fashioned the parents are instructed to take care of the stoma. Usually the colostomy is closed at two to three months of age.

Complications and long-term results

Many factors have led to an improvement in the results of patients with colonic atresia, including early postnatal diagnosis, improved neonatal intensive care and anesthesia, and more efficient transport facilities. Today, mortality related to the colonic atresia or its treatment is rare. In the series reported by Davenport *et al.*[5] no deaths occurred in the patients who underwent surgery, although one patient, who was never operated on, died of concomitant abnormalities. The mortality rate in earlier series varied from 9 to 33%, in many cases as a result of associated anomalies, but also attributable to late diagnosis, nutritional deficiencies, infectious complications, and technical errors.[6,7,13,14,17] Etensel *et al.*[15] recently reported a lethal outcome in 27% of the cases collected for a literature review.

Powell and Raffensperger[13] reported 15 postoperative complications in 19 patients. Problems related to the colostomy were encountered in three of 11 patients treated with colostomy and delayed anastomosis, whereas anastomotic strictures were seen in six of the 19 patients. Boles *et al.*[14] reported significant complications in four of 11 cases. The use of contemporary principles of neonatal surgery has, however, reduced the morbidity rate and Davenport *et al.*[5] reported recovery without complications.

RECTAL ATRESIA

Introduction

Rectal atresia is a very rare lesion, which has been reported to account for 0.3–1.2% of all anorectal anomalies.[27–29] Interestingly, a much higher incidence of 14% has been reported from Tamilnadu in the southern part of India.[30] The reason for this high incidence has been poorly understood. However, in recent years the incidence in Tamilnadu has been reduced and is now similar to that in other parts of the world.

Although it has been proposed that rectal atresia should be classified as a colonic atresia,[6] it is usually considered to be part of the spectrum of anorectal malformations. Rectal atresia was classified as a type IV anomaly in the Ladd and Gross classification of anorectal anomalies.[31] In the International classification and the Wingspread classification, it was also classified as a separate type of high anomaly.[32,33] Peña's classification describes rectal atresia as a separate entity.[34,35] The more recent Krickenbeck classification describes rectal atresia/stenosis among rare or regional variants of anorectal malformations.[36] Five types of rectal atresia have been distinguished, namely: type 1 with a membrane and intact bowel wall; type 2 with blind ends separated by less than 2 cm, which is the most commonly encountered type; type 3 with a long distance between the blind ends; type 4, which is rectal stenosis; and type 5 with a urinary fistula accompanying the rectal atresia.[37]

Etiology

Magnus[38] described the autopsy findings in a female neonate with multiple atresias of the small and large bowel, including a rectal atresia. It was found that there were intact remnants of the internal sphincter, that the epithelium of the anal canal was normally developed, and that the external sphincters were normal (Fig. 53.5). There was a fibromuscular band between the blind rectal pouch and the anal canal. Based on the findings in the autopsy specimen, the author suggested that rectal atresia is the result of vascular insufficiency, rather than a developmental defect. It is speculated that this could be the result of an intrauterine infection. It was also estimated that the lesion occurred between the 65 mm and 112 mm stages of development. Dorairajan[30] has suggested that the middle rectal artery is involved, rather than the superior rectal artery, which has been proposed by other investigators.

Presentation

Neonates with rectal atresia present with abdominal distension and failure to pass meconium, indicating distal bowel obstruction. The perineum and anal canal are normal and the

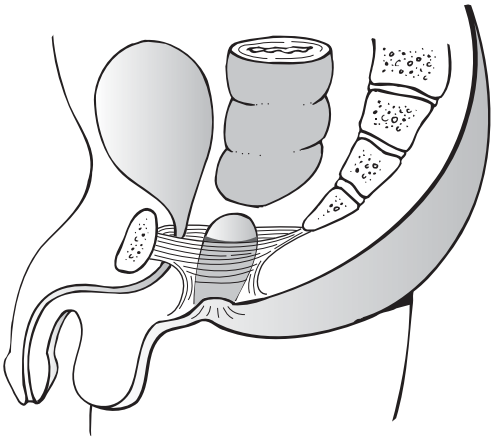

Figure 53.5 Diagrammatic representation of the anatomy in rectal atresia. Except for the high atresia, the anorectum is virtually normally developed.

diagnosis may therefore easily be delayed. The atresia is usually located 1–3 cm above the anal verge.

The incidence of associated anomalies in patients with rectal atresia has been considered to be extremely low.[39] In the series reported by Dorairajan,[30] associated anomalies were found in 2% of the 147 cases. No significant abnormalities were found in the urinary tract. Patients with rectal atresia usually have a normal perineum and a normal sacrum. However, associated malformations do occur; for instance, the author was recently involved in the management of a boy with rectal atresia, who had a concomitant cardiac malformation and vertebral anomalies, similar to that usually seen in patients with vertebral anorectal cardiac tracheoesophageal renal/radial limb (VACTERL) association. Rectal atresia occurs in patients with multiple atresias of the bowel.[38] Two of Dorairajan's[30] patients had ileal atresia and one had multiple small bowel atresias.

Diagnosis

The condition is diagnosed when an attempt is made to pass a thermometer or a tube to decompress the colon. After a colostomy has been opened, a contrast study with simultaneous injection of contrast material through the colostomy into the rectal pouch and the anal canal clearly outlines the anatomy of the anomaly (Fig. 53.6).

Management

In the past, several different techniques, such as abdominoperineal and sacroperineal pull-through procedures, referred to by Stephens and Smith[40] and de Vries *et al.*[41] were used to treat this condition. More recently, other methods have been described. Gauderer and Izant[42] placed a string across the membrane using fluoroscopy and progressively dilated the rectal canal in one patient. Zia-ul-Miraj Ahmad *et al.*[43] used a Duhamel procedure in seven cases with rectal atresia and rectal stenosis. Dorairajan[30] fashioned a transverse colostomy

Figure 53.6 Simultaneous injection of contrast material into the upper pouch (via the sigmoid colostomy) and the anorectum clearly outlines the distance between the two pouches.

in the newborn and did a definitive sacroperineal pull-through operation at approximately one year of age. If the blind rectal pouch ended above the pubococcygeal line, a sacro-abdominoperineal or an abdominoperineal approach was preferred. The third stage comprised closure of the colostomy. In the first edition of this book, Upadhyaya[37] recommended his previously described approach, transanal end-to-end rectorectal anastomosis.[44] One advantage of this technique is that luminal continuity is restored without injuring the functional anatomy of the region. A sigmoid colostomy is opened in the neonate and the definitive procedure is performed at approximately three months of age. A Hegar dilator is advanced distally from the colostomy until it pushes the rectal pouch into the anal canal. The end of the anal canal is opened and the margins retracted with stay sutures. Then the rectal pouch is opened and the edges of the anal canal and the rectal pouch are approximated to form an end-to-end anastomosis.

Peña *et al.*[45] suggested that posterior sagittal anorectoplasty (PSARP) is a very useful method for the repair of rectal atresia and stenosis. It is recommended that a diverting colostomy is opened in the newborn and the definitive procedure is performed at a later stage.[34] A midline skin incision is performed and the levator muscle and muscle complex are separated exactly at the midline to expose the bowel. The blind end of the rectum is usually separated from the anal canal with a few millimeters of fibrous tissue. The rectum has to be mobilized to allow an end-to-end anastomosis to be performed without tension. Then the

wound is closed by reconstruction of the muscle structures. Daily dilatations are performed starting 2 weeks postoperatively. The colostomy is closed approximately three months after the operation, provided the diameter of the anastomosis is appropriate.[45] Very few pediatric surgeons gain more than limited experience with the management of rectal atresias. However, many pediatric surgeons are familiar with the posterior sagittal approach to treat other types of anorectal malformations. For this reason, an end-to-end anastomosis performed through the posterior sagittal approach seems to be an attractive option for these patients.

In utero repair of rectal atresia was recently reported in a fetus that also had a sacrococcygeal teratoma.[46]

Complications and long-term results

In patients with rectal atresia, the anal canal, sacrum, and sphincteric mechanisms are virtually normal. Therefore, the prognosis with respect to functional outcome is favorable. Although the number of cases reported is very limited, the outcome in patients with rectal atresia or stenosis treated through a posterior sagittal approach is excellent. Peña[34] reported voluntary bowel movements with total continence and without soiling in all of his five cases. However, two of the five patients had constipation. Constipation has also been reported to occur frequently after other procedures used to treat rectal atresia or stenosis.[43] Upadhyaya[44] reported an uneventful recovery and normal continence in two patients treated with his method. Dorairajan[30] was able to follow up 37 of 60 patients that were treated with sacroperineal pull-through operations and who had their colostomy closed. The outcome was excellent in 20% of the patients, whereas 65% had occasional soiling at night, and 15% had soiling also in daytime. The mortality rate in this series was 35%.

Meconium ileus

GUIDO CIPRANDI AND MASSIMO RIVOSECCHI

INTRODUCTION

Meconium ileus is an early manifestation of cystic fibrosis (CF), due to abnormal, inspissated and viscid mucus of intestinal origin. In children affected by this condition, the impacted meconium produces an intraluminal obstruction occurring in the midileum, leading to a progressive distension. As an ultimate evolution, different mechanical complications can be associated, including intestinal volvolus, atresia, gangrene and necrosis, perforation, peritonitis with abdominal calcifications, and finally, meconial pseudocyst. In this view, meconium diseases in infancy cannot be firmly separated into three categories such as meconium plug syndrome, meconium ileus, and meconium peritonitis, nor can therapy of each condition.

HISTORY

Intestinal occlusion, both associated with inspissated meconium and gross pathologic pancreatic changes, was firstly reported by Landsteiner[1] in 1905 and subsequently confirmed by Kornblith and Otani[2] and Fanconi *et al.*,[3] who correlated a chronic lung disease and a pancreatic insufficiency. In 1936, Fanconi and Uehlinger described this complex and lethal newborn condition as a cystic fibrosis of the pancreas.

In the mid-twentieth century, Bodian's[4] perception of an abnormal sticky intestinal mucus, with a lower content of water, advanced the basis for a modern treatment with intraoperative saline irrigations, thus avoiding undue small bowel resections. Mikulicz, Gross, Bishop and Koop, Santulli and others were responsible, in those years, for different surgical techniques including distal or proximal enterostomies.[5] More recently, Noblett[6] and Shaw[7] reported relief of the intestinal obstruction, irrigating with various solutions, such as normal saline, 1% *N*-acetylcysteine, hyperosmolar gastrografin enema, surfactant, DNase. With respect to different types of surgical and medical efforts, the survival rate at one year increased from 10 to 90% and the operative mortality drastically decreased to 15–23% of treated newborns.[8]

INCIDENCE

Meconium ileus accounts for 9–33% of all neonatal intestinal obstructions (300 new cases in Italy each year), and could be defined as the third most common cause of neonatal small bowel obstruction after ileal and duodenojejunal atresia and malrotation.[9]

It is more frequently observed in Caucasian countries, where the presence of CF is higher, ranging from 1 in 1200 to 1 in 2700 live births. In contrast, the disease is almost absent in some Asian and African populations. Although meconium ileus can rarely occur in otherwise normal patients, the majority of children affected by this condition have CF. The mean incidence of meconium ileus in CF is at least 18%, with no difference in the gender; when this association coexists, meconium ileus is the presenting symptom in 12% of these children.[10] Different to this pathology, meconium plug syndrome is more commonly seen in premature infants, is characterized by colonic obstruction, and is infrequently associated with CF.[11] Approximately half of neonates with meconium ileus present with complicated intestinal obstruction and they always require a surgical procedure. In contrast, only 6–10% of uncomplicated forms fail a non-operative management using a water-soluble contrast enema; these patients are candidates for a temporary diversion or a major procedure.[12,13]

PATHOGENESIS

Meconium ileus is an essential expression of CF, which is the most common lethal autosomal recessive disorder in white populations, and is characterized by dysfunctional chloride ion transport across epithelial surfaces. Parents are not affected, but both are heterozygotes carrying the abnormal gene(s).

Intestine, pancreas, lungs, sweat glands, liver, and salivary glands are all involved as a result of an abnormal exocrine gland activity. However, these organs will be differently affected during life, the pancreas being the first, because the progressive retention of secretions and the atrophy of the acinar cells starts during fetal life; in contrast, the lungs are normal at birth and the mucous plugging of the distal airways will be responsible for a progressive pulmonary insufficiency during adolescence. Meconium ileus is a rare expression of CF in premature infants, suggesting that the intestinal abnormalities take place during the last period of fetal life.

Although recurrent lung infections and pulmonary insufficiency are the principal causes of morbidity and death, gastrointestinal signs and symptoms commonly precede the pulmonary findings and may suggest the diagnosis in infants and young children. The gastrointestinal manifestations of CF result primarily from abnormally viscous luminal secretions within hollow viscera and the ducts of solid organs. As a result bowel obstruction may be present at birth due to meconium plug syndrome or meconium ileus. The first biochemical studies of the altered meconium showed a lower content of carbohydrate, more proteins, and the so-called 'mucoproteins' and albumin, which had been previously used as a screening. Meconium ileus more recently appeared as a result of abnormal intestinal secretions, but not so closely related to the sweat electrolyte defect (high levels of sodium and chloride). In fact, the impermeability of CF epithelia to chloride ions is not correlated to the severity of intestinal involvement and the pancreatic lesions play a secondary role. The sweat test is the main laboratory test used for diagnosis, but after the 1990s genetic analysis has been commonly used for diagnostic as well as prognostic purposes.

From a genetic point of view, the CFTR, or cystic fibrosis transmembrane conductance regulator, is the gene product defective in CF, and was first identified in 1989.

This gene is normally located in the apical membrane of the epithelial cells from the stomach to the colon: a mutation of CFTR on chromosome 7 is responsible for CF evidence. The most common mutation is ΔF-508 and can be identified using DNA testing in affected neonates as well as in family members, possible carriers of the specific gene.

The CFTR gene codes for a 1480 amino acid protein that act as a chloride channel, regulated by cyclic AMP. In the small intestinal wall, the clinical expression of CF depends largely on the decreased secretion of fluid and chloride ions, the increased permeability of the paracellular space between adjacent enterocytes, and the sticky mucous cover over the enterocytes. As a rule, the brush border enzyme activities are normal and there is some enhanced active transport as shown for glucose and alanine. As a result, the gastrointestinal content in children affected by meconium ileus differs mainly from the normal condition by the lower acidity in the foregut and the accretion of mucins and proteins resulting in intestinal obstruction in the ileum but also in the colon. During growth, the small intestinal mucosa will not be functioning at maximal capacity. Better understanding of the CF gastrointestinal phenotype may contribute to improvement of the overall well-being of these first-seen newborn patients. In recent years, the Na^+-dependent amino acid transporter called ATB(0), which has been previously localized in the 19q13.3 region, did not appear to be associated with CF-MI disease; however, fine chromosomal mapping of other genetic factors and loci, in human as well as in animal models, such as in mouse, could be useful in determining the association with the intestinal phenotype of CF. We assume that this work will be very difficult because more than 1000 mutations have been identified in the CFTR gene and the final impact of these mutations on the genotype–phenotype correlation is unknown. In addition, the discordant phenotype observed in CF siblings suggested that genes other than CFTR modulate the CF phenotype.[14–16]

HISTOPATHOLOGY

In the meconium ileus, the intestine shows different aspects if the proximal, the middle, and the distal ileum are considered. In the first portion, a nearly normal evidence is present, with a progressive dilatation at the mid-portion borderline. In the proximal ileum, the content has a semiliquid consistency and is not yet viscous. A marked and severe dilatation of the middle ileum is always seen; the intestine contains thick, dark green and putty-like meconium, firmly adherent to the walls. The intestinal obstruction causing an hyperperistalsis is responsible for the congestion and hypertrophy of the walls. The distal ileum is full of concretions called 'rabbit pellets', gray stained and with a beaded typical appearance. This small bowel condition is responsible for a narrow, empty, and small colon, which is never used, and is called a microcolon.[17]

When the meconium ileus is complicated, more severe aspects can be seen: the dilatation is responsible for wall perforation and secondary meconium peritonitis, with calcifications. The spontaneous healing of the ileal perforation can lead to resorption of the involved portion of bowel and finally to an intestinal atresia. When the peristalsis is vigorous, the twisting of the ileal tract full of dense meconium may result in a massive volvolus, with a high risk of perforation. Sometimes, when the bowel perforation is massive, an intense reaction to the meconial spillage may produce a giant meconial pseudocyst. Obviously, postnatal perforative evolution of meconium ileus is complicated by bacterial peritonitis.

CLINICAL PICTURE

Polhydramnios is the most frequent feature observed in prenatal diagnosis of complicated forms of meconium ileus. The presence of fetal hyperechogenic bowel on the ultrasound, associated with dilated bowel and/or ascites could be indicative of an intestinal obstruction. A family history of CF is clearly evident in almost 25% of these patients. Meconium ileus is uncommon in premature infants (5–12%), and associated congenital anomalies are rare.[18]

Main symptoms include abdominal distension (96%), bilious vomiting (50%), and delayed passage of meconium (36%). From a clinical point of view, it is possible to recognize two different conditions: a simple, uncomplicated type not requiring surgery, and a complicated, severe type, with a mortality of at least 25% of all cases. In the first type (58%),

signs and symptoms of a distal ileal obstruction are seen not later than 48 hours after birth. These are generalized abdominal distension with dilated and visible as well as palpable loops of bowel, bilious vomiting, no stools, and narrowing of the anus and rectum, with only a dense and rubber-like gray meconium sticking to the anal wall. In the second type (42%), the neonate represents a surgical emergency which must be treated within 24 hours before birth, when the signs of a hypovolemic shock or sepsis are not well established. Fetuses with complex meconium ileus are at increased risk for postnatal bowel obstruction and perforation.[19]

In this serious illness, the progressive abdominal distension may culminate in respiratory distress. If a perforation occurs, a pneumoperitoneum and sepsis are the unfavorable consequences. Infrequently, meconium in the vagina or scrotum are evidence of a fetal perforation. Sometimes, the onset is directly with meconium peritonitis, which could involute in a giant meconial pseudocyst. When this happens, the abdominal skin edema and translucency are evident and associated with a palpable right lower mass.

At present, whatever the clinical presentation picture, the overall survival rate is at least 95%.[20]

PRENATAL ULTRASOUND AND RADIOLOGIC PATTERN

Meconium usually fills the small bowel during the 20th week of gestational age, so that identification of meconium ileus before this period is rare. Prenatal ultrasound has led to confidence in the antenatal diagnosis of intestinal obstruction allowing counseling and birth planning. In this regard, the presence of fetal hyperechogenic bowel on the ultrasound, associated with dilated bowel and/or ascites could be indicative of an intestinal obstruction. The increased echogenicity of the intestinal loops is due to a higher density of the intraluminal content (hyperdense and dry meconium). However, it is not easy to determine exactly whether this feature arises from intra- or from extraluminal structures and other different conditions may present with a similar ultrasound pattern, such as prenatal infections, neoplasm, or chromosomal trisomy. In addition, these findings may also represent transient normal variants.[18,21,22]

When the meconium ileus evolutes in a volvulus, the ultrasound shows enlarged hyperechogenic loops without peristalsis. Polhydramnios is the most frequent feature observed in prenatal diagnosis of complicated forms of meconium ileus. Obviously, if the parents are found to be carriers for a CF mutation, the correlation between ultasound findings and meconium ileus is achieved.

Plain x-ray shows distendend and gas-filled intestinal loops (Fig. 54.1). Sometimes, air–fluid levels are seen (one-third of cases), thus mimicking an ileal atresia. Where a sharp stop image is evident, this is the exact point of the obstruction. A usual image of fine, granular soap-bubble (Singleton's sign) or ground-glass appearance (Neuhauser's sign) is due to a dense meconium mixed with air, typical of the distal ileum; this picture is usually located in the midabdomen or in the right iliac fossa. Nevertheless, this image has also been observed in

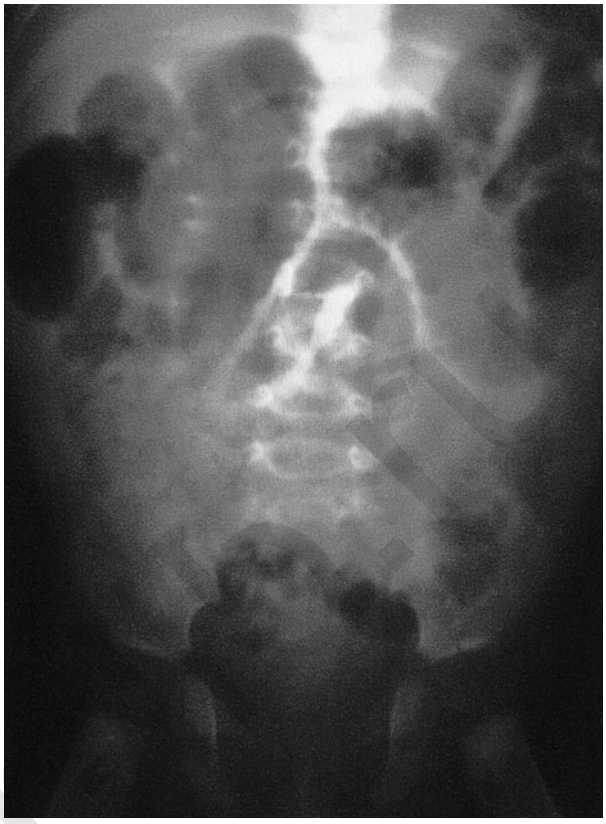

Figure 54.1 Plain x-ray showing distended loops of intestine and Neuhauser's sign.

neonates with meconium plug syndrome, Hirschsprung's disease, or small bowel atresia. The meconium hyperdensity may produce various images, depending on the length or localization of the obstructed bowel, but also on the filling (complete or partial) of the intestinal loops affected. When the meconium ileus is complicated, the abdominal x-ray may show calcification as a result of meconium peritonitis due to a fetal perforation of the intestine. A double-bubble image or air–fluid levels can be seen when a secondary ileal atresia (single or double) is the final bowel remodeling after a complete volvulus associated with severe ischemic damage. If the intestinal perforation occurs early in the antenatal period, the x-ray appearance of a round rim of calcification underlines a meconium pseudocyst. The colon is always a microcolon (unused colon), because the meconium never fills the large bowel during fetal life. Thus the length is normal but the caliber is small because of the small amount of feces (thick and dry meconium) passing through.

A water-soluble contrast enema is useful both for diagnostic and therapeutic purposes: the iso-osmolar agents facilitate evacuation of meconium without loss of large amounts of fluids and solutes (Fig. 54.2).

DIAGNOSTIC CRITERIA AND DIFFERENTIAL DIAGNOSIS

The sweat test provides a quantitative estimate of sodium and chloride on a sample of sweat usually collected from the

Figure 54.2 Contrast enema showing microcolon and pellets in terminal ileum.

forearm. A cholinergic drug acts to stimulate the sweat production with the help of a mild electrical current applied for 3–6 minutes (pilocarpine iontophoresis technique). Concentrations of these two cations above 60 mEq/L are diagnostic if at least 100 mg of sweat is collected. However, in the early neonatal stage, it is difficult to obtain a sufficient quantity of sweat to provide an accurate analysis and the collection must be done two or three times before a satisfactory quantity is achieved. In borderline cases, results are not significant for CF and further analysis is needed. Another problem is the high levels of sodium and chloride in neonates otherwise normal. In this situation, it is necessary to wait and provide another series of results after an interval of at least a month after the first test. More recently, the DNA probe analysis test for the ΔF508 mutation and other common alleles allows for a precise diagnosis, and misses only a small percentage of patients affected by CF. This method detects both affected children as well as heterozygote carriers.

Other causes of distal intestinal obstruction of the newborn may present with similar clinical patterns, including jejuno-ileal atresia, Hirschsprung's disease, meconium plug syndrome, and neonatal small left colon syndrome. In particular, a congenital megacolon is suspected when the bowel contents are liquid and air–fluid levels are constantly seen in the dilated bowel.

Other conditions may mimic surgical obstruction, such as delayed peristalsis associated with prematurity (the so-called functional immaturity) and adynamic ileus from sepsis. If a volvulus without malrotation or neonatal invagination are seen, these patients may undergo a sweat test to exclude CF. Although unusual, meconium ileus can exist as an isolated entity, not associated with CF. These patients account for 6–12% of the total, and the course of the illness is more often benign and without complications.[23]

MEDICAL AND SURGICAL TREATMENT

The first step of treatment includes nasogastric tube decompression, antibiotic prophylaxis with cephalosporin and aminoglycosides, and correction of dehydration, electrolytes, and hypothermia.

A contrast enema with water-soluble and hyper- or iso-osmolar contrast is the medical treatment of choice and mucosal safe, for uncomplicated meconium ileus. A recent study which used various enema solutions administered in a mouse model showed that surfactant and Gastrographin were the most efficacious for the *in vivo* relief of constipation, in comparison with perflubron, Tween-80, Golytely, DNase, *N*-Acetylcysteine, and Viokase. Intestinal mucosal damage was absent and viscosity had been significantly reduced *in vitro*.[24]

Enema evacuation should be obtained under fluoroscopic control, with a gentle and progressive increasing of intraluminal pressure, thus avoiding unexpected fractures of the colon. A correct procedure prevents leakage of the contrast medium by taping the buttocks, as well as catheter dislocation. If the contrast medium fails to progress into the dilated small bowel loops, the presence of an acquired atresia is definite and the radiologist must stop the examination because of the high risk of perforation. Fifty percent of neonates given this procedure benefit from enema alone over the next 48 hours, without any additional treatment. Iin some cases, a second enema may be used with a complete evacuation of the meconium filling the ileal loops. Acetylcysteine administered by mouth is useful and helps to relieve the obstruction. X-rays are done at 3, 6, 12, 24, and 48 hour intervals, with the aim of evaluating progression and possible complications. At this time feeding is begun. Hypovolemic shock and early perforation are possible problems, but an appropriate and meticulous procedure can avoid these complications.

When medical treatment is unsuccessful in spite of an uncomplicated meconium ileus, surgery is mandatory and an open evacuation, resection, and ileostomy are the possible options. In a simple meconium ileus, the surgeon should carry out the minimal procedure to free the lumen of all materials, such as pellets, sticky meconium, and sometimes, small calcifications. In this case, limited enterotomy and repeated warm saline irrigations through a smooth catheter provide the best result. In this event, meconium discharge may be manually supported, using the enterotomy placed in the dilated hypertrophic ileum. The catheter is two-way directed with care, clearing the small as well as the large bowel. At the same time as irrigation, the surgeon controls the enema progression, and the bowel may be inspected for distension degree, mesenteric orientation, covered perforation, gangrenous tract, and atretic single or multiple segments. The colon is inspected too, searching for possible perforation or microperforation. The T-tube ileostomy can be an additional, effective, and safe treatment, without any

additional surgery in 90% of treated patients; the T-tube should be removed within the first 8 weeks after surgery.[25,26]

At the end of this treatment, discussion is about whether to resect or not, because some authors stress the risk of a leakage at the anastomotic site. It must be borne in mind that resection and termino-terminal anastomosis are possible only if any signs of infection or sepsis is absent.

Usually a resection is done with the aim to promptly restore normal peristalsis; in these patients, the intestinal resection is limited to a huge dilation, at risk for foci of regional infection. In fact, bowel resection with primary anastomosis has proven to be as effective and safe as stoma formation, but is associated with a reduced length of initial hospital stay.[20] However, in complicated forms of meconium ileus, primary resection and anastomosis should have some advantages, such as shorter hospital stay and no later surgical procedure for stoma closure.[27]

Ileostomy can be performed in different fashions. The simplest method is a double-barreled ileostomy (Mikulicz), with the two loops brought out side-to-side; this solution is quick and avoids an intra-abdominal anastomosis. However, neonates may lose a large amount of fluids and solute from this method; in selected cases, as an alternative to a peripheral line a central venous catheter is scheduled, both for nutritional and medical purposes. Several alternatives have been described: distal ileostomy with end-to-side ileal anastomosis (Bishop–Koop), which is termed 'distal chimney enterostomy'; proximal chimney enterostomy is the Santulli procedure, with a proximal ileostomy with end-to-side ileal anastomosis.

The enterostomy is closed between 7 and 12 days after surgery by an end-to-end anastomosis.

In a few selected cases, gastrostomy may be needed, but only when recovery of intestinal functions is expected to be delayed.

In general, the shorter the length of the intervention and the less extended the resection, the earlier the recovery of peristalsis and the less complicated and uneventful will be the postoperative care.

Complications include pulmonary infections, which is the most important one, with an incidence of at least 8–10%. Anastomotic leakage occurs for different reasons: a technical mistake, an insufficient blood supply, a distal unrecognized obstruction. Delayed recovery of peristalsis is another frequently observed complication and is due to abnormal stretching of the intestinal walls during fetal life. Total parenteral nutrition is the support of choice and a central venous catheter is mandatory in these situations.

PROGNOSIS

Meconium ileus may be an early indication of a more severe phenotype of CF. This was suggested by the significantly lower pulmonary function found in children with a history of meconium ileus compared to age- and sex-matched children who did not have meconium ileus.[28] The complicated form is susceptible to a greater number of long-term surgical complications, including especially small bowel obstructions and blind loop syndromes. Long-term complications in neonates affected by uncomplicated meconium ileus who were non-operatively treated are never seen, and only mild and transient complications have been observed in newborns treated with minor surgical procedures, such as enterotomies and irrigations.

Survival of neonates with meconium ileus has improved over the last two decades because of neonatal intensive care, improved surgical techniques, and medical treatment. In general, an overall immediate survival of 90% is achieved using modern protocols, and nearly all deaths are pertinent to adolescents. Only few children die due to liver and/or septic complications. Deaths are mainly due to staphylococcal or Pseudomonas sepsis, primary or secondary to a pulmonary interstitial emphysema or to an aspiration pneumonia. In a large series reported and analyzed by Fuchs, only one child died because of the meconium ileus itself. More recently, different studies suggest that adequate initial nutritional and medical management of meconium ileus allows further quite similar nutritional and lung well-being compared with children affected by an early discovered and symptomatic CF.[29] In conclusion, even if meconium ileus is often associated with longer hospitalization, surgical procedures, high-risk infections, and sepsis, an early diagnosis of CF did not impair the long-term pulmonary outcome in these patients.[30]

Meconium peritonitis

JOSE BOIX-OCHOA AND JOSE L PEIRÓ

INTRODUCTION

Meconium peritonitis is an aseptic peritonitis caused by spill of meconium in the abdominal cavity through one or several intestinal perforations which have taken place during intrauterine life. Extravasation of sterile meconium into the fetal peritoneal cavity causes an intense chemical and foreign body reaction with characteristic calcification. Often, the perforations seal before the infant is born. Gastrointestinal perforations that occur following birth, even though the gut still contains meconium, constitute an entirely different group of clinical problems and should not be included in the syndrome of meconium peritonitis.[1,2]

Meconium peritonitis was first reported by Morgagni in 1761 in *De sedibus et causis morborum*. Simpson[3] managed to find 25 cases in 1838 and it was Agerty[4] in 1943 who reported the first successful operation.

The estimated incidence of meconium peritonitis is currently 1:30 000.[5,6]

A review of the world literature up to 2004 revealed 1681 cases of meconium peritonitis with 946 survivors (Table 55.1). Previous collected series have made this task easier.[7–13]

In the last 15 years, continuing progress in prenatal diagnostic procedures and postnatal intensive care has decreased mortality rates to less than 10% in some series,[14,15] and in our last experience the mortality rate fell to 7.2%.

Table 55.1 Mortality rate in meconium peritonitis among 1681 cases reported in the world literature.

Years	Total	Survivors	Mortality (%)
Before 1952	100	8	92
1952–1962	102	19	81.4
1963–1968	145	51	64.8
1969–1988	752	375	50.1
1989–1995	210	150	28.6
1996–2004	374	343	8.3
	1681	946	56.3

The current authors' experience is based on 67 cases of pure meconium peritonitis that underwent surgical treatment. All of these patients presented with the classical picture of meconium peritonitis at laparotomy and had histological evidence of (1) meconium inclusions (Fig. 55.1) or reaction to foreign bodies, and (2) visible perforation or microscopic evidence of intestinal cicatrization.

ETIOLOGY

Intrauterine intestinal perforation may result from various causes. Patients with meconium peritonitis are divided into those with and without associated intestinal obstruction. In the case of meconium peritonitis without obstruction, there is no clear-cut explanation for the perforation. Various hypotheses, such as segmental absence of the muscular coats,[13] absence of the muscularis mucosa,[16] vascular occlusion,[17] and general hypoxia of the fetus in the perinatal period[18] have been put forward. None of these hypotheses has been substantiated. In the current authors' research with rats, it has been clearly demonstrated that all these findings

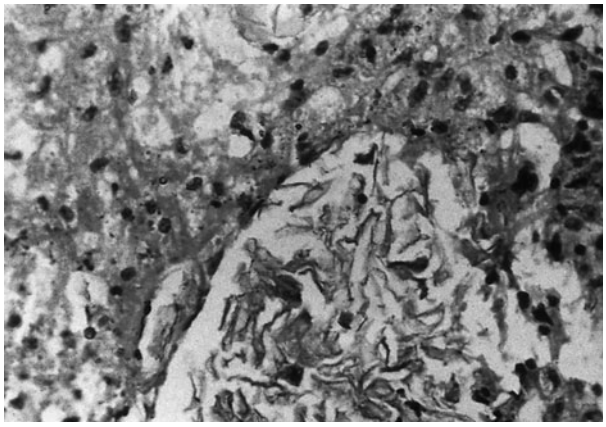

Figure 55.1 Granulomatous tissue with giant cells of foreign bodies related to meconial corpuscles.

are a consequence of meconium peritonitis and not primary etiology.[19] In the current authors' experience, intestinal atresia, intestinal volvulus, and meconium ileus constitute 94% of etiological factors (Table 55.2). Other causes include Hirschsprung's disease, meconium plug syndrome, congenital bands, internal hernias, Meckel's diverticulum, and rectal perforation.

The incidence of cystic fibrosis in infants with meconium peritonitis was previously reported to vary between 8 and 40%.[20]

However, in some cases it is impossible to find its etiology, in spite of pathological changes. The tabulation of the medical and perinatal reports demonstrated that 80% of these patients had neonatal anoxia and respiratory distress.

Labor research demonstrates the consequences of the hypoxia on the splanchnic area and blood distribution in the studied animals.[21,22]

If these findings are correlated with the current authors' studies, it can be postulated that there is diminished blood flow to the intestine of the hypoxic infant. The mucosa, which is very sensitive to ischemia, undergoes diminished mucin production and degenerative alterations. The proteolytic enzymes can now attack the bowel wall, which is normally protected by mucin. The consequence of this is a break in the mucosal integrity followed by perforation. Sometimes, the 'jamming' of this reflex mechanism prevents the return to normality and can cause such severe ischemia that it leads directly to a covered perforation. The less vascularized zones, and therefore the more exposed to ischemia and perforation, are situated in the ileocecal region and splenic flexure, where the current authors have found 60% of all idiopathic lesions.

PATHOLOGY

In the current authors' experimental work with rats, it has been shown that meconium gives rise to a peritoneal reaction with rapid fibroblastic proliferation enveloping the lesion. Later, foreign body granulomas and calcifications are seen. This reaction may be local or generalized, the parietal peritoneum having lost its sheen. The intestinal loops are intimately adherent structures with a fibrous tissue which is difficult to dissect, calcifications or meconial inclusions are disseminated, and the perforation is hard to identify. When the intestinal perforation does not cicatrize and there is a fibrinous reaction instead, the consequence is the formation of a cyst, the walls of which are formed of fibrin, meconium, and intestinal loops, intimately united. Such a cyst may occupy two-thirds of the abdomen (Fig. 55.2). The possibility of meconium spreading out by a hematologic or lymphatic route (via the brain or lungs) has been described.[23]

Lorimer and Ellis[24] described three major types of meconium peritonitis: fibro-adhesive, generalized, and cystic. Two other types which have been described are the healed form of meconium peritonitis and microscopic meconium peritonitis.

The fibro-adhesive type is the result of an intense fibroblastic reaction in response to the severe chemical peritonitis caused by the digestive enzymes in the meconium. This type produces obstruction by adhesive bands and the site of perforation is usually sealed off.

The cystic type occurs when the site of perforation is not effectively sealed and a thick-walled cyst is formed by the fixed intestinal loops.[25–28] This condition prevents communication of the perforation with the remainder of the viscera. Calcium deposits line the cyst wall. The formation of a pseudocyst represents an attempted intra-abdominal healing process to confine the perforation.

The generalized type usually occurs perinatally.[29–35] Calcified meconium is scattered throughout the peritoneal cavity and the bowel loops are adherent by thin fibrinous adhesions. In the current authors' experience, this is the most frequent type (74% of all cases).

The healed form of meconium peritonitis, presenting as an inguinal or scrotal mass, is clinically and pathologically of special interest. These patients usually present with no relevant recent clinical history, although the majority show a unilateral hydrocele at birth. Radiological studies of the scrotum and abdomen are usually helpful in making the diagnosis by demonstrating scrotal as well as peritoneal calcifications.[36–45] This combination is pathognomonic of meconium peritonitis.[37,45,46] In some cases, the peritoneal calcifications are the only symptomatology. In cases in which the diagnosis can be established clinically, no surgical intervention is necessary and, in the majority of these cases, the nodules regress spontaneously.[46–49] Microscopic examination of the resected specimen shows a fibrosis of the serous membrane, dissociation of the muscular layer, foci of

Table 55.2 Associated congenital malformations and operative findings.

calcification, and granulomatous lesions with foreign body giant cells.

There is another type of microscopic meconium peritonitis described by Tibboel *et al.*[50] without clinical or therapeutic significance. In the majority of cases it is a casual finding during laparotomy for other causes (Fig. 55.3). Many patients with this 'microscopic' type of meconium peritonitis present with atresia and the current authors feel that such an atresia should be regarded as scarring of the site of a perforation which must have occurred at a relatively early stage of fetal development. A careful microscopic examination of the visceral and parietal peritoneum will, however, reveal bile pigment and/or squamous cell remnants. The presence of these meconium components proves that a perforation must have occurred. The presence of collagen, calcium deposits, and giant cells surrounding meconium particles indicates that the peritoneal cavity must have contained meconium for a considerable length of time. Its etiology should be examined for intestinal perforations at an early stage of development, resulting in intestinal atresia induced by a vascular lesion. At other times, the perforation can achieve complete recovery and not lead to any significant tissue deterioration; the only remnant of this pathology is the microscopic meconium peritonitis as a casual finding and without clinical significance.

SYMPTOMATOLOGY AND DIAGNOSIS

The diagnosis of meconium peritonitis in the postnatal period is based on clinical and radiological, and ultrasonographic findings of intestinal obstruction, and occasionally one or more of the following: calcification, pneumoperitoneum, cyst formation, or ascites. The clinical symptomatology is that of any intestinal obstruction. A typical baby with meconium peritonitis is born with abdominal distension, or develops it soon after birth, and this is accompanied by bile-stained vomiting and failure to pass meconium. Occasionally, severe abdominal distension may result in dystocia or respiratory distress. Sometimes, cryptorchidism is the indication that the fetal abdominal pathology has prevented the physiological descent of the testicles. Pathognomonic of this is the appearance of a scrotal edema or hydrocele with retention of the testes and intrascrotal calcification.[51] X-ray and ultrasound[52] examination show the intestinal ileus, the ascites when it exists, the ground-glass appearance of the abdomen due to the meconium, and rarely the presence of a pneumoperitoneum, since the quick formation of adhesions prevents the intestinal gas from escaping.

Intra-abdominal calcifications are characteristic[53–55] and can easily be seen on plain abdominal films (Fig. 55.4). It is the current authors' belief that the origin of these calcifications may be the catalytic effect of the fatty meconial compounds on the precipitation of calcium salts. Proof of this is that in their investigations in laboratory animals with low serum levels of calcium, it has not been possible to reproduce calcifications. Faripor[56] is of the opinion that the pathogenesis of calcifications, after the analysis of seven cases with light microscopic observation, is undoubtedly in response to keratin debris. Keratin, however, cannot be the only source because of the presence of granulomas devoid of keratin. Due to the fact that some of these granulomas resemble gouty tophi, it may be as a result of inflammation caused by uric acid present in meconium. So early do the calcifications appear, that the prenatal diagnosis of meconium peritonitis is easily made on sonographic examination.[57–70] Diagnosis of associated pathology is of vital importance because of its repercussions in the immediate postoperative period.[71,72] Finkel and Slovis[73] indicate that the presence of intraperitoneal calcifications does not exclude but favors a diagnosis of cystic fibrosis in spite of the fact that they are scarcer than in the other types of meconium peritonitis. Detection of cystic fibrosis[74] is done by screening for the most common gene mutations and sweat chloride test, and also is recommended screening for congenital infections, including herpes simplex virus, cytomegalovirus, parvovirus B19, and toxoplasmosis.

Figure 55.3 Causal finding of calcifications on an intestinal atresia without the clinical evidence and operative findings of meconium peritonitis. This case is not included in our material.

Figure 55.4 Pathognomonic abdominal calcification in a case of meconium peritonitis.

Newborns presenting with scrotal swelling with or without discoloration resulting from calcified meconium within the patent processus vaginalis have been described with increased frequency.[40,45,46]

Meconium peritonitis may result in a number of genital manifestations, including inguinal and scrotal or labial hydrocele containing meconium or calcifications and hard tumor-like scrotal masses.[75]

Early diagnosis is a decisive factor for the prognosis of these newborns, because the commencement of bacterial colonization of the meconium starts after birth. In a study carried out by the current authors in 134 normal newborns, meconium cultures were positive in 24% at 12 hours of life and in 86% at 72 hours.[19] On the other hand, the laboratory studies carried out by the current authors already demonstrated the existence of a 'meconium spreading factor' which accelerates and worsens the sepsis. Owing to this, it is not then surprising that early diagnosis is of paramount importance. In the current authors' series of 67 cases, the patients who were operated on after 36 hours of life had a mortality rate three times higher than those who were operated on during the first 24 hours of life (Table 55.3). Tibboel and Molenaar[12] reported a 91% mortality rate for patients operated on after 48 hours of life.

The natural history of meconium peritonitis diagnosed *in utero* is markedly different from that diagnosed in the newborn because some cases diagnosed prenatally normalize spontaneously during the gestational follow up. The normal ultrasound features are polyhydramnios, fetal ascites, intra-abdominal calcifications, and dilated intestinal loops.[76]

Recently, it was reported[14] that magnetic resonance imaging afforded higher prenatal diagnostic accuracy of meconium peritonitis than ultrasonography (57.1 versus 42%). Ultrasonography, however, is most widely used as a primary tool.

Zangheri *et al.*[15] proposed a prenatal classification that was divided into four grades of progressive severity, based on the number of pertinent ultrasonographic findings: grade 0, isolated intra-abdominal calcifications; grade 1, intra-abdominal calcifications and ascites, pseudocyst, or bowel dilatation; grade 2, two associated findings; and grade 3, all sonographic features.

Patients with a score greater than grade 1 have a high probability for urgent neonatal surgery and therefore should be transferred *in utero* to a tertiary center with available neonatal surgery.

The cases in grades 0 where initial prenatal ultrasound findings subsequently disappeared during gestation can deliver at term without any complication at 40 weeks of gestation.

For fetuses with suspected intrauterine meconium peritonitis, pathological sonographic findings detectable throughout the pregnancy, such as intra-abdominal calcifications, ascites, meconium pseudocyst, bowel dilatation, hydrops fetalis, and polyhydramnios, an elective preterm delivery by Cesarean section is recommended at a median gestational age of 35 weeks[77] in order to stop evolution of the disease and to operate on the patient earlier. In recent years, with improvement in antenatal diagnosis, parents can decide upon termination of the pregnancy in some cases of meconium peritonitis with other severe associated anomalies. Early detection is not associated with poor neonatal outcome, and selective termination is unnecessary.[78]

Dirkes *et al.*[20] reported that only 22% of fetuses with prenatal diagnosis of meconium peritonitis developed complications that required surgery, and the overall mortality rate in their series was 11%.

Table 55.3 Time of operation related to prognosis.

Time (hours)	Total	Survivors	Mortality (%)
<24 postnatally	25	23	8
24–36	31	26	16.1
36–48	6	4	33.3
>48	5	1	80
	67	54	19.4

TREATMENT

The indication for operation in newborns with meconium peritonitis is a clear sign of intestinal obstruction or perforation. The diagnosis of meconium peritonitis without intestinal obstruction or pneumoperitoneum does not constitute an indication for operation. Infants with neonatal meconium calcifications, meconium ascites with hydrocele, or calcified meconium found in the hernial sac do not require operation, but they have to be observed and feeding withheld for 48 hours. With an absence of clinical symptoms, enteral feeding can be started with caution, gradually progressing to formula. Antibiotic coverage is desirable. After a prenatal diagnosis, fetal paracentesis could sometimes be beneficial to reduce intra-abdominal pressure, to improve mesenteric vascular supply, and to remove inflammatory debris.[79]

Surgical treatment

All the conditions for the preparation of the newborn for surgery, such as monitoring for vital signs, control of temperature and measures for impeding its loss and ambient temperature in the operating theater, should be adhered to. An i.v. cannula should be placed for i.v. fluids. Blood should be cross-matched and prophylactic antibiotics started.

Operative treatment

Based on our experience of 67 cases with a survival rate of 92.8% in the past 15 years, the current authors act according to the following protocol:

1. If the perforation is visible, do not try to suture it. Intestinal resection and end-to-end anastomosis is performed.

2. In cases of localized or generalized peritonitis, attempt the lysis of the adhesions only to discover the perforation or to relieve obvious obstructions. Only when necessary should an attempt be made to dissect the adhesions, since fibro-adhesive peritonitis disappears after 8–14 days; this has been confirmed in the current authors' patients who had the two-stage operation and in investigation with laboratory animals.
3. Once the etiology has been determined (atresia, stenosis, or meconium ileus), an attempt must be made to perform an end-to-end anastomosis according to Louw's technique[80] if the condition of the patient and the difference in the intestinal calibers allow it.

Rehbein's two-stage operation[9] (exteriorization followed by laparotomy and anastomosis) is used only if the patient's condition is very serious, or if the existing peritonitis can endanger the suture line, or when there are great differences in caliber of the two loops of bowel. The anastomosis is performed 2 weeks later, if the newborn's general status allows the second stage of the operation. During the interval between the two operations, enteral and total parenteral nutrition are indispensable for maintaining the newborn in the best condition as well as the stimulation of the distal portion with the contents of the proximal end. The two-stage operation offers a series of advantages that should always be considered by the surgeon:

- Rapid solution of the surgical problem.
- It allows the surgeon to deal with the peritonitis which would endanger the suture in a one-stage operation.
- It allows recovery of the general state of the patient with the increase of energy reserves by means of parenteral nutrition and antibiotic therapy.
- It allows time for the disappearance of bowel adhesions and the normalization in caliber and absorptive function of the intestinal mucosa by means of the growth stimulation offered by perfusion of the enteral diet through a soft silicone feeding tube in the distal portion.
- It allows the maturation of the neuroendocrine system.

The two-stage operation has been associated with a lower mortality rate in the current authors' series when compared with the one-stage operation (7.2 versus 22%).

When faced with a meconial cyst, in view of the small number of successful cases published,[24,81–83] the current authors always perform decortication with great care and a two-stage operation.[84]

Another option is cyst drainage by ultrasound-guided punction and later laparotomy. A drainage procedure was always accompanied by supportive treatment of decompression, broad-spectrum antibiotics, and parenteral nutrition. Tanaka *et al.*[85] reported two cases of cystic meconium peritonitis which initially underwent emergency percutaneous drainage with ultrasonic guidance under local anesthesia. They found that such procedure is safe and effective in decompression of gastrointestinal tract and prevention of bacterial infection. They recommended cyst drainage just after birth and elective surgery later based on the general condition of the baby. During the second operation, the general condition is more stable, the adhesions will be less, the identification of the bowel loops easier, and the bleeding minimal.[86]

To summarize, the current authors are convinced that the low morbidity rate achieved by them is due to the planning of the operation in two stages, whenever faced with the slightest doubt as to the probable success of a primary anastomosis.

With early diagnosis, the advances in surgical techniques, and postoperative treatment, current survival of the patients with meconium peritonitis is near to 100%.[87]

COMPLICATIONS

Among the postoperative complications, adhesion ileus is the most frequent. In the current authors' series of 67 patients, seven developed adhesion ileus, five had anastomotic leakage, two had necrosis of the ileostomy stump, and one had an enterocutaneous fistula. There were 13 deaths in the series, seven directly attributable to lung complications in patients with cystic fibrosis. The other six patients died of sepsis. Gentle and delicate operative manipulation is required to reduce the morbidity.

ALAN MORTELL AND PREM PURI

INTRODUCTION

Duplications of the alimentary tract are rare spherical or tubular structures which can occur anywhere in the tract from mouth to anus.[1–3] Ladd,[4] in 1937, introduced the term 'alimentary tract duplication' in the hope of clarifying the nomenclature which had previously included descriptive terms such as enteric or enterogenous cysts; giant diverticula; ileal, jejunal, or colonic duplex, an unusual Meckel's diverticulum. Ladd proposed that the unifying term 'alimentary tract duplications' be applied to congenital anomalies that involved the mesenteric side of the associated alimentary tract and shared a common blood supply with native bowel.[4] Most duplications might indeed be called simply 'enterogenous cysts', since in only very few cases is there an actual doubling of the alimentary tract and these are therefore deserving of the name 'duplication'.

EMBRYOLOGY

Numerous theories have been developed to account for the multitude of gastrointestinal (GI) tract duplications. In a comprehensive review of gastrointestinal duplications, Stern and Warner[1] outlined the most widely held theories regarding GI duplication.

Embryologically, duplications have been categorized into foregut, midgut, and hindgut types.[1] Foregut duplications include the pharynx, respiratory tract, esophagus, stomach, and the first portion and proximal half of the second portion of the duodenum. Midgut duplications include the distal half of the second part of the duodenum, the jejunum, ileum, cecum, appendix, ascending colon, and proximal two-thirds of the transverse colon. The hindgut is composed of duplications of the distal third of the transverse colon, the descending and sigmoid colon, the rectum, anus, and components of the urological system. In one series, 39% of duplications involved the foregut, whereas 61% represented duplications of both mid- and hindgut.[5]

Partial twinning

Certain duplications appear to represent partial twinning, particularly the tubular duplications of the terminal ileum and colon.[6–10] There is a wide spectrum of abnormalities, from complete twinning of the lower trunk and extremities to mere doubling of the lumen of hindgut structures. These lesions are often associated with duplication of the lower urinary tracts.[11–13] Many rare examples of abortive cephalic twinning have also been described.[14] When there is complete doubling of the colon, one or both lumens may open as a fistula into the perineum or into the genitourinary (GU) tract, and may be associated with an imperforate anus. Doubling of the anus, vagina, and bladder have all been detailed and often can be associated with other severe deformities, such as double spines or two heads.

Split notochord

The most satisfactory of several theories of the origin of GI duplications is that relating to the development of the neurenteric canal. Saunders,[15] in 1943, noted that thoracic duplications are frequently associated with abnormalities of the cervical and thoracic vertebrae. These duplications may be attached to the vertebral bodies or connected to the spinal canal. These findings gave rise to the Bentley and Smith 'split notochord theory'.[16–18] The embryo initially has two layers: ectoderm and endoderm. Mesoderm forms between the two but for a short time these two layers remain adherent. A transient opening (the notochordal plate) appears, connecting the neural ectoderm with the intestinal endoderm. This notochordal plate normally migrates dorsally and becomes 'pinched' off from the endoderm by the ingrowth of mesodermal cells from each side. If the notochordal plate fails to migrate as a result of adhesions to the endodermal lining, the spinal canal cannot close ventrally and a tract resembling a diverticulum is established with the primitive gut. This tract may remain open, leaving a fistula between the gut and the spinal canal, or close leaving only a fibrous tract.

However, in the majority of cases it disappears completely, leaving only the duplication of the GI tract. This theory explains the formation of thoracic and caudal duplications, which may be associated with vertebral anomalies. However, the absence of spinal defects in many alimentary tract duplications makes this theory less tenable as a unifying model of their origin.

Embryonic diverticula and recanalization defects

In a study on human (4–23 mm) and animal embryos, Lewis and Thyng[19] found tiny bands of intestinal epithelium protruding into the subepithelial connective tissue. The identification of numerous diverticula in the intestines of embryos, led to the proposal of an extension of the diverticula into duplications. The frequent ileal position of these diverticula is congruous with the frequent ileal location of human GI duplications. Although this theory could explain duplications in the absence of spinal anomalies, it fails to account for the variability of the mucosal lining and specifically for the frequency of heterotopic gastric mucosa. Furthermore, the diverticula identified in this pathological series were located throughout the bowel circumference as opposed to the general locations of duplications on the mesenteric side of the intestine.

The occurrence of tubular duplications would also not be explained by this theory (Fig. 56.1). Bremer[20] believed that abnormal recanalization of the intestinal lumen after the solid stage of development of the primitive gut in the sixth to seventh week of gestation resulted in duplications.[21] Such duplications, however, would not be confined to the mesenteric side of the bowel. Also opposing this theory is the finding that the solid stage of development in the human does not usually extend beyond the duodenum.[21]

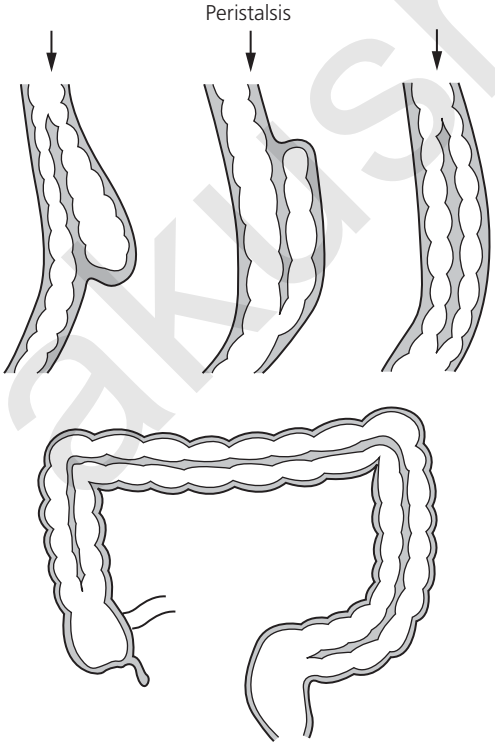

Figure 56.1 Various types of tubular duplications of the intestine.

In 1961, Mellish and Koop[22] proposed an environmental theory, which held that trauma or hypoxia could induce duplications and twinning in lower orders. Based on the work of Louw, they concluded that vascular insufficiency could lead to the recognized GI duplications seen in humans.[23] In addition, intrauterine vascular accidents are known precipitators of other congenital anomalies, such as gastrointestinal atresias.

PATHOLOGY

Duplications are hollow structures that involve the mesenteric side of the associated GI tract.[24] They tend to share a common muscular wall and blood supply with its mature bowel, although each has its own separate lining.[25] They are usually isolated lesions and are more often cystic than tubular with a variable size. The lesions have a muscular coat in two layers and are usually lined with epithelium similar to that found in the associated portion of the alimentary tract. The duplications, however, are occasionally lined with heterotopic epithelium; the presence of colonic mucosa has been described at the base of the tongue and sinuses lined with gastric mucosa have been found near the anus.[26] Duplications containing gastric mucosa are at risk of peptic ulceration, perforation, and hemorrhage.[27] Patches of ectopic gastric mucosa along the GI tract may represent the mildest manifestation of duplication abnormalities. Ectopic pancreatic tissue has been reported in duplications of the stomach, ileum, and colon.[28] The contents of a duplication vary with the type of epithelial lining of the structure, the presence or absence of a communication with the proximate part of the GI tract, and the absence or necrosis of the duplication wall. If an opening is present, the duplication contents will be similar to that of the adjacent intestinal tract. Communication between the two structures is rare and the cysts usually contain chyle or mucus. Multiple duplications can occur in the same patient.[26,29,30] There is an increased incidence of other associated anomalies such as vertebral anomalies,[31] myelomeningocele,[32] imperforate anus,[33] malrotation of the bowel,[34] genital anomalies,[30] polysplenic syndrome,[35] and duodenal atresia.[36] No genetic tendency has been demonstrated.

Malignant carcinomatous changes are rare complications of intestinal duplications. Adenocarcinomas arising from small bowel as well as large bowel duplication cysts have been reported in adult life.[37–40]

INCIDENCE

Duplications of the alimentary tract are rare. Table 56.1 summarizes the larger published series of duplications.

Table 56.1 Incidence and locations of duplications.

Author	Total No.	No. neonates	Cervical	Mediastinal	Thoraco-abdominal	Gastric	Duodenal	Jejunal-ileal	Colonic	Rectal

Holcomb *et al.*[28]	96[d]	36	1	20	3	8	2	47	20	–

[a]One patient had two, one had three, and one had five duplications.
[b]One patient had three duplications.
[c]Two patients each had two duplications.
[d]Ninety-six patients had 106 atresias.

In many cases the numbers of patients reported represent up to 40 years' work in these centers. Only a small percentage of the total cases reported actually present in the neonatal period.[40–44]

ESOPHAGEAL DUPLICATION

The esophagus is a relatively common site for foregut duplications (19%) with the majority being intramural, non-communicating cystic structures related to the right side of the esophagus. Patients often present late in childhood as they cause relatively few symptoms; however, cervical esophageal duplications can cause significant respiratory distress requiring urgent surgery. Some lesions do not share a common wall with the esophagus and can be easily removed through open or minimally invasive techniques.[45] Plain x-rays may show an air or fluid-filled structure adjacent to the esophagus, although this is not usually enough to confirm the diagnosis. Contrast studies can provide useful information regarding the mass effect of the lesion and whether or not their lumens communicate. Ultrasound and computed tomography (CT) are useful for establishing a diagnosis and also for ruling out multiple lesions, which can be present in 10–20% of cases. Technetium scans (^{99m}Tc) may reveal the presence of heterotopic gastric mucosa in the case of gastrointestinal bleeding.

Treatment

The surgical approach depends largely on the location of the cyst. Cervical esophageal duplications can be removed through a supraclavicular incision, with particular attention being paid to the vagus and phrenic nerves as well as the thoracic duct to avoid unnecessary damage. Intrathoracic duplications are resected through a standard posterolateral thoracotomy or a thoracoscopic approach.[46] A chest drain may be left *in situ* but is not always required.

THORACO-ABDOMINAL DUPLICATION

Thoraco-abdominal duplications are rare representing only 4% of all gastrointestinal duplications. They often lie separate from the esophagus, more often on the right than the left side, but may be attached to other important structures, such as the aorta, azygous vein, and tracheobronchial tree. They frequently lie in the posterior mediastinum and pass through the diaphragm to communicate with the stomach, duodenum, or small bowel. The imaging studies employed are similar to those for esophageal duplications, with special attention being paid to imaging of the vertebral column/spinal cord for a possible intraspinal component. CT and/or magnetic resonance imaging (MRI) are particularly useful in this regard, especially if neurological symptoms of spinal cord compression or bony spinal abnormalities are present.

Treatment

These challenging duplications require resection of the thoracic and abdominal components through two different open procedures or alternatively they may be dealt with by a combined thoracolaparoscopic approach.[47] Although the abdominal portions are often asymptomatic, the thoracic components can cause symptoms as a result of mass effect on the lungs and airway. The presence of gastric mucosa within the thoracic duplication cyst can lead to peptic ulceration and possible erosion into the lung parenchyma, presenting with hemoptysis. This complication may require a lobectomy. Once the lesion is mobilized in the thorax, it is freed from the posterior aspect of the diaphragm prior to mobilization and removal of the abdominal component.

GASTRIC DUPLICATION

The stomach is one of the less common sites of duplications, accounting for only 9% of all GI duplications. Over 60% of

cases are diagnosed during the first year of life, with a significant number (40%) appearing in the neonatal period by the finding of a palpable cystic mass in the upper abdomen accompanied by vomiting and weight loss.[48,49] Rarely, they undergo peptic ulceration and if the cyst communicates with the stomach, hematemesis and/or melena may be the presenting feature. Rarely, a carcinoma may arise within a gastric duplication cyst.[50] Gastric outlet obstruction, mimicking hypertrophic pyloric stenosis, is also a common presenting feature of this duplication.[51] Gastric duplications occur twice as often in females as in males.[24] Gastric triplication, although rare, has been described in the literature.[52]

It is often difficult to make a preoperative diagnosis of gastric duplication. Plain x-rays are usually negative and therefore unhelpful. A contrast meal may show compression of the stomach, usually along the greater curvature. Contrast may delineate a connection between the stomach and duplication, but only in a small minority of cases. In these cases, contrast may be retained in the duplication long after the remainder has passed from the GI tract. Ultrasonography has been shown to be useful in the diagnosis of gastric duplications. The vast majority of gastric duplications are located in the greater curvature (Table 56.2). Occasionally these are pedunculated,[32,53] but most are closed spherical cysts or tubular structures.

Associated anomalies occur in 3% of gastric duplications.[54] The most common is another cyst, usually of the esophagus.[55] Dual duplications of the stomach and pancreas have been reported.[56,57] These are thought to arise from an error in rotation of the ventral pancreatic anlage.

Table 56.2 Location of duplications of stomach in 87 reported cases.

Location	No. cases
Greater curvature	55
Lesser curvature	7
Anterior wall	9
Posterior wall	9
Others	7

Treatment

The management of gastric duplications is surgical because of the high incidence of complications due to obstruction, bleeding, or peritonitis. As most duplications occur in the greater curvature, a wedge of stomach is excised together with the cyst and the gap closed with a single layer of horizontal inverting mattress sutures (Fig. 56.2). Partial gastrectomy should be avoided in children if possible, and if necessary only 25–30% of the stomach should be resected because of the associated long-term complications.

When extensive resection of the adjoining stomach is impractical, as with the long tubular duplications of the greater curvature (Fig. 56.3a), the main part of the duplication is excised and the mucosa stripped off (Fig. 56.3b). The remaining seromuscular cuff can be sutured over the denuded area (Fig. 56.3c) after checking that the common wall between the stomach and duplication has not been perforated, by insufflating the stomach with air. The use of a stapling gun to divide the common wall along the length of the greater curvature has also been described.[58]

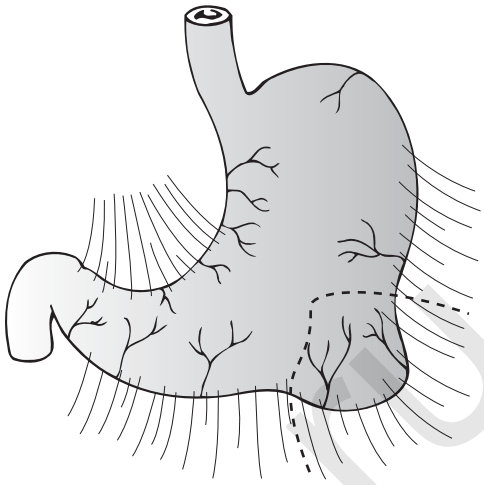

Figure 56.2 Gastric duplication located at the greater curvature. A wedge of stomach is excised together with the cyst and the gap closed with a single layer of horizontal inverted mattress sutures.

PYLORIC DUPLICATIONS

True pyloric duplications are extremely rare, with very few being reported in the English literature and most of these presenting within the first week of life.[48,59–62] They simulate the symptoms and signs of hypertrophic pyloric stenosis.[63] Vomiting, weight loss, and a palpable abdominal mass are the main findings. There are certain physical features which are consistent with duplication: the mass is usually large and smooth, in contrast to the smaller and often more mobile 'olive' mass in hypertrophic pyloric stenosis.[63]

Because of the non-specific physical examination, radiographic procedures are essential for diagnosis. Plain film x-rays may show signs of gastric outlet or duodenal obstruction with a lack of distal bowel gas,[64] or rarely calcification within a cyst wall.[65] Ultrasonography may demonstrate an inner echogenic mucosal layer and outer hypoechoic muscular layer differentiating the duplication from a mesenteric cyst. Contrast studies may help differentiate the duplication from pyloric stenosis. If there is a clinical concern, then preoperative endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiography (PTC), or magnetic resonance cholangiography/pancreatography (MRCP) should be performed to evaluate the involvement of the biliary/pancreatic ducts.

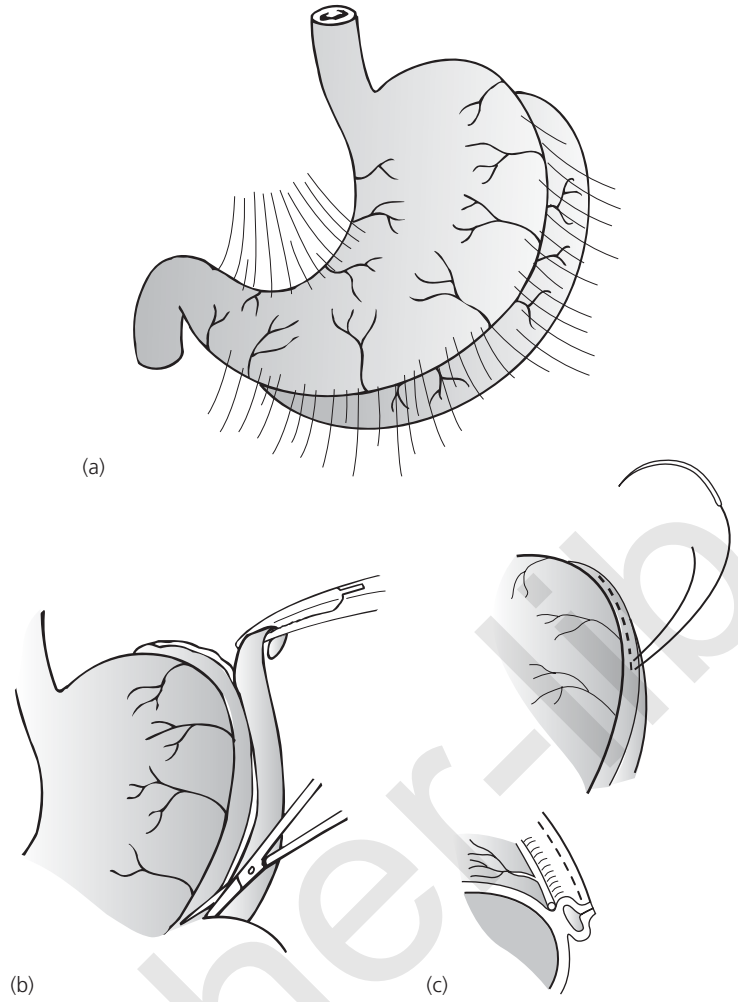

Figure 56.3 (a) Tubular duplication of the greater curvature of the stomach. (b) The mucosa is stripped from the entire length of the duplication. (c) The seromuscular cuff is closed over the denuded area.

Treatment

Of the cases of pyloric duplication reported, the majority underwent simple surgical excision after opening the pyloric canal longitudinally. The pylorus was then closed transversely with no complications.[48,58,61] However, if there is a risk of damage to pancreatic or bile ducts an acceptable alternative is to drain the cyst into the duodenum or into a Roux limb of upper small bowel.

DUODENAL DUPLICATIONS

The duodenum is involved in only 4% of all duplications. They are often behind the duodenum and do not communicate with the bowel lumen.[66] Vomiting secondary to partial or complete duodenal obstruction and an upper abdominal mass are present in the majority of cases.[67] They may present with hematemesis or perforation, as gastric mucosa is present in 10–15% of cases.[68] Alternatively, because of their location, they may present with biliary obstruction or pancreatitis. If the duplication is of sufficient size, it may appear on plain x-rays as a large opacity in the right side of the abdomen displacing the intestine (Fig. 56.4a). Contrast studies will show the duodenum to be displaced upwards and a 'beak-like' projection due to compression of the duodenal lumen by the duplication (Fig. 56.4b).[69] Contrast entering into the cyst confirms the presence of a luminal communication. Ultrasonography may show a cystic lesion below the liver and a classical double-layered appearance or 'muscular rim' sign (Fig. 56.5a).

Treatment

In view of the occasional occurrence of gastric mucosa in the duplication cyst, these lesions should, if possible, be dissected from the duodenum and excised, closing the resulting defect in the duodenum in two layers. Intraoperative cholangiography will help determine the relationship of the cyst to the biliary and pancreatic ducts.[70]

If the lesion is extensive (Fig. 56.5b), or if eversion of the cyst may compromise the biliary system, then cystoduodenostomy may be performed.[71] The cyst may also be only partially excised, stripping off all the lining mucosa and leaving the part of the cyst which is adherent to the duodenum or pancreas.[70]

DUPLICATIONS OF THE SMALL INTESTINE

Small bowel duplications constitute 45% of all alimentary tract duplications.[72] The vast majority of small bowel duplications are spherical cysts in the terminal ileum. Jejunal and ileal cysts are found on the mesenteric side of the bowel, sharing a common muscularis with the adjacent bowel. They may cause obstruction by external pressure on the lumen,[73] by acting as a lead point for intussusception[74,75] or occasionally by causing a volvulus.[76]

Tubular duplications have the same features as the cystic variety, but they communicate with the normal lumen of the intestine and are more likely to contain gastric mucosa.[77] Pancreatic mucosa has also been described in these duplications. Tubular duplications can range in length from a few millimeters to the whole length of the small bowel.[78,79] The communication may be at the cephalad end, which will cause the duplication to become grossly distended with intestinal contents, or if at the caudal end, will allow the duplication to drain freely. Communication at several different points may be present.

Hemorrhage occurs most often in tubular duplications, but perforation has been reported as well.[80,81] Plain abdominal x-rays may show non-specific displacement of bowel gas shadows by the cyst, or signs of intestinal obstruction or perforation. Ultrasonography can help to differentiate between a mesenteric and a duplication cyst. A contrast meal may demonstrate displacement of the bowel (Fig. 56.6).

Treatment

Cystic duplications are relatively straightforward to deal with. Resection of the cyst with adjacent bowel (Fig. 56.7a) is performed; the two ends of the bowel are anastomosed with one layer of horizontal inverting mattress sutures and the mesenteric defects are closed (Fig. 56.7b).

Tubular duplications, if very short, can be resected as in a cystic lesion, but the majority involve a considerable length of small bowel and much ingenuity and patience may be required to meet the needs of any one particular case.

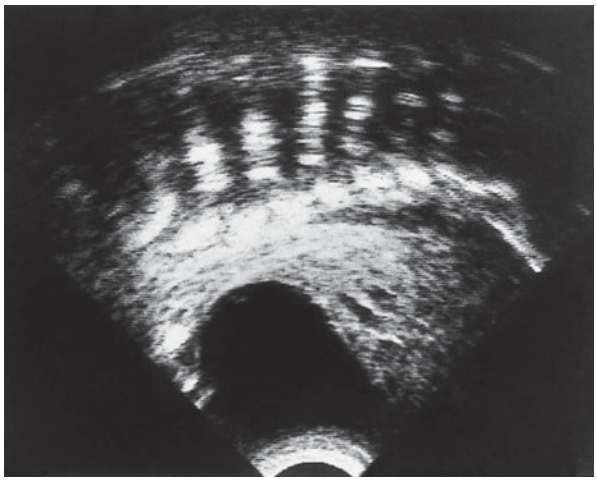
Wrenn[82] suggested coring out the mucosal lining of a long tubular duplication through multiple seromuscular incisions in the wall of the duplication.

Norris *et al.*[83] employed a technique first described by Bianchi[84] for bowel lengthening, to separate two leashes of blood vessels passing to each side of the small intestine (Fig. 56.8). Using this method, the entire mucosa and almost the entire muscle wall can be excised. The remaining cuff of muscle wall can be oversewn, preserving the blood supply to the normal bowel.

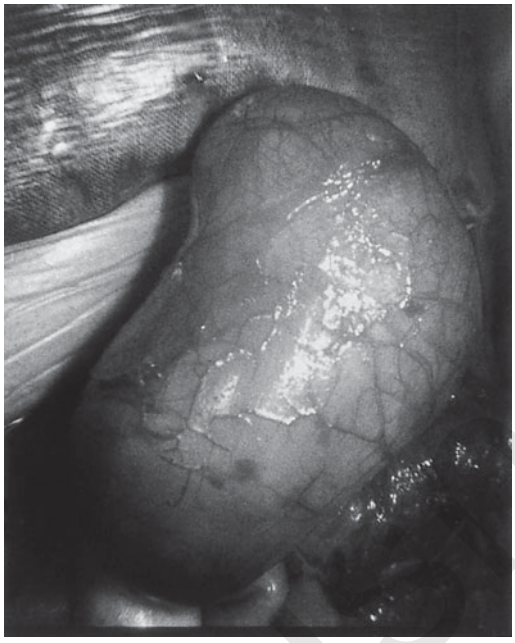
Bishop and Koop[85] described the techniques of anastomosing the distal end of the duplication to adjacent normal intestine, allowing free drainage of the contents. Malignant change in the mucosa has, however, been described as a late complication of this procedure.[86] Whichever technique is utilized, it is essential that the junction of normal and duplicated bowel is resected since heterotopic gastric mucosa is frequently present in tubular intestinal duplications.

COLONIC DUPLICATIONS

Colonic duplications are among the rarest reported. They are frequently diagnosed in infancy and some reports suggest a female predilection. McPherson *et al.*[87] proposed a simple classification of colonic duplications: type I mesenteric cysts, type II diverticula, and the more common type III tubular



(a)



(b)

Figure 56.5 Duodenal duplication. (a) Ultrasound shows the cystic lesion below the liver. (b) Large duodenal duplication cyst.

colonic duplication. A number of etiological factors may be involved in the development of the 'double colon'. The most valid theory suggests division of the hindgut into two parts at a stage during which the anlage possessed a multi-organ developmental potential.[87,88] The hindgut anlage normally forms the distal ileum, colon, rectum, bladder, and urethra. Division of the anlage at the same initial stage could therefore be responsible for duplication of the lower urinary tract as well.[87]

Simple cysts (type I) and diverticula (type II) occasionally result. They can be identified on plain x-rays or on contrast studies. A contrast enema may demonstrate a communication between the colon and duplications in types II and III. Associated genitourinary and lumbosacral spinal abnormalities can also be demonstrated on the appropriate radiographic studies, particularly when dealing with type III

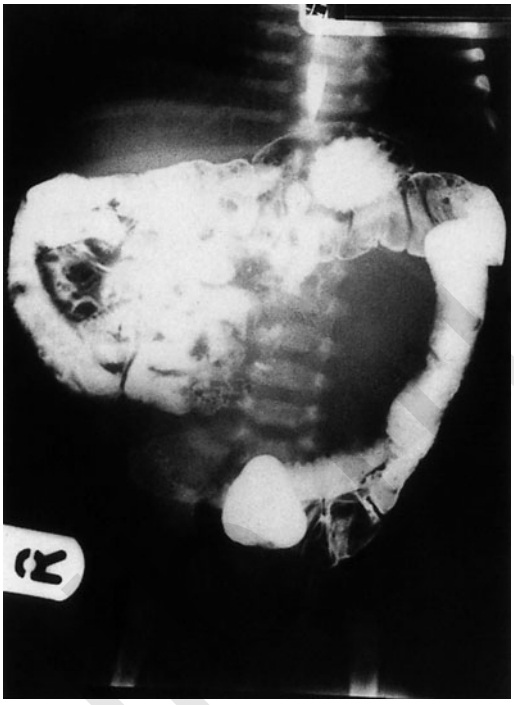


Figure 56.6 Barium study demonstrates a space-occupying lesion displacing bowel. At laparotomy a large ileal duplication cyst was found.

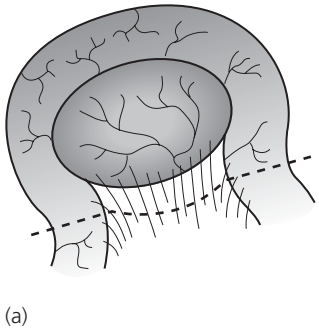
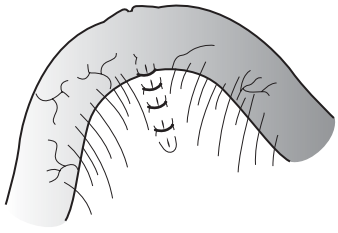


(a)



(b)

duplications. Isotope scans are rarely of benefit with colonic duplications, as they contain only colonic mucosa.

Complete duplication of the colon is usually asymptomatic in the neonatal period unless duplication of the anus or an abnormal orifice, in addition to the normal orifice in the perineum, is present. One or both orifices at the distal end of the colon may end as rectovaginal or recto-urethral fistulas.[88]

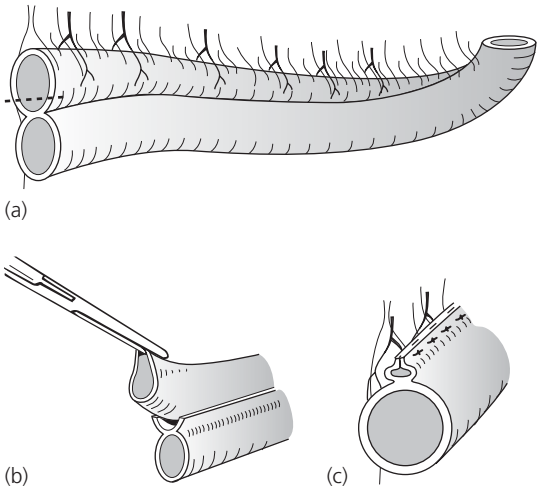

Figure 56.8 Tubular duplication of small bowel. (a) The main part of the tubular duplication is excised. (b) The mucosa is stripped from the entire length of the duplication. (c) The sermuscular cuff is closed over the denuded area.

Treatment

Surgery for colonic duplication is rarely indicated in the neonatal period unless there are complications, e.g. obstruction or an associated imperforate anus. All cystic and most tubular colonic duplications can be dealt with by simple resection and anastomosis utilizing a single-layer extramucosal technique. With rare total colonic duplication, the principal aim of management is to end up with two colons draining through one anal orifice. If one part of the colon has already reached the perineum, then the other colon is divided and anatomosed to its partner. This can be achieved by using a linear stapling device. If neither colon reaches the perineum, then a formal pull-through procedure will be required. Neonatal management in any of these situations is confined to fashioning a defunctioning colostomy to drain both colons.

RECTAL DUPLICATIONS

Approximately 70 cases of rectal duplications have now been reported in the literature, comprising only 5% of all gastrointestinal duplications. More than 50% of these have been examples of hindgut twinning.[89]

The embryogenesis of rectal duplication cysts is attributed to a 'pinching off' of a diverticulum in the 20–30 mm embryo,[90] in contrast to the 'caudal twinning' which occurs in the 10 mm embryo and is associated with complex hindgut anomalies.[91,92]

Rectal duplications often present in the neonatal period with a fistula or perineal mucosal swelling extending to the perianal area. Presentation of the cysts depends on: (1) size and their mass effect, (2) fistulas, (3) infection, (4) ulceration if they contain gastric mucosa, and (5) malignancy.[93] The duplication cyst usually forms in the retrorectal space and contains colorless mucus, which can become infected. They frequently present in 20–45% of cases.[89,90] No cases of a fistula between the rectum and urinary tract have been described. Malignant degeneration has been reported in the rectal duplication from the fourth decade onwards.[94,95]

Treatment

Treatment of the rectal duplication cyst is surgical excision or fenestration of the common wall. Depending on the anatomical variations, a transanal or transcoccygeal (Kraske) approach can be employed. For longer or more complicated cysts, a longer posterior sagittal incision will provide better exposure. As with other duplications, it is of prime importance to remove all mucosa in the duplication. The muscularis can be left *in situ*.

Associated anomalies such as presacral tumours (16%) and anorectal malformations (21%) are frequently described in the literature.[96] Management of these lesions may be difficult and often requires preoperative evaluation of both the gastrointestinal and genitourinary tract. Continence of both systems is imperative, and therefore, treatment strategies must be individualized based on the findings of each patient.

It is clear that duplications of the GI tract represent a diverse and complex group of anomalies. Small duplications in readily accessible areas (i.e. the small intestine) may be excised with adjacent bowel. In other locations, where resection would endanger adjacent structures, simple anastomosis between the cyst and normal intestine can be performed, provided that there is no gastric mucosa in the cyst. If bleeding has been a persisting complaint, the presence of gastric mucosa can be assumed. If resection is contraindicated, the lining mucosa may be stripped from the cyst, leaving the muscle wall *in situ*.

Mesenteric and omental cysts

BENNO URE

INTRODUCTION

The first report on a mesenteric cyst was published by an Italian anatomist in 1507.[1] Since then, the origin and classification of mesenteric and omental cysts has been a matter of debate. Moynihan attempted in 1897 a differentiation of abdominal cysts on the basis of fluid content.[2] Serous cysts are characterized by a translucent, straw-colored fluid of low specific gravity. Their chemical composition is similar to plasma. In contrast, chylous cysts contain an opaque fluid of high specific gravity, with lipids and fat globules contributing to the fluid content. Subsequent attempts at a more appropriate classification of intra-abdominal cysts have been based on suspected etiology initially proposed by Beahrs *et al.* in 1950.[3] However, the etiology of many intra-abdominal cysts is questionable, rendering classifications of this type of limited clinical usefulness. A more appropriate classification, based on histologic findings, was proposed in 1987 by Ros *et al.*[4] This differentiation is applicable to all operative cases and can provide the basis for a more uniform evaluation of the clinical and pathologic characteristics of these cysts (Box 57.1).

Up to the present day, the terminology is still descriptive of anatomic location without information as to the specific histology or pathology of mesenteric, mesothelial, or omental cysts. Several authors suggested differentiating cystic lymphangiomas from mesenteric and omental cysts.[5,6] A lymphangioma wall shows endothelial cells, small lymphatic spaces, lymphoid tissue, and smooth muscle cells. Mesenteric cysts do not have lymphatic spaces and smooth muscles and the cells of their wall are cuboidal or columnar (Box 57.2).[7] All these cystic lesions are generally of isolated pathology with few reports of associated developmental anomalies.

The incidence of mesenteric and omental cysts is rare and has not been systematically determined in the general population. Large reviews have indicated a male predominance.[8]

Box 57.1 Classification of abdominal cysts[1,6,13]

- Embryonic/developmental
  - enteric
  - urogenital
  - dermoid
  - embryonic defects of lymphatics (retroperitoneal, mesenteric, and omental cysts)
- Traumatic/acquired
  - Hemorrhagic (sanguinous)
  - Ruptured lacteal
  - Chylous extravasation
- Neoplastic
  - benign (lymphangioma)
  - malignant (lymphangioendothelioma)
- Infectious
  - mycotic
  - parasitic
  - tuberculous
  - hydatid
  - cystic degeneration

SPECTRUM AND MORPHOLOGY

Lymphangiomas represent approximately 90% of the cysts encountered in the mesenterium and omentum of the neonate. They are characterized by multiple thin-walled cystic spaces with a distinct endothelial lining similar to that seen in the subcutaneous location. These lesions are presumed to be congenital, with an etiology secondary to proliferating lymphatic tissue without access to adequate drainage. Lymphangiomas appear most frequently in the mesentery of the small bowel and may be encountered in the mesocolon and

omentum. Extension to the retroperitoneum has been frequently described.[8,9] Gross, solitary multiloculated, fluid-containing cysts are encountered, which can reach an enormous size (Fig. 57.1). The fluid may be serous or chylous with chyle being characteristic of a small bowel location and the associated high lymphatic fat content. Hemorrhagic fluid is not uncommon.

Mesothelial cysts are less common, but represent the majority of non-lymphangiomatous congenital cysts encountered in the omentum (Fig. 57.2). They may also occur within the mesentery. Mesothelial cysts are generally unilocular, serous-containing, and lined by mesothelium. They are thought to arise from incomplete fusion of the mesothelial leaves of omentum or mesentery.

Enteric duplication cysts are not included under the heading of mesenteric cysts, but should be mentioned due to their frequent neonatal presentation, mesenteric location, and occasional similarity in appearance (Fig. 57.3). Therefore, they should be included in the differential diagnosis of intra-abdominal cystic lesions in the neonate. These cysts may occur anywhere along the gastrointestinal tract as saccular or tubular unilocular lesions, usually within the mesentery adjacent to a normal intestine. Histologically, they are composed of all the layers seen in normal intestine and they share a common blood supply with the adjacent

intestine. Duplication cysts may contain mucous-producing cells.

CLINICAL CHARACTERISTICS

The cysts may be diagnosed *in utero* with the use of routine prenatal ultrasonography.[10] However, most series report mean ages of three to five years at presentation,.[11–13] and the age at diagnosis has gradually decreased over the years. Omental and mesenteric cysts may be an incidental finding, but more than half of these children present with acute clinical problems.

The symptoms of mesenteric or omental cysts are related to mechanical forces due to cyst location and size. The majority of children present with abdominal complaints, such as pain, vomiting, and distension (Table 57.1). Several

Miscellaneous[a]	23

[a]Failure to thrive, nausea, gastrointestinal bleeding, diarrhea, etc.

authors have suggested that the high incidence of symptoms in children versus adults may be related to the higher incidence of lymphangiomas in young individuals.[8,9] A palpable mass is the most common physical finding, but this may be apparent in only 60% of affected children due to the flaccidity and mobility of the cyst. The mass, if present, is generally smooth, not tender and mobile in character. Of the affected children, 50% or more will present with complications. Intestinal obstruction, either partial or complete, is frequent and usually due to compression of the adjacent intestine. Volvulus can occur around the cyst and result in infarction of the bowel with perforation, peritonitis, and shock.[14] Hemorrhage within the cyst secondary to expansion or erosion may lead to rapid enlargement and pain.[15] Torsion of the cyst itself, rupture, and urinary obstruction have been reported.[15,16]

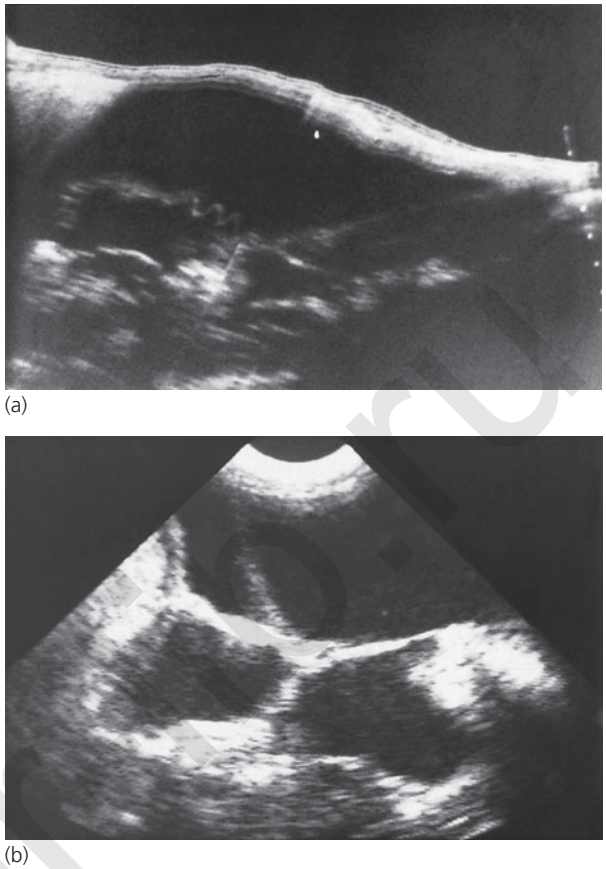
DIAGNOSIS

In most cases, a definitive preoperative diagnosis is not possible. Laboratory evaluation is pertinent only to complications which may be associated with the cyst. Sonography is the most useful diagnostic modality and represents the imaging technique of choice. The lesions appear as a well-defined, hypoechoic to anechoic smooth-walled mass, with echogenicity related to the cyst contents. In lymphangiomas, multiple thin septae may be apparent (Fig. 57.4).

Computer tomography (CT) or magnetic resonance imaging (MRI) may be used in the differential diagnosis of these lesions. They frequently demonstrate a fluid-filled mass, but the thin septae, diagnostic of lymphangioma, may not be apparent. Ros *et al.*[4] suggested that a lymphangioma is usually a multiloculated cyst that shows no discernible wall on CT and that may have characteristics of fat. A basic x-ray of the abdomen is not routinely indicated and may demonstrate a mass, ascites, or evidence of intestinal obstruction. Contrast radiography is rarely useful and may evidence a mass effect with varying degrees of compression of normal bowel in mesenteric cysts.

DIFFERENTIAL DIAGNOSIS

Other intra-abdominal lesions sometimes difficult to distinguish from a mesenteric or omental cyst mostly include ovarian cysts, choledochal cysts, pancreatic cysts, splenic cysts, and enteric duplication. The majority of these can be differentiated preoperatively by sonography and/or CT. Enteric duplication cysts have a thick wall, and a common muscular wall with the adjacent bowel. A mucosal line may be visible on sonography.



(a)

(b)

Figure 57.4 (a,b) Longitudinal and transverse abdominal ultrasound of a child with a large omental lymphangioma demonstrating a hypoechoic, septated mass immediately beneath the anterior abdominal wall.

Large cysts may mimic ascites in the neonate. Unless the ascites is loculated, shifting will occur with movement and the bowel will flow centrally as opposed to in the lateral dislocation associated with mesenteric or omental cysts.

Remaining lesions commonly referred to as mesenteric and/or omental cysts are non-pancreatic pseudocysts with no distinct cellular lining. They are seldom encountered in the neonate and are secondary to inflammation or trauma. Because of this etiology, the contained fluid may be hemorrhagic or purulent. A non-pancreatic pseudocyst is usually a unilocular or multilocular cyst with abundant debris sonographically and an enhancing wall on CT. An enteric duplication cyst is a unilocular cyst, but also with an enhancing wall.

TREATMENT

Preoperatively, the diagnosis may be in doubt and parents have to be informed that management may require intestinal

resection. Routine mechanical bowel preparation and intraoperative bladder catheterization are not required. Routine broad-spectrum antibiotics are only administered in cases with bacterial contamination, i.e. bowel resection.

In recent years, minimally invasive techniques have been suggested for the management of cystic abdominal masses and alimentary duplications.[17,18] The initial aim of laparoscopy is to locate the cyst and to determine its nature. The patient is placed in a supine position and the surgeon, pathology, and the monitor are placed in line. The optimal position of the ports is determined after exploration of the abdominal cavity via the first umbilical trocar. Mesenteric and omental cysts can be resected laparoscopically, but the location and fragility of the cyst wall may interfere with the feasibility of laparoscopy. Intraoperative aspiration of the cyst and subsequent analysis prior to removal is not indicated unless there is a question of biliary or pancreatic origin. Large cysts may be punctured to reduce the size and improve exposition, but this may make dissection more difficult. Management options include enucleation or resection. If any obvious plane exists between the cyst and adjacent bowel wall, enucleation should be undertaken. In cases requiring a limited resection of bowel, the cyst and affected loop are exteriorized via the umbilical approach and the resection and anastomosis are performed outside the abdominal cavity. Alternatively, a transverse mini-laparotomy may be used after the optimal location has been determined by laparoscopy.

The conventional operation is performed via a supra-umbilical transverse approach. Omental cysts are generally immediately apparent upon entering the peritoneal cavity. They present as large, translucent, solitary fluid-filled sacs overlying the bowel. The omentum and associated cyst is gently withdrawn from the abdomen and placed on the abdominal wall. The cyst may then be easily removed by transection at the junction with normal omentum or transverse colon (Fig. 57.5). Care should be taken to ligate the numerous omental vessels at the level of the transection. Larger mesenteric cysts may also be apparent upon opening the peritoneal cavity or, if they are smaller, require exploration. Once localized, the area of involvement is mobilized, eviscerated and the remaining bowel secured with sponges to facilitate exposure and resection (Fig. 57.6).

If any obvious plane exists between the cyst and adjacent bowel wall, enucleation should be undertaken. In larger cysts, enucleation may require incision on both sides of the mesentery. Generally, a plane of loose areolar tissue is present, enabling mobilization. This may be facilitated with gentle downward traction on the cyst wall (Fig. 57.7). Dissection is continued circumferentially until the cyst can be totally enucleated (Fig. 57.8). Following enucleation, the mesenteric defect is closed, approximating both leaves of the mesentery (Fig. 57.9).

In instances where a definite plane between the cyst and adjacent bowel cannot be identified, resection of the intestine in continuity with the cyst is required. Dissection should be

planned so as to remove as little bowel as possible (Figs 57.10 and 57.11).

OUTCOME

The outcome of resection or enucleation of mesenteric and omental cysts is very favorable. However, recurrence has been reported in up to 14% of patients, mostly with retroperitoneal cysts, which requires re-resection.

Neonatal ascites

PREM PURI AND ELKE RUTTENSTOCK

INTRODUCTION

Ascites is defined as an abnormal accumulation of intraperitoneal fluid in the peritoneal cavity, that consists of transudate (low protein count and low specific gravity) or exudate (high protein count and high specific gravity. The relatively rare condition of ascites in the newborn may occur due to a wide range of medical and surgical causes. The surgical conditions that most likely result in neonatal ascites are obstructive uropathy, spontaneous perforation of the extrahepatic biliary tree, and chylous ascites.

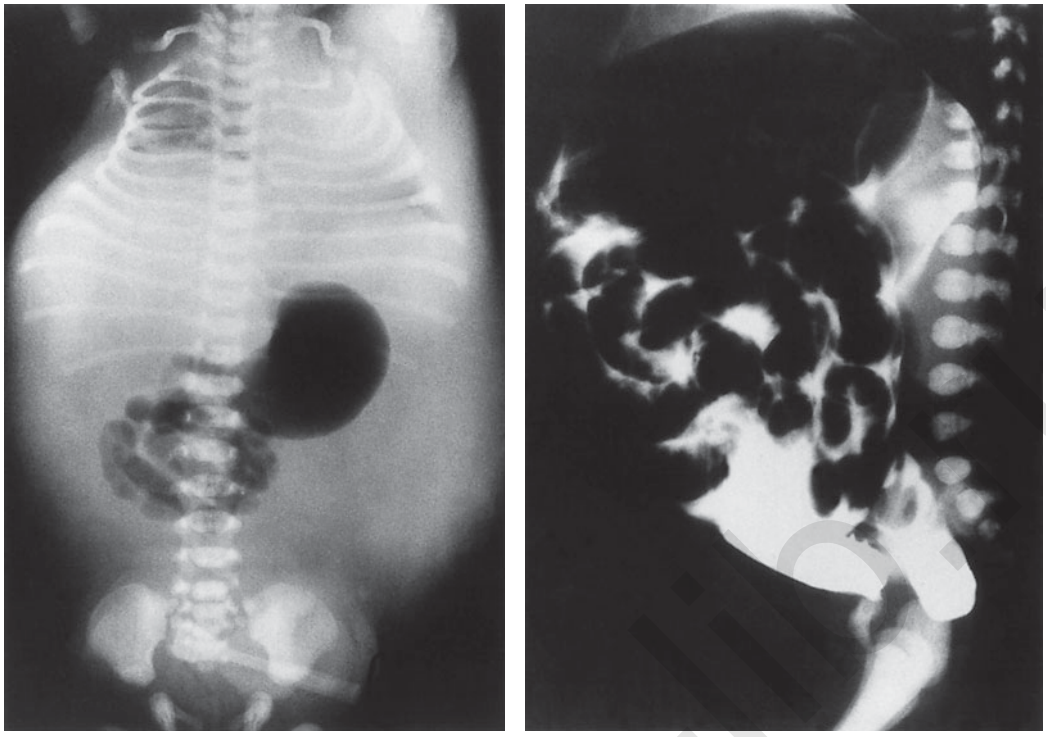
URINARY ASCITES

Urinary ascites which occurs almost exclusively in boys is an uncommon, life-threatening condition which accounts for up to 30% of all cases of neonatal ascites.[1] Abdominal distension sufficient to cause respiratory embarrassment, ascites, and signs of renal insufficiency are known as the most common presenting symptoms. Urinary tract obstruction from posterior urethral valves is the most reported cause of urinary ascites.[1,2] Other causes include ureteropelvic junction obstruction, ureterocele, lower ureteral atresia, bladder neck obstruction, and neuropathic bladder.[3] Ascites due to bladder rupture is also recognized, most commonly secondary to umbilical arterial catheterization.[4,5] Rarely, urinary ascites may occur in the absence of a demonstratable urinary tract obstruction.[6,7] The ascites usually results from extravasation of urine into the peritoneal cavity due to urinary tract perforation above a point of obstruction. The perforation may occur in the bladder, but most often occurs in the upper tracts.[3] In obstructive causes of extravasation, prolonged high pressure in the kidney leads to atrophy and dysplasia, which predispose to rupture of the collecting system. Urine may collect as a perinephric urinoma within Gerota's fascia encapsulating the kidney, or as urinary ascites in the peritoneal cavity.[8]

The presence of urine in the peritoneal cavity leads to an autodialysis effect, in which solutes and water follow their concentration gradients. This effect explains why ascites fluid with sodium and potassium results are not dissimilar from plasma, as well as hyponatremia and hyperkalemia. Furthermore, in all cases one would expect higher levels of urea and creatinine with lower levels of bicarbonate in the ascites fluid than found in blood. This unique biochemical profile, in the presence of renal impairment, is peculiar to a diagnosis of urinary ascites.[4,9]

The diagnosis of urinary ascites is based on clinical assessment, together with ultrasonography and abdominal x-rays.[1,10] The typical patient with neonatal urinary ascites is a male infant who presents with gross abdominal distension and ascites at birth. The abdominal distension may be severe enough to cause respiratory distress. Plain abdominal films will show diffuse opacity (Fig. 58.1a). If the amount of intraperitoneal fluid is large, splaying of the lower rib cage and centrally located floating intestines will be demonstrated. Micturating cystourethrogram is necessary to diagnose posterior urethral valves and ipsilateral vesico-ureteral reflux may further elucidate the diagnosis (Fig. 58.1b). Computed tomography (CT) has been recommended to reveal the underlying pathology.[11] Intravenous pyelography may show a characteristic 'halo' sign produced by extravasation of contrast material into the perirenal area. Abdominal paracentesis confirms the diagnosis via elevated creatinine levels and urine in the fluid.[4,12]

Treatment of neonatal urinary ascites must be individualized, depending upon the general condition of the baby at diagnosis and also on the site of perforation. Fluid and electrolyte imbalance are first corrected. Immediate drainage of the ascites is not necessary unless respiratory compromise or an abscess is present.[13] Prophylactic antibiotics are given in the face of urinary obstruction until definitive correction is undertaken. Prompt decompression of the urinary tract by nephrostomy or bladder catheter drainage upon the site of perforation has been recommended, but if the respiratory status is stable and an adequate urinary output has been established, conservative management with serial ultrasound may be elected.[14,15] Correction of the underlying pathology may then be carried out electively.



(a) (b)

Figure 58.1 Urinary ascites. This infant had severe respiratory distress at birth due to gross abdominal distension requiring abdominal paracentesis. (a) Supine film immediately after removal of 650 mL of fluid shows stomach and small bowel loops floating centrally in the peritoneal fluid. Note splaying of ribs. (b) A micturating cystourethrogram shows leakage of contrast into the peritoneal cavity. Spontaneous perforation of the bladder was found at operation. There was no demonstrable anatomical obstruction in the urinary tract.

Long-term outcome of bladder and kidney function is reported to be surprisingly good in cases of neonatal urinary ascites secondary to severe obstructive uropathy.[3] Intrauterine pressure relief in the collecting system through urinary extravasation ('pop-off' mechanism) protects renal function and this decompression of the urinary tract prevents severe secondary changes to bladder function.[16,17]

CHYLOUS ASCITES

Chylous ascites is a rare condition seen during the newborn period and infancy; however, it is a challenging disorder with regard to its successful treatment.[18,19] Generally, it presents with abdominal distension with or without respiratory embarrassment and occasional signs of peritoneal irritation and malabsorption.[20] About 10% of all infants with chylous ascites have lymphedema of the limbs.[21] The most common cause of chylous ascites (45–60% of cases) is congenital malformation of the lymphatic channels, such as atresia or stenosis of the major lacteals, mesenteric cysts, and generalized lymphangiomatosis.[19,22] The other causes are external compression with obstruction of the lymphatics, namely intestinal malrotation,[23] trauma, child abuse,[24] incarcerated hernia, and inflammatory lesions (25–30% of cases).[25]

Infants with chylous ascites present with abdominal distension at birth or it may develop in the first few days of life. Plain abdominal x-ray shows opaque distended abdomen, indicating ascites.

Abdominal paracentesis is not only a diagnostic but also a therapeutic method in the management of chylous ascites.[26] The chyle is usually color free; however, its appearance and composition are not constant and depend on multiple factors, such as the size of fat particles, cellular content, and diet.[27] After oral feedings have been started, the chylous fluid is milky white with a high fat content. Diagnosis is confirmed by determining high lipid content in the ascitic fluid. Although lymphangiography is the gold standard in defining the cause of the lymphatic obstruction, lymphoscintigraphy is also useful to evaluate the patency of the lymphatic vessels.

Treatment of chylous ascites is usually conservative. The majority of patients respond to abdominal paracentesis and an enteral diet containing medium-chain triglycerides (MCT) and high protein. Dietary management is an important treatment modality in chylous ascites. An MCT-based diet is accepted as the first measure to implement for reducing the chyle production in the peritoneal fluid.[28] MCTs are not re-esterified within the intestinal cell and thus bypass the enteric lymphatics and directly enter the portal system. It is believed that the reduction in dietary long-chain fats reduces lymphatic flow and pressure within the lymphatic system and decreases the amount of lymph leakage. For severe or complicated chylous ascites or chylous ascites that persists after a maximum of 10 weeks of diet, total parenteral nutrition (TPN) has been successfully used in treating these infants by resting the gastrointestinal tract.[29] Somatostatin analogs have been demonstrated to be effective in reducing

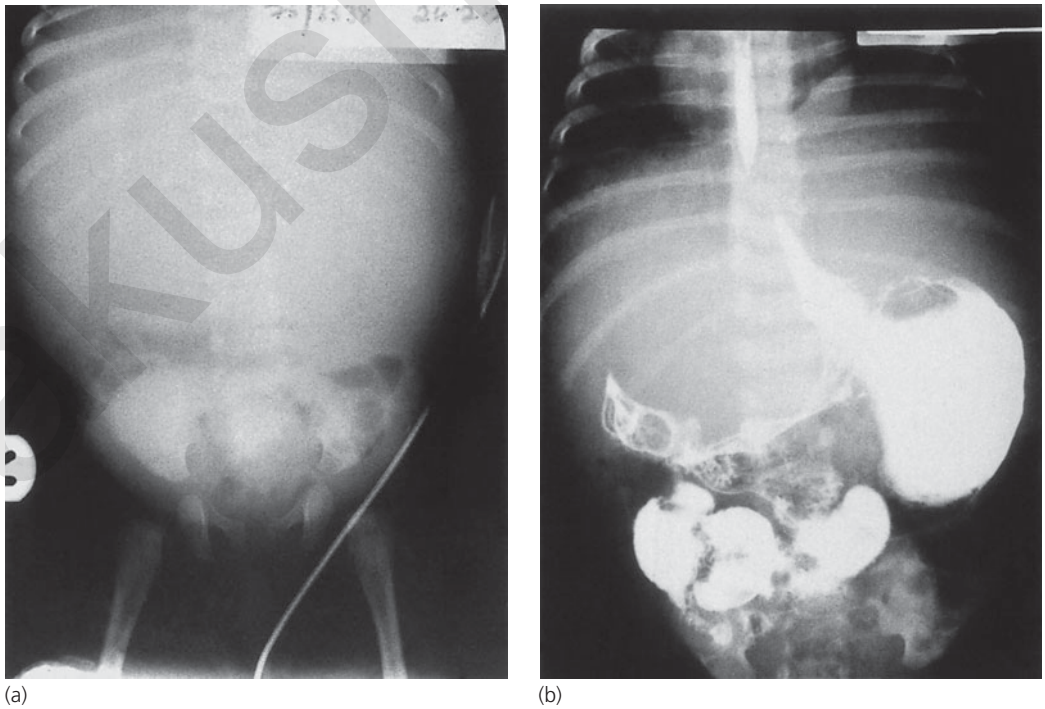
lymphorrhea and may be proposed prior to considering the surgical approach. The exact mechanisms of somatostatin on drying lymphatic flow are not completely understood. It has been previously shown to decrease the intestinal absorption of fats, lower triglyceride concentration in the thoracic duct, and attenuate lymph flow in the major lymphatic channels.[30] Satisfactory results were achieved by the administration of the somatostatin combined with TPN.[31,32] Surgical intervention is recommended if one to two months of conservative approach has failed.[33] Successful surgical treatment of congenital chylous ascites by resecting the macroscopically localized anomaly or by ligation of an identifiable lymphatic leak has been described.[31] A peritoneovenous shunt, of either Leveen or Denver type, has been also reported to be successful, at least temporarily, in children in whom repeated attempts at medical or surgical approach have failed.[19,34]

BILE ASCITES

Bile ascites in infancy is a rare condition usually resulting from spontaneous bile duct perforation (SBP).[35–37] Most often, SBP is seen in infants aged 2–20 weeks, but it has been reported in neonates as young as 3 days.[36,38] The site of perforation is most often the junction of the cystic duct with the common bile duct. The exact cause of SBP is unknown. Numerous etiologies have been proposed, such as congenital mural weakness of the common bile duct, ischemia, stones, infection, distal bile duct stenosis, inspissated bile, and pancreatic reflux from anomalous pancreaticobiliary ductal union (APBDU).[36,37,39,40] In the majority of cases, there is no apparent cause for the perforation. Some authors suggest that spontaneous bile duct perforation is not merely spontaneous but may be related to APBDU and choledochal cyst, i.e. the perforation of the bile duct and congenital choledochal cyst may be interrelated problems with a common pathogenesis.[41] Occasionally, the perforation is secondary to bile duct obstruction.[42]

Affected patients are typically previously healthy infants with unremarkable birth and perinatal histories. Signs and symptoms generally appear gradually and subacutely, but they can also present acutely with peritonitis, septic shock, or even pulmonary collapse.[38,43] The classic subacute presentation occurs in 80% of infants with fluctuating mild jaundice, normal to acholic stools, slowly progressive ascites, and abdominal distension.[44] Associated symptoms may include irritability, anorexia, failure to thrive, nonbilious emesis, mild fever, and dark urine.[45] In some cases, bile staining of hydroceles or inguinal hernias is present from distension of the tunica vaginalis by the bilious ascites.[45]

The diagnosis may not be made before surgery, but should be suspected in the presence of abdominal distension, intermittent jaundice, and ascites. Abdominal x-rays will show ascites and barium meal may demonstrate collection of fluid between the liver and stomach (Fig. 58.2). If paracentesis is performed, the concentration of bilirubin in the ascetic fluid is higher than in the serum. However, paracentesis is not necessary to establish the diagnosis if a hepatobiliary scan confirms the presence of biliary leakage.[36] Ultrasound is the imaging modality of choice in children, especially for



(a) (b)

Figure 58.2 Biliary ascites. (a) Marked abdominal distention with opacity in upper and central abdomen and downward displacement of bowel loops. (b) Barium study shows compression with downward displacement of stomach and duodenum. At operation, perforation of common hepatic duct was found.

evaluating jaundice. Free or loculated intraperitoneal fluid with normal intrahepatic and extrahepatic ducts will confirm the presence of SBP.[46] Hepatobiliary scintigraphy is highly sensitive and specific for SBP and it is the preoperative test of choice when SBP is suspected.[47,48] It can provide useful information about liver function, biliary patency, site of perforation based on localized accumulation of radiotracer, and any biliary leakage into the peritoneum. Magnetic resonance cholangiopancreatography (MRCP) is also useful in children, including infants.[49,50] Loculated fluid collection or pseudocyst formation can be more easily visualized on MRCP than ultrasound.

Surgical management is mandatory as soon as the diagnosis of SBP is confirmed.[51] A preoperative cholangiogram should be performed to delineate the location of the perforation and exclude distal obstruction. If the perforation is in the gallbladder or cystic duct, simple cholecystectomy is curative.[36,45] Several surgical approaches have been described, including simple drainage with or without cholecystectomy, primary repair with or without external drainage, and hepaticojejunostomy if pancreaticobiliary malformation or distal obstruction is present.[47,52,53] Most authors recommend a conservative approach of draining the abdomen to decompress the biliary tree, unless there is distal biliary tract obstruction requiring biliary-intestinal anastomosis.[39,54] Spontaneous closure is typical even with distal obstruction, once the biliary tree is decompressed.[43] The drains should not be removed too early, since this can lead to reaccumulation of bile in the peritoneal cavity. In situations where the surgeon encounters biliary perforation without a preoperative diagnosis, the safest policy is to drain the area and place a T-tube through the perforation. Suture repair of the bile duct or biliary reconstruction remains controversial because of the potential for stricture formation resulting from inflammation.[55] Reported complications have included portal vein thrombosis, bile leak, and cholangitis.[56] In a few cases, further surgery, including biliary revision and portosystemic shunting, was reported.[56] Overall, the prognosis is good with early recognition and surgical management.

Necrotizing enterocolitis

SHANNON CASTLE, TRACY GRIKSCHEIT, AND HENRI R FORD

INTRODUCTION

Necrotizing enterocolitis (NEC) is the most common medical and surgical emergency affecting the gastrointestinal tract of infants in the neonatal intensive care unit. NEC affects 1–5% of all preterm infants.[1,2] Up to 50% of neonates who develop NEC eventually require surgical intervention,[3,4] with the mortality rate for these patients varying from 20 to 50%,[5,6] and approaching 100% for infants with pan-intestinal NEC.[6] The majority of infants who develop NEC have extremely low birth weight. As advances in neonatal medicine have resulted in increased survival of these infants, the incidence of NEC continues to rise.

Multiple risk factors have been implicated in the pathogenesis of NEC; these include prematurity, hypoxia, initiation of enteral feeding, congenital heart disease, and bacterial infection. The majority of cases develop in infants less than 36 weeks of gestational age, though NEC has also been described in term infants, particularly those with cyanotic heart disease.[7] NEC is characterized by intestinal inflammation and mucosal destruction, leading to gut barrier failure. In its most severe form, NEC is characterized by full-thickness destruction of the intestinal wall leading to intestinal perforation, peritonitis, sepsis, and death. Infants who recover from NEC may encounter significant morbidity, including intestinal obstruction from stricture formation, short bowel syndrome as a result of extensive intestinal resection, intestinal dysmotility, as well as complications related to parenteral nutrition.[5,8,9]

ETIOLOGY

Immature intestinal barrier

The intestinal epithelium consists of a single layer of polarized epithelial cells (enterocytes) whose primary functions include absorption of micronutrients and digestion of macronutrients from the intestinal lumen, as well as formation of a selective barrier to protect the host from luminal pathogens.[10,11] Both extrinsic and intrinsic barriers prevent translocation of various antigens and microbes across the epithelial barrier. Extrinsic barriers include epithelial tight junctions, gastric acidity, intestinal peristalsis, and mucin production, all of which serve to limit adhesion of bacteria to the cell surface, the first step in the process of translocation.[12–14] Gastric acidity serves as a first line of defense against bacterial passage into the proximal intestine. Intrinsic barriers include the plasma membrane of the epithelial cells and intercellular tight junctions.[15]

Intestinal bacteria

Bacterial colonization is believed to be a prerequisite for the development of NEC.[16,17] Although no single bacterial or viral species has been consistently isolated in cases of NEC, a variety of pathogens have been implicated in the disease, including *Enterobacteriaceae*, *Clostridia*, and *Staphylococcus*.[18,19] NEC occurs in both sporadic and clustered distributions, which support the role of pathogenic bacteria in the development of the disease.[19] Although at birth the intestine is sterile, it is rapidly colonized by bacteria from the environment. While there is considerable variability among infants, *Escherichia coli* and streptococci rapidly colonize most infants, along with *Enterobacter* sp. Colonization with other bacteria, including *Enterococci*, *Lactobacilli*, *Clostridia*, and *Bacteroides* sp. follows.[20,21] Factors influencing the type of bacterial colonization include the birth method (vaginal or Cesarean section), the environment at birth, hygienic measures employed, and the type of feeding administered. Initial colonization in preterm infants is heavily influenced by the hospital environment.[17] Abnormal bacterial colonization patterns of neonates admitted to the neonatal intensive care unit may further increase susceptibility to NEC.[22]

Role of enteral feeding

Aggressive advancement of enteral feedings has been associated with the development of NEC. By contrast, early

trophic feeds have not been associated with increased risk of developing NEC. Optimal strategy for advancing feeds in low birth weight infants remains controversial.[23,24] The practice in the 1970s and 1980s was generally to withhold enteral feeds in preterm infants because of the known increased risk of NEC after starting feeds.[25] Multiple trials subsequently failed to show an increased risk of NEC in infants given low-volume (2–24 mL/kg/day) feeds.[26,27] Advancing feeds beyond these minimal volumes in the first 10 days of life in preterm infants, however, has been shown to significantly increase the rate of NEC.[28] Compared to formula, breast milk has been shown to protect against the development of NEC in both human as well as animal studies.[23,29,30] The mechanism by which breast milk protects against NEC is unknown and remains an active field of study.

Probiotics

Probiotics are non-pathogenic microbial organisms that colonize the intestinal tract and modulate the gut immune response.[31] The most commonly studied bacteria for prevention of NEC are *Lactobacillus* and *Bifidobacteria* species,[32] but the healthy adult and child intestine contains a wide variety of commensal bacteria, including abundant anerobes and moderate numbers of facultative anerobes.[20] Such non-pathogenic bacteria have been studied as a potential therapy for neonatal NEC, given the hypothesis that abnormal bacterial colonization of the preterm infant intestine increases the risk of NEC. Studies have been limited by the fact that there are diverse species of commensal bacteria with possibly diverse effects. There are also safety concerns because, even though administration of probiotics has not been shown to cause bacteremia or sepsis in infants with NEC, they have been implicated in bacteremia in adults, children, and infants when used for treatment of other conditions. Some recent studies have shown a decrease in NEC in groups treated with probiotics.[33,34] While the use of probiotics for prevention and treatment of NEC shows promise, further studies are needed prior to adopting this approach as a standard treatment modality.

Inflammatory mediators and NEC

The current hypothesis regarding the pathogenesis of NEC is that a hypoxic or infectious insult allows bacteria to invade the intestinal wall, inciting an inflammatory cascade that ultimately leads to gut barrier failure.[19,35] Various inflammatory mediators have been implicated in the development of NEC, including TNF-alpha, platelet activating factor, IL-1, IL-6, IL-18, endothelin-1, thomboxanes, and oxygen free radicals.[36–39]

Nitric oxide (NO) has been implicated as a key inflammatory mediator in the pathogenesis of intestinal barrier failure in NEC. NO is the product of nitric oxide synthase (NOS), which exists in three isoforms. Two of these, endothelial NOS and neuronal NOS, are expressed constitutively at low levels. The third, inducible NOS, is expressed at high levels during inflammation. The resultant NO then damages the intestinal barrier via its toxic intermediate, peroxynitrite ($ONOO^-$).[38,40]

Prostanoids are inflammatory mediators formed by conversion of membrane lipid arachadonic acid to prostaglandin G2 by cyclooxygenase (COX). Prostaglandin G2 is then converted to multiple biologically active prostanoids by specific synthases.[41] The COX enzymes are critical in the maintenance of intestinal barrier function, and have also been implicated in the pathogenesis of NEC. Induction of high levels of COX-2 seen during inflammation may damage the gut barrier and exacerbate the disease process, while low levels present under normal conditions are protective.[42]

DIAGNOSIS

Clinical features

Neonates with NEC may present with gastrointestinal and systemic signs, including feeding intolerance, abdominal distension, blood in the stool, hypoxia, apnea, respiratory distress, and hypoperfusion. Age at presentation is variable; NEC tends to occur later in infants born at an earlier gestational age.[43] Full-term infants may present in the first few days of life.[44]

In 1978, Bell introduced a grading system for NEC, in order to standardize diagnoses based on clinical and radiographic criteria.[45] It has been widely used since, with one modification to distinguish between perforated and non-perforated NEC (Box 59.1).[46] The Bell criteria allow for categorization of the severity of NEC for purposes of research as well as for treatment guidelines. Since its introduction, however, increased viability of infants at lower gestational ages, due to surfactant therapy and other advances in neonatal medicine, has resulted in an arguably more heterogeneous group of preterm infants. Some authors have argued that the Bell criteria need re-evaluation and modification as cases that are better classified as having focal intestinal perforation have been grouped with NEC under the old system for purposes of research and treatment.[47]

Laboratory findings

Laboratory abnormalities in NEC include thrombocytopenia, leukocytosis or leukopenia, metabolic acidosis, hypercapnea, and hypoxia.[48] While the white blood cell count may initially be elevated, neutropenia is common, with roughly 37% of severe cases having a WBC less than 1.5×10^9.[49,50] Thrombocytopenia is also common and severe thrombocytopenia (<100) is associated with worse outcomes.[50] An elevated C-reactive protein, while not specific for NEC, is useful in differentiating NEC from more benign abdominal conditions, such as ileus. Persistently elevated C-reactive protein has been shown to predict complications, such as abscess or stricture formation, or the need for surgical management.[51] Bacteremia is present in up to 50% of patients.[17]

Box 59.1 Modified Bell's stages of necrotizing enterocolitis

I Suspected disease
- IA:
  - Mild systemic signs (apnea, bradycardia, temperature instability)
  - Mild intestinal signs (abdominal distension, gastric residuals, occult blood in stool)
- IB:
  - Mild systemic signs (apnea, bradycardia, temperature instability)
  - Mild intestinal signs (abdominal distension, gastric residuals, occult blood in stool)
  - Non-specific or normal radiological findings

II Definite disease
- IIA:
  - Mild systemic signs (apnea, bradycardia, temperature instability)
  - Additional intestinal signs (absent bowel sounds, abdominal tenderness)
  - Specific radiologic signs (pneumatosis intestinalis or portal venous air)
  - Laboratory changes (metabolic acidosis, thrombocytopenia)
- IIB:
  - Moderate systemic signs (apnea, bradycardia, temperature instability, mild metabolic acidosis, mild thrombocytopenia)
  - Additional intestinal signs (absent bowel sounds, abdominal tenderness, abdominal mass)

III Advanced disease
- IIIA:
  - Severe systemic illness (same as IIB with additional hypotension and shock)
  - Intestinal signs (large abdominal distension, abdominal wall discoloration, peritonitis, intestine intact)
  - Severe radiologic signs (definite ascites)
  - Progressive laboratory derangements (metabolic acidosis, disseminated intravascular coagulopathy)
- IIIB:
  - Severe systemic illness (same as IIIA)
  - Intestinal signs (large abdominal abscess, abdominal wall discoloration, peritonitis, intestinal perforation)
  - Severe radiologic signs (definite ascites and pneumoperitoneum)
  - Worsening laboratory derangements (metabolic acidosis, disseminated intravascular coagulopathy)

Differential diagnosis

The differential diagnosis of NEC includes infectious enterocolitis (both bacterial and viral), cow's milk allergy, sepsis, and ileus.[47,52] In addition, obstruction due to Hirschsprung's disease, intussusception, volvulus, meconium ileus, or intestinal atresia may mimic NEC.

Focal intestinal perforation (FIP), which is more commonly seen in very low birth weight infants, is generally recognized as a distinct disease from NEC, with different pathologic characteristics.[53,54] In particular, FIP seems to be related to inhibition of mucosal blood flow regulation in the distal ileum due to combined presence of COX inhibitors and steroids. As a result, FIP tends to be truly focal and is associated with less risk of significant stricture. It also tends to be more common in very premature babies with chronic lung disease and symptomatic patent ductus arteriosus.

RADIOGRAPHIC STUDIES

Abdominal x-rays

Plain abdominal x-rays (anteroposterior and a left lateral decubitus) should be obtained at the first suspicion of NEC. X-ray findings pathognomonic for NEC include intramural gas (pneumatosis intestinalis), portal venous gas, and, when perforation is present, free intraperitoneal air.[55] Pneumatosis intestinalis is a hallmark of NEC, and is seen as the presence of air in the intestinal wall (Fig. 59.1).

Dilation of the bowel with gas is an early, non-specific sign, but the presence of a persistent loop of bowel on x-ray that remains unchanged in position over serial films is referred to as a 'fixed loop', and is associated with transmural necrosis. Portal venous gas is present in up to 30% of preterm patients with NEC, and is the result of intramural gas being absorbed by the venous system (Fig. 59.2). With increasing gestational age, the presence of portal venous gas is more common.[56] While the presence of portal venous gas has previously been thought to be associated with worse outcomes and the need for surgical intervention, recent studies have challenged this notion.[57–59] In a single-center study of

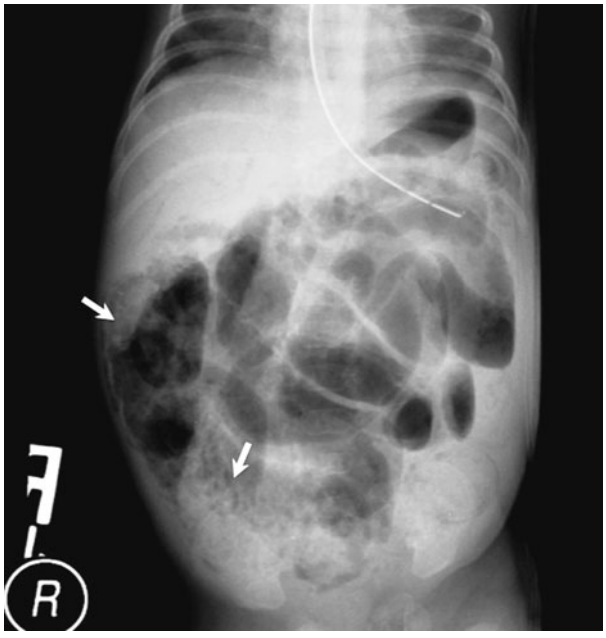

Figure 59.1 Abdominal x-ray of an infant with necrotizing enterocolitis. Arrows indicate area of pneumatosis intestinalis.

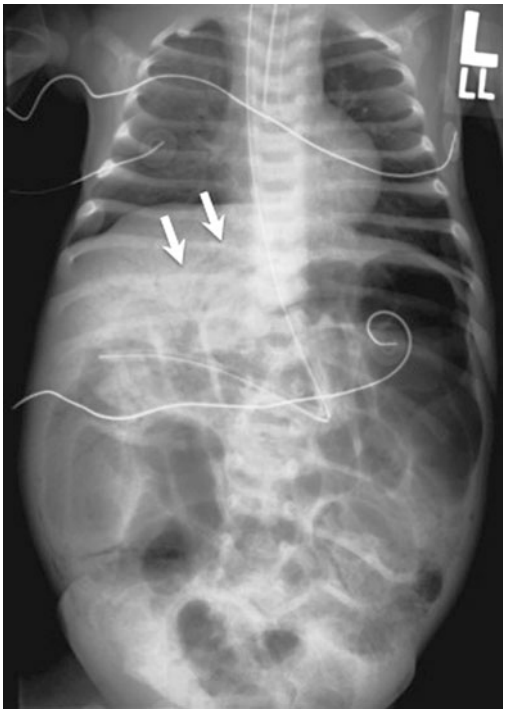

Figure 59.2 Abdominal x-ray of an infant with necrotizing enterocolitis demonstrating portal venous gas, indicated by arrows.

194 infants, there was no difference in survival with and without portal venous gas (17 versus 20%).[59]

Contrast studies

There is no indication for contrast studies in the initial evaluation and diagnosis of NEC. However, patients with a history of NEC who subsequently develop intestinal obstruction should be evaluated with contrast studies to look for intestinal strictures.[60]

Ultrasound

The use of abdominal ultrasound in the evaluation of infants with suspected or confirmed NEC is advantageous in that it can show bowel wall thickness and fluid collections with greater sensitivity than plain films. It can also evaluate bowel gas patterns, the presence of intramural air, and the presence of free air or portal venous gas.[61,62] It remains dependent on operator experience for its sensitivity and thus has not replaced plain abdominal x-rays as the standard of care.

PATHOLOGY

Histologic examination of the diseased bowel in infants with NEC may reveal epithelial sloughing, edema, and submucosal gas (Fig. 59.3).[63] More severe cases show transmural necrosis, with or without perforation. The terminal ileum is the most commonly affected site, but NEC can occur anywhere in the small or large intestine, with pan-necrosis of the bowel developing in the most severe cases. However, NEC is ultimately a clinical, rather than a pathologic diagnosis.

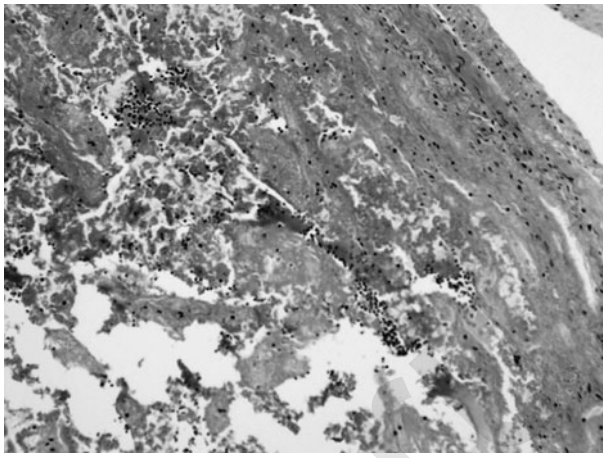

Figure 59.3 Hematoxylin-eosin staining of intestinal tissue from an infant with necrotizing enterocolitis showing edema and cellular infiltrate.

MANAGEMENT

Medical management

When NEC is suspected or confirmed, initial management should include bowel rest (cessation of oral feeds and placement of an orogastric tube) and broad-spectrum antibiotics. Fluid resuscitation is vital as most patients are hypovolemic because of accompanying sepsis. Patients may require ventilatory support and/or hemodynamic support with pressors, depending on the severity of illness. Acidosis should be corrected by implementing proper resuscitation measures, and coagulopathy or thrombocytopenia corrected with the infusion of blood products.

The infant should be monitored for progression of disease with serial abdominal x-rays and close monitoring of laboratory values.[64] For infants who do not require surgical intervention, medical therapy should continue for 7 days before bowel rest and antibiotics are stopped. While there is insufficient evidence to support a particular antibiotic regimen or duration, the use of broad-spectrum antibiotics is based on the high rate of bacteremia. There is evidence from animal models that antibiotics improve survival.[45,64,65] Commonly used antibiotic regimens include ampicillin with either gentamicin or a third-generation cephalosporin (i.e. cefotaxime), plus metronidazole or clindamycin, or piperacillin-tazobactam. Vancomycin may be added for staphylococcal coverage.

Surgical management

Surgical intervention is indicated when necrosis extends through the bowel wall and causes intestinal perforation. However, extensive necrosis can occur in the absence of perforation or free air on abdominal x-ray. Surgery may also

be indicated in the presence of diffuse peritonitis with hemodynamic instability.

Surgical management of NEC remains a subject of ongoing controversy. Ein *et al.*[66] first introduced the concept of peritoneal drainage (PD) as a temporizing measure in the management of hemodynamically unstable infants with perforated NEC, prior to definitive treatment with laparotomy. Subsequent reports have advocated PD as definitive treatment for some infants, and this approach has gained popularity over the last three decades. Some authors have advocated primary PD in all patients with stage III NEC,[67,68] but others report that the majority of these infants eventually require laparotomy and that in patients with birth weight >1000 g, the overall outcome is unchanged.[69] A meta-analysis of ten studies from 1978 to 1999 failed to show any superiority of PD over laparotomy.[70] A subsequent prospective, non-randomized multi-institutional study by Demestre *et al.*[71] of 44 neonates showed improvement in 86% of infants after PD; 54% required surgery after PD. Overall survival was 95% for infants over 1000 g. Blakely *et al.* prospectively studied long-term outcome in extremely low birth weight infants (<1000 g) undergoing primary PD versus laparotomy for perforated NEC. They did not find a significant survival difference between infants treated with primary laparotomy versus PD.[5,72] Twenty-three percent of patients required subsequent laparotomy after initial PD. This study included patients with a preoperative diagnosis of NEC and FIP. It showed that while PD was more likely to be used with FIP, and laparotomy with NEC, survival after PD without laparotomy was only 32% in NEC compared to a survival of 57% in the cohort treated with initial laparotomy.[72]

Moss *et al.*[73] conducted a multi-institutional randomized controlled trial of PD versus laparotomy in 177 patients under 34 weeks' gestational age and weighing <1500 g, with perforated NEC. The primary outcome measure was 90-day mortality, and the secondary outcomes examined were the need for long-term total parenteral nutrition (TPN) and length of stay (LOS). They reported that the PD and laparotomy groups had similar mortality rate (34.5 versus 35.5%) and there was no difference in TPN need or LOS in survivors. Roughly 38% of those randomized to PD needed subsequent laparotomy for deteriorating status. Interestingly, in non-enrolled infants, those who underwent PD had a 41% mortality rate compared to a mortality rate of 15% for those undergoing initial laparotomy. These data suggest the possibility that better outcomes can be achieved with careful patient selection for laparotomy. Rees *et al.*[74] also published a randomized multicenter study, involving 31 countries. A total of 69 infants with birth weight <1000 g and a diagnosis of NEC or FIP were enrolled. They found a trend towards increased survival in those treated with primary laparotomy. They noted that rescue laparotomy was required in 26/35 (74%) of those randomized to PD. Only 11% of the infants received PD as definitive treatment. The authors argue that there was no benefit to PD in this population.

Infants weighing >1500 g and requiring surgical intervention for perforated NEC are probably best managed with laparotomy and resection of the necrotic intestine. Disease may be limited to a short segment or to several segments of intestine, or it may be more diffuse, with necrosis of a large percentage of the gut. The goal is to limit the extent of intestinal resection to preserve the maximum amount of viable intestine and avoid the complication of short bowel syndrome.[45]

For infants with segmental NEC and a focal or isolated perforation, controversy exists regarding whether resection and primary anastomosis is indicated in this setting or whether resection with ostomy creation should be performed. Proponents of primary repair cite the high morbidity associated with ostomy creation and subsequent takedown in very low birth weight infants.[75] Multiple authors have reported 'safe' use of primary anastomosis,[76–78] even in infants weighing <1000 g.[79] A study from Great Ormond Street Hospital published in 1996, examined the outcome of 18 infants with NEC in whom a primary anastomosis was performed after resecting the diseased segment.[76] There were no anastomotic leaks, and the mortality ($n=2$, 18%) was comparable to published rates in infants managed with enterostomies. Although the mean birth weight in this group was 1494 g, a subsequent paper from the same institution reported ten infants under 1000 g managed with primary anastomosis.[79] Six of these had a final diagnosis of NEC (versus focal intestinal perforation). In both papers, the authors concluded that primary anastomosis, in selected patients, has comparable morbidity and mortality to stoma formation.

Proponents of intestinal diversion argue that ostomies are very well tolerated in infants and that there is a higher rate of survival with enterostomy versus primary anastomosis. Cooper *et al.*[80] reviewed 173 patients over a 14-year span; 27 underwent primary repair, based on surgeon's preference, while the remainder was treated with resection and stoma creation. They reported a 48% survival rate in the primary repair group versus 72% in the enterostomy group.

With pan-necrosis of the bowel, different authors have proposed different surgical techniques. The various options include resection of necrotic bowel with creation of multiple ostomies, proximal diversion with or without a 'second-look' procedure, and the 'clip and drop-back' technique introduced by Vaughan et al. in 1996.[81] The creation of multiple ostomies, an approach that was widely used in the past for patients with multiple segments of necrotic intestine, leads to loss of viable bowel. Initial aggressive resection of all non-viable appearing bowel leads to sacrifice of segments with borderline viability. Therefore, some authors have advocated proximal diversion and a 'second-look' procedure when there are multiple areas with questionable viability.[82] Proximal diversion alone has been shown to limit the extent of resection without increasing morbidity or mortality.[83] A variation of this approach is the 'clip and drop-back' technique in which the proponents resect all non-viable bowel without anastomosis at the time of initial laparotomy.[81,84] A second-look operation is then performed after 48–72 hours. Due to small numbers of reported patients and the lack of randomized, prospective studies, the ideal management remains controversial.

At our institution, we favor management of segmental necrosis with resection and enterostomy. Infants with pan-involvement are treated with initial laparotomy and proximal diversion alone. Those too unstable for laparotomy may be

treated with PD as part of their initial resuscitation followed by delayed laparotomy. If the infant does not improve clinically in 24–48 hours, a second-look laparotomy may be indicated.

COMPLICATIONS

Acute

Infectious complications associated with NEC include sepsis, meningitis, peritonitis, and on occasion, intra-abdominal abscess formation. The resultant inflammation may lead to coagulopathy and disseminated intravascular coagulation, respiratory and cardiovascular compromise, and metabolic complications, such as hypoglycemia and acidosis. Thus, any infant with suspected or confirmed NEC should be carefully monitored and aggressively resuscitated.

Chronic

Long-term complications include strictures, which occur in over 30% of patients with medically or surgically treated NEC,[8,85,86] and short bowel syndrome, which occurs in 10% of patients after surgical intervention.[8] Strictures may occur anywhere in affected bowel, but the most common location is in the colon.[87] If a stricture is suspected based on clinical symptoms of obstruction, the preferred radiographic evaluation is with water-soluble contrast enema or upper gastrointestinal study. Any stricture requires surgical resection. Short bowel syndrome occurs when the amount of functional intestine remaining after resection of diseased segments is insufficient for absorption of fluids and nutrients.[88] A patient with short bowel syndrome (or intestinal failure) is thus dependent on parenteral nutrition, which carries a risk of i.v. line infection and sepsis, cholestatic liver disease and liver failure.[89,90] Surgical treatment of short bowel syndrome with intestinal lengthening procedures is indicated in some, and some success has been reported with small bowel transplant.[91]

Survivors of NEC, in particular very low birth weight infants, have an increased risk of neurodevelopmental impairment.[92] The incidence appears to be higher in patients requiring surgical intervention, presumably due to more severe disease.[93] Strategies for optimal management to avoid these complications in survivors of NEC are a subject of ongoing research.

In summary, the etiology of NEC is multifactorial, primarily affecting premature infants with immature intestinal barrier function in the face of other risk factors such as hypoxia, aggressive enteral feeding, or abnormal bacterial colonization of the gut. Diagnosis is based on classic radiographic findings and laboratory abnormalities. While less severe NEC may be managed with bowel rest and antibiotics, surgical intervention is absolutely indicated for bowel perforation. Preferred management of segments of necrotic bowel is with resection and enterostomy, followed by a second operation for re-anastamosis. Survivors of NEC may have long-term complications including strictures, short bowel syndrome, and neurodevelopmental impairment.

Hirschsprung's disease

PREM PURI

INTRODUCTION

Hirschsprung's disease (HD) is a relatively common cause of intestinal obstruction in the newborn. It is characterized by absence of ganglionic cells in the distal bowel beginning at the internal sphincter and extending proximally for varying distances. The aganglionosis is confined to rectosigmoid in over 80% of patients. In the remaining patients, the aganglionosis extends beyond the rectosigmoid involving the descending colon and transverse colon or it may involve the entire colon along with a short segment of terminal ileum. Total intestinal aganglionosis with an absence of ganglion cells from the duodenum to the rectum is the most rare form of HD and is associated with high morbidity and mortality.[1–4]

The incidence of HD is estimated to be 1 in 5000 live births (Table 60.1).[5–7] Spouge and Baird[6] studied the incidence of HD in 689 118 consecutive live births in British Columbia and reported an incidence rate for this disease to be 1 in 4417 live births. Significant interracial differences in the incidence of HD have been reported: 1 in 10 000 births in Hispanic subjects, 1 in 6667 white subjects, 1 in 4761 in black subjects, and 1 in 3571 Asian subjects.[8] The disease is more common in boys, with a male-to-female ratio of 4:1.[7,9] The male preponderance is less evident in long-segment HD, where the male-to-female ratio is 1.5–2:1.[5–7]

ETIOLOGY

Neural crest cell migration

The enteric nervous system (ENS) is the largest and the most complex division of the peripheral nervous system. It provides the gastrointestinal tract with its unique network of innervation within its walls and functions largely independently of the central nervous system. The ENS contains more neurons than the spinal cord and is responsible for the coordination of normal bowel motility and secretory activities. Most of the neurons are located in either myenteric ganglia or submucosal ganglia and a few scattered within the mucosa. It is generally accepted that the enteric ganglion cells are derived primarily from the vagal neural crest cells.[10–13] During normal development, neuroblasts migrate from the vagal neural crest along the bowel wall in a cranio-caudal direction from esophagus to anus. The embryonic neural crest arises in the neural tube, originating with the central nervous system, but neural crest cells detach from this tissue via reduction of cell–cell and cell–matrix adhesion. The epithelio-mesenchymal transformation allows crest cells to migrate along pathways. Pathway selection is most likely achieved by balanced combinations of molecules that promote and reduce adhesion.

In the human fetus, neural crest-derived neuroblasts first appear in the developing esophagus at 5 weeks, and then migrate down to the anal canal in a cranio-caudal direction during the 5th to 12th weeks of gestation. The neural crest cells first form the myenteric plexus just outside the circular muscle layer. The mesenchymally derived longitudinal muscle layer then forms, sandwiching the myenteric plexus after it has been formed in the 12th week of gestation. In addition, after the cranio-caudal mitration has ended, the submucous plexus is formed by the neuroblasts, which migrate from the myenteric plexus across the circular muscle layer and into the submucosa; this progresses in a cranio-caudal direction during the 12th to 16th weeks of gestation.[13] The absence of ganglion cells in HD has been attributed to a failure of migration of neural crest cells. The earlier the arrest of migration, the longer the aganglionic segment is.

Several investigators have suggested that the enteric neurons follow a dual gradient of development from each end of the gut toward the middle, with vagal neural crest cells providing the main source of enteric neurons and sacral–neural crest cells innervating the hindgut.[14–16] Whether the sacral neural crest contributes to the ENS in the human is less clear. Failure of the vagal-derived neural crest cells to colonize the hindgut results in failure of ENS development in this region, suggesting an interaction between sacral and vagal enteric neural crest cells may be necessary for sacral neural crest cell contribution to the ENS.[16]

Genetic factors

Genetic factors have been implicated in the etiology of HD. HD is known to occur in families. The reported incidence of familial cases varied from 3.6 to 7.8% in different series.[17] A familial incidence of 15–21% has been reported in total colonic aganglionosis and 50% in the rare total intestinal aganglionosis.[3,18]

Recurrence risk to siblings is dependent upon the sex of the person affected and the extent of aganglionosis. Badner *et al.*[19] calculated the risk of HD transmission to relatives and found that the recurrence risk to siblings increases as the aganglionosis becomes more extensive (Table 60.2). The brothers of patients with rectosigmoid HD have a higher risk (4%) than sisters (1%). Much higher risks are observed in cases of long-segment HD. The brothers and sons of affected females have a 24% and 29% risk of being affected, respectively. The relationship with Down syndrome also tends to suggest a probable genetic component in the etiology of HD. Down syndrome is the most common chromosomal abnormality associated with aganglionosis and had been reported to occur in 4.5–16% of all cases of HD.[20–22] Other chromosomal abnormalities that have been described in association with HD include interstitial deletion of distal 13q, partial deletion of 2p, and reciprocal translocation, and trisomy 18 mosiac.[17] A number of unusual hereditary syndromes have been reported in patients with HD. These include Waardenburg syndrome, Von Recklinghausen's syndrome, type D brachydactyly, and Smith-Lemli-Optiz syndrome.[17]

During the past 15 years, several genes have been identified that control morphogenesis and differentiation of the enteric nervous system. These genes, when mutated or deleted, interfere with enteric nervous system development. So far, 14 genes are known to be involved in the development of Hirschsprung's disease (Table 60.3). One of these genes, the RET gene, encoding a tyrosine-kinase receptor, is the major gene causing HD.[23,24] Mutations in the coding region of RET are responsible for 50% of familial HD cases and 15% of sporadic ones.[25,26] All the genes that have been implicated in the development of HD together only account for 20% of all cases of HD.[27–30]

This implies that other genes are also involved in the development of Hirschsprung's disease.

PATHOPHYSIOLOGY

The pathophysiology of HD is not fully understood. It has long been recognized that obstructive symptoms in HD are secondary to the abnormal motility of the distal narrow segment, but there is still no clear explanation for the occurrence of the spastic or tonically contracted segment of bowel.[31] Several abnormalities have been described to explain the basis for motility dysfunction in the contracted bowel.

Cholinergic hyperinnervation

In association with aganglionosis, there is a marked increase in cholinergic nerve fibers in the intermuscular zone and submucosa of the aganglionic segment. These fibers appear as thick nerve trunks and correspond to extrinsic preganglionic parasympathetic nerves.[32–36] The continuous acetylcholine release from the axons of these parasympathetic nerves results in an excessive accumulation of the enzyme acetylcholinesterase that is typically found in the lamina propria mucosae, muscularis mucosae, and circular muscle with histochemical staining techniques.[30] Both the thick nerve trunks and the increased acetylcholinesterase activity are most pronounced in the most distal aganglionic rectum and progressively diminish proximally as normal bowel is approached.[37] The proximal extent of increased cholinergic activity does not necessarily correspond to the extent of the aganglionosis,

which usually extends more proximally to a variable degree. Pharmacologic investigations of the colon in HD have demonstrated higher acetylcholine release in the aganglionic segment at rest and after stimulation compared with the proximal ganglionic bowel.[38,39] Acetylcholinesterase concentration has also found to be higher in the serum and erythrocytes of children suffering from HD.[40] Cholinergic nerve hyperplasia has been proposed as the cause of spasticity of the aganglionic segment since acetylcholine is the main excitatory neurotransmitter. However, in the chemical animal model of aganglionosis, after application of benzalkonium chloride or corrosive sublimate, the aganglionic bowel does not show hypertrophic nerve bundles and the bowel still appears narrow and animals exhibit typical obstructive symptoms.[41,42] Therefore, the cholinergic hyperinnervation does not seem to be a prerequisite to the appearance of a narrow spactic segment.

Adrenergic innervation

Fluorescent-histochemical studies for localization of adrenergic nerves have demonstrated that they are increased in number in the aganglionic colon of HD and have a chaotic distribution. They are also present in the circular and longitudinal muscle layers as well as in the mucosa whereas they are almost never found in normal ganglionic colon.[43–45] However, the sensitivity of the aganglionic bowel to epinephrine is apparently not increased, despite the elevated number of adrenergic fibers.[46,47] The tissue concentration of norepinephrine is two to three times higher in the aganglionic bowel than in the normal colon; and also there is a corresponding increase in tyrosine hydroxylase, an enzyme that regulates norepinephrine biosynthesis.[44] Because adrenergic nerves normally act to relax the bowel, it is unlikely that adrenergic hyperactivity is responsible for increased tone in the aganglionic colon.[48]

Nitrergic innervation

Nitric oxide (NO) is considered to be one of the most important neurotransmitters involved in relaxation of the smooth muscle of the gut.[49] It is synthesized in a reaction catalyzed by nitric oxide synthase (NOS) and depends on L-arginine and molecular oxygen as co-substrates to form L-citrulline and NO. Nitric oxide binds to cytosolic guanylate cyclase and increases the production of 3′5′-cyclic guanosine monophosphate (cGMP) with subsequent relaxation of smooth muscle.[50] NOS has been shown to colocalize with reduced nicotine adenine dinucleotide phosphate (NADPH) diaphorase, which has been demonstrated to have identical functions.[51,52] Several investigators have studied NOS distribution in the ganglionic and aganglionic bowel in patients with HD using nitric oxide synthase immunohistochemistry or NADPH diaphorase histochemistry.[53–58] In normal and ganglionic colon from patients with HD, there is a strong NADPH diaphorase staining of the submucous and myenteric plexuses and a large number of positive nerve fibers in the circular and longitudinal muscle as well as in the muscularis mucosae.[50] In the aganglionic segment of HD patients, there are no ganglia and there is an absence or marked reduction of NADPH diaphorase positive nerve fibers in both muscle layers and in the muscularis mucosae. The typical hypertrophied nerve trunks appear weakly stained.[50] Kusafuka and Puri[59] examined the expression of neural NOS mRNA in the aganglionic segment from seven patients who had HD and demonstrated that NOS mRNA expression was decreased at least 1/50 to 1/100 of the level expressed in ganglionic bowel. These findings indicate that there is impaired NO synthesis in the aganglionic bowel in HD and this deficiency could prevent smooth muscle relaxation, thereby causing the lack of peristalsis in HD. In an interesting experiment, Bealer *et al.*[60] compared the effect of an exogenous source of NO, *S*-nitroso-*N*-acetylpenicillamine (SNAP) on the isometric tension of smooth muscle strips from aganglionic bowel and demonstrated a 70% reduction of resting tension. These results suggest that the defective distribution of nerves containing NOS may be involved in the pathogenesis of HD.

Interstitial cells of Cajal

Abnormalities of interstitial cells of Cajal (ICC) have been described in several disorders of human intestinal motility including HD. Vanderwinden *et al.*[53] using c-kit immunohistochemistry first described that ICC were scarce and its network appeared disrupted in aganglionic segments of HD whereas the distribution of ICC in the ganglionic bowel of HD was similar to that observed in controls. Yamataka *et al.*[61,62] found few c-kit positive cells in the muscle layers in HD and a moderate number around the thick nerve bundles in the space between the two muscle layers in the aganglionic bowel. Horisawa *et al.*[63] reported no differences in c-kit immunopositive cells in aganglionic segments compared with the corresponding area of ganglionic bowel. Rolle *et al.*[64] using whole-mount and frozen sections stained with c-kit immunohistochemistry preparations showed an altered distribution of ICC in the entire resected bowel of HD patients and not only in the aganglionic segment. Moreover, gap junctions connecting ICC were immunolocalized by anti-Connexin 43 antibody and found to be absent from the aganglionic part of HD bowel and highly reduced from the transitional zone.[65] Rolle *et al.*[64] proposed that persistent dismotility problems after pull-through operation in HD may be due to altered distribution and impaired function of ICC.

Enteroendocrine cells

Using the generic enteroendocrine cell immunohistochemical markers chromogranin A and synaptophysin, Soeda *et al.*[66] demonstrated that the number of enteroendocrine cells in the aganglionic colon in patients with HD were significantly increased compared with the number in the normal ganglionic segment. The increase of enteroendocrine cells in the mucosa of aganglionic colon may well influence sustained contraction of the bowel wall mainly mediated by the release of 5-hydroxytryptamine.

Smooth muscle

Since smooth muscle is the final effector for bowel motility, it is likely that it could also be abnormal in HD. The smooth muscle cell's cytoskeleton consists of proteins whose primary function is to serve as a structural framework that surround and support the contractile apparatus of actin and myosin filaments in the body of the smooth muscle cell. Nemeth *et al.*[67] studied the distribution of cytoskeleton in the smooth muscle of HD bowel by means of immunohistochemistry and found that dystrophin, vinculin, and desmin immunoreactivity was either absent or weak in the smooth muscle of aganglionic bowel, whereas it was moderate to strong in the smooth muscle of normal bowel and ganglionic bowel from patients with HD. Neural cell adhesion molecule (NCAM) is a cell surface glycoprotein involved in cell–cell adhesion during development that has been suggested to play an important role in development and maintenance of the neuromuscular system.[68–70] NCAM is present in the innervation of normal infant bowel and, less densely, in some components of the enteric smooth muscle. Contradictory results have been published regarding the NCAM expression in the smooth muscle of aganglionic bowel. Kobayashi *et al.*[54] have described a lack of expression of NCAM in the muscularis propria of the aganglionic bowel compared with the ganglionic segment, whereas Romanska *et al.*[71] have found an increased NCAM expression in muscle, particularly in the muscularis mucosae. In any case, both authors agree that there is a strong expression of NCAM in the hypertrophic nerve trunks from the aganglionic segment.

Extracellular matrix

Although extracellular matrix (EM) abnormalities have been described mainly related to the pathogenesis of HD, they could also have an influence on its pathophysiology. The lethal spotted mouse, an animal model which develops aganglionosis in its distal bowel, displays an abnormal distribution of EM components including laminin, collagen type IV, glycosaminoglycans and proteoglycans in the smooth muscle layer.[72,73] Parikh *et al.*[74] have demonstrated that the laminin concentration in aganglionic bowel was twice as high as in the normoganglionic bowel of HD and three times higher than in age-matched controls. Moreover, by means of immunohistochemistry, they found an uneven distribution of laminin and collagen type IV in the muscularis propria of aganglionic bowel, being more intensely expressed in the circular layer than in the longitudinal layer.[75] The same authors have described that EM components tenascin and fibronectin are more intensely expressed in aganglionic bowel from HD.[76]

PATHOLOGY

The characteristic gross pathological feature in HD is dilation and hypertrophy of the proximal colon with abrupt or gradual transition to narrow distal bowel (Fig. 60.1).

Figure 60.1 Typical gross pathology in Hirschsprung's disease, with transitional zone at rectosigmoid level.

Although the degree of dilation and hypertrophy increases with age, the cone-shaped transitional zone from dilated to narrow bowel is usually evident in the newborn.

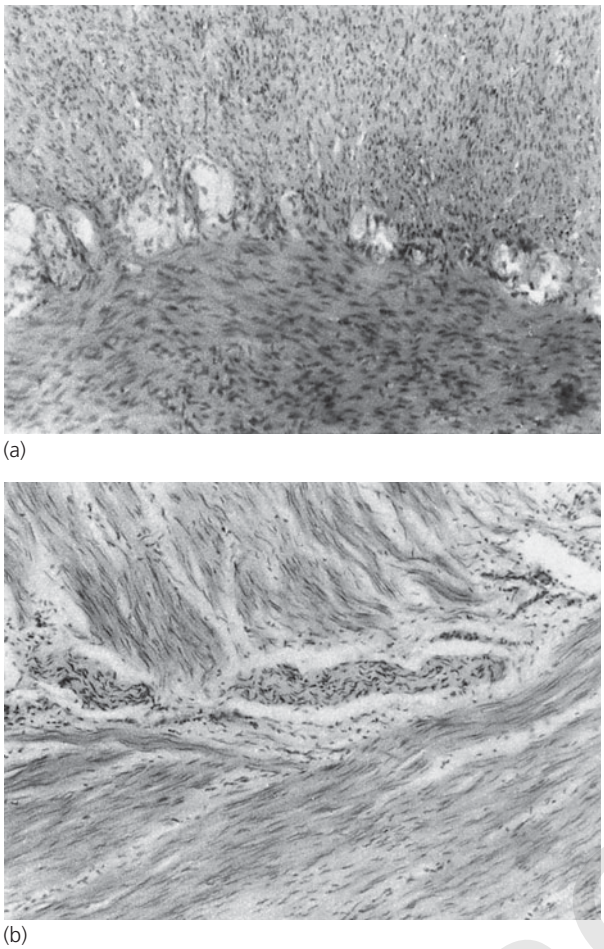
Histologically, HD is characterized by the absence of ganglionic cells in the myenteric and submucous plexuses and the presence of hypertrophied non-myelinated nerve trunks in the space normally occupied by the ganglionic cells (Fig. 60.2). The aganglionic segment of bowel is followed proximally by a hypoganglionic segment of varying length. This hypoganglionic zone is characterized by a reduced number of ganglion cells and nerve fibers in myenteric and submucous plexuses.

DIAGNOSIS

The diagnosis of HD is usually based on clinical history, radiological studies, anorectal manometry, and in particular on histological examination of the rectal wall biopsy specimens.

Clinical features

Of all cases of HD, 80–90% produce clinical symptoms and are diagnosed during the neonatal period. Delayed passage of meconium is the cardinal symptom in neonates with HD. Over 90% of affected patients fail to pass meconium in the first 24 hours of life. The usual presentation of HD in the neonatal period is with constipation, abdominal distension, and vomiting during the first few days of life (Fig. 60.3). About one-third of the babies with HD present with diarrhea. Diarrhea in HD is always a symptom of enterocolitis, which remains the most common cause of death. Enterocolitis may



(a)

(b)

Figure 60.2 (a) Auerbach's plexus, containing ganglion cells. (b) Hypertrophied nerve trunks in rectal biopsy from a patient with Hirschsprung's disease.

resolve with adequate therapy or it may develop into a life-threatening condition, the toxic megacolon, characterized by the sudden onset of marked abdominal distension, bile stained vomiting, fever and signs of dehydration, sepsis, and shock. Rectal examination or introduction of a rectal tube results in the explosive evacuation of gas and foul-smelling stools. In older children, the main symptom is persistent constipation and chronic abdominal distension.

Radiological diagnosis

Plain abdominal films in a neonate with HD will show dilated loops of bowel with fluid levels and airless pelvis. Occasionally, one may be able to see a small amount of air in the undistended rectum and dilated colon above it raising the suspicion of HD (Fig. 60.4a). Plain abdominal x-rays obtained from patients with total colonic aganglionosis (TCA) may show characteristic signs of ileal obstruction with air–fluid levels or simple gaseous distension of small intestinal loops.

In patients with enterocolitis complicating HD, plain abdominal x-ray may show thickening of the bowel wall with

Figure 60.3 A 2-day-old infant with marked abdominal distention and failure to pass meconium. Suction rectal biopsy confirmed Hirschsprung's disease.

mucosal irregularity or a grossly dilated colon loop, indicating toxic megacolon. Pneumoperitoneum may be found in those with perforation. Spontaneous perforation of the intestinal tract has been reported in 3% of patients with HD.[77]

Barium enema performed by an experienced radiologist, using careful technique should achieve a high degree of reliability in diagnosing HD in the newborn. It is important that the infant should not have rectal washouts or even digital examinations prior to barium enema, as such interference may distort the transitional zone appearance and give a false-negative diagnosis. A soft rubber catheter is inserted into the lower rectum and held in position with firm strapping across the buttocks. A balloon catheter should not be used due to the risk of perforation and the possibility of distorting a transitional zone by distension. The barium should be injected slowly in small amounts under fluoroscopic control with the baby in the lateral position. A typical case of HD will demonstrate flow of barium from the undilated rectum through a cone-shaped transitional zone into dilated colon (Fig. 60.4b). Some cases may show an abrupt transition between the dilated proximal colon and the distal aganglionic segment, leaving the diagnosis in little doubt.

In some cases, the findings on the barium enema are uncertain and a delayed film at 24 hours may confirm the diagnosis by demonstrating the retained barium and often accentuating the appearance of the transitional zone (Fig. 60.5). In the presence of enterocolitis complicating HD, a barium enema can demonstrate spasm, mucosal edema, and ulceration (Fig. 60.6).

In TCA, the contrast enema is not pathognomonic and may not provide a definitive diagnosis. The colon in TCA is of normal caliber in 25–77% of cases.[78]

Figure 60.6 Enterocolitis complicating Hirschsprung's disease. Spasm in rectosigmoid shown in barium enema, with fine mucosal ulceration and mucosal edema giving cobblestone appearance.

Anorectal manometry

In the normally innervated bowel, distension of the rectum produces relaxation of the internal sphincter rectosphincteric reflex. In normal individuals, upon distending the rectal balloon with air, the rectum immediately responds with a transient rise in pressure lasting 15–20 seconds; at the same time, the internal sphincter rhythmic activity is depressed or abolished and its pressure falls by 15–20 cm, the duration of relaxation coinciding with the rectal wave.

In patients with HD, the rectum often shows spontaneous waves of varying amplitude and frequency in the resting

phase. The internal sphincter rhythmic activity is more pronounced. On rectal distension, with an increment of air, there is complete absence of internal sphincter relaxation. Failure to detect the rectosphincteric reflex in premature and term infants is believed to be due to technical difficulties and not to immaturity of ganglion cells. Light sedation, particularly in infants and small children, may overcome technical difficulties encountered in this age group.

Rectal biopsy

The diagnosis of HD is confirmed on examination of rectal biopsy specimens. The introduction of histochemical staining technique for the detection of acetylcholinesterase (AChE) activity in suction rectal biopsy has resulted in a reliable and simple method for the diagnosis of HD.[79–81] Full-thickness rectal biopsy is rarely indicated for the diagnosis of HD except in total colonic aganglionosis. In normal individuals, barely detectable acetylcholinesterase activity is observed within the lamina propria and muscularis mucosa, and submucosal ganglion cells stain strongly for acetylcholinesterase. In HD, there is a marked increase in acetylcholinesterase activity in lamina propria and muscularis which is evident as coarse, discrete cholinergic nerve fibers stained brown to black (Fig. 60.7).

In TCA, AChE activity in suction rectal biopsies presents an atypical pattern, different from the classic one. Positive AChE fibers can be found in the lamina propria as well as the muscularis mucosae. However, cholinergic fibers present a lower density than in classical HD.

DIFFERENTIAL DIAGNOSIS

Several conditions must be considered where an infant is being evaluated for HD. Box 60.1 provides a list of common differential diagnoses. Colonic atresia gives similar plain film findings to HD but is readily excluded with barium enema showing complete mechanical obstruction. Distal small bowel atresia shows gross distension of the bowel loop immediately proximal to the obstruction with the widest fluid level in it.

In meconium ileus the typical mottled thick meconium may be seen. Also clear, sharp fluid levels are not a feature in erect or lateral decubitus views. However, HD can sometimes simulate meconium ileus in plain films and may give equivocal findings on Gastrografin or barium enema.

Meconium plugs obstructing the colon can present as HD with strongly suggestive history and plain films. Small left colon syndrome with marked distension proximal to narrowed descending colon also simulates HD at the left colonic flexure. These two conditions usually resolve with Gastrografin enema, but a minority of these cases will actually have HD which should be excluded clinically.

MANAGEMENT

Once the diagnosis of HD has been confirmed by rectal biopsy examination, the infant should be prepared for surgery. If the newborn has enterocolitis complicating HD, correction of dehydration and electrolyte imbalance by infusion of appropriate fluids will be required. It is essential to decompress the bowel as early as possible in these babies. Deflation of the intestine may be carried out by rectal irrigations, but some babies may require colostomy.

In recent years, the vast majority of cases of HD are diagnosed in the neonatal period. Many centers are now performing one-stage pull-through operations in the newborn with minimal morbidity rates and encouraging results. The advantages of operating on the newborn are that the colonic dilation can be quickly controlled by washouts and at

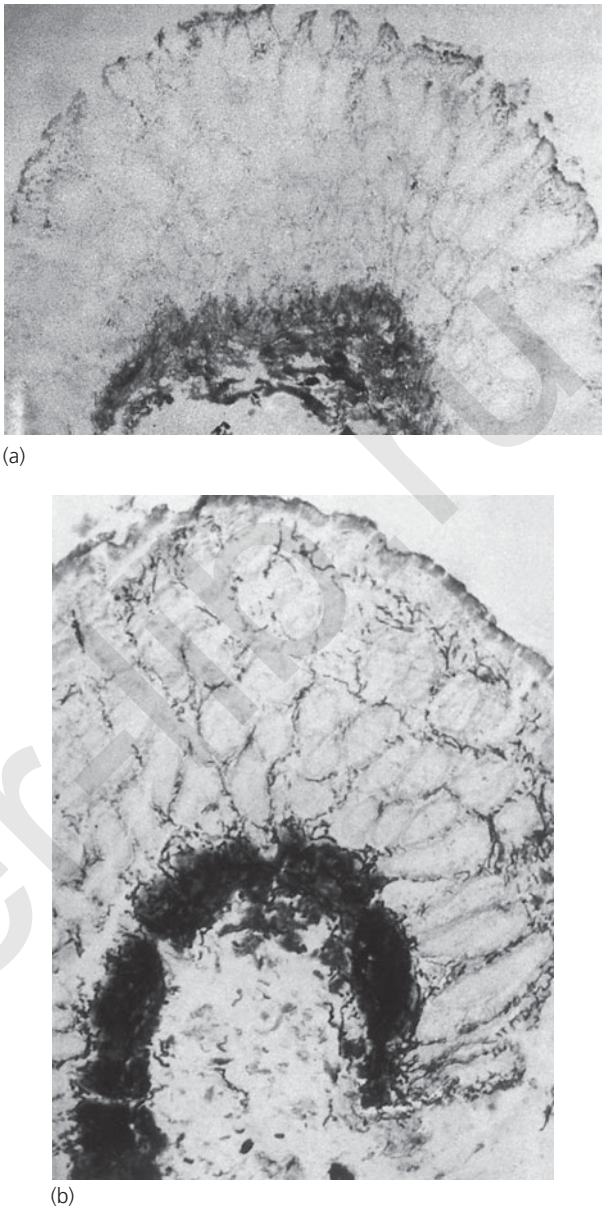

Figure 60.7 Acetyl-cholinesterase staining of suction rectal biopsy. (a) Normal rectum showing minimal acetyl-cholinesterase staining in mucosa, lamina propria, and muscularis mucosae (× 4). operation the caliber of the pull-through bowel is near normal, allowing for an accurate anastomosis that minimizes leakage and cuff infection. A number of different operations have been described for the treatment of HD. The four most commonly used operations are the rectosigmoidectomy developed by Swenson and Bill, the retrorectal approach developed by Duhamel, the endorectal procedure developed by Soave, and deep anterior colorectal anastomosis developed by Rehbein.[82] The basic principle in all these procedures is to bring the ganglionic bowel down to the anus. The long-term results of any of these operations are satisfactory if they are performed correctly. Recently, a number of investigators have described and advocated a variety of one-stage pull-through procedures in the newborn using minimally invasive laparoscopic techniques. More recently, a transanal endorectal pull-through operation performed without opening the abdomen has been used with excellent results in rectosigmoid HD.

Transanal one-stage endorectal pull-through operation

Over 80% of patients with HD have rectosigmoid aganglionosis. A one-stage pull-through operation can be successfully performed in these patients using a transanal endorectal approach without opening the abdomen. This procedure is associated with excellent clinical results and permits early postoperative feeding, early hospital discharge, no visible scars, and low incidence of enterocolitis.[83–85] The author prefers transanal endorectal pull-through operation in patients with classical segment rectosigmoid HD.

PREOPERATIVE MANAGEMENT

A good barium enema study is essential for this technique. A typical case of rectosigmoid HD will demonstrate flow of barium from undilated rectum through a cone-shaped transition zone into dilated sigmoid colon (Fig. 60.4b). Once the diagnosis of HD is confirmed by suction rectal biopsy, the newborn is prepared for surgery. Rectal irrigations are carried out twice a day for 2–3 days prior to surgery. Intravenous gentamicin and metronidazole are started on the morning of operation.

OPERATIVE TECHNIQUE

The patient is positioned on the operating table in the lithotomy position. The legs are strapped over sandbags. A Foley catheter is inserted into the bladder. A Denis-Browne retractor or anal retractor is placed to retract perianal skin. The rectal mucosa is circumferentially incised using the cautery with a fine-tipped needle, approximately 5 mm from the dentate line, and the submucosal plane is developed. The proximal cut edge of the mucosal cuff is held with multiple fine silk sutures, which are used for traction (Fig. 60.8). The endorectal dissection is then carried proximally, staying in the submucosal plane.

When the submucosal dissection has extended for about 3 cm, the rectal muscle is divided circumferentially, and the full thickness of the rectum and sigmoid colon is mobilized out through the anus. This requires division of rectal and sigmoid vessels, which can be done under direct vision using cautery.

When the transition zone is encountered, full-thickness biopsy sections are taken, and frozen section confirmation of ganglion cells is obtained. The rectal muscular cuff is split longitudinally either anteriorly or posteriorly. The colon is then divided several centimeters above the most proximal normal biopsy site (Fig. 60.8), and a standard Soave-Boley anastomosis is performed (Fig. 60.8). No drains are placed. The patient is started on oral feeds after 24 hours and discharged home on the third postoperative day. Digital rectal examination is performed 2 weeks after the operation. Routine rectal dilatation is not performed unless there is evidence of a stricture.

COMPLICATIONS

Early postoperative complications which can occur after any type of pull-through operation include wound infections, anastomotic leak, anastomotic stricture, retraction or necrosis of the neorectum, intestinal adhesions, and ileus. Late complications include constipation, enterocolitis, incontinence, anastomotic problems, adhesive bowel obstruction, and urogenital complications.

Anastomotic leak

The most dangerous early postoperative complication following the definitive abdominoperineal pull-through procedure is leakage at the anastomotic suture line. Factors responsible for anastomotic leak include ischemia of the distal end of the colonic pull-through segment, tension on the anastomosis, incomplete anastomotic suture lines, and inadvertent rectal manipulation. If a leak is recognized in a patient without a colostomy, it is imperative to perform a diverting colostomy promptly, to administer i.v. antibiotics and to irrigate the rectum with antibiotic solution a few times daily. Delay in establishing fecal diversion is likely to result in an extensive pelvic abscess which may require laparotomy and transabdominal drainage.

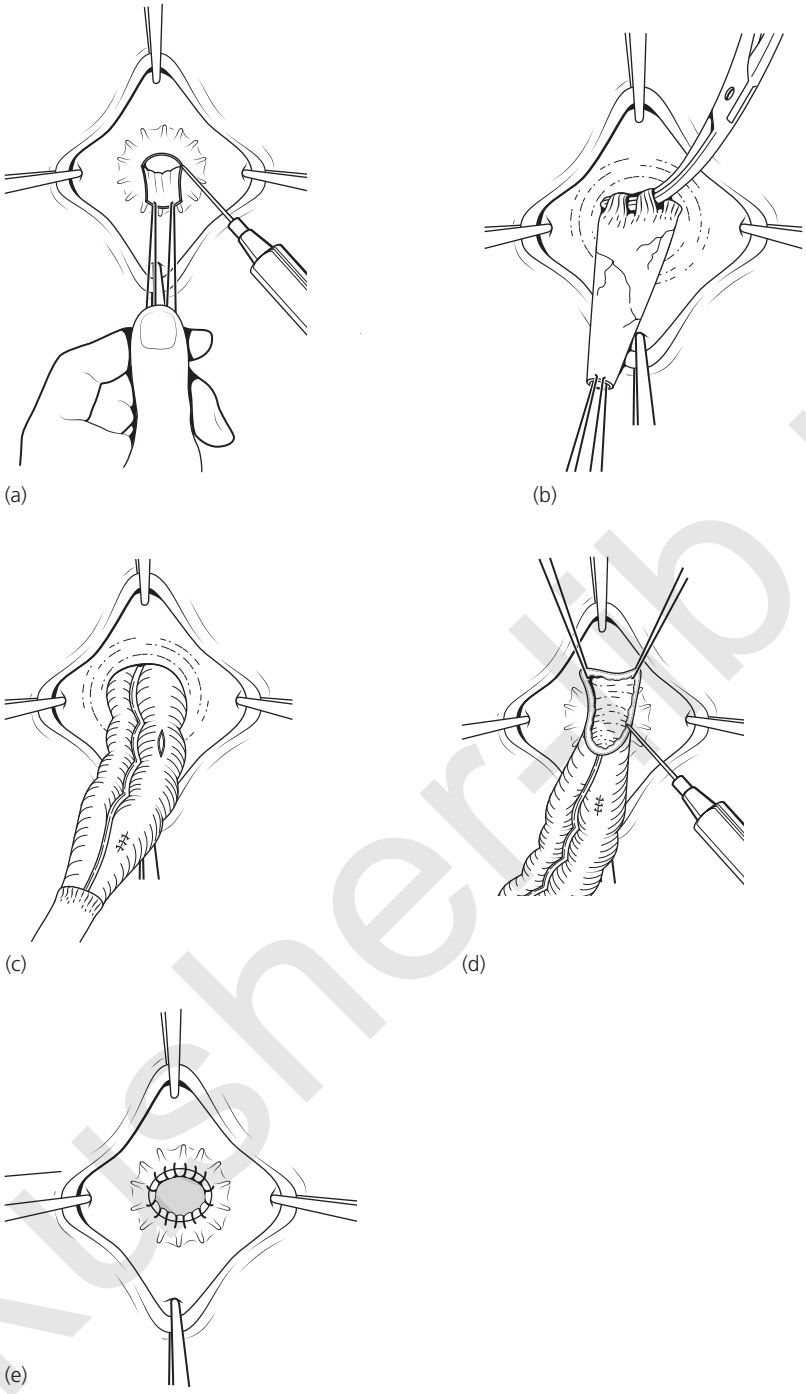

Figure 60.8 Transanal endorectal pull-through (a) Rectal mucosa is circumferentially incised using the needle-tip cautery approximately 5 mm above the dentate line and the submucosa plane is developed. (b) When the submucosal dissection is extended proximally for about 3 cm, the muscle is divided circumferentially, and the full-thickness of the rectum and sigmoid colon is mobilized out through the anus. (c) On reaching the transition zone, full-thickness rectal biopsies are taken for frozen section to confirm ganglion cells. (d) Colon is divided several centimeters above the most proximal biopsy site. (e) A standard Soave-Boley anastomosis is performed.

Retraction of pull-through

Retraction of a portion or all of the colonic segment from the anastomosis can occur and is usually seen within 3 weeks of the operation. Evaluation under general anesthesia is generally necessary. In occasional patients, resuturing the anastomosis may be feasible transanally. For those with separation of less than 50% of the anastomosis, but with adequate vascularity of the colon, a diverting colostomy for approximately three months is necessary. For patients with wide separation at the anastomosis, early transabdominal reconstruction of the pull-through is recommended.

Perianal excoriation

Perianal excoriation occurs in nearly half of the patients undergoing pull-through procedure, but generally resolves within three months with local therapy and resolution of diarrhea. It is helpful to begin placing a barrier cream on the perianal skin promptly after the operation and to continue after each movement for the first few weeks. Resolution of diarrhea will often hasten the clearance of perianal skin irritation.

Enterocolitis

Hirschsprung's associated enterocolitis (HAEC) is a significant complication of HD both in the pre-and postoperative periods.[77] HAEC can occur at any time from the neonatal period onwards to adulthood and can be independent of the medical management and surgical procedure performed. The incidence of enterocolitis ranges from 20 to 58%.[77] Fortunately, the mortality rate has declined over the last 30 years from 30 to 1%. This decrease in mortality is related to earlier diagnosis of HD and enterocolitis, rectal decompression, appropriate vigorous resuscitation, and antibiotic therapy. It has been reported that routine postoperative rectal washouts decrease both the incidence and the severity of the episodes of enterocolitis following definitive surgery. In episodes of recurrent enterocolitis, which can develop in up to 56% of patients, anal dilatations have been recommended. However, prior to commencing a treatment regime, a contrast enema should be performed to rule out a mechanical obstruction. Patients with a normal rectal biopsy may require a sphincterotomy.

Constipation

Constipation is common after definitive repair of HD and can be due to residual aganglionosis and high anal tone. Repeated and forceful anal dilations of botulinum toxin injection into the sphincter under general anesthesia may resolve the problem. In some patients, internal sphincter myectomy may be needed. In patients with scarring, stricture, or intestinal neuronal dysplasia proximal to aganglionic segment, treatment consists of treating the underlying cause.

Soiling

Soiling is fairly common after all types of pull-through operation, its precise incidence primarily dependent on how assiduously the investigator looks for it. The reported incidence of soiling ranges from 10 to 30%.[85] The attainment of normal postoperative defecation is clearly dependent on intensity of bowel training, social background, and respective intelligence of the patients. Mental handicap, including Down syndrome, is invariably associated with long-term incontinence. Those patients with preoperative enterocolitis would also seem to have a marginally higher long-term risk of incontinence. In some patients in whom soiling is intractable and a social problem, a Malone procedure may be needed to stay clean.

LONG-TERM OUTCOME

The vast majority of patients treated with any one of the standard pull-through procedures achieve satisfactory continence and function with time.[78,84–87] The attainment of normal continence is dependent on the intensity of bowel training, social background, and respective intelligence of patients. Mental handicap, including Down syndrome, is invariably associated with long-term incontinence.[88]

Anorectal anomalies

MARC A LEVITT AND ALBERTO PEÑA

INTRODUCTION

Anorectal anomalies present with a spectrum of defects. This spectrum extends from patients with minor malformations that require minimal treatment who usually achieve excellent surgical results, to patients who are very sick with a complex defect. These more critical patients pose a serious technical challenge, and typically do not achieve perfect bowel, urinary, and sexual function despite accurate anatomic reconstruction. A newborn with an anorectal malformation may represent a surgical emergency related to intestinal obstruction or associated urologic or gastrointestinal defects requiring aggressive and efficient management. Other patients with these defects do not represent an emergency because they have a fistula that allows intestinal decompression. In these cases, the repair of the defect can become an elective procedure or, if the baby is in good condition, can be definitively managed in the newborn period.

Frequency

Anorectal malformations occur with a frequency of approximately 1 to 4000 or 5000 newborns.[1–3]

Classification

Box 61.1 gives a practical classification that is anatomically based.[4,5]

Box 61.1 Classification of anorectal malformations

Male defects
- Rectoperineal fistula
- Recto-urethral bulbar fistula
- Recto-urethral prostatic fistula
- Rectovesical (bladder neck) fistula
- Imperforate anus without fistula
- Rectal atresia and anal stenosis

Female defects
- Rectoperineal fistula
- Rectovestibular fistula
- Imperforate anus without fistula
- Rectal atresia and anal stenosis
- Cloacal malformation

CLINICAL FEATURES AND DIAGNOSIS

Male defects

RECTOPERINEAL FISTULA

This is the lowest defect seen in males and often presents with a 'bucket-handle' malformation (Fig. 61.1). The common anatomic feature is the fact that the rectal opening is located anterior to the center of the sphincter mechanism, as demonstrated by electrical stimulation during the repair (Fig. 61.2). We prefer to avoid terms such as 'anterior ectopic anus', since this opening is not really an anus as it has no pectinate line and is not surrounded by a sphincter. A rectoperineal fistula is a more accurate description. The fistula can occur anywhere along the median raphe; the closer to the scrotum the longer the common wall between the rectum and urethra. These defects can be treated primarily without a protective colostomy. Most of the time, the patient is able to pass small amounts of meconium through the fistula. Sometimes it takes a few hours before the baby passes meconium. Often a midline raphe subepithelial fistula is seen which looks like a black or white ribbon; also evidence of this type of defect (Fig. 61.3). Otherwise, the patients have a normal-looking perineum. The diagnosis is made by clinical inspection and usually no radiologic studies are necessary. The chance of having an associated genitourinary defect is extremely low. The patient's spine should be screened for an associated, albeit rare, tethered cord.

Figure 61.1 'Bucket handle' malformation.

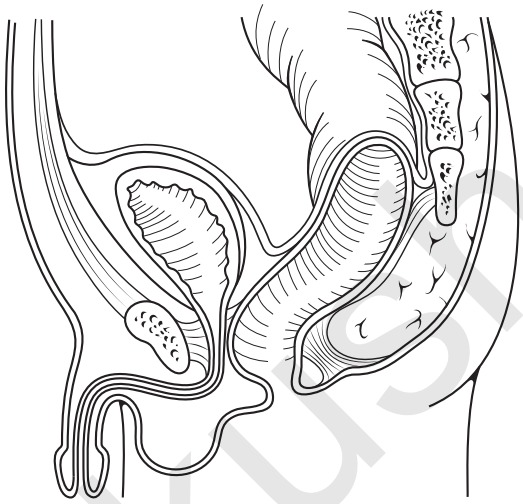

Figure 61.2 Rectoperineal fistula – sagittal view.

Figure 61.3 Cutaneous (subepithelial) fistula.

RECTO-URETHRAL BULBAR AND RECTO-URETHRAL PROSTATIC FISTULAS

The rectum can open into the bulbar urethra (Fig. 61.4) or into the prostatic urethra (Fig. 61.5). Both rectum and urethra have a common wall located above the fistula site which is longer in the case of bulbar fistula and shorter in the prostatic type.

These two types of defects are similar from a clinical point of view. However, the patient has more chance of having a 'good-looking' perineum connoting good sphincters in a case of recto-urethral bulbar fistula (Fig. 61.6); this means having a prominent midline groove and anal dimple. In cases of recto-urethral prostatic fistula, the chances of having a short sacrum and a flat perineum (Fig. 61.7) increase.

The neonatal nurse may notice that the baby is passing meconium through the urethra. A cross-table lateral film, with the patient in the prone position and the pelvis elevated, is a reliable study but depends on dilated distal rectum overcoming compression by the sphincteric funnel.[6] Fig. 61.8 shows a rectum very close to the perineal skin and Fig. 61.9 shows a higher rectum. The chances of recto-urethral fistula cases being associated with urological problems vary from 25% in cases of urethral bulbar fistula, to 66% in cases of urethral prostatic fistula. These newborns need a diverting colostomy.

RECTOVESICAL (BLADDER NECK) FISTULA

This defect accounts for approximately 10% of all anorectal defects in males. The rectum opens into the bladder neck in a 'T' fashion (Fig. 61.10). The entire pelvis of these babies seems to be hypodeveloped. It is frequently associated with poor muscle development and the perineum looks rather flat in most patients (Fig. 61.7); although some patients with this defect may have a 'good-looking' perineum (Fig. 61.6) with a midline groove and a prominent anal dimple. The frequency of associated urological anomalies in this specific defect is very high (up to 90%),[7] and therefore a urologic work up is mandatory. A cross-table lateral film, with the patient in the prone position and with the pelvis elevated, shows an image consistent with air much higher than the pubococcygeus

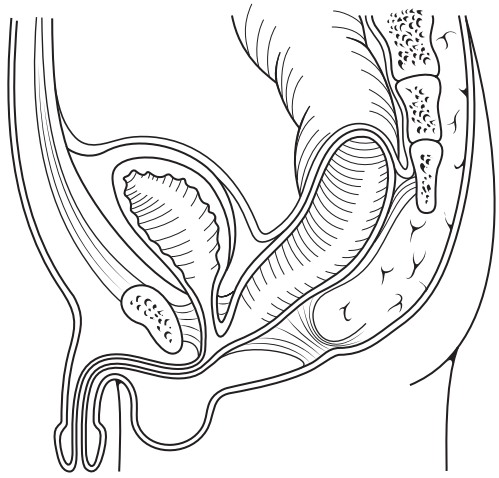

Figure 61.4 Recto-urethral bulbar fistula – sagittal view.

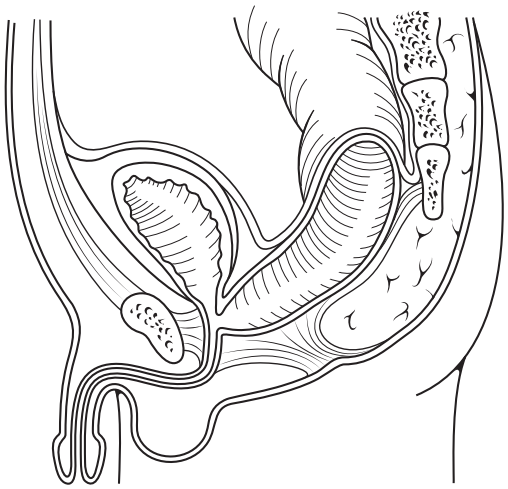

Figure 61.5 Recto-urethral prostatic fistula – sagittal view.

line (Fig. 61.9). The neonatal nurse may note that the baby is urinating meconium. Manifestations of intestinal obstruction will become evident during the first 12–24 hours. In addition to these symptoms, the baby may show symptoms consistent with acidosis and sepsis secondary to an obstructive uropathy. These patients require a colostomy. They will also require an abdominal approach (laparoscopic or laparotomy) during the definitive repair, in addition to the posterior sagittal approach.

IMPERFORATE ANUS WITHOUT FISTUAL

In this type of defect, the blind rectum is usually located at the level of the bulbar urethra. Even when there is no communication between rectum and urethra, the wall that separates both of them is very thin and has no surgical plane of separation. This defect is uncommon, but it has good muscle development, and therefore most of the time the perineum is a 'good-looking' one. The frequency of this defect is approximately 5% of male defects.[8] However, a distal colostogram that is not done properly with the aim of demonstrating a recto-urethral fistula will give an incorrect assessment of 'no fistula'. A successful colostogram requires the injection of contrast into the blind rectal pouch under enough hydrostatic pressure as to demonstrate the passage of contrast material into the urethra.[9] The rectum in all types of malformations is surrounded by voluntary muscle (Figs 61.2, 61.4, 61.5, and 61.10) and the hydrostatic

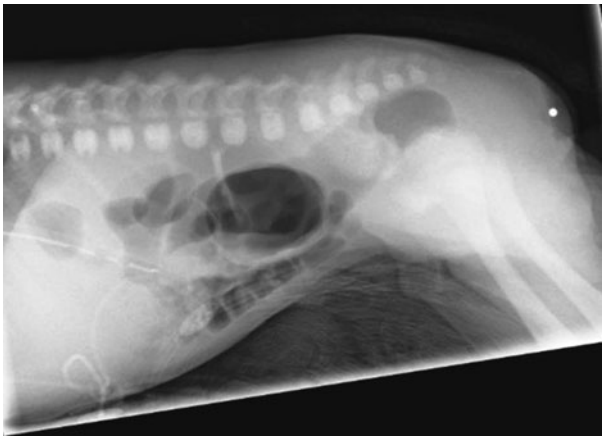

Figure 61.9 Cross-table lateral film of a rectum that is greater than 2 cm from the perineal skin representing probably a recto-urethral or rectobladder neck fistula.

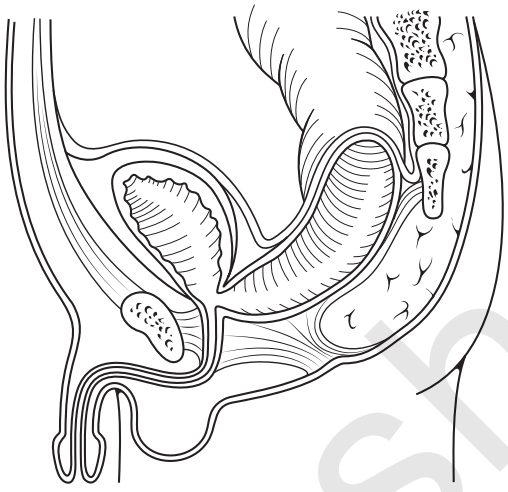

Figure 61.10 Rectovesical (bladder neck) fistula sagittal view.

pressure must be high enough to overcome the muscle action which is compressing the distal rectum. The lack of pressure represents a frequent error that may explain the reporting of higher numbers of imperforate anus without fistula when actually this is a rather unusual defect. It is interesting to note that out of all our cases of imperforate anus with no fistula, approximately half of the cases have Down syndrome. The other half is predominantly made up of patients with other syndromes. Also, in all of our Down syndrome patients with imperforate anus, 95% have no fistula, clearly pointing to a genetic impact on anorectal malformations.[10,11] These patients also require a newborn diverting colostomy. The chances for these patients to have an associated defect are low.

RECTAL ATRESIA AND ANAL STENOSIS

This is a rare type of defect classically described as the one that is diagnosed by the nurse while passing the thermometer during the initial newborn physical examination. The reason for this is that these babies are born with a normal anal canal and have an atresia located appoximately 1–2 cm above the anal verge. Superior to that, there is a dilated rectal pouch. In some cases, the patient actually has a stenosis. The separation between the blind pouch and the anal canal may be a very thin membrane, but more frequently there is a thick fibrous septum of 3–7 mm in length. These patients need a colostomy. The perineum looks normal, the sacrum is usually normal, and the chances of associated defects are extremely low. A presacral mass must be looked for by ultrasound and/or magnetic resonance imaging. These patients have all the necessary anatomical elements to become totally continent; the muscles are intact and the anal canal has normal sensation.

Female defects

RECTOPERINEAL FISTULA

This is the lowest defect seen in females and it is equivalent to the same defect already described in males. The fistula site is located anywhere between the vestibule and the center of the anal dimple (Fig. 61.11). The entire fistula site is surrounded by skin and therefore it is also given the name 'cutaneous fistula'. The orifice is variable in size and may be sufficient for a full-bowel evacuation. If not, anal dilations can be utilized to provide good bowel movements if the repair will not be done in the neonatal period. Our routine is to do the repair in the newborn period and then to keep the patient NPO (nothing by mouth) on i.v. nutrition for 7 days after the repair.

These patients do not require a protective colostomy as part of their treatment. The most prominent anatomical feature in this type of defect is that the rectum and vagina do not share a common wall (Fig. 61.11). Thus, the technical implication is that the rectum can be mobilized without risking injury to the vagina. Patients have otherwise normal muscle structures and a normal sacrum. The incidence of associated defects of the urinary tract or spine is very low.

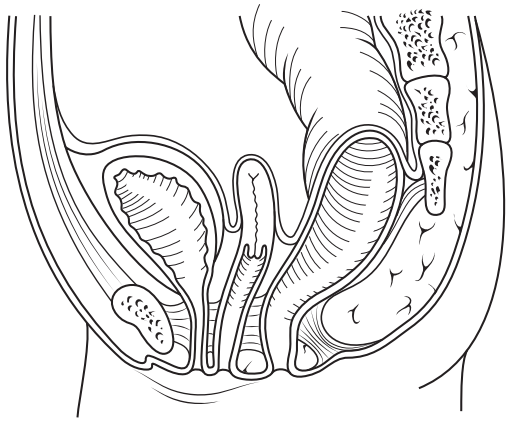

Figure 61.11 Rectoperineal fistula in a female patient.

RECTOVESTIBULAR FISTULA

This is the most frequent defect seen in females. The distal rectum opens into the vestibule, which is the space located immediately outside the hymen (Fig. 61.12). The most notable anatomic feature in this defect is the presence of a very long common wall between rectum and vagina located above the fistula site (Fig. 61.12). The vagina must be completely separated from the rectum in order to achieve good mobilization and a tension-free repair. There is no surgical plane of separation between these two structures and one must be carefully created. The fistula is usually represented by a short (5–15 mm), narrow rectal opening, which sometimes is not wide enough to decompress the bowel and requires dilatations if the surgeon is not proceeding with a newborn repair. Above that, there is a completely normal rectum. Sometimes the orifice is wide enough to allow a satisfactory decompression. The opening of a colostomy is the safest way to manage these babies but an experienced surgeon can operate on this defect primarily without a colostomy if the baby is otherwise healthy. In such a case, we would operate in the newborn period and would keep the patient NPO and on i.v. nutrition for 7 days after surgery. The incidence of associated urogenital malformations is 30%,[7] and the sacrum is usually normal. The perineum of these babies shows a prominent mid-line groove and a very obvious anal dimple. Occasionally in this type of defect we see a 'poor-looking' perineum as well as a short or abnormal sacrum.

RECTOVAGINAL FISTULA

A true rectovaginal fistula is a very unusual defect. Less than 1% of females have this malformation. On the other hand, rectovaginal fistula is presented in the traditional literature as a relatively common defect. A recent review of the authors' own experience with reoperations in female patients showed 80 female patients operated on at other institutions with a diagnosis of rectovaginal fistula. During our reoperations, objective evidence indicated that none of these patients actually had rectovaginal fistulas. In fact, two-thirds of them had cloacas. The original surgeons were unaware of the correct diagnosis; they repaired the rectal component of the malformation and left the patient with a persistent urogenital sinus. The remaining one-third of the patients actually had rectovestibular fistulas and that diagnosis was also missed by the surgeon.[12] The importance of this observation is not only semantic; the group of patients who were born with cloacas were mislabeled as having rectovaginal fistulas and these patients missed a good opportunity to have their entire malformation repaired during the first operation. The results of a second procedure are never as good as the first one. Furthermore, the patients with a rectovestibular fistula were erroneously subjected to an unnecessary abdominal perineal procedure and, as a result, suffer from fecal incontinence from resection of the rectosigmoid. Therefore, it is very important to increase the index of suspicion for malformations such as cloaca and rectovestibular fistula, and to recognize that rectovaginal fistulas are almost non-existent defects.

To make the diagnosis of a real rectovaginal fistula (Fig. 61.13), it is necessary to perform a meticulous inspection of the genitalia which is sometimes not easy to perform in the newborn period due to swelling. Patients with rectovaginal fistulas would show meconium coming from inside the vagina through the hymen. These babies may have a significant incidence of associated urological defects (around 70%).[7] If the rectum is high in the pelvis and the

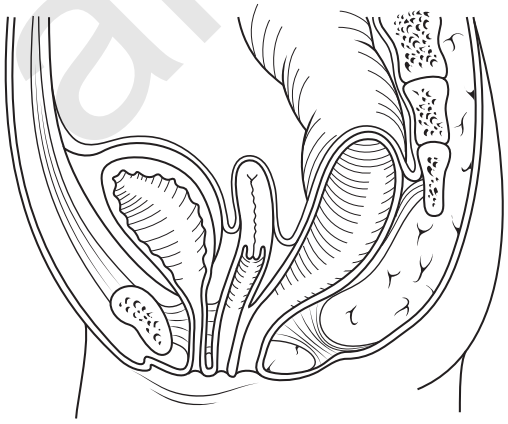

Figure 61.12 Rectovestibular fistula.

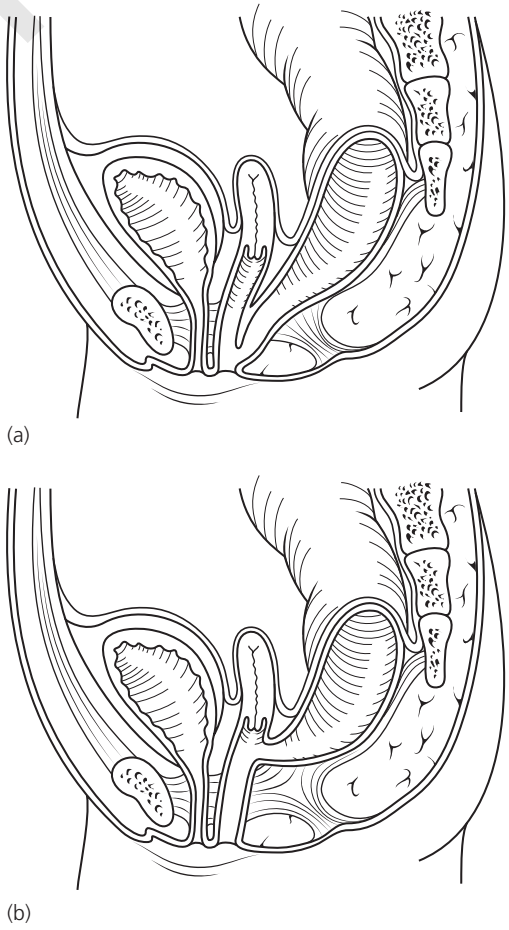

Figure 61.13 Rectovaginal fistula: (a) low; (b) high.

urethra and vagina are normal, this is a rare but useful indication for a laparoscopy in a female with anorectal malformation.

IMPERFORATE ANUS WITHOUT FISTULA

All that was written regarding this defect in males is valid regarding females, the only difference obviously being that the anterior rectal wall is separated from the posterior vaginal wall, not the urethra.

RECTAL ATRESIA AND ANAL STENOSIS

This type of defect is identical to the one described in males, except that its frequency in females seems to be higher. The clinicians must always remember to screen for a presacral mass.

PERSISTENT CLOACA

This is the most complex anorectal malformation seen in females. It represents approximately 10% of the total number of anorectal defects. A cloaca is defined as the junction of rectum, vagina, and urethra into a single common channel (Fig. 61.14). Cloacas represent another spectrum by themselves. At one end of the spectrum a rather benign, short common channel (<3 cm) type of cloaca with good prognosis and no associated defects may be found. At the other end of the spectrum, there exists a more complex defect with a common channel geater than 3 cm in length, a very short vagina, severe associated obstructive uropathy as well as a very poor sacrum and poor muscles (Fig. 61.15). Therefore, the prognosis for this last type of case will be very poor for bowel and urinary control. The spectrum of cloacas include many different types, among them patients with a very dilated vagina which becomes evident as a palpable abdominal mass called 'hydrocolpos'. The dilated vagina usually causes urinary obstruction from compression of the ureters at the trigone (Fig. 61.16). A frequent finding is a double vagina and double uterus; and the rectum may open at different levels in the mid-vaginal septum (Fig. 61.17). The majority of these long channel cloacas require an abdominal approach during the definitive repair, in addition to the perineal operation.[13]

The most important fact to remember in this type of defect is the high incidence of associated urinary tract

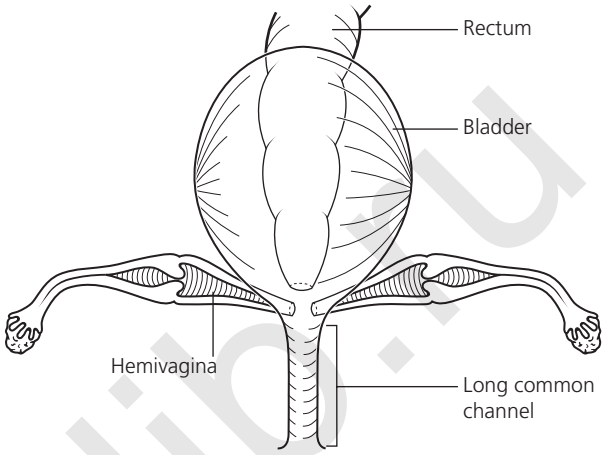

Figure 61.15 High cloaca with common channel of 5 cm.

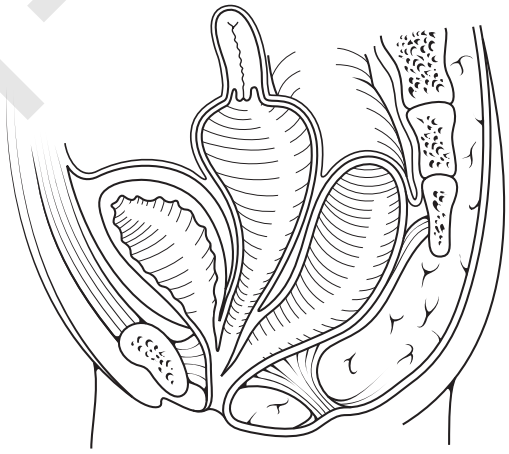

Figure 61.16 Cloaca with hydrocolpos.

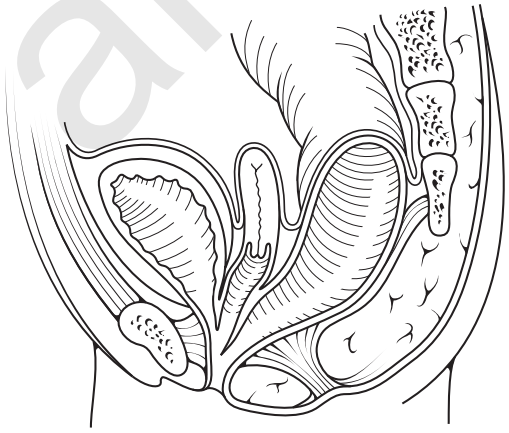

Figure 61.14 Persistent cloaca.

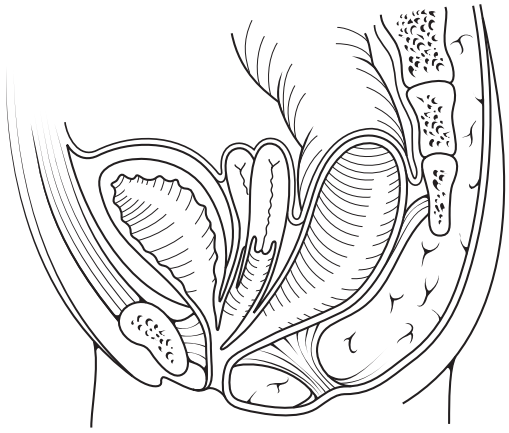

Figure 61.17 Duplicate Müllerian system.

obstruction (70–90%).[7] Obstructive uropathy is the main cause of morbidity and even mortality in these patients. The diagnosis of a cloaca is a clinical one. General practitioners, pediatricians, and neonatologists, as well as pediatric surgeons, must suspect this defect if they want to detect it and make an early diagnosis. A baby girl with absent anus and small-looking genitalia must arouse the suspicion for the presence of a persistent cloaca (Fig. 61.18). If the labia minora is separated, a single orifice becomes evident. These findings are pathognomonic for a cloaca. At that point, the priority in a newborn is the evaluation and treatment of the associated defects of the urinary tract. The external appearance of the perineum in these babies may vary. Sometimes a 'poor-looking' perineum is found, which means a flat bottom, a very poor midline groove, and almost absent anal dimple. However, a cloaca with good muscles and a good sacrum may be found. A cloaca always needs a completely diverting colostomy. If a hydrocolpos is present the patient also needs a vaginostomy. Very rarely a vesicostomy is indicated. In addition to the urologic evaluation (mandatory in cases of cloacas), x-ray films done during the newborn period in females with anorectal malformations are seldom useful, since most of these patients have a visible fistula opening or pass stool through the perineum.

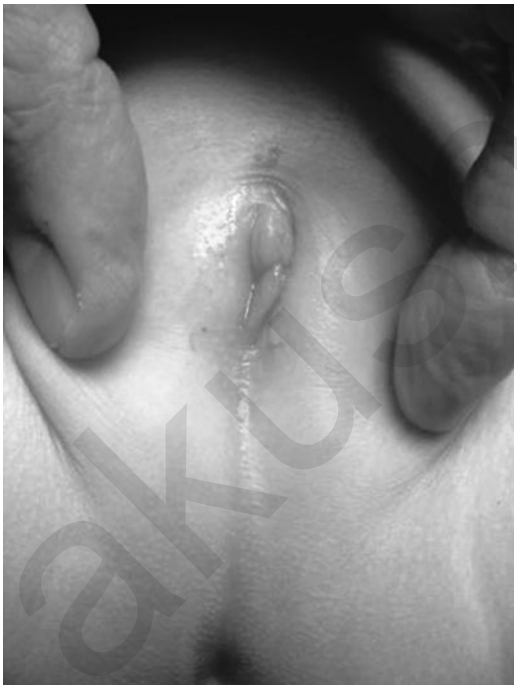

Figure 61.18 Cloaca, perineal appearance.

PREOPERATIVE CARE

Figs 61.19 and 61.20 show decision-making algorithms for the initial management of newborns with anorectal malformations.

In approximately 90% of the males, physical examination (perineal inspection) produces enough information to determine whether or not the patient needs a colostomy. The presence of a rectoperineal subepithelial midline raphe fistula or a 'bucket-handle' defect are all in the group of defects traditionally known as 'low'. These can be treated during the newborn period with a simple anoplasty and without a protective colostomy. In cases of very ill babies, a series of anal dilatations may be enough to allow bowel decompression, leaving the anoplasty to be done later as an elective procedure. On the other hand, a flat bottom, evidence of meconium in the urine, a very abnormal sacrum or spine, or other severe associated defects are enough information to proceed with a colostomy. These babies receive an emergency colostomy, and 4–8 weeks after the colostomy, provided that the patient is growing well, and after radiologic evaluation of the distal colon, a posterior sagittal anorectoplasty (PSARP) is performed.

The remaining 10% of males have questionable clinical evidence. In these cases, we recommend the cross-table lateral film with the patient in prone position.[6] An intraluminal bubble located more than 1 cm from the skin is considered an indication for a colostomy (Fig. 61.9). If the patient does not have signs of a recto-urinary fistula, the case most likely is one of imperforate anus with no fistula. If the patient has Down syndrome,[11] it is even more likely that there will be no fistula. On the other hand, if the rectum is located closer than 1 cm from the skin (Fig. 61.8), the patient was probably born with a rectoperineal fistula and stool has not yet passed out of the fistula. The surgeon should inspect the perineum again and may find a tiny orifice, so narrow that it does not allow the passage of meconium in the first hours of life. The baby can then be treated with a minimal PSARP without a colostomy.

Fig. 61.20 shows the decision-making algorithm used for the initial management of newborn females with anorectal defects. The process of decision-making in females is easier than in males, mainly because the vast majority of females have some form of fistula either to the perineum, vestibule, or genitalia which indicates the type of defect that they have.

The presence of a cloaca (single perineal) orifice, as previously discussed, represents an indication for an urgent urological evaluation. In addition, the patient will require a colostomy and sometimes a vaginostomy. Provided the baby is growing well, the patient may undergo the definitive repair of her defect at the age of three to six months.

For cases in which the meconium comes from the vestibule, an experienced surgeon can perform a primary repair or else a protective colostomy is needed. Often the fistula opening is large enough to decompress the bowel, and therefore there is no need for an emergency colostomy and the definitive repair can be delayed for several months.

The presence of a cutaneous (rectoperineal) fistula indicates that the baby has the most benign type of anorectal defect. This can be treated with a 'minimal' posterior sagittal anoplasty without a protective colostomy. If the rectoperineal fistula is large enough to decompress the intestine, the anoplasty can be postponed and done on an elective basis. The remaining 5% of female patients who have no fistula need a colostomy followed by a PSARP 4–8 weeks later.

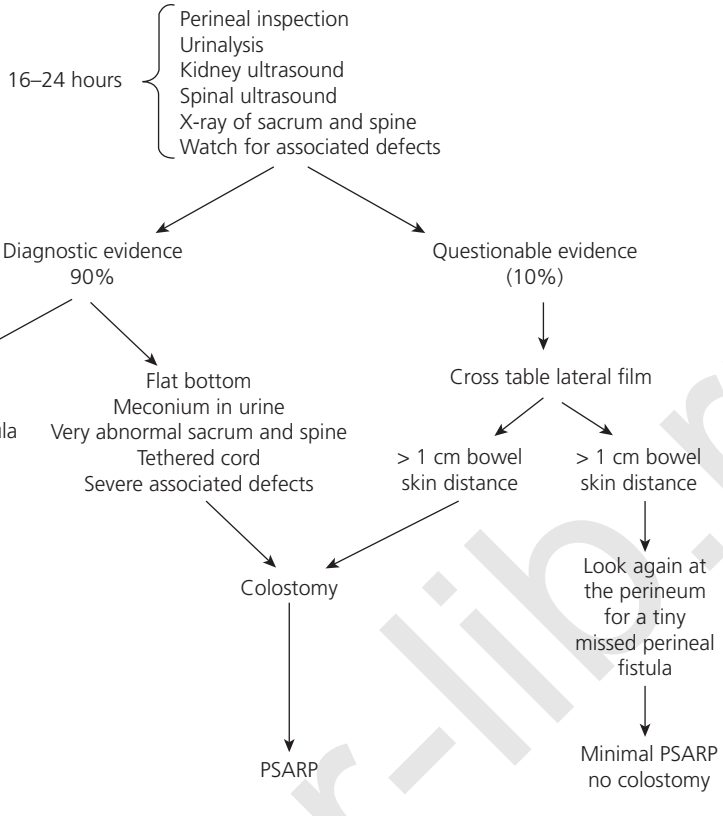

Figure 61.19 Male newborn algorithm for anorectal malformations. PSARP, posterior sagittal anorectoplasty.

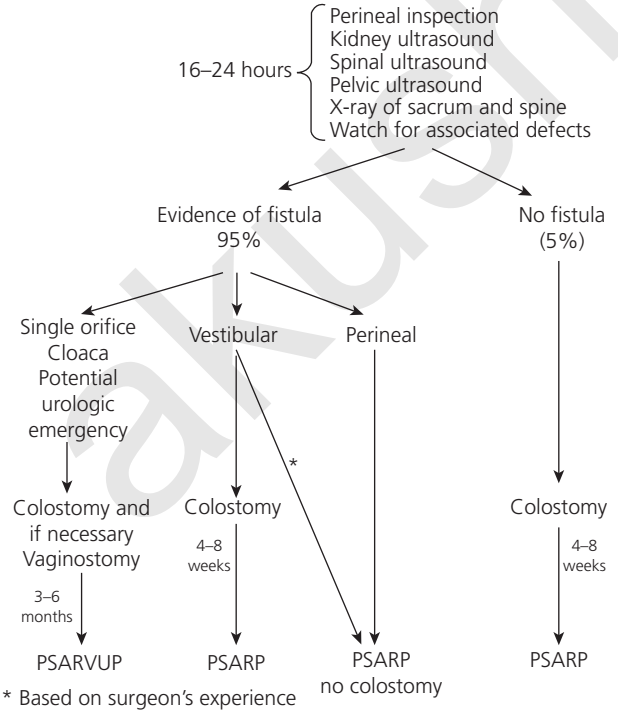

Figure 61.20 Female newborn algorithm for anorectal malformations. PSARP, posterior sagittal anorectoplasty; PSARVUP, posterior sagittal anorectovaginourethroplasty.

Every surgeon must develop their own learning curve for the surgical management of these defects. We prefer to do the repair in the newborn period if appropriate, and otherwise within the first one to three months of life. As one gains confidence with this technique, the main repair can be done earlier and earlier. There are both theoretical and practical advantages to doing these repairs early in life. From the theoretical point of view, placing the rectum in its normal position early may allow the creation of new nerve synapses which may be advantageous in terms of future bowel control.[14] From a practical point of view, it is much easier to dilate the anus of a small baby than trying to do it in an older patient. The healing of the perineal repair is also quicker in a baby who does not yet crawl.

We promote the trend to operate on newborns with anorectal malformations primarily, without a protective colostomy when feasible.[15] When compared to the alternative of three operations (colostomy, main repair, and colostomy closure), a single procedure is highly attractive. However, what remains to be seen is whether or not such treatment will result in better functional results. Those who embrace the new treatment modality are morally obligated to report their results, including complications. Concerning the laparoscopic approach of these malformations,[16] it must be kept in mind that as we have described, 90% of the male cases can be repaired via the posterior sagittal route without opening the abdomen. These patients experience minimal pain, eat the same day of surgery, and could even go home the same

day of the operation. Laparoscopy was created and conceived as minimally invasive surgery but it is not clear whether it is better to repair malformations through the peritoneal cavity that are able to be repaired in an extra-abdominal and extraperitoneal way. There is one particular defect (recto-bladder neck fistula), that represents 10% of all malformations in males, that we feel is ideally suited to a laparoscopic approach. For rectoprostatic fistulas, the approach should be based on which technique the surgeon feels most skilled to perform, laparoscopic or PSARP. For other malformations such as recto-urethral bulbar fistula, no fistula, or in females, we do not think laparoscopy is appropriate.

In general, babies with anorectal malformations look healthy unless they have a severe associated defect, mainly urologic, cardiac, or at another site of the gastrointestinal tract. The frequency of associated urologic defects in babies with anorectal malformation varies.[17–22] In our series, approximately half of the patients with anorectal defects had a significant associated urologic defect, and this frequency varies depending on the level of the fistula site. This, we believe, may help neonatologists and pediatricians suspect, detect, and treat these defects early. A constellation of associated findings (single kidney, absent scrotum, esophageal atresia, etc.) can also be detected prenatally.[23] Before the performance of the colostomy, every baby must have an abdominal ultrasound performed to rule out the presence of obstructive uropathy.

Concerning the passage of meconium, decisions should not be made during the first 16–24 hours of life since meconium often does not appear until after that period of time. Abdominal distension does not become a problem during the first 16–24 hours of life. Therefore, decisions as to whether the baby should undergo primary repair or a colostomy should wait for 16–24 hours for clinical evidence of the anorectal defect.

COLOSTOMY

Once the decision has been made to perform a colostomy, a nasogastric tube is placed in the stomach and i.v. fluids started. Prophylactic antibiotics are recommended.

Fig. 61.21a shows the type of colostomy that the authors recommend in the management of anorectal malformations. The advantages of this colostomy[24] over other types include:

- defunctionalizes only a small portion of the distal intestine, allowing better water absorption;
- is completely diverting;
- allows for an adequate length of bowel for the pull-through, a significant problem if the stoma is placed too distal in the sigmoid (Fig. 61.21b);
- allows decompression of urine that may pass from the urinary tract back into the rectum;
- simplifies cleaning of the distal intestine
- makes the distal colostograms easier than when dealing with a more proximal colostomy;
- reduces the incidence of prolapse to virtually zero.

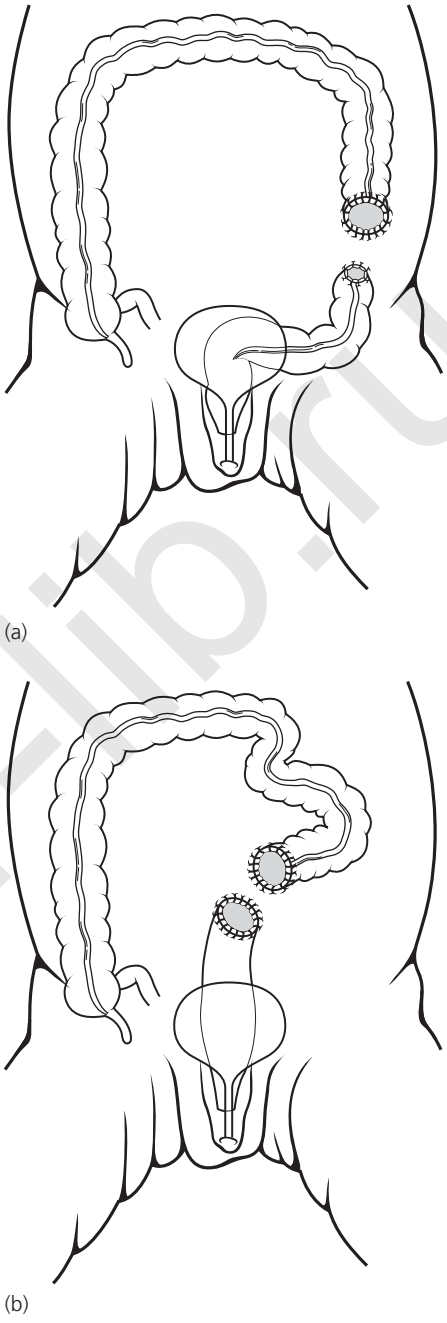

Figure 61.21 (a) Ideal colostomy. (b) Too distal colostomy.

Loop colostomies are problematic because they allow feces to pass into the distal stoma provoking fecal impaction, megarectum, and urinary tract infection. There is also a risk of contamination and infection after the main repair.

The recommended incision measures approximately 6 cm, is made in the left lower quadrant and is oblique. The proximal functional stoma is placed in the upper and lateral portion of the incision and the mucous fistula (non-functional) distal stoma is made small and placed in the lower and medial portion of the incision. The two stomas must be far enough apart so that the stoma bag does not

cover the mucous fistula. The distal bowel must be irrigated with saline solution during the operation to evacuate all of the meconium. In this way, the bowel remains completely clean, does not get distended, and the patient does not need any preparation prior to the main repair.

A colostomy must be considered a serious, delicate procedure. The surgeon must carefully identify the piece of intestine that they are going to exteriorize to avoid serious mistakes. The most frequent errors in performing colostomies seen by the authors include:[25]

- A colostomy placed too distal in the sigmoid.
- Opening of a right upper sigmoidostomy. The surgeon thought they were opening a transverse colostomy and actually grabbed the sigmoid colon and exteriorized it in the right upper quadrant. This interferes with the pull-through.
- Retracting colostomies. In these cases the bowel was probably handled poorly and may suffer from ischemia and retraction. In addition, the bowel is poorly fixed to the abdominal wall. To avoid this, the authors' suggestion is to fix the bowel to the peritoneum and to the anterior fascia.
- Prolapsed colostomies. Choosing the very proximal sigmoid for the functional end avoids prolapse because of the left colon's attachment to the retroperitoneum.

After the colostomy, once feedings are advanced, the baby can be discharged. If the baby is growing well, the main repair can be performed 4–8 weeks post-op. Prior to the final repair, it is mandatory to perform a distal colostogram in order to determine the precise type of anatomic defect that one is dealing with. This has important prognostic and therapeutic implications. This study must be done under fluoroscopy. A Foley catheter is introduced into the distal stoma, its balloon is inflated and water-soluble contrast material (never barium) is injected under enough hydrostatic pressure to overcome the contraction of the funnel-like muscle structure that surrounds the lowest part of the rectum. The dye injection is done by hand with a 60cc syringe. Failure to observe these principles will most likely show the dye staying above the pubococcygeus line, erroneously indicating the presence of a very high defect and not showing the fistula, simply because of the lack of hydrostatic pressure.[9] Figs 61.22–61.24 show distal colostograms in a case of recto-urethral bulbar fistula, rectoprostatic fistula, and rectovesical (bladder neck) fistula. Having this information, the surgeon will be able to plan the surgical procedure. When dealing with a case of rectovesical (bladder neck) fistula, the surgeon will be able to predict that the prognosis in terms of bowel function will not be as favorable as in other types of defects.[5] In addition, the main repair will take approximately 3–4 hours. A laparotomy or laparoscopy will also be necessary in order to mobilize the rectum. Most importantly, the surgeon will avoid looking for the rectum through a posterior sagittal incision where it will not be found, because that would risk injury to the urinary tract, vas deferens, seminal vesicles, and ectopic ureters. The posterior sagittal approach in this case will be used only to show the trajectory of the pull-through after its mobilization

Figure 61.22 Distal colostogram in a recto-urethral bulbar fistula.

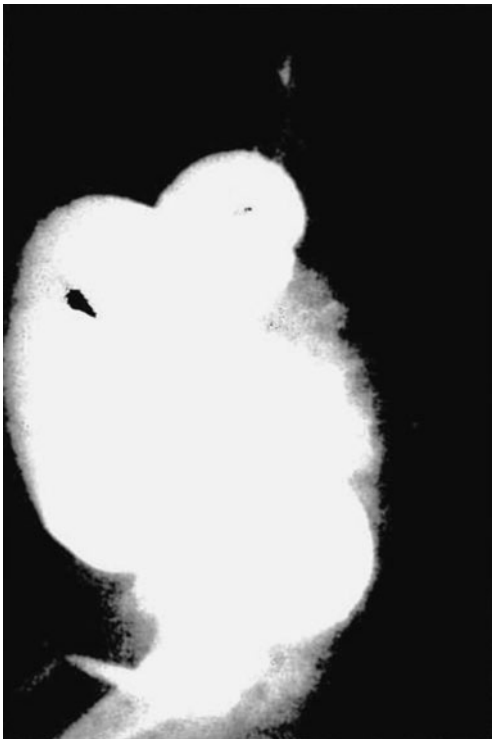

Figure 61.23 Distal colostogram in a recto-urethral prostatic fistula.

Figure 61.24 Distal colostogram in a rectovesical (bladder neck) fistula.

through laparoscopy or via laparotomy, and to allow tacking of the rectum to the muscle complex.

DEFINITIVE REPAIR

Minimal posterior sagittal anoplasty

This operation is done in all the so-called 'low' defects, including rectoperineal (cutaneous) fistulas in both males and females. In cases of male newborns it is important to place a Foley catheter in the bladder during the operation. The rectum and urethra are very close together despite not having a communication. The incision is very small and divides the posterior sphincter mechanism and continues around the fistula in a 'racket-like' fashion (Fig. 61.25a). Multiple 6-0 sutures are placed taking the mucocutaneous junction of the fistula. This serves the purpose of exerting uniform traction which helps in the dissection. The distal fistula is mobilized, as well as part of the rectum, sufficiently to be relocated comfortably within the limits of the sphincter without tension (Fig. 61.25b). The rectum is anchored to the muscle complex and then a 16-stitch anoplasty is done, as shown in (Fig. 61.25c).

Limited posterior sagittal anorectoplasty

This procedure is performed in cases of rectovestibular fistula in female newborns. The incision is very similar to the one just described but it is extended more cephalad, as far as necessary to achieve enough bowel mobilization. The main difference to the previous defect is the fact that the rectum and vagina share a rather long common wall. The most vital part of the operation consists of separating the rectum and vagina by creating a plane of separation without injuring either one (Fig. 61.26). The separation is carried out all the way up until both structures have a full-thickness normal wall. Lack of adequate rectal mobilization is the main cause of dehiscence after this repair. The separation of the rectum from the vagina requires a meticulous and delicate technique and is performed with a

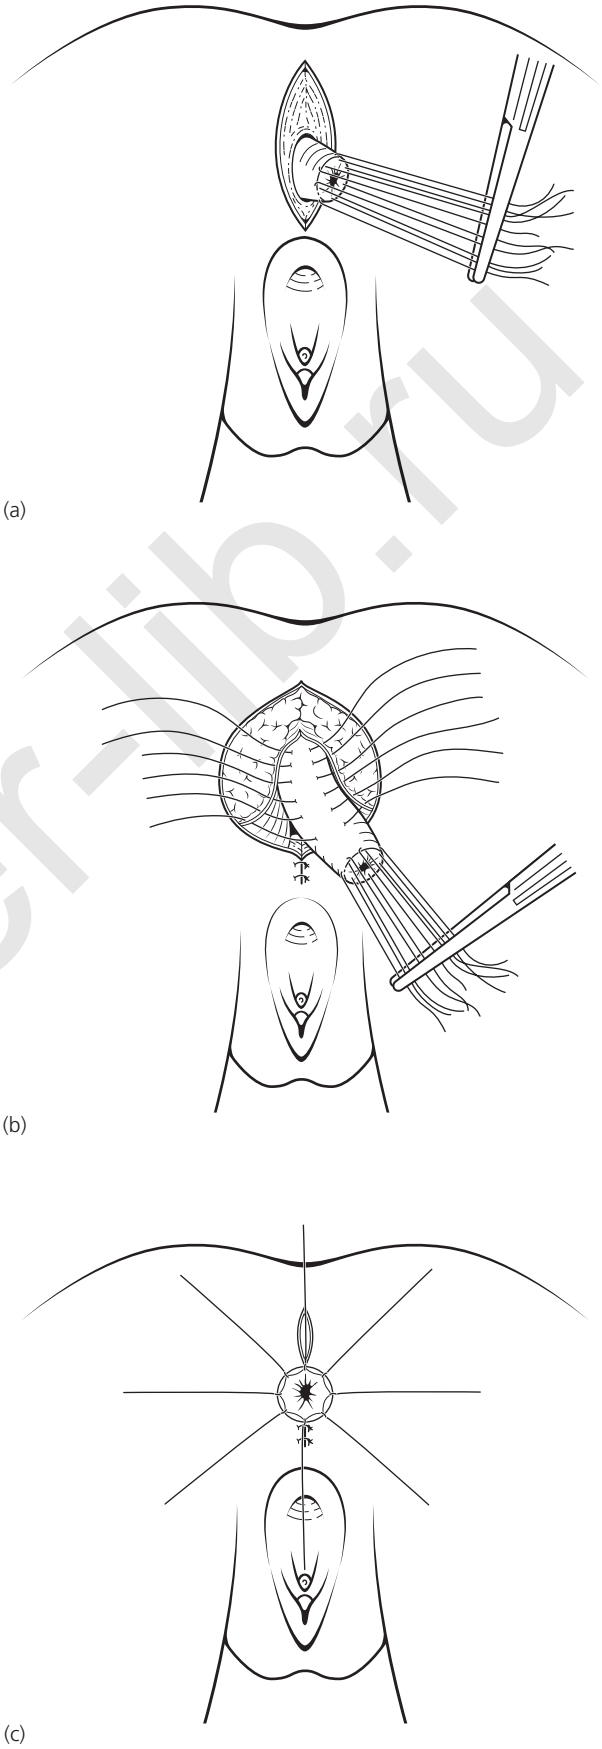

Figure 61.25 Rectoperineal fistula repair: (a) incision; (b) reconstruction: (c) anoplasty.

needle-tip cautery, changing from cutting to coagulation where necessary to provide meticulous hemostasis. Once the rectum has been completely separated, the limits of the external sphincter are determined by electrical stimulation. This will indicate where the rectum should be placed. The perineal body is then reconstructed with long-term absorbable sutures (Fig. 61.27a). The rectum is anchored to the posterior edge of the muscle complex (Fig. 61.27b) and then a 16-stitch anoplasty is performed in the same way as previously described (Fig. 61.27c,d). If a colostomy is present, these patients can have oral feedings on the same day as surgery and can go home the following day. If undiverted, our routine is to keep them NPO and on i.v. nutrition for 7–10 days. Antibiotic ointment is applied to the wound three times a day for 1 week.

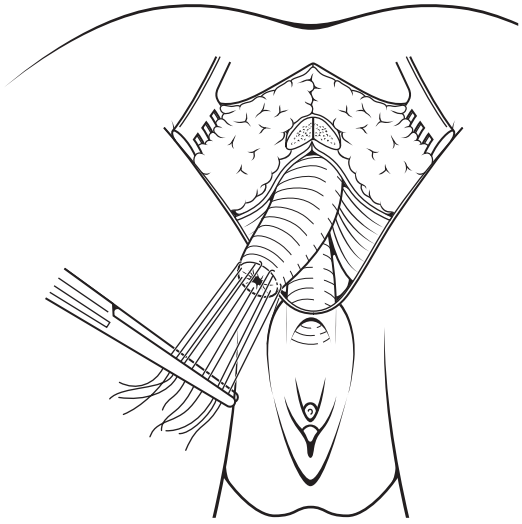

Figure 61.26 Rectovestibular fistula repair. Separation of rectum.

Posterior sagittal anorectoplasty

This technique is used for the repair of a recto-urethral fistula or a rectovaginal fistula. The patient is placed in the prone position as previously described, with the pelvis elevated and with a Foley catheter in the bladder. Electrical stimulation of the perineum will allow the surgeon to identify the anal dimple. The incision runs from the lower portion of the sacrum down and through the sphincter mechanism, staying exactly in the midline, leaving equal amounts of muscle on both sides. After opening of the skin and subcutaneous tissue, the parasagittal muscle fibers can be identified. The incision is deepened and after another area of fat (the ischiorectal space) the levator muscle is found. The levator muscle flows

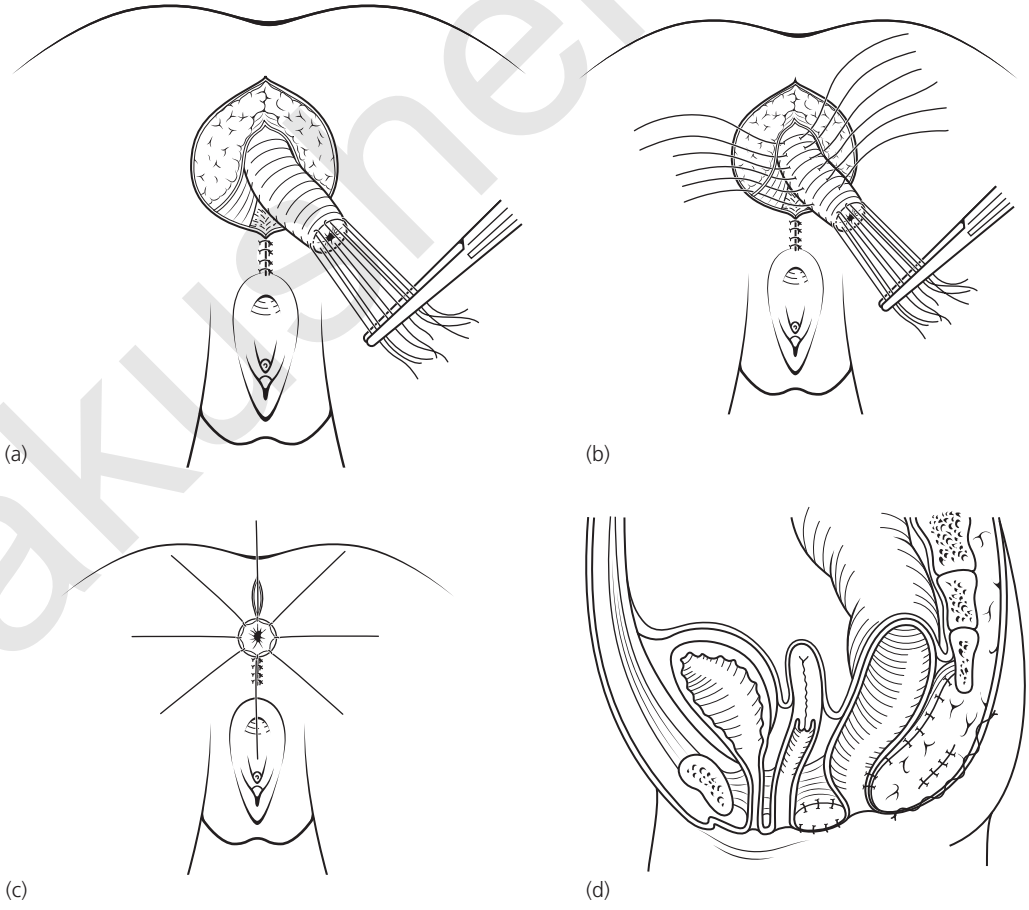

Figure 61.27 Rectovestibular fistula repair: (a) perineal reconstruction; (b) anchoring rectum to muscle complex; (c) anoplasty; (d) operation completed.

into the muscle complex up to the skin of the anal dimple, forming a funnel-like structure. Parasagittal fibers that run on both sides of the midline will close the lumen of the anus once this is reconstructed. Muscle complex fibers run perpendicular to the parasagittal ones and also medially. The muscle complex and parasagittal fibers cross perpendicularly, forming the posterior and anterior limits of the new anus (Fig. 61.28). The contraction of the muscle complex and levator pulls in the anus. The levator muscle is opened exactly in the midline. The rectum is then opened along its posterior wall between two traction sutures. Once the rectum is opened, the fistula site can be visualized. It must be remembered that the rectum and urethra share a common wall immediately above the fistula. Accordingly, a submucosal dissection must be carried out above the fistula site (Fig. 61.29). After approximately 1 cm of submucosal dissection, the dissection continues taking the full thickness of rectal wall. Once the rectum has been separated from the urethra, the fistula is closed with interrupted long-term absorbable sutures. The rectum is then dissected in a circumferential manner, so as to gain enough length to reach the perineum without tension (Fig. 61.30).

Tapering, as shown in Fig. 61.31 is rarely needed, but if necessary must be carried out in the posterior aspect of the rectum. The bowel must then be closed in two layers of interrupted sutures. The rectum is then placed in front of the levator muscle within the limits of the sphincter mechanism, and is also anchored to the posterior edge of the muscle complex to prevent prolapse (Fig. 61.32). The anoplasty is done as previously described (Figs 61.33 and 61.34).

Following the operation, the Foley catheter must remain in place for 7 days. If the catheter comes out accidentally, it is better to leave it out rather than trying to pass it back into the bladder and thus risking a urethral perforation at the urethral

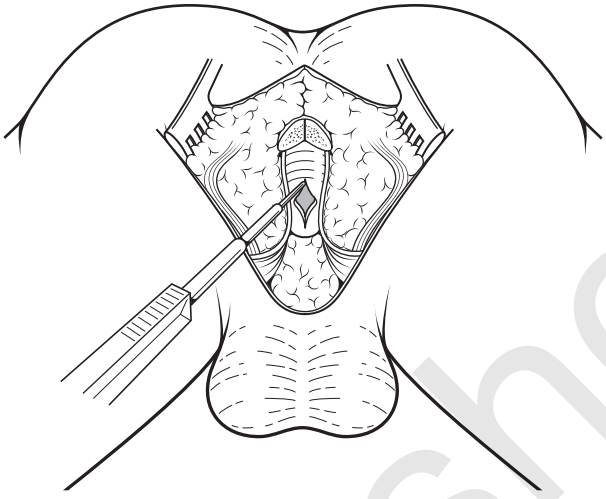

Figure 61.28 Anatomy exposed. Parasagittal fibers, muscle complex, and levator muscle have been split in the midline. The rectum is open in the midline.

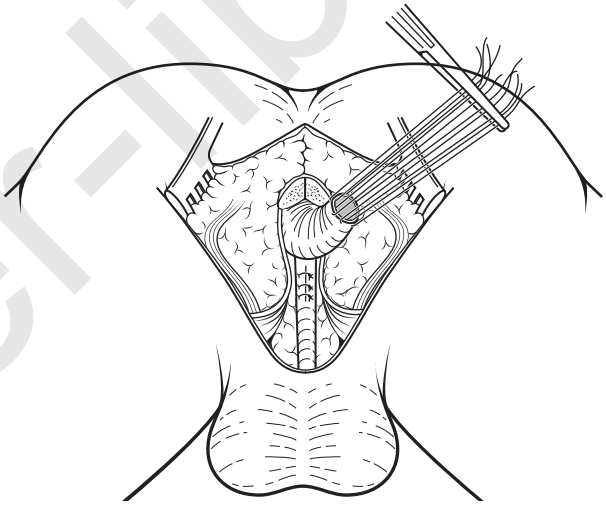

Figure 61.30 Rectum separated from urethra.

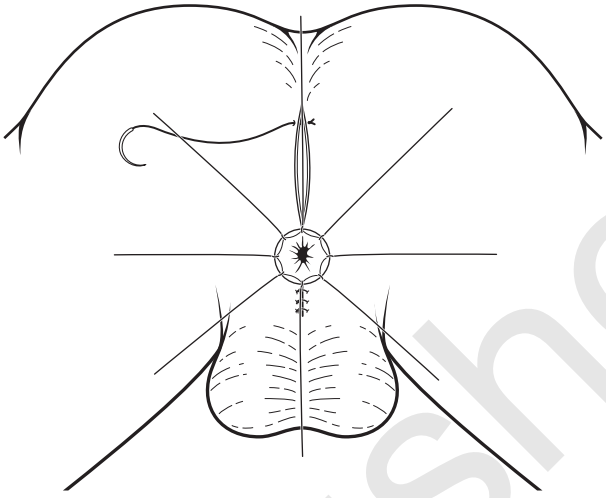

Figure 61.33 Anoplasty.

suture site. Most of the time, babies will be able to void with no difficulty. If this is not the case, which luckily is rare, then a suprapubic cystostomy is recommended.

Posterior sagittal anorectoplasty and laparoscopy or laparotomy (recto bladder neck fistula or high prostatic fistula)

This technique is used in cases of very high defects, the recto bladder neck or high rectoprostatic fistulas in males.

The operation is started with the patient in the supine position. The baby is prepared with a total body preparation from the nipples down. A Foley catheter is placed in the bladder. The abdomen is entered with laparoscopy, the peritoneal reflection is opened and the sigmoid colon is dissected down to the fistula site where it is ligated and divided. The rectum in these cases opens into the bladder neck in a 'T' fashion with no common wall, and therefore the

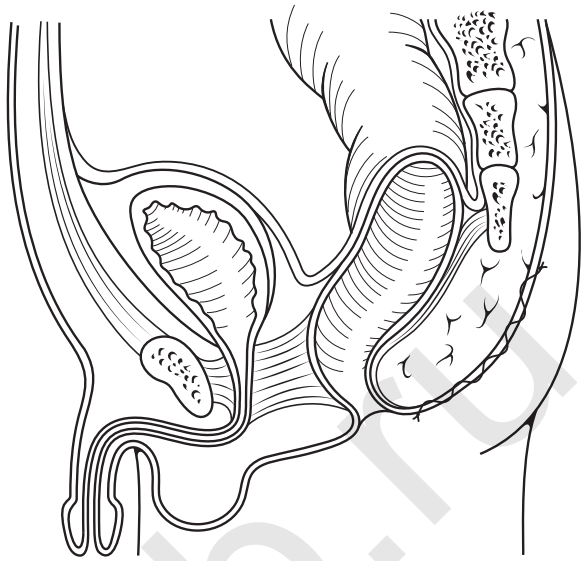

Figure 61.34 Anoplasty – operation completed.

separation from the bladder is relatively easy. Care must be taken to avoid damage to the vas deferens which are close in proximity. The perineal incision is the same as previously described for the posterior sagittal anoplasty but can be done in the supine position with the patient's legs elevated. The muscle structures are divided in the midline and the presacral space is identified. Getting a high rectum to reach the perineum is challenging and requires a meticulous dissection along the rectal wall, which is dependent on the rectum's excellent intramural blood supply. A colostomy placed too distal in the sigmoid may interfere with the rectal mobilization. Also, if the distal rectum requires tapering this may need to be done with an open incision or via the posterior sagittal incision. Once mobilized, the rectum is pulled-through to the perineum. The rectum is tacked to the posterior edge of the muscle complex and the anoplasty is done as previously described. The Foley catheter remains in the bladder for 7 days.

The posterior sagittal approach has also been used since 1982 to repair cloacas.[13] Since cloacas represent a spectrum, the operations to repair these defects may last from 3 to 14 hours and should be carried out by surgeons with significant experience. The technical maneuver that is called the total urogenital mobilization has greatly facilitated the repair.[26] Using the total urogenital mobilization, the rectum is separated from the vagina and then both the urethra and vagina are mobilized together down to the perineum. This maneuver also avoids the formation of urethrovaginal fistulas as well as vaginal stenosis. The more complex cases with common channels of 3 cm or greater require a variety of surgical maneuvers including specialized vaginal mobilizations or replacements to complete the repair.[13]

TWO WEEKS POSTOPERATIVELY

After 2 weeks, the anus is calibrated and the parents are taught to dilate, which they do twice a day. They are instructed to go up in size each week until the desired size is reached, at which

point the colostomy can be closed. Dilations are continued thereafter with a tapering protocol:

- once a day for a month
- every other day for a month
- every third day for a month
- twice a week for a month
- once a week for a month
- once a month for three months.

The ideal sizes of Hegar dilators are:

- number 12 for 1–4 months old
- number 13 for 4–8 months
- number 14 for 8–12 months old
- number 15 for 1–3 years old
- number 16 for 3–12 years old

Results

Each defect has a different prognosis. The patients with lower defects usually have excellent results, except when technical errors have been made or if they have associated sacral or spinal problems.

Table 61.1 shows the results obtained in our series. The patients with a sacral ratio (Fig. 61.35) of less than 0.3 and flat perineums have fecal incontinence regardless of the type of malformation or quality of the repair. Normal sacral ratios (>0.7) usually correlate with good functional prognosis.

Because persistent cloacas themselves represent another spectrum of defects, the potential for bowel and urinary control will vary. The length of the common channel seems to be the most important prognostic factor.

For patients suffering from fecal incontinence as a sequelae of their anorectal malformation (25% of patients), we implement a bowel management program that is used after the child reaches three years of age.[27] The goal is to send these children to school in normal underwear. The program is implemented by trial and error over a period of 1 week. It consists of teaching the family to clean the patient's colon once a day with an enema tailored to the specific child. This implementation is radiologically monitored every day during the week until the specific type of enema is found that is capable of cleaning the colon and keeping it completely clean

for 24 hours.[28] Every year, during vacation time, the patient is subjected to a laxative trial; the enemas are stopped and the capacity of the patient to become toilet-trained without enemas is evaluated. If the patient is not successful, they go back to the enema program. Patients sometimes express dissatisfaction with rectal enemas; they want more privacy and do not want their parent giving them enemas. In order to further improve their quality of life, the family is offered a procedure called 'continent appendicostomy' (Malone procedure) (Fig. 61.36).[29,30] This procedure allows patients to independently administer the enema through the umbilicus.

Congenital pouch colon

AMULYA K SAXENA AND PRAVEEN MATHUR

INTRODUCTION

Congenital pouch colon (CPC) is a congenital malformation of the large bowel in which the entire large bowel or segments of varying lengths of the large bowel exhibit enormous dilatations in the form of a pouch and communicate distally through a fistula with the urogenital system. CPC is associated with a high form of anorectal malformation with large variations in the size of the dilatations of the affected large bowel segment. Although not included in the Wingspread classification of aorectal malformations, CPC has been recognized as a rare form of aorectal mlformation and has been included in the Krickenbeck classification.[1]

An unusal feature of CPC is the prevalence of this malformation in the Indian subcontinent with the highest incidence in the west and north of India. Despite the growing global awareness of CPC and the increase in reporting of this congenital malformation, contemporary literature shows that approximately >98% of the patients reported to present with CPC are managed at pediatric surgical centers in India. The increased awareness has also led to the better recognition and management of these neonates and children. Congenital pouch colon, which is the most appropriate terminology to describe this malformation, has been referred to with synonyms such as pouch colon, pouch colon syndrome, short colon, colonic reservoir, and congenital short colon in preliminary reports that emerged during the 1970s and 1980s.

HISTORICAL BACKGROUND

Although CPC is an extremely rare congenital malformation beyond the Indian subcontinent, this anomaly was initially recognized in the West at the beginning of the twentieth century. The first description of this anomaly was documented by Spriggs from a specimen he carefully observed at the London Hospital Museum in 1912.[2] Spriggs described the specimen with an absence of half of the large bowel and rectum, and considered the dilatation to be the result of a congenital occlusion of the gastrointestinal tract. The next description of this congenital malformation was almost half a century later in a report from Canada. In 1959, a more accurate account was provided by Trusler *et al.*[3] who reported more typical characteristics of this malformation, such as the pouch-like dilatation of the shortened large bowel and its association with a high form of anorectal malformation. Almost a decade later in 1967, El-Shafie[4] described this malformation in detail as a congenital shortening of the small intestines which accompanied a cystic dilatation of the colon associated with an ectopic anus.

The first report of this malformation from India emerged in 1972, when Singh and Pathak[5] coined the term 'short colon' after observing this condition in a series of six patients. In the same report, Singh and Pathak also speculated on the possible embryogenesis of the malformation. Later, in a successive report in 1977, Singh *et al.*[6] described the anatomy of this malformation. An important contribution to this congenital anomaly was made by Chiba *et al.* in 1976, who not only made the first attempts to classify this malformation but also reported the management of this malformation with the technique of 'coloplasty'.[7] The term 'colonic reservoir' was coined by Gopal in 1978 in a report of this malformation with the distal end of the reservoir terminating in the female genitals via a rectovaginal fistula.[8] A further effort to describe this malformation as a 'short colon malformation' associated with an atresia of the anus was done by Li in 1981.[9]

In 1984, Narasimha *et al.*[10] suggested the term 'pouch colon syndrome' and after observing variations in the presentation of this malformation proposed a classification based on the length of normal colon preceding the pouch dilatation. In 1987, Cloutier *et al.*[11] described the malformation as a 'rectal ectasia' in a newborn with a low anorectal malformation and reported an incidence of 5% of terminal bowel ectasia in their patients with low anorectal deformities. Elaborate nomenclatures were suggested by Wu *et al.* in 1991 with acronyms such as 'association of imperforate anus with short colon' (AIASC) or 'association of imperforate anus with exstrophia splanchnica' (AIAES).[12] However, in 1994 Chadha *et al.*[13] introduced the term 'congenital pouch colon' which is the nomenclature to aptly describe this anomaly.

INCIDENCE

There is an extreme variation in the incidence of CPC around the world with the large patient series being reported exclusively from India. Smaller series of patients have been emerging from the neighboring countries in the Indian subcontinent, such as Pakistan and Nepal; however, surprisingly, an extremely low incidence has been observed in Bangladesh.[14] Only sporadic cases of CPC have been reported from the Middle East, Far East, the European continent, and the North American continent.[15–18] The incidence of CPC is highest in the western and northern regions of India and is estimated to be in the range of 5–18% of the total number of neonates managed for anorectal malformations.

In India, the states of Rajasthan, Uttar Pradesh, Punjab, Kashmir along with the union territories of Delhi and Chandigarh account for the majority of cases of CPC. Despite the high density of population in all these states, the management of CPC is generally not performed at primary or secondary health care centers and most neonates are referred to tertiary university medical centers with specialist care teams and expertise in pediatric surgery, a trend that has better enabled the estimation of incidences. Among the Indian tertiary care centers reporting large series of CPC, Udaipur in the western state of Rajasthan has reported the highest incidence of CPC in India, accounting for 37% of the high forms of anorectal malformations (which is more than double reported in Delhi – 15.2%).[19]

CPC more frequently affects the male population with a male:female distribution of 4:1. The sex ratios of CPC reported in case reports or small series outside India predict equal gender distribution, which are not accurate since the sample size is too small to derive valid conclusions.

ETIOLOGY

The exact embryogenesis of CPC is not known and the etiology is still quite elusive. Since the majority of the patients with CPC belong to the rural population of agricultural families in northern India, environmental factors in this region have been speculated upon. The widespread use and direct contact with pesticides in these agriculture-based communities have been regarded as the possible factor in the triggering of events that lead to CPC. It is also important that the effect of these factors influences the fetus after conception at a time when the hindgut is differentiating into the urinary and colonic tracts. Additional environmental factors that could play a role in the development of CPC are the deficiency of iodine or vitamin B; however, the role of these factors is rather questionable since their deficiencies are encountered in many communities throughout the world.

Various theories have been hypothesized to explain the formation of the pouch. The chronic obstruction theory proposed that the expansion of the large bowel was a result of chronic obstruction of the distal colon.[3] However, this theory has been rejected since the dilated pouch does not return to assume normal proportions even after a colostomy has been placed to relieve the obstruction. The next hypothesis was the interference of hindgut growth and migration proposed by Dickinson.[20] This theory proposed that the interference in the longitudinal growth of the hindgut (distal to the allantois) and failure of its migration into the pelvis following the obliteration of the inferior mesenteric artery in the early embryonic life was responsible for the formation of the short colon. The altered hindgut stimulation theory was hypothesized by Chatterjee.[21] This theory proposed that the cecum and the right colon normal development was stimulated by the normal developing hindgut, and development alterations in the hindgut resulting from a primary disorder were responsible for the altered development of the cecum or the right colon. The faulty rotation and fixation theory proposed by Wu *et al.*[12] hypothesized that the faulty rotation and fixation of the large bowel were responsible for the disturbances in longitudinal growth. The vascular insult theory was proposed by Chadha *et al.*,[13] in which degrees of vascular insult at the time of the partitioning of the cloaca by the urogenital septum were deemed responsible for the malformation and could explain its variations. The vascular insult theory was also supported by Mathur *et al.*[19] in explanation of double pouch formation in CPC. At present, vascular insult best explains the formation of CPC, since vascular supply to the pouch is always abnormal. Also, the overwhelming vascular support provided by the superior mesenteric artery to the entire distal bowel emphasizes this point, since the inferior mesenteric artery has been identified only in few patients with CPC during surgery.

PATHOLOGY

CPC is recognized by certain pathological characteristics that are solely found to be associated with this congenital malformation (Fig. 62.1).

Figure 62.1 Operative view of the exteriorized grossly dilated congenital pouch colon segment visualized from a left lower quadrant 'hockey stick' incision.

Gross pathology

Characteristics are as follows:

- The most striking feature is the presence of anorectal malformations which differentiates this entity from segmental dilatation of the colon.
- Irrespective of the type of CPC, there is a decrease in the length of the large bowel due to the presence of the pouch.
- The pouch formations may differ in length and diameter and are fecal or meconium impacted at the time of surgery.
- The pouch wall is thick with a stiff consistency and is abruptly connected to the normal bowel without the presence of the transition zone.
- There is an absence of haustrations, taenia, and appendices epiploicae in the pouch colon.
- Furthermore, during surgery, an abnormal vascular supply to the pouch can always be identified.
- A fistula can occur in the urinary tract in male neonates (colovesical fistula) and the genito-urinary tract in females (colocloacal, colovaginal, or colovestibular fistula).
- Appendiceal anomalies are present which may vary from complete absence to the presence of double appendices.

Histopathology

Histological studies of resected pouch colon have demonstrated extreme variations in CPC. In the majority of patients, acute and chronic inflammation of the mucosal and submucosal layers are present with varying degrees of hemorrhage along with the presence of disorganized muscle layers in the colon wall (Fig. 62.2). Generalized hypotrophy of the muscle layers has also been observed which is more predominant in the outer muscle layer of the pouch.[22] Although, in other specimens, extreme variations in the muscle layer (both circular and longitudinal) have also be demonstrated that have ranged from fibrosis, atrophy to hypertrophy along with muscle disruption.[23] Investigations have also exhibited variations such as the presence of normal colon wall with normal ganglion cells in some patients, to a poorly developed colon wall musculature with decreased or absent ganglion cells in others.[6,10,13,24] Interestingly, heterotrophic tissue, such as gastric mucosa, small intestinal mucosa with characteristic villi, and pancreatic tissue have also been found in pouch specimens of CPC patients.[10,22]

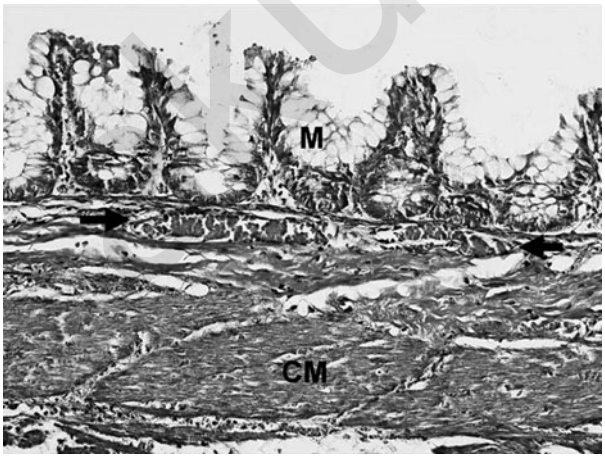

Figure 62.2 General features in the histopathology of pouch colon include inflammation of the mucosa (M) and disorganized colonic wall musculature (CM). Submucosal hemorrhage (arrows) is evident in this specimen. (Stain: Massom Trichome ×20 magnification.)

CLASSIFICATION

CPC can present as various types and efforts have been made to classify CPC in order to provide a basis for surgical management as well as for evaluating the outcomes.

The first efforts to classify CPC were made using a classification based on characteristics of short colon that grouped pouch colon into five types.[7] However, many features described in this classification were not associated with the CPC pathology. CPC was then classified by a classification based on presence of normal colon length proximal to the pouch into four types.[10] Although this classification identified the major forms of CPC, it had major drawbacks since the length of the normal colon was determined using terms such as 'short segment' and 'significant length' and appropriate parameters or anatomic landmarks to determine the normal colon length were absent. A further classification was proposed based on coloplasty which divided CPC into two types.[24] This classification was further modified into one based on pull-through which also broadly divided CPC into two types.[25] The last two classifications considered the surgical approach with regards to coloplasty or pull-through; however, neither offered any information about the length of the normal colon in CPC patients.

The Saxena–Mathur classification for CPC is based on anatomic morphology and divides CPC into five types (Fig. 62.3):[26]

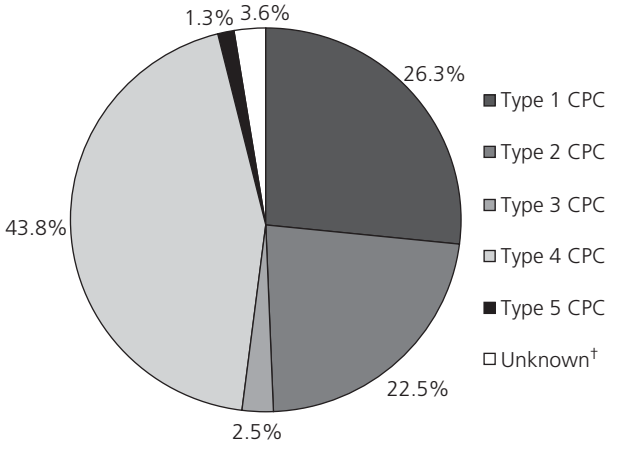

Figure 62.3 Distribution of patients ($n = 80$) into five types of congenital pouch colon according to the Saxena–Mathur classification. †In two patients with severe septicemia the type was not known due to fatal outcomes during resuscitation attempts prior to surgery.

Type 1: normal colon absent and ileum opens into pouch colon
Type 2: ileum opens into a normal cecum which opens into pouch colon
Type 3: normal ascending colon and transverse colon opens into pouch colon
Type 4: normal colon with rectosigmoid pouch
Type 5: double pouch colon with short normal interpositioned colon segment

This classification employs anatomic landmarks to determine the length of the normal colon, as well as identifies the relation of the pouch to the normal colon. It also includes rare forms of CPC such as double pouch colon and offers clear guidelines towards management of CPC.

HISTORY AND PHYSICAL EXAMINATION

The presence of an anorectal malformation with gross distention of the abdomen is the hallmark of the physical examination. In the male neonates, discharge of meconium (meconurea) or stool through the urethra via the colovesical fistula is evident and these neonates are generally referred for treatment in the immediate neonatal period. However, in female patients meconium and fecal discharge through a cloacal, uterine, or vaginal fistula may delay referral in a stable neonate. Furthermore, when a colocloacal fistula (common in females with CPC) is present, it is associated with a large fistula opening that permits decompression of the pouch colon contents, the presence of which can further delay presentation in female subjects for a period of several months after birth. At the time of referral, these patients with colocloacal fistulas are frequently obstipated and physical examination shows the discharge of stools from the ectopic site.

PRESENTATION

The majority of patients with CPC are presented in the immediate neonatal period due to the anorectal malformation. The absence of the anal canal and excessive distention of the abdominal cavity are the two characteristic signs that raise suspicion of CPC. Although in CPC the pouch ends through a fistula in the genitourinary tract, meconurea may be present or absent. Another symptom commonly observed in these neonates is serial episodes of bilious vomiting which is a major symptom that leads to referral. Delayed referrals or grossly distended pouch colon neonates are not uncommonly presented with colonic perforations, which present a major challenge in the management of the newborn with septicemia and peritonitis which further accentuates the respiratory distress already initiated by the massive abdominal distension. Delay in diagnosis and late referrals even in the neonatal period have been largely responsible for the high mortality in CPC. Awareness of the condition and development of proper management strategies especially through improvement in neonatal intensive care at the tertiary centers in India have drastically reduced the mortality from 40% to the present rate of 15%.[27]

DIAGNOSIS

Plain erect abdominal x-rays performed to diagnose patients with CPC demonstrate a classical solitary grossly dilated air fluid bowel loop that occupies more than 75% of the abdominal cavity with displacement of the small intestines (Fig. 62.4). The position of the pouch and the displacement of the intestinal loops depends on CPC type.[24] Although plain abdominal x-rays can predict the CPC type, the definitive diagnosis and CPC type can be determined only after surgical exploration. False diagnosis of CPC based on plain x-rays is possible in patients with (1) significant dilatation of the sigmoid colon, (2) pneumoperitoneum after perforation in anorectal malformations due to late presentation, and (3) in females neonates with recto-uterine fistula when severe dilatation of the meconium-filled uterus and gas exhibit the classical images of CPC x-rays.[28]

Although plain erect abdominal x-rays with the classical presentation of CPC are sufficient to establish the diagnosis, conventional invertograms used for the diagnosis in anorectal malformations are additionally performed. Prior to surgical management further investigations such as abdominal ultrasonography, i.v. pyelography, or voiding cysto-uretherography and echocardiography are mandatory since a wide range of genitourinary, gastrointestinal and other forms of associated anomalies are present in patients with CPC (Box 62.1).

Figure 62.4 Plain abdominal erect x-ray demonstrating the classic grossly dilatated pouch colon segment occupying over 75% of the left abdomen, thereby displacing the small intestines towards the lower quadrant in the right abdomen.

Box 62.1 List of associated anomalies reported in congenital pouch colon patients

Genitourinary anomalies
- Hydronephrosis
- Vesico-ureteral reflux
- Bicornuate uterus
- Cryptorchidism
- Hydroureteronephrosis
- Hypospadias
- Renal aplasia/agenesis
- Renal dysplasia
- Double uterus
- Double vagina
- Septate vagina
- Ectopic kidney
- Urethera duplication (males)
- Uretheral diverticula
- Bifid penis
- Megalourethra
- Urethral strictures
- Bladder exstrophy
- Duplicate bladder exstrophy

Gastrointestinal anomalies
- Absent appendix
- Double appendix
- Malrotation
- Colon duplication
- Meckel's diverticulum
- Double Meckel's diverticulum
- Esophageal atresia
- Small intestinal duplication
- Rectal atresia

Other organ anomalies
- Sacral agenesis
- Congenital heart disease
- Myelomeningocele
- Prune belly syndrome
- Hemivertebrae
- Congenital talipes equinovarus
- Perineal teratoma
- Absent ribs
- Down syndrome

MANAGEMENT

Preoperative management

The preoperative management is broadly dependent on the condition of the pouch (intact versus perforated). In stable neonates, preoperative management includes gastric decompression using a wide bore nastrogastric tube, i.v. fluid replacement to correct the effects of dehydration and electrolyte imbalance, and placement of a urinary bladder catheter. Antibiotic therapy is commenced and extended depending on the state of the inflammation in the pouch colon evaluated during surgery. In neonates presenting with pouch perforations along with signs or either peritonitis or septicemia, aggressive intensive care management is necessary to stabilize the neonate for the emergency surgical procedure which is limited to evacuation of the meconium or stool from the peritoneal cavity, placement of a ileostomy or colostomy, and closure of the perforation site. The intention in surgical management in neonates with perforations is to perform the surgery with the smallest possible incision and to complete the procedure in a short time.

Operative management

The management algorithm of CPC is based on the type of pouch according to the Saxena–Mathur classification (Fig. 62.5).[29] An abdominal incision in the lower left quadrant in the shape of a 'hockey stick' has been found to offer optimal access to inspect the malformation with the primary intention of fistula ligation irrespective of CPC type. After the fistula has been exposed and ligated, the condition of the pouch dictates the further operative strategy. Staged procedures, employing the placement of a protective ileostomy or colostomy with ligation of the fistula in the first stage, followed by an abdominoperineal pull-through in the second stage, still offer the safest option when compared to one-stage surgery which is associated with a higher incidence of morbidity and even mortality. The intention of surgical management in CPC is to evaluate the amount of large bowel affected and to salvage its maximum length in order to restore or partially restitute the function of the large bowel, such as absorption, transportation, and containment.

In types 1 and 2 CPC a one-stage procedure (pouch excision and pull-through) or three-stage procedure (ileostomy, pouch coloplasty with pull-through and ileostomy closure), depending on the condition of the pouch (ischemic or healthy) can be performed. In the case of severe ischemia and perforations, resection of the pouch remains the only alternative. If the pouch is resected, either a direct pull-though of the ileum or placing a protective ileostomy with delayed ileum pull-through offer the best surgical options. However, if the pouch is healthy, the surgical approach is focused on attempts to rescue and taper the pouch and to perform a pouch coloplasty through pouch tubularization. Pouch tubularization is performed after pouch mobilization and longitudinal incision on the antimesenteric side (to preserve the vascular supply) with edge reapproximation over a cathether. Although tubularized pouch coloplasty is performed in both types 1 and 2 CPC, it is not uncommonly associated with increased morbidity in terms of incontinence and complications resulting from redilatation of the tubularized pouch.[30,31] Also, variations in the outcomes of surgery have been reported by various centers. [12,30,32,33] The function or the absorptive capability of the tubularized pouches is not understood; however, it is reported to be decreased since attempts to patch or augment healthy pouch colon onto normal pull-through ileum in type 1 CPC with the intention of rescuing the absorptive surface area have been reported with success.[34]

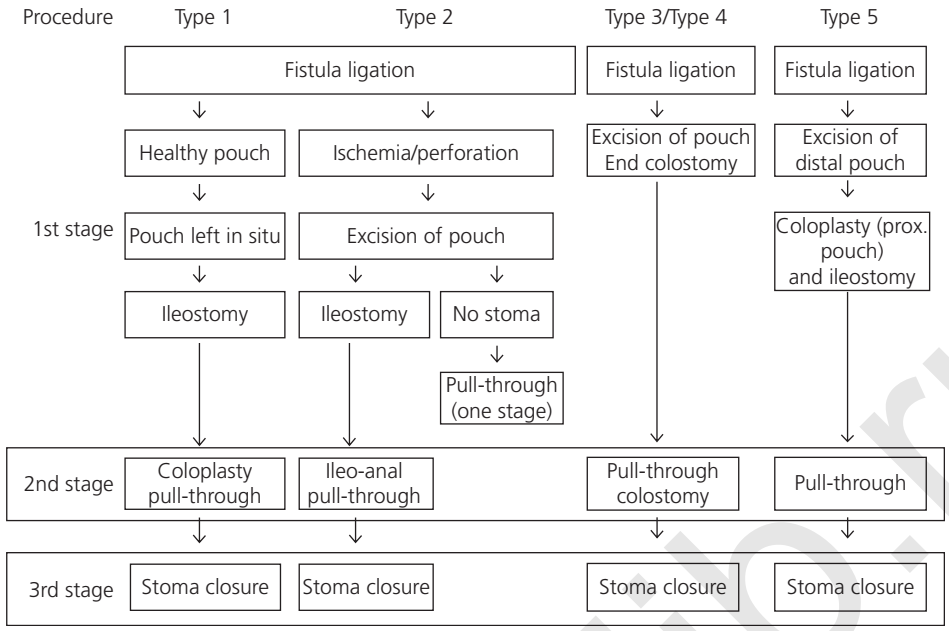

Figure 62.5 Management overview of the various types of congenital pouch colon with outline of the operative stages.

When referring to redilatations of tubularized pouches, the technique of 'window' colostomy needs to be addressed. This technique involves the placement of a stoma directly on the pouch colon, which is the most prominent part of the dilated bowel in an attempt to provide primary decompression in a sick neonate, when extensive surgical exploration is not possible. Window colostomies are more frequently performed by surgeons not well acquainted with this malformation, which are commonly associated with urinary complications when the fistula is left open. Furthermore, large prolapse of the pouch and failure to thrive have been also related to the placement of window colostomies.[35] Window colostomy is also associated with mortality in patients who have been managed with this option. The option of window colostomy should not be considered in a stable infant.

The significance of the Saxena–Mathur classification in differentiating types 1 and 2 CPC (despite the similarities in surgical approach as proposed by Wakhlu *et al.*[24] and Gupta and Sharma[25] in classifications based on the need for coloplasty) is to recognize the presence of the normal cecum in type 2 CPC which is underestimated in the classifications on surgical approach. Various investigations and experimental studies have demonstrated the significance of the cecum and ascending colon or parts of the ascending colon in the absorption of sodium which influence the exchange of chloride and bicarbonate in these tissues.[36,37] However, investigations need to be performed to validate these differences in patients and compare type 1 and type 2 CPC patients. Similarly, the absorption of potassium, which is significant in the descending colon in experimental studies,[38,39] highlights the difference between type 3 and type 4 CPC since the normal functioning descending colon only present in type 4 CPC.

The presence of considerable lengths of normal colon in types 3 and 4 CPC enable total resection of the pouch and a staged abdominoperineal pull-through of normal colon. The approach to types 3 and 4 involve the ligation of the fistula, excision of the pouch, and placement of a stoma which is followed by a delayed abdominoperineal pull-through. Although it is debatable whether a protective colostomy should be placed, or a prior high colostomy be closed during the pull-through procedure, the authors prefer the first option and place a protective colostomy during the pull-through which is returned at a later point in time. In types 3 and 4 CPC, if the high colostomy is opted for (instead of the end colostomy) appropriate placement of the colostomy is advocated since improper placement of a high colostomy may interfere with the pull-through procedure, especially if the length of the colon to be pulled-through is too short.

Management of type 5 CPC requires the approach to two pouch colon segments that are separated by a segment of normal colon and is best treated by a three-stage procedure.[19] The first procedure involves the ligation of the fistula, excision of the distal pouch and tubularization of the proximal pouch, and the placement of a protective ileostomy. The second procedure involves the abdominoperineal pull-through, keeping the protective ileostomy. In the third procedure, the protective ileostomy is returned. Another option of type 5 CPC would be to tubularize both the proximal and distal pouch.

Surgical management of female neonates with pouch colon is complex due to the frequent association with the cloaca, as well as the associated anomalies of the genital system.[40,41] Depending on the complexity of the genital anomalies a one- or three-stage approach is preferred; however, there is no consensus on the approach to date. The pouch colon has been tubularized to create a neo-vagina

and reconstruct the anorectum with preserved vaculature also using the longitudinal incision technique.[16]

Postoperative

The postoperative management depends on the condition of the pouch. In patients with pouch perforation, intensive care support along with parenteral nutrition is necessary until complete recovery. The use of antibiotics and duration of treatment is also dependent on the surgical findings. In patients with protective colostomy feeds are commenced earlier than those who have undergone tubularization and pull-through procedures. Monitoring of bowel movements are necessary to achieve success in these patients.[42] Regular postoperative follow up is necessary to document the bowel movements which could range from diarrhea when the pouch is resected to obstipation which could result in tubularized pouch redilatation and necessitate further surgical procedures.

COMPLICATIONS

Complications in the management of CPC can be divided into five distinct categories which are related to: (1) window colostomy, (2) protective colostomy, (3) tubularized pouch colon, (4) complete pouch resection, and (5) pull-through procedure. Window colostomy leads to a wide range of complications, such as incomplete pouch decompression, prolapse, stoma recession, stoma stenosis, pouchitis, enetrocolitis, and failure to thrive. The complications of protective colostomy or pull-through procedures are general complications associated with these procedures and are not specific for CPC. Tubularization of the pouch colon could be associated with complications of leakage along the suture line with consequent rupture. Also, redilatation after tubularized colon has been observed with long-term follow up in patients with salvaged pouch colon.[31,43] Complete pouch resection is associated with complications of recurrent watery diarrhea, excoriation around the anus, perineum or genitals, and poor weight gain. Severe complications in neonates with pouch perforations are not only limited to septicemia and peritonitis but have also been found to negatively influence the respiratory status as well as the anesthesia efforts intraoperatively and postoperatively with lethal outcomes.[44]

LONG-TERM RESULTS

It should always be remembered that CPC is a complex form of high anorectal malformation and the muscle complex responsible for maintenance of continence directly influences the long-term outcome in these patients. Patients who present with a well-developed muscle complex attain variable degrees of continence and have better outcomes when compared to those with a poorly developed muscle complex with sacral agenesis and who are incontinent. Continence levels may vary in different reported series as it is dependent on the surgical expertise that a center can offer. Education of the parents as well as their socioeconomic status are also important factors that have a direct impact on the successful implementation of any bowel management regimes.

As well as the muscle complex, the types of pouch colon also influence the level of continence. When resection of the entire pouch is necessary in the absence of normal large bowel, watery diarrhea and loose stools are frequent. The frequency of stools decreases as well as the consistency increases over a period of time. In types of CPC where sufficient normal bowel is present (types 3 and 4), better results have been achieved in patients when the entire pouch has been resected and the normal large bowel is pulled through. This is because the pouch colon tissue investigated has demonstrated a lack of normal spontaneous contractions despite maintaining acetylcholine and histamine-induced contractility.[45] Also, fibrous tissue replaces the muscle layers of the pouch colon and affects motility adversely.[23,46] Hence, in cases where the pouch colon tissue is salvaged and a tubularized coloplasty performed, utilization of approximately 15 cm of tissue has been associated with a favorable outcome.

Complex malformations that are present as associated anomalies also influence the long-term outcome in these patients. Gastrointestinal anomalies that affect CPC patients do not add to long-term morbidity. Also, severe forms of cardiac defects are not common and do not influence long-term outcome. However, the severity of the genitourinary malformations may directly influence the quality of life in these patients as they reach adolescence and adulthood.

Congenital segmental dilatation of the intestine

HIROO TAKEHARA AND HISAKO KUYAMA

INTRODUCTION

Congenital segmental dilatation of the intestine is a rare lesion defined as limited bowel dilatation with three- to four-fold increased size with an abrupt transition between normal and dilated bowel and no intrinsic or extrinsic barrier distally to the dilatation. This condition is complicated by obstruction of the intestines or chronic constipation from birth. Since Swenson and Rathauser first described three patients with segmental dilatation of the colon in 1959,[1] 59 cases (30 newborns, 25 children, and 4 adults) with this condition (41 in the small intestine and 18 in the colon) were reported in the world literature by 1996.[2] Since then, the number of case reports has increased greatly.

Despite the many reports, the etiology of the disease remains elusive. Although the current study attempts to evaluate the roles of interstitial cells of Cajal, enteric nervous system, and smooth muscle in segmental dilatation of small bowel, the causal relation is not clarified.

ETIOLOGY

The etiology of segmental dilatation of the intestine remains unknown. Some etiologic hypotheses have been proposed:

- An obstructive insult to the developing bowel[3]
- Presence of heteroplastic tissue in the bowel wall may result in primary dysplasia of the intestinal segment or may interrupt the myenteric plexus[4–11]
- Anomalous tortuous vessels on the mesenteric side of the dilated segment[12,13]
- Unequal proliferation or vacuoles in smooth muscle at the epithelial stage[8,14]
- Deficiency of interstitial cells of Cajal, pacemaking cells of non-neural crest origin in enteric nervous system, and smooth muscle of bowel segmental dilatation[15–17]

PATHOLOGY

The common morphological feature of congenital segmental dilatation of the intestine is the presence of a single, well-defined segment of dilated intestine with a more or less abrupt transition to normal bowel both proximally and distally, with no evidence of intrinsic obstruction or deficient innervation.

Cases can be divided into two groups according to histopathologic findings. One group has a hypertrophic muscular layer within the dilated segment and the other a very thin or absent muscular layer. From reviews of 39 neonatal cases,[3–9,12,14,18–40] there were five with hypertrophic muscular layer,[12,22,26,32,40] and eight with hypotrophic or atrophic muscular layer.[3,5,7,19,21,34] Abnormal prominent, tortuous vessels on the mesenteric side of the dilated segment were reported in 11 cases.[3,12,22,29,32,38,40] Heteroplastic foci were found in the resected segment in five cases.[5–7,31,38]

The congenital segmental dilatation of the intestine is associated with numerous other malformations. In these series, one or more malformations were reported in 36 cases (78.2%).[3–9,12,14,18–22,41]

Histological examination shows no abnormality in the enteric nervous system. There are a few reports describing deficiency of interstitial cells of Cajal, pacemaking cells of non-neural crest origin, in mesenteric plexus, and smooth muscle of bowel segmental dilatation.[15–17] However, they may not be of enteric nervous system in origin, or abnormality of small bowel pacemaking, but of possible localized myopathy of the smooth muscle.[14]

CLINICAL FEATURES AND DIAGNOSIS

Many cases of congenital segmental dilatation of the intestine localized in the small intestines often present intestinal obstructions during the neonatal period,[1,3,8,12,13,18,23,32,42]

and consequently this condition is diagnosed during the early period after birth. Neonates with missed and accordingly delayed diagnosis appear with abdominal pain, vomiting, and intermittent attacks of diarrhea. Chronic constipation and abdominal distension, similar to the presentation of Hirschsprung's disease, is more common when the colon is involved.[1,3,18,31,32,35,42,43] In segment dilatation of the colon, the findings on contrast enema are very similar to those in Hirschsprung's disease (Fig. 63.1), but the two conditions can be differentiated by anorectal manometry.[43] In addition, histochemical studies demonstrate no proliferation of cholinergic nerve fibers of the rectal mucosa.[43]

Rarely, the patient may present with peritonitis due to perforation of the dilated segment.[19]

MANAGEMENT

As congenital segmental dilatation is often confused with mechanical intestinal obstruction or Hirschsprung's disease, the surgeon must make every effort to establish the diagnosis as precisely as possible prior to initiating surgery. A thorough preoperative radiological evaluation is necessary to distinguish the two, as well as to determine the site of the dilated segment. Preparation for the laparoscopic surgery includes the administration of preoperative oral and i.v. antibiotics. It is necessary to empty the gut by using total parenteral nutrition.

Surgery for segmental dilatation of the small intestine or the colon should be performed with a laparoscopic procedure. The main advantage of laparoscopic surgery in children is that it is a minimally invasive procedure that provides safe and superior cosmetic results.[2]

For cases complicated by a segmental dilated lower rectum, rectum is pulled out by using the endorectal pull-through method following devascularization of the mesorectum laparoscopically (Figs 63.2–63.4). The oral feeding is begun 3 or 4 days after surgery when there is evidence of bowel function. The patient is discharged when an oral diet is tolerated. Rectal examination is performed 2–3 weeks after surgery.[44]

Figure 63.1 Barium enema shows segmental dilatation of the lower rectum.

LONG-TERM RESULTS

Most patients experience an uncomplicated postoperative course following cosmetic and minimally invasive intervention with laparoscopic surgery for congenital segmental

Figure 63.2 Laparoscopic photograph showing a segmental dilatation of the lower rectum with anomalous tortuous vessels on the mesenteric side.

Figure 63.3 Devascularization (dotted line) of the dilated lower rectum was performed laparoscopically using an ultrasonic coagulation cutting device.

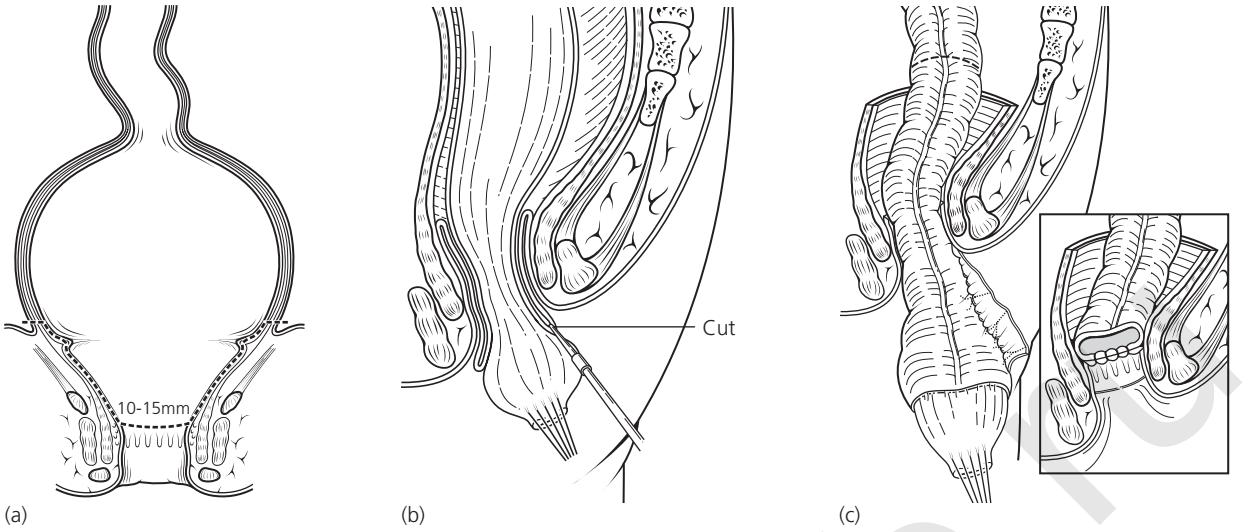

Figure 63.4 Transanal dissection of rectal mucosa begins 10–15 mm above the dentate line and the dotted line shows mucosectomy line (a). The submucosal plane is extended proximally until the colorectum is turned inside out, indicating that the transanal dissection has advanced to the level of the internal perirectal dissection (b). The segmental dilated rectum is pulled down to the anus and secured with interruped suture (c).

dilatation of the intestine. The survival rate is excellent unless other serious complications or anomalies exist.

Intussusception

SPENCER W BEASLEY

PRENATAL INTUSSUSCEPTION

Prenatal intussusception is a recognized cause of intestinal atresia.[1,2] The presentation is that of a bowel obstruction at birth. Preoperative evaluation usually fails to yield a definite diagnosis[1] and the diagnosis is made at laparotomy.[2] Prenatal intussusception may be associated with fetal ascites[3] or meconium peritonitis.[4] Some cases are due to a Meckel's diverticulum.[5] Prenatal intussusception may result in an ileal atresia.[4]

NEONATAL INTUSSUSCEPTION

Although intussusception is common in the first year of life, it is rare in neonates and premature infants,[3,6] accounting for fewer than 1% of cases. The intussusceptions may be multiple[6,7] in which situation there may be no obvious pathological lesions at the lead points. Generally, however, when intussusception occurs in a neonate or infant, the possibility of a pathological lesion at the lead point must be entertained, and of these, a duplication cyst, inverted Meckel's diverticulum, or an ileal polyp are the most likely.[8] An early rotavirus vaccine (Rotashield®) was withdrawn from the market because of its association with intussusception. In contrast, the new live, oral, attenuated rotavirus vaccines (RotaTeq® and Rotarix®) appear to have no increased risk of intussusception.[9,10]

It is now well recognized that in the neonate and infant under three months of age, the likelihood of a pathological lesion at the lead point is significantly greater than in intussusception that occurs later in the first year of life.[1,11]

CLINICAL ASSESSMENT

When intussusception occurs in premature infants or in the neonatal period, its presentation may mimic neonatal necrotizing enterocolitis: the infant develops bile-stained vomiting, increased nasogastric aspirates, blood in the stools, and intestinal dilatation – but without evidence of intramural gas (pneumatosis intestinalis) that is pathognomonic of necrotizing enterocolitis.[12] It is not surprising that diagnostic confusion with necrotizing enterocolitis can lead to delay in appropriate treatment.[13] Similarly, in the neonate, the combination of bowel obstruction and rectal bleeding may lead to confusion with malrotation and volvulus; given the rarity of the condition in this age group, the diagnosis is often made only at operation.

In the older infant, vomiting, lethargy, pallor, and colic are the most common symptoms.[14] In long-standing cases, the infant may appear shocked and septicemic, with abdominal distension. Where abdominal distension and tenderness are not pronounced, an abdominal mass may be palpable and there may be evidence of blood mixed with the stool on rectal examination. Transanal protrusion of an intussusceptum is rare, but when it occurs it may be confused with rectal prolapse, and is associated with significant morbidity.[15]

NON-OPERATIVE TREATMENT

Indication for enema

When a diagnosis of intussusception is suspected and there is no clinical evidence of necrotic bowel (i.e. peritonitis or septicemia), reduction of the intussusception by gas enema should be attempted.[16] As alternatives, hydrostatic reduction under ultrasonographic control,[17] or in institutions where gas enemas are not available, a barium enema may be employed. Duration of symptoms, radiological evidence of small bowel obstruction,[18] and the position of the apex[19] per se are not contraindications to attempted enema reduction. Unfortunately, in the neonate, contrast enema is diagnostic in relatively few cases, mainly because the intussusception may not extend through the ileocecal valve, which may remain competent. Abdominal ultrasonography may assist in the

early diagnosis (Fig. 64.1) and in many centers is performed routinely where intussusception is suspected.[17]

Preparation for gas enema

There is considerable evidence that the gas enema is more effective and safer than the barium enema for reduction of intussusception that extends beyond the ileocecal valve (Fig. 64.2).[20–22] A gas enema should be performed in a pediatric surgical center by an experienced pediatric radiologist in the presence of a pediatric surgeon.[20] An i.v. line should be inserted and rehydration commenced before undertaking the enema. The child should be placed on a warming blanket during the procedure to prevent heat loss.

Technique of enema reduction

Gas (usually oxygen from a wall supply) is pressure controlled and run into the colon through a Foley catheter, which has been inserted through the anal canal, as with a conventional barium enema reduction.[20] The infant lies prone with buttocks taped and squeezed tightly together by the radiologist to avoid air leakage. The upper limit of pressure can be controlled by a manometer and the entire procedure is performed under continuous fluoroscopic control (Fig. 64.3).

Figure 64.1 Ultrasonographic appearance of intussusceptum with the concentric rings of the intussesception within the intussuscipiens.

Cessation of gas enema

Flooding of the small bowel with gas signifies a complete reduction of the intussusception (Fig. 64.4). If free intraperitoneal gas is observed, the enema should be ceased immediately. If the initial attempt at reduction is unsuccessful and the infant remains in good condition, repetition of the gas enema after 2–3 hours is likely to be successful in about 50% of cases.[23] It is now our standard practice to repeat the enema after several hours if there has been partial reduction of the intussusception (as far as the cecum) in an infant whose clinical condition remains satisfactory.[23] Gas reduction tends to occur more rapidly than barium reduction. Both techniques have a similar recurrence rate[24] but the perforation rate may be more common after a gas enema than a barium enema.[25,26]

INDICATIONS FOR SURGERY

Clinical evidence of peritonitis or septicemia is an absolute indication for surgery, as it signifies that dead bowel is likely and resection is required (Box 64.1). Other indications for surgery include failure of repeated gas enemas to reduce the intussusception or early recurrence of intussusception after a successful enema (suggesting the presence of a pathological lesion at the lead point). Occasionally, a pathological lesion at the lead point may be seen during attempted enema reduction, but usually when a pathological lesion is present the intussusception cannot be reduced by enema. In the neonate who presents with an established bowel obstruction, the diagnosis is made when the intussusception is discovered at the time of laparotomy. Surgical management involves resection of non-viable bowel, and primary anastomosis. Until recent years, the mortality rate was over 20%,[6] largely because of delay in diagnosis. Recurrence is rare.

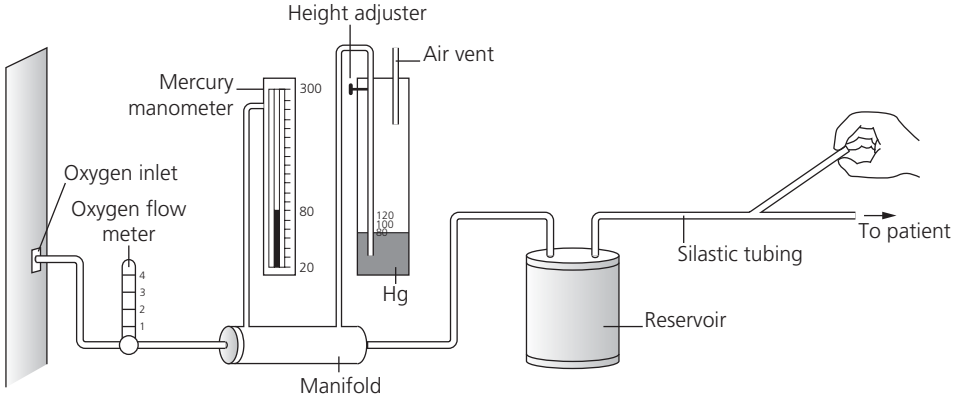

Figure 64.2 Schematic representation of the apparatus used to achieve gas (oxygen) reduction of intussusception.

Figure 64.3 Gas reduction of intussusception: the pressure-controlled oxygen runs through the anus and outlines the intussusceptum in the transverse colon.

Figure 64.4 Sudden flooding of the small bowel signifies complete reduction of the intussusception.

Preparation for surgery

Prior to the general anesthetic, a nasogastric tube is inserted to empty the stomach. Prophylactic antibiotics are given intravenously at induction. The infant is paralyzed and intubated. A warming blanket must be used to prevent excessive heat loss, and temperature is monitored with a rectal or mid-esophageal probe. An oximeter monitors oxygen saturation.

Box 64.1 Indications for surgery

- Clinical evidence for dead bowel, i.e. peritonitis, septicemia
- Failure of enema reduction
- Early or multiple recurrences (relative indication)
- Evidence of pathological lesion at the lead point

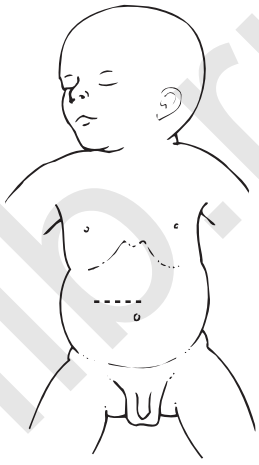

Figure 64.5 Right supra-umbilical transverse incision.

SURGICAL TECHNIQUE

Approach

A right, supra-umbilical transverse incision is made, dividing the ventral abdominal wall muscles in the line of the incision (Fig. 64.5). This gives good exposure, irrespective of the length of intussusception. Free peritoneal fluid is aspirated and the bowel is delivered into the wound.

Alternatively, a laparoscopic approach using a 5 mm umbilical port for the telescope and two 3 or 5 mm working ports is performed. The abdominal wall of the neonate is thin enough that a small incision may allow the 3 mm instruments to be introduced directly. A laparoscopic approach may be difficult in the presence of marked gaseous distension of the bowel, necessitating conversion to an open approach.

Manual reduction

The intussusception is carefully reduced by manipulation of the intussusceptum within the intussuscipiens in a proximal direction (Fig. 64.6). This is performed by gently squeezing the bowel between the fingers and in the cup of the hand. Time must be allowed to enable edema to dissipate. The intussusception is most difficult to reduce in the region of the

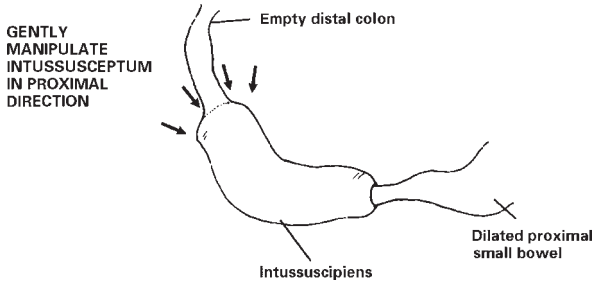

Figure 64.6 Gentle pressure on the distal limit of the intussusception coerces the intussusceptum proximally. Pulling on the bowel as it enters the intussuscipiens is not advised, as it tends to be more traumatic and less efficient at reducing the intussusception.

ileocecal valve. Care must be taken to avoid splitting the serosa. A similar technique is used in the laparoscopic approach, but reduction is completely reliant on instrumental manipulation.

Check for a pathological lead point

After full reduction of the intussusception, a dimple at the lead point is a common sight. Look for evidence of a duplication cyst, inverted Meckel's diverticulum, or another lesion at the lead point, because if these are present they should be resected.

Technique of resection

The indicators for resection are shown in Box 64.2. The aim should be to remove as little viable bowel as possible (Fig. 64.7). The small bowel mesentery is ligated and divided, and the bowel at the edges of resection is divided with scissors. A one-layer 4-0 Vicryl interrupted suture end-to-end anastomosis is performed. The defect in the mesentery is closed to prevent internal herniation.

Box 64.2 Indications for resection

- Inability to reduce intussusception manually
- Necrosis or gangrene of the bowel
- A pathological lesion at the lead point

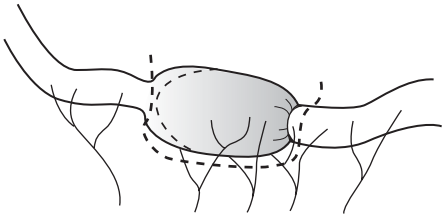

Figure 64.7 Line of resection of an irreducible intussusception.

Closure

The peritoneal cavity is irrigated with warm saline. The peritoneum and posterior rectus sheath and anterior rectus sheath are closed with continuous 3-0 sutures. The skin is closed with 5-0 subcuticular Monocryl. No drainage is required. When a laparoscopic approach has been used, the 5 mm umbilical wound should be sutured, but the 3 mm working ports do not need to be closed with sutures, and the risk of incisional hernia is low.

Postoperative instructions

A nasogastric tube is usually not necessary unless there has been severe obstruction or a prolonged ileus is anticipated. Oral fluids are resumed when the infant appears to be hungry and the abdomen is becoming soft to palpation.

Inguinal hernia

THAMBIPILLAI SRI PARAN AND PREM PURI

INTRODUCTION

Inguinal hernia is one of the most common surgical conditions in infancy, with a peak incidence during the first three months of life. The diagnosis of inguinal hernia is made with increasing frequency in newborns; this period carries a particularly high risk of incarceration. The incidence of hernia is much higher in premature infants who survive in increasing numbers after sophisticated intensive care management. As a consequence, more and more indications for early surgical repair are proposed in a population in which there are additional surgical and anesthetic risks.

ETIOLOGY

Direct hernia is exceedingly rare at this age[1] and practically all congenital indirect inguinal herniae develop because the processus vaginalis remains patent after birth. This processus is an outpouching of the peritoneum through the inguinal canal that is first seen during the third month of intrauterine life. It accompanies the gubernaculum and the testis during their descent through the inguinal canal and reaches the scrotum by the seventh month of gestation. In the female, the processus extends along the round ligament. Obliteration of the processus vaginalis commences soon after the descent of the testis is completed and continues after birth. Most infants have a patent processus vaginalis several months after birth. Patency has been reported to be 80–94% in the newborn period, 57% in the 4–12-month age group, and 20% in adulthood;[2] this patency is not equivalent to an inguinal hernia and most often has no clinical relevance.

EPIDEMIOLOGY

The incidence of congenital indirect inguinal hernia in full-term neonates is 3.5–5%.[3] The incidence of inguinal hernia in preterm infants is considerably higher and ranges from 9 to 11%.[4] The incidence approaches 60% as birth weight decreases from 500 to 750 g.[2] Inguinal hernia is more common in males than in females. Most series report a male preponderance over females ranging from 5:1 to 10:1.[5] Of all inguinal hernias, 60% occur on the right side, 25–30% on the left, and 10–15% are bilateral.[2,6] Bilateral hernias are more common in premature infants and are reported to occur in 44–55% of patients.[4,7,8] The reported risk of a metachronous contralateral hernia is 7–10%.[9–12] There is a higher familial incidence and inguinal hernia has been observed with increasing frequence in twins and siblings of patients.[13] There is no geographic or racial predominance reported in the literature.

ASSOCIATED CONDITIONS

There is an increased incidence of inguinal hernia in patients with the following conditions:

- Undescended testis
- Ventriculoperitoneal shunts[14,15]
- Peritoneal dialysis[16,17]
- Cystic fibrosis
- Increased abdominal pressure[18] secondary to meconium ileus, necrotizing enterocolitis, chylous ascites, tight closure of gastroschisis, omphalocele
- Bladder exstrophy[19,20]
- Connective tissue disorders, such as cutis laxa,[21] Ehlers–Danlos and Marfan syndromes, or Hurler–Hunter mucopolysaccharidoses.[22]

CLINICAL FEATURES

Inguinoscrotal hernia can be diagnosed prenatally by ultrasonographic screening.[23] In the newborn, the presenting feature is a bulge in the groin which increases in size with

crying and which is usually noticed by the mother. This bulge may disappear spontaneously when the patient is quiet and relaxed but sometimes it remains visible and palpable for hours causing crying, obvious discomfort, and sometimes vomiting. When the lump in the groin is reduced, it is usually possible to feel thickening of the structures of the cord due to a hernial sac. A reliable clinical history along with palpation of a thickened cord is highly suggestive of inguinal hernia. In girls, the lump intermittently felt in the groin is usually less obvious and often a tender, non-reducible, ovoid-shaped mass corresponding to the ovary slided within the sac can be palpated.

Some premature infants with previous apneic episodes stopped having them after inguinal hernia repair. The obvious interpretation is that there can be some association between both clinical conditions.[24]

Although this eventuality is exceedingly rare, acute inflammation of the appendix within the hernial sac has been reported in premature and full-term newborns.[25–28]

INCARCERATED INGUINAL HERNIA

Incarceration occurs when the contents of the sac is blocked at its neck and cannot be easily reduced into the abdominal cavity. Strangulation occurs when there is vascular compromise of the contents of the sac because of the persistent constriction at its neck. The contents of the hernial sac may consist of small bowel, appendix, omentum, or ovary and Fallopian tube. If there is delay in treatment, incarceration rapidly progresses to strangulation and can lead to intestinal necrosis and even fecal fistula.[29]

The incidence of incarceration in neonates and young infants is reported to vary between 24 and 40%.[3,30,31] The incarceration rate is much higher in premature infants compared with full-term infants.

Testicular infarction has been reported in up to 30% of infants younger than three months of age with incarcerated inguinal hernia[32] and testicular atrophy following emergency operation for incarceration ranges between 10 and 15%. However, testicular volume in a group of children who had incarcerated inguinal hernia reduced by taxis during infancy and subsequently had elective herniotomy was not significantly different from age-matched controls, suggesting that this risk has been overemphasized.[30] Ovarian infarction is also possible after incarceration in females[4] and vaginal bleeding has been reported in an infant after uterine incarceration in the hernial sac.[33] The risks of gonadal damage when the slided ovary cannot be reduced justify the fact that most surgeons advise prompt operation in these cases.[34]

DIAGNOSIS

A newborn with incarcerated inguinal hernia usually presents with irritability, vomiting, a moderately distended abdomen, and a tender groin lump (Fig. 65.1). Occasionally, the infant may pass blood per rectum. Local examination reveals a tense, tender lump in the groin, the upper margin of which is not well defined. The homolateral testis may be normal or swollen and hard due to vascular compromise. Rectal examination usually is not necessary but, if done, the contents of the hernia can be palpated at the internal ring.

Figure 65.1 Large incarcerated right inguinal hernia in a 1-day-old infant. The hernia was reduced by taxis and herniotomy performed 2 days later.

The diagnosis of incarcerated inguinal hernia is usually made on clinical grounds. Abdominal x-rays may occasionally show bowel gas within the lump in the groin and confirm the diagnosis (Fig. 65.2). If intestinal obstruction is present,

Figure 65.2 Supine abdominal film in a 10-day-old infant who presented with an irreducible lump in the right groin shows distended bowel loops extending into the right inguinal hernia.

plain abdominal films will show dilated loops of bowel with fluid levels. Ultrasonography can help diagnosis in some cases.[35]

DIFFERENTIAL DIAGNOSIS

Clinical diagnosis of incarcerated inguinal hernia is usually easy but it may be difficult to differentiate from the following conditions.

Hydrocele

It is possible to get above the swelling, which is non-tender. Transillumination is not a reliable sign in infants, as bowel can be transilluminant because of its thin wall.

Hydrocele of the cord or cyst of canal of Nuck is difficult to differentiate from incarcerated hernia. There is no previous history of reducible groin lump in these patients. Since the lower half of the abdomen is accessible to digital palpation through the rectum, rectal examination may be useful in excluding incarcerated hernia.

Inguinal lymphadenitis

The examination of the area of drainage will most often reveal the source of infection. The cord and testes are found to be normal.

Torsion of the testes

In a scrotal testicular torsion, it is possible to get above the swelling. The testis is tender and slightly higher than on the other side, while the torsion of the testes, which is situated in the superficial inguinal pouch, will be associated with an empty scrotum on the same side.

MANAGEMENT OF INGUINAL HERNIA

The treatment of inguinal hernia is surgery and, in our opinion, there is no place for the use of trusses or other so-called conservative procedures, even in low birth weight (LBW) infants.[36] The ideal time for surgery is as soon as possible after the diagnosis has been made not only because of the high risk of incarceration[37] but also because it has been shown that comfort and weight gain of premature infants with inguinal hernias improve after repair.[38] Nowadays, most inguinal hernia operations are done as day-case procedures,[34] although premature infants and children with cardiac, respiratory, or other conditions have an increased risk of anesthetic complications. However, most authors consider it reasonably safe to operate on these patients on a day-case basis.[39,40]

ANESTHESIA

General anesthesia with endotracheal intubation is preferred in small infants. Premature infants undergoing surgery have an increased risk of life-threatening postoperative apnea.[41] The use of spinal anesthesia in LBW infants undergoing inguinal hernia repair is associated with a lower incidence of postoperative apnea.[42,43]

OPERATION

Inguinal herniotomy is the procedure employed in the treatment of congenital persistence of processus vaginalis. The operation consists of simple ligation of the hernial sac without opening the external ring.

Position

The infant is placed in the supine position on a heating blanket.

Incision

A 1.5 cm transverse inguinal skin crease incision is placed above and lateral to the pubic tubercle (Fig. 65.3a).

Exposure of external ring

Hemostats are placed on subcutaneous tissue, which is cut or spread until the cord is seen to emerge from the external ring (Fig. 65.3b,c).

Separation of sac

The external spermatic fascia and cremaster are separated along the length of the cord by blunt dissection. The hernial sac is seen and gently separated from the vas and vessels (Fig. 65.3e). A hemostat is placed on the fundus of the sac.

Herniotomy

The sac is twisted so as to reduce its content into the abdominal cavity. The spoon can be used to keep vas and vessels away from the neck of the sac. The sac is transfixed with a 4-0 stitch at the level of internal ring, which is marked by an extraperitoneal pad of fat (Fig. 65.3b). The part of the sac beyond the stitch is usually excised, but there are no obvious advantages of removing the distal part of the sac after its division and closure, particularly if there is complete persistence of the peritoneovaginal duct, and therefore the operation should remain as simple as possible.[44] In girls, the operation is even more straightforward since there is no risk

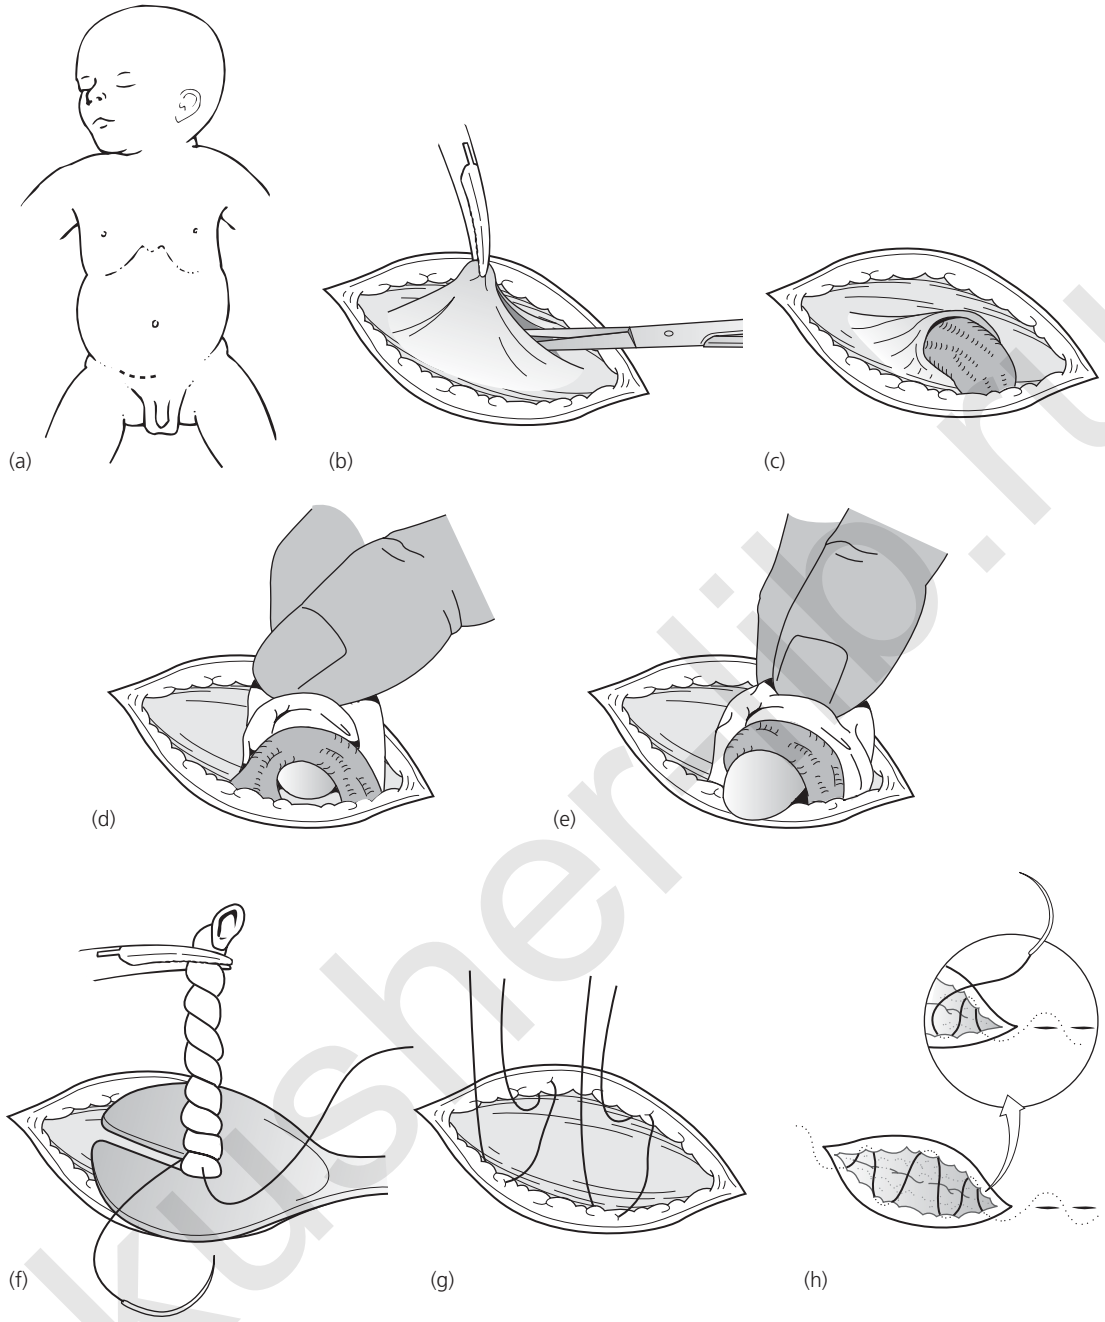

Figure 65.3 (a) Skin incision. (b,c) Exposure of external inguinal ring. (d) Isolation of the spermatic cord. (e) Separation of the hernial sac. (f) Transfixation of the hernial sac. (g) Closure of subcutaneous tissue. (h) Subcuticular closure of skin.

for the vas or the vessels and the external orifice can be closed after excising the sac.

Closure

Subcutaneous tissues are approximated using two or three 4-0 absorbable interrupted stitches (Fig. 65.3g) and the skin is closed with a 5-0 absorbable continuous subcuticular suture (Fig. 65.3h). A recent alternative is the use of cyanoacrylate adhesives for approximating the skin edges. A small dressing can be applied over the wound if necessary. At the end of the operation, the testis, always tractioned upwards during operative maneuvers, must be routinely pulled back into the scrotum to avoid iatrogenic ascent.[45]

Laparoscopic inguinal hernia repair

Laparoscopic hernia repair in infancy is still debatable. There are many techniques available for laparoscopic repair of inguinal hernia in infants. In recent years, several authors have reported that laparoscopic hernia repair in infants is feasible, safe, and effective.[46–49] However, it is associated with long operative time and higher recurrence rate compared to open herniotomy.

Contralateral exploration

Contralateral exploration is often performed in premature babies because of the high incidence of bilateral hernia in them, which ranges from 44 to 55% according to different authors.[4,7,8] Otherwise, contralateral exploration is not necessary as only around 10% of these children will subsequently proceed to develop a clinically apparent inguinal hernia on the other side.[10–12]

POSTOPERATIVE MANAGEMENT

Adequate postoperative analgesia is achieved by regional anesthesia, ilio-inguinal and ilio-hypogastric nerve block, which is administered either before or at the end of operation. Feeding is resumed as soon as the infant is awake. Most patients can be discharged home the same day. Postoperative apnea is a well-known risk of inguinal hernia operation in premature infants.[50] Although most episodes of postoperative apnea in these babies occur in the first 4 hours following the end of the procedure,[51] they are often admitted for 24 hours for observation in order to prevent this complication.[52] Postoperative apnea is inversely correlated with gestational and postconceptual ages[53] but absolute weight at operation and previous respiratory dysfunction are apparently the best independent variables to be correlated with such risks.[54]

MANAGEMENT OF INCARCERATED HERNIA

In a stable patient, there is no doubt that the preferred treatment for incarcerated hernia is reduction. This policy of non-operative reduction is based on the following facts: the likelihood of reducing strangulated bowel in infants is extremely rare and the complication rates are higher with emergency operations for irreducible hernia.[55]

The infant is placed in the Trendelenburg position, which helps to relieve the edema and allows mild traction of the hernial contents. Adequate sedation is given to the infant so as to relax the abdominal muscles. If the hernia is not reduced within 1 hour with these measures, an attempt is made to reduce it with gentle taxis, where constant gentle pressure is applied on the fundus of the sac in the direction of the cord. The vast majority of incarcerated hernias reduce with these non-operative techniques. After the hernia is reduced, the infant is kept in the hospital and observed. Elective operation is carried out after 24–48 hours, when edema and swelling have subsided.

Operative management

Failure to reduce the hernia and strangulation are indications for emergency operation. In girls, when the ovary is non-reducible, at least half of the surgeons in a recent US survey advise emergency operation.[34]

Preoperative support

Infants need to be stabilized prior to surgery. Nasogastric suction and correction of fluid and electrolyte imbalance are undertaken, and antibiotics are given, but this period should be kept to a minimum.

Operation

The patient is anesthetized. If the hernia is spontaneously reduced, the sac is opened and the intestine inspected. Herniotomy is performed if there is no evidence of intestinal ischemia. The bowel should be examined through the same incision or through right lower quadrant laparotomy on suspicion of reduction of non-viable bowel, as indicated by blood-stained fluid in the sac or if blue bowel is seen in the abdomen through the opened sac.

If the bowel does not reduce spontaneously when the patient is anesthetized, no attempts are made to reduce the hernia. The sac is opened and the contents are examined. If the bowel is viable, it is reduced. In case of difficulty in reducing the contents, the internal ring is either dilated or split superiorly. On the other hand, if viability of the bowel is questionable, it is delivered out and warm saline soaks are applied. The intestine is examined after 5–10 minutes. If its color returns to normal with adequate perfusion, peristalsis is visible and mesenteric arterial pulsations are seen, the intestine is returned to the abdomen and herniotomy is completed. If the bowel is nonviable, resection and anastomosis are performed, either through the same incision or through laparotomy. Testes are put in the scrotum irrespective of whether they are normal or ischemic. Only frankly necrotic gonads may be removed.

Postoperative care

If resection and anastomosis are carried out, nasogastric aspiration and i.v. fluids are continued in the infant until peristalsis returns and feeds are established. Antibiotics are continued for 5 days.

COMPLICATIONS

The overall complication rates after elective hernia repair are low at about 2%,[56] while these are increased to 8–33% for the incarcerated hernias requiring emergency operations.[4,55]

Complications of inguinal hernia repair include:

- Hematoma – can be avoided with meticulous attention to hemostasis. It is rarely necessary to evacuate wound, cord, or scrotal hematoma.
- Wound infection – low risk and should not exceed 1%.[3,57,58]
- Gonadal complications – occur due to compression of the vessels by incarcerated viscera. Though large numbers of testes look non-viable in patients with incarcerated hernia, the actual incidence of testicular atrophy is low[30] and

therefore, unless the testis is frankly necrotic, it should not be removed.

- Intestinal resection. This is necessary in about 3–7% of patients in whom the hernia is not reduced and it may cause some additional morbidity corresponding to resection itself and contamination of the field.[4]
- Iatrogenic ascent of the testes. This event is relatively rare since only slightly more than 1% of patients operated upon for inguinal hernia during infancy subsequently required orchidopexy.[45] This complication is probably due to entrapment of the testis in the scar tissue or failure to pull it down into the scrotum at the end of the operation and to maintain it there.
- Recurrence. The acceptable recurrence rate for inguinal hernia repair is less than 1%[56] but when operation is performed in the neonatal period this complication can occur in up to 8%.[58] The factors which predispose to recurrence are ventriculoperitoneal shunts, sliding hernia, incarceration, and connective tissue disorders.[59] Recurrence may be indirect or direct. Indirect recurrence is due to either failure to ligate the sac at high level, tearing of a friable sac, a slipped ligature at the neck of the sac, missed sac, or wound infection. Direct hernia may be due to inherent muscle weakness or injury to the posterior wall of the inguinal canal.
- Mortality. In a present-day situation, the mortality rate of inguinal hernia operation should be zero.

Short bowel syndrome and surgical techniques for the baby with short intestines

MICHAEL E HÖLLWARTH

INTRODUCTION

The short bowel syndrome (SBS) in term neonates was defined by Rickham, in 1967, as an extensive resection of all but a maximum of 75 cm of the small gut.[1] This corresponds to 30% of the total jejuno-ileal length in term newborns. SBS in premature newborns also corresponds to 30% of the calculated intestinal length for the given gestational age.[2]

In the past, extensive loss of small bowel in newborns and babies used to be a catastrophic event nearly always followed by malnutrition and death. Reviewing the literature in 1965, Küffer found only nine surviving children with SBS.[3] In 1972, Wilmore reviewed 50 babies younger than two months with SBS and found survival was possible with 15 cm jejuno-ileum with the ileocecal valve, or with 38 cm jejuno-ileum without the ileocecal valve.[4] Recently, Dorney and colleagues reported that long-term nutritional support today allows survival in infants with as little as 11 cm of jejuno-ileum with the ileocecal valve (5% of the total), or with 25 cm of jejuno-ileum without the ileocecal valve (10% of the total).[5]

Intestinal adaptation is the term which characterizes the pathophysiology that follows intensive intestinal resection, and by which more than 80% of the babies with SBS do finally reach a normal life with entirely oral nutrition. Adaptation is characterized by an early increase of blood flow to the intestinal remnants[6] and by long-term stimulation of intestinal growth which enormously enlarges the absorptive surface area.[7] The latter includes an increase of villus height, crypt depth, intestinal length, intestinal thickness, and intestinal diameter. Additionally, water and solute absorption is enhanced in the colon, and colonic bacteria ferment undigested carbohydrates and proteins into short-chain fatty acids, which act as important energy providers and apparently, as additional promoters of adaptation.[8,9]

The precise mechanisms of adaptation are not clear, but intraluminal nutrients and endogenous intestinal secretions stimulate growth.[10–12] Recently it has been shown that ω-3 fatty acids from fish oil have a beneficial effect on liver function and ameliorate parenteral nutrition associated liver disease.[13] In general, the higher the workload required for digestion and absorption, the more potent is the stimulus for adaptation. In response to the nutrients and secretions, a large number of trophic polypeptides and other mediators are secreted. Over the years, some of them have attracted attention regarding their possible clinical value in promoting adaptation in SBS patients. First, gastrin was demonstrated to exhibit trophic effects on the small bowel.[14] Later, enteroglucagon was shown to stimulate the adaptive response on the intestinal tract in animal experiments and humans.[15] Since monoclonal antibodies failed to block this trophic effect, recently precursors of enteroglucagon are considered to be responsible for the intestinal effects. Glucagon-like peptide-2 is a trophic hormone that has an important role in controlling intestinal adaptation.[16,17] Human growth hormone (GH) in combination with epidermal growth factor, or with insulin-like growth factor-1 (IGF-I) have also been shown to regulate small intestinal growth and adaptation.[18–22] IGF-I receptors have been identified in all segments of the gastrointestinal tract, and IGF-I stimulates DNA and RNA synthesis and cellular amino acid uptake.[23] The endogenous GH-IGF-I system is an important regulator of small intestinal growth and adaptation.[21] Among the amino acids, glutamine (GL) plays an important role in the maintenance of intestinal structure and function by providing the energy required by cells with a rapid turnover, such as macrophages and enterocytes. Patients after major trauma or in chronic catabolic states benefit from GL supplementation.[24] In addition, Ziegler *et al.* have shown that human growth hormone increases glutamine uptake after intestinal resection, supporting the evidence that glutamine exerts trophic effects in the small intestine and the colon of patients with SBS.[19,25] More research however is needed, since studies by Vanderhoof *et al.* could not confirm a role for GL or GH as trophic agents for the intestinal tract.[26] Prostaglandin (Pg) E2 and polyamines have also been shown to stimulate cell

proliferation in animal experiments by increasing blood flow and DNA synthesis.[27,28] Experimental evidence exists that testosterone enhances adaptation after small bowel resection in cats.[29]

Within one year in more than 80% of the patients, adequate intestinal adaptation occurs and they can be weaned off parenteral nutritional support.[30,31] However, this process can cause significant embarrassment and psychological stress to the child and their family, as well as complications such as septicemia, cholecystitis, and chronic liver fibrosis.[32] Therefore, the ability to reliably predict whether a patient has the potential to be weaned from parenteral nutrition has gained significant attention. Citrulline is a free amino acid in plasma and is produced by the metabolism of glutamine and proline in small bowel enterocytes. It has been shown that plasma estimations of citrulline correlate well with the bowel length in children and adults and can be used as a predictor of whether weaning from parenteral nutrition will be possible or not.[33,34] The cut-off point distiniguishing children who reach independence of parenteral nutrition seems to be 15 μmol/L.[34]

While intestinal transplantation has still limited clinical applicability with long-term survivors, ongoing interest exists in surgical methods to enhance nutrient absorption. This chapter reviews current surgical techniques for patients with SBS, with special emphasis on their clinical applicability.

SURGICAL TACTICS IN SITUATIONS REQUIRING EXTENSIVE INTESTINAL RESECTION

Malformations, such as multiple intestinal atresias or gastroschisis with atresia can cause a congenital SBS in the newborn. Acquired conditions, such as intestinal strangulation by midgut volvulus or necrotizing enterocolitis, may require extensive intestinal resection. For patients at risk of SBS, surgery must be adapted to preserve as much small bowel as possible.

In intestinal atresias, dilated intestinal loops should be preserved instead of resected in the usual way. In volvulus, second-look procedures can help the surgeon decide which parts of the intestine are definitely lost. In extensive necrotizing enterocolitis, intestinal loops of questionable viability should be decompressed by an enterostomy, not resected. The ileum is more important than the jejunum, since it is the site of vitamin B_{12} and bile acid absorption. Also, the ileum has a much greater capacity for intestinal adaptation. When resection has been completed, the remaining jejunum and ileum should be measured from the ligament of Treitz all the way down to the ileocecal valve, with a thread laid along the antimesenteric border. Intestinal loops shrink considerably during manipulations, and the real intestinal length is difficult to measure *in vivo*. This may be one reason that survival does not seem strictly related to the length of the remaining bowel.

SURGICAL TECHNIQUES IN PATIENTS WITH SBS

General agreement exists that the therapeutic priorities in patients with SBS consist of the stabilization of patients' conditions, the evaluation of the adaptive capacities of the intestinal remnants, and the clarification of patients' special needs. Therefore, the primary surgical aim is restoration of the bowel continuity as soon as possible in order to allow all remaining intestinal segments to take part in the adaptation process. Additional surgical strategies come into play only if:

- the absorptive area is definitely too small to allow enteral feeding;
- dysmotility in grossly dilated loops entails stagnation of chyme;
- intestinal transit is too fast to allow sufficient absorption of nutrients (Table 66.1).

Intestinal transplantation (TPX) is, of course, the most effective method to increase the intestinal absorptive area immediately. Indications for TPX are patients after a catastrophic abdominal event with little or no small bowel remaining, and patients with SBS and irreversible liver failure due to progressive total parenteral nutrition-associated hepatic dysfunction. Until recently, the results of intestinal TPX had been poor, mainly due to a high rejection rate. With the introduction of new immunosuppressive drugs, such as tacrolism and OKT3, in addition to steroids, significant progress has been achieved with a one-year transplant survival rate approaching 75% in recent series. However, the adverse effects including lymphoproliferative diseases related to Epstein–Barr virus infections are reaching an incidence of 20%, and therefore much progress is still needed before transplantation can be recommended as a routine treatment replacing long-term home parenteral nutrition in a larger number of patients with SBS.[35–37]

Augmentation of the absorptive surface area has been attempted – almost exclusively in animal experiments – by autologous mucosal transplantation into demucosized intestinal loops and by patching surgically created intestinal defects with adjacent serosal surfaces which causes new intestinal mucosa to grow over the exposed serosal surface.[38–40] Digestive and absorptive function of this neomucosa is considerably lower compared to native mucosa and clinical experience with intestinal patching has not been reported.[41,42]

Therefore, current surgical procedures usually support only one or two of the above factors. The predominant problem in a given patient has to be evaluated carefully to choose the method most likely to enhance the absorptive capacity of the intestinal remnants. General agreement exists

Table 66.1 Surgical strategies in patients with short bowel syndrome.

To increase passage time	To increase absorptive surface area	To improve peristalsis
Antiperistaltic segment	Serosa patching	Tapering
Colon interposition	Mucosa transplantation	Tapering and lengthening
Intestinal valves	Small bowel intestinal transplantation	
Artificial invagination		

that most of such techniques are not indicated as a primary procedure. The priorities are: (1) stabilization of the patient's condition, (2) evaluation of the adaptive capacity of the intestinal remnants, and (3) clarification of the patient's special needs.

INEFFICIENT PERISTALSIS

Tapering

In a newborn with multiple intestinal atresias resulting in SBS, bowel which is congenitally enlarged due to chronic obstruction should be preserved. However, the low contraction pressure in such bowel segments results in inefficient to-and-fro peristalsis, easily demonstrated by radiological studies. Inefficient peristalsis can lead to stasis of the chyme, symptoms of obstruction, and a contaminated bowel syndrome caused by bacterial overgrowth. Tapering of dilated loops can be accomplished by a triangular resection of an antimesenteric segment (Fig. 66.1). The disadvantage of this type of tapering is that it reduces the available intestinal surface area. Thus, the technique can be recommended only for patients with sufficient intestinal length and absorptive area in whom inadequate peristalsis is the main problem.

Tapering can also be accomplished simply by turning in the redundant tissue (Fig. 66.1). This technique avoids reduction of intestinal surface area and results in normal bowel function.[43–45] Whichever method is used, effective and propulsive peristalsis takes at least 3 weeks to return.

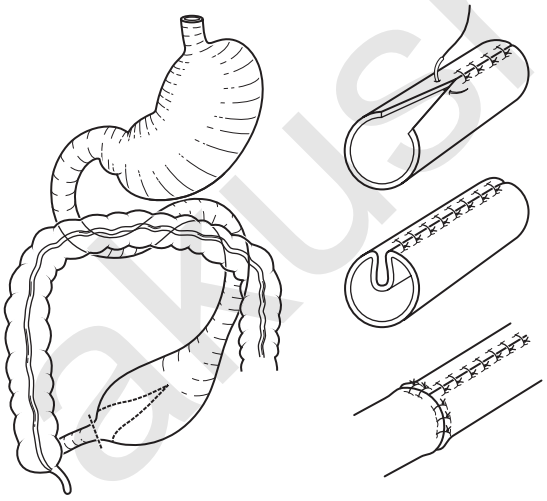

Figure 66.1 Tapering can be performed either by resection of a triangular antimesenteric segment or by turning in the redundant tissue. The latter method saves all the available resorptive surface area.

Tapering and lengthening

In 1980, Bianchi reported an experimental procedure combining the tapering of dilated loops with use of the redundant tissue for lengthening the bowel.[46] Anatomically, the mesenteric vessels from the last parallel arcade divide into anterior and posterior branches entering the bowel from either side of the midline. Especially in dilated segments, a relatively broad avascular plane in the midline can be used to separate the vascular layers. Longitudinal division of the bowel can be accomplished this way, while preserving sufficient nutrient vessels to either half of the intestine. Longitudinal closure of each intestinal segment and isoperistaltic end-to-end anastomosis doubles the intestinal length of this segment.

Bianchi in his experimental reports and Boeckmann and Traylor in the first clinical report used a GIA stapler to divide the intestinal parts.[47,48] Although the procedure using the GIA stapler is fast, it produces two rigid intestinal segments and consumes absorptive surface area. Aigrain *et al.* recommended division with scissors and a manually sutured anastomosis.[49] Seromuscular stitches guarantee a maximum of preserved mucosa (Fig. 66.2a). Since both sections of the bowel hang on the same mesenteric segment, a helix-like isoperistaltic anastomosis is easier to perform than an anastomosis with the two segments sliding one on the other. The helix technique avoids traction on the nutrient vessels, which is critical because necrosis of the divided segments has been reported (Fig. 66.2b).[50] Recent experimental studies in dogs showed that intestinal tapering and lengthening may impair nutritional status as well as intestinal adaptation and absorption.[51]

Bianchi's method has been used in more than 50 infants. Necrosis of half of the segments occurred in only one baby.[50] In some of these infants, the primary length of the intestinal segments was as long as 40–80 cm, which would question the indication of some of these procedures. According to Bianchi's own experience, the method has proved successful when performed not in newborns or the early phase of a short bowel problem, but in a later stage of the disease on so-called 'self selected survivors', i.e. patients in stable general conditions and free of severe complications, such as liver failure.[52] This statement can be confirmed by the author's experience with two SBS newborn babies with 15 cm and 20 cm small bowel remnants, no ileocecal valve, 40% of the normal colonic length. Although Bianchi's procedure was performed completely uneventfully and nearly doubled the intestinal length, both babies suffered from a poor peristalsis and died at the age of one year with progressive liver failure.

Another method of bowel tapering and elongation has been published by Kimura. This procedure consists of an initial coaptation of the small bowel remnant to a host organ (liver, abdominal wall) and, after collaterals have been developed, a secondary longitudinal split of the bowel is done to provide two loops, one from its antimesenteric half and the other from its mesenteric half. This procedure has been successfully used in two infants.[53,54]

A recently published procedure which can be used in cases with insufficient peristalsis due to dilated intestinal loops and also as a lengthening procedure is the so-called STEP (serial transverse enteroplasty).[55,56] The refashioning of dilated intestinal loops is achieved by serial alternating and opposite transsections of one-third or half of the intestinal lumen creating a zigzag-like figure (Fig. 66.3). The method has the

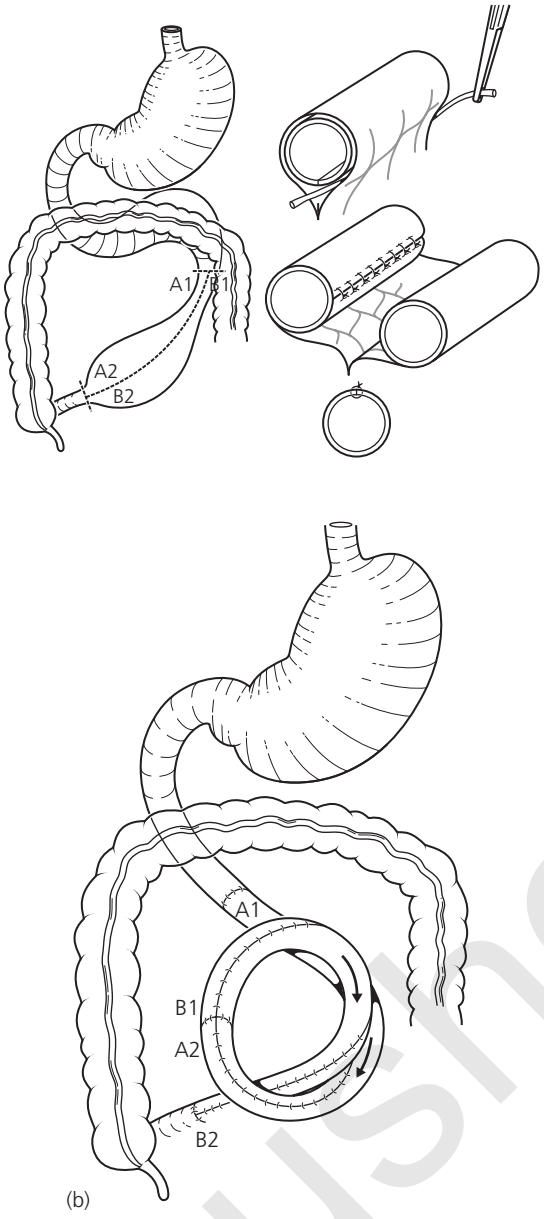

Figure 66.2 (a) Bianchi's tapering and lengthening is critical for the intestinal circulation. A Penrose drain facilitates the division of the segments. Seromuscular stitches save as much mucosal surface area as possible. (b) The helix-like arrangement of the two separated parts allows the anastomoses to be performed with minimal traction on the vessels.

advantage that it is technically much easier than Bianchi's procedure and the achieved lengthening is significantly longer. A retrospective analysis by a Canadian group for the improvement of intestinal function and treatment including 14 patients after a STEP procedure did not show significant differences when compared with an older group of patients except a lower mortality after liver failure, mainly as a consequence of an earlier referral and increased survival after transplant.[57] Long-term results including patients with comparable short bowel length are still unavailable, but the preliminary results in single patients are promising.

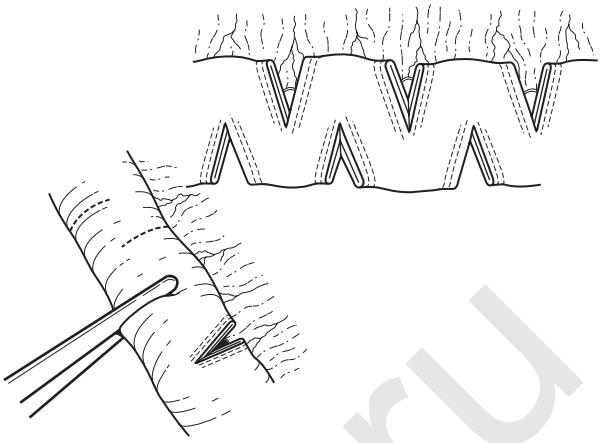

Figure 66.3 Serial transverse enteroplasty (STEP) consists of semicircular alternating incisions with the GIA stapler resulting in a zigzag-like elongation of the small bowel.

INADEQUATE INTESTINAL TRANSIT TIME

For a long time, the ileocecal valve was supposed to prolong intestinal transit time. Today, its beneficial role in patients with SBS has been challenged. A review by Dorney *et al.* showed that the presence of an intact ileocecal valve is crucial to survival of newborns after extensive loss of small bowel.[5] These findings have been confirmed by the author's experience: all babies with SBS and preserved ileocecal valve survived while all patients with fatal outcome did not have the valve.[58] In contrast, Coran *et al.*[59] and Kaufmann *et al.*[60] have not shown a difference in outcome of SBS patients with regard to the presence or absence of the valve. Furthermore, experimental evidence exists that bacterial translocation in SBS rats without ileocecal valve is significantly lower when compared to animals with preserved ileocecal valve.[61,62] While definite evidence of a beneficial role of the ileocecal valve in SBS patients is lacking, nevertheless, the valve should be preserved whenever possible; and it probably plays a role with regard to the prolongation of the intestinal transit time. Recently, Kosloske and Jewell[63] published a technique of appendiceal interposition that allowed preservation of a very short ileal stump with the ileocecal valve.

Antiperistaltic small intestinal segment

Reversal of distal small bowel loops has been studied experimentally for years. Since Gibson and colleagues' original report of the use of reversal of small intestine in an adult,[64] this has been the most commonly used method for patients with SBS (Fig. 66.4). The antiperistaltic small bowel segment acts as a physiological valve by causing retrograde peristalsis; therefore, it should always be located at the end of the intestinal remnants. The ideal length of the reversed segment appears to be 10 cm in adults and 3 cm in infants.[30,64,65] This may explain why the method has not consistently resulted in clinical improvement.[64,66] In a three-month-old patient in the author's department, a 3 cm antiperistaltic segment (out of a total of 11 cm small bowel)

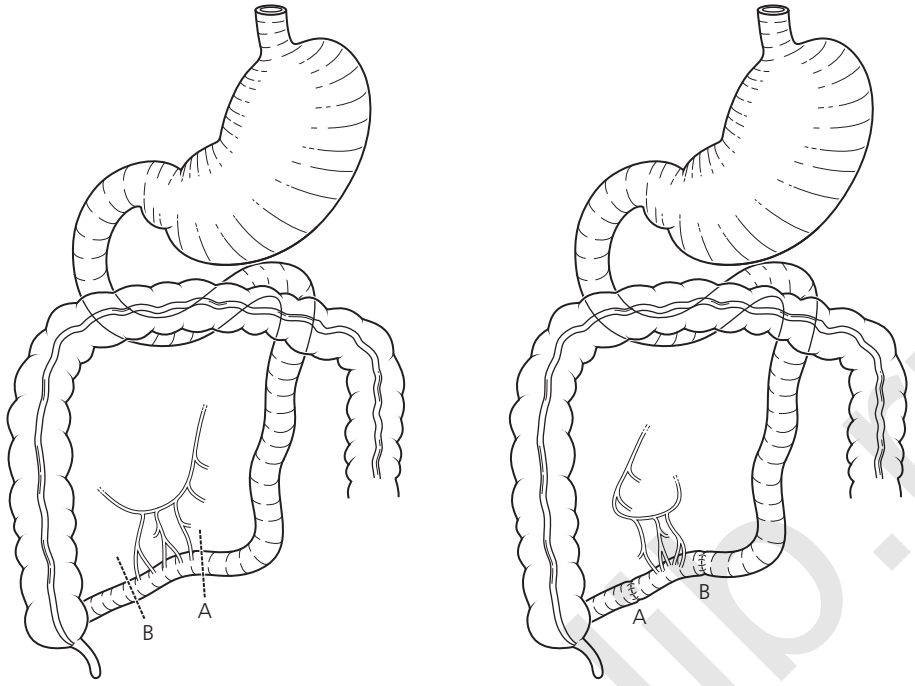

Figure 66.4 The antiperistaltic intestinal segment should be interposed close to the ileocecal valve or at the end of the small bowel. The optimal length in newborns is around 3 cm.

was helpful for intestinal adaptation. At four years of age, when the child was fed completely orally, the total radiological small bowel length had reached 1 m, with a swinging of the opaque meal at the probable location of the antiperistaltic segment.[30]

Colonic interposition

Isoperistaltic or antiperistaltic interposition of colon has the advantage of using none of the small intestinal remnants. The method was developed by Hutcher *et al.*[67,68]

The isoperistaltic segment should thus be interposed proximally either between the jejunum and ileum if the jejunal segment is short and the ileal segment long, or between the duodenum and jejunum if the latter is long and the ileum short (Fig. 66.5).[69] Isoperistaltic colonic interposition slows down the rate at which nutrients are delivered to the distal intestine by slowing peristaltic activity.[69] The optimal length of an interposed colon has not been defined. Glick *et al.*[70] used 10–15 cm-long segments in small babies, while Garcia and colleagues[71] used a 24 cm segment in a 14-month-old infant.

A reversed colonic interposition primarily causes a partial functional obstruction by delaying the emptying of the proximal bowel. It should therefore always be placed distally to the small bowel remnants.[69]

Besides the beneficial effect of slowing peristaltic activity, the interposed colonic segment increases the bowel length between the duodenum and cecum. Furthermore, colonic loops adapt to the function of the small bowel and can absorb water, electrolytes, and nutrients by active transport mechanism.[72] Experimental studies in rats have shown a significant increase in crypt depth, mucosal thickness, and maltase concentration of the interposed segment.[73]

Reported clinical results show that out of seven infants with isoperistaltic interposition four survived.[70,71] In two, the length of the intestinal remnants was not reported; in the other two they were 39 and 63 cm. An adult patient with 5 cm of jejunum and 7 cm of ileum after a midgut volvulus could be weaned from parenteral nutrition completely after interposition of an 18 cm-long isoperistaltic colon.[74] The sole reported infant with a reversed colonic interposition died.[75]

Recent experience in our department with proximal isoperistaltic colonic interposition and an additional distal STEP procedure in newborns with very short bowel, e.g. after gastroschisis with intrauterine volvulus and vanishing bowel, seems to be very promising.

Intestinal valves and pouches

As mentioned above under Inadequate intestinal transit time, while the benefits of the ileocecal junction on long-term outcome of babies with SBS has been questioned, there exists a large body of evidence as to its powerful impact on intestinal transit time by slowing the passage of intraluminal nutrients into the colon.[76] Therefore, a variety of experimental surgical procedures have been devised to slow down the intestinal transit time by creation of artificial valves. Constriction of the bowel by sutures and artificial sphincters,[77] mechanical or chemical denervation of segments,[66,78] and intussusception techniques have been studied extensively.[79–81] Clinical experience with intussuscepted valves is very limited. Waddell *et al.* performed a reversed intussusception of the colon into the jejunum in three adults, one of

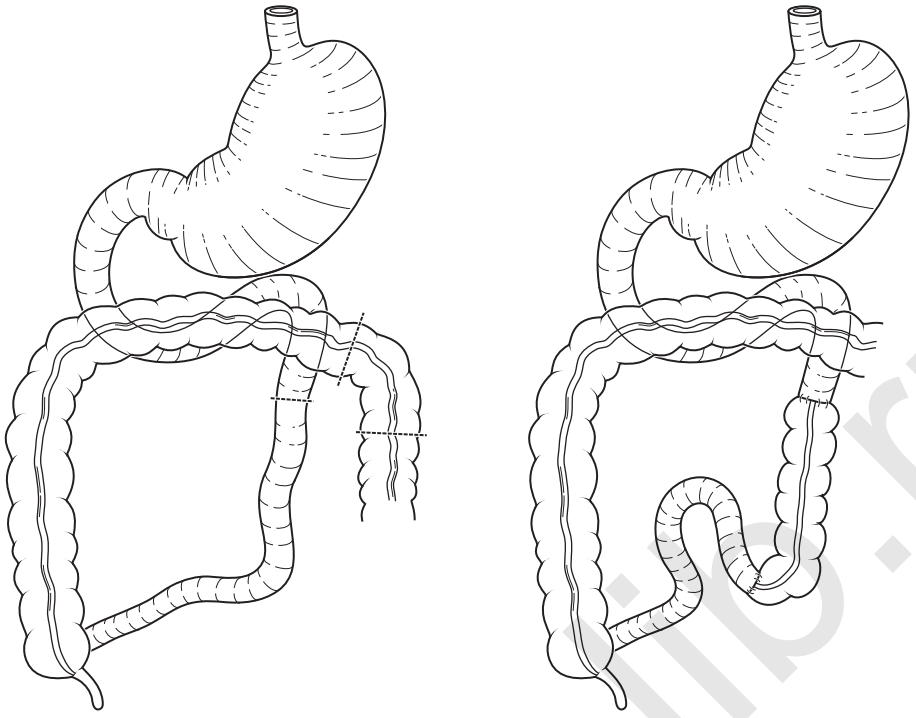

Figure 66.5 The isoperistaltic colonic interposition should be interposed proximally (while the reversed colonic interposition should be used distally). The length of an isoperistaltic interposition is recommended within 10–20 cm.

whom subsequently developed an obstruction.[82] Ricotta *et al.* constructed a 4 cm-long nipple-like ileocecal valve (Fig. 66.6) in a 15-year-old boy, which appeared to be helpful.[80] Cywes created a duodenojejunal pouch in a 21-month-old child who previously had 4 cm of jejunum reversed. The midsegment of the pouch acted as a reversed segment. While the transit time was prolonged at three months, late results were not encouraging.[40]

CONCLUSIONS

Despite the variety of surgical techniques designed to support intestinal adaptation after extensive loss of small bowel, none can be recommended unequivocally.[83,84] In the past, the overwhelming majority of babies with SBS have been treated exclusively by parenteral nutritional support until intestinal adaptation allowed entirely oral nutrition. Full enteral feeding has ultimately been attained in infants with originally as little as 15 cm of the small bowel with the ileocecal valve preserved, or 25 cm of jejuno-ileum when it was missing.[5,30,85] Survival rates of 75–83% are being reached in newborns, and 100% in children at or above two years of age.[55,86,87]

Surgery is indicated only in selected patients, either to achieve effective propulsive peristalsis or to prolong intestinal transit time. However, adjunctive surgical procedures should be postponed until the special needs of individual patients are evident. Approximately 10% will benefit from surgical interventions, either by prolongation of transit time or by remodeling parts of the intestine.[88]

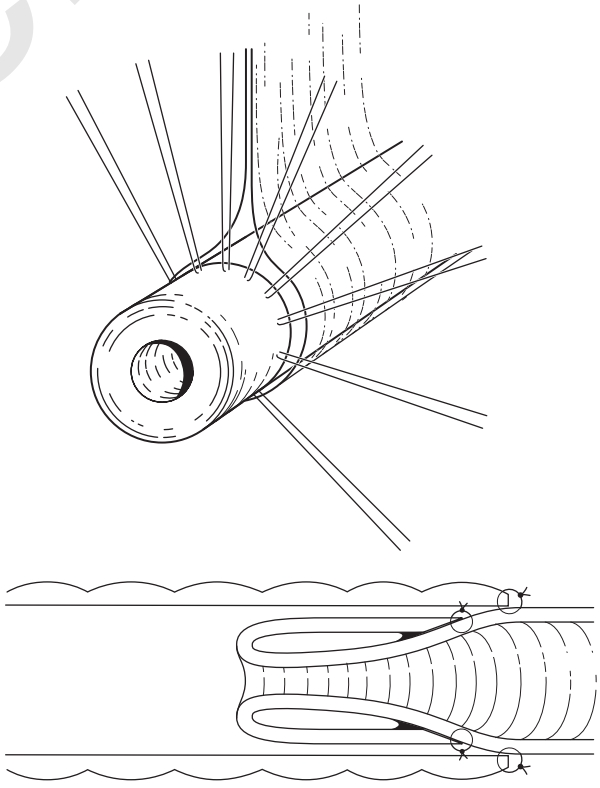

Figure 66.6 Nipple-like ileocecal valve according to Ricotta *et al.*[80] The optimal length in newborns is not defined, but will be around 1–2 cm. In a 15-year-old boy, a 4 cm-long valve worked well. Seromuscular stitches allow the precise adaptation of the mucosal layers.

Patients with total loss of small bowel or progressive liver failure may benefit from the progress made by intestinal TPX, although five-year survival rate does not lie much above 50%.[35] Survival rates after intestinal TPX as well as quality of life will hopefully significantly improve in the future. Most importantly, a reduction in adverse effects by finding new forms of immunosuppressive therapy in the future will be beneficial.

Megacystis microcolon intestinal hypoperistalsis syndrome

PREM PURI AND JAN-H GOSEMANN

INTRODUCTION

Megacystis microcolon intestinal hypoperistalsis syndrome (MMIHS) is a rare congenital and generally fatal cause of functional intestinal obstruction in the newborn. The main characteristics of this syndrome are abdominal distension, caused by a massive enlarged non-obstructed urinary bladder, microcolon, and decreased or absent intestinal peristalsis.[1] MMIHS is usually associated with incomplete intestinal rotation and shortened small bowel.

PATHOGENESIS

MMIHS was first described by Berdon *et al.* in 1976.[1] To date, over 220 cases have been reported in the literature.[2–25] Although several hypotheses have been proposed to explain the pathogenesis of MMIHS (genetic,[26–33] neurogenic,[29,30,34–41] myogenic,[42–45] and hormonal[39,46] origin), the etiology of this syndrome remains unclear.

In the majority of MMIHS patients, histologic studies of the myenteric and submucosal plexuses of the bowel revealed normal ganglion cells. In some patients, decreased amounts of ganglion cells or hyperganglionosis together with giant ganglia were found.[29] In 1983, Puri *et al.* showed vacuolar degenerative changes in the smooth muscle cells (SMCs) with abundant connective tissue between muscle cells in bowel and bladder of patients with MMIHS.[44] This led to the suggestion that a degenerative disease of SMCs could be the cause of this syndrome. Several subsequent reports have confirmed evidence of intestinal myopathy in MMIHS.[42,43,45]

More recently, Piotrowska *et al.* reported absence of interstitial cells of Cajal (ICCs) in bowel and urinary bladder of patients with MMIHS.[43,47] ICCs are pacemaker cells which facilitate active propagation of electrical events and neurotransmission. Their absence may result in hypoperistalsis and voiding dysfunction in MMIHS.

Furthermore, absence or marked reduction in α-smooth muscle actin and other contractile as well as cytoskeletal proteins in the smooth muscle layers of MMIHS bowel have been reported.[43,45] Contractile and cytoskeletal proteins are important structural and functional components of SMCs and play a vital role in the interaction of filaments in smooth muscle contraction.

Rolle and Puri showed pathological changes within the bladder smooth muscle cells and markedly increased collagen deposits within the bladder wall of MMIHS patients. The authors concluded that the detrusor muscle is strikingly abnormal and this is the likely cause of voiding dysfunction in the affected patients.[48]

Other studies support the hypothesis that the absence of a functional α3 subunit of the neuronal nicotinic acetylcholine receptor (ηAChR) is responsible for the predominant intestinal manifestation of smooth muscle myopathy, leading to manifestation of MMIHS.[16,49,50] This lack of functional alpha 3 and the absence of smooth muscle actin in the circular layer of small bowel muscularis was recently suggested to be associated with a *de novo* deletion of the proximal long arm of chromosome 15 (15q11.2).[51]

The occurrence of MMIHS in 19 sets of affected siblings together with consanguinity in four sets of parents, reported by Puri and Shinkai, suggests an autosomal recessive pattern of inheritance.[2,31,32,52]

PRENATAL DIAGNOSIS

One hundred and eighty-two cases of MMIHS reported in the literature were reviewed by Puri and Shinkai.[2] The most frequent finding reported on fetal sonography ($n = 54$) associated with MMIHS was enlarged bladder (88%) together with hydronephrosis (57%). In 59% of the fetuses, normal amniotic fluid volume was detected, whereas 33% revealed increased volume and 7% had decreased volume. Only 5%

showed abdominal distension caused by dilated stomach. Three cases (5%) of oligohydramnios during the second and early third trimesters were reported, which may probably be related to the functional bladder obstruction (Table 67.1).

Enlarged bladder, detectable from 16 weeks of gestational age, was shown to be the earliest finding in MMIHS in serial obstetrical ultrasonography (Fig. 67.1). A later finding is hydronephrosis, caused by the functional obstruction of the bladder. Usually polyhydramnios develops late, appearing during the third trimester.

Recent reports have described prenatal magnetic resonance imaging (MRI) in patients with suspected genitourinary and gastrointestinal tract abnormalities following ultrasound examination.[10,14,25] In contrast to sonography, MRI not only demonstrated urologic abnormalities but identified also early stages of gastrointestinal pathology. Hence, the authors advocate MRI as an ancillary imaging technique whenever routine ultrasonography screening demonstrates genitourinary pathology with need for further investigation.

CLINICAL PRESENTATION

Review of the current literature reveals that females are more affected in MMIHS than males (2.4:1 ratio).[2–25] With regard to the duration of pregnancy, 59% of the reported patients were born at term, 26% at 36–39 weeks of gestation, 12% at 32–35 weeks, and 3% at 31 weeks and less. In four of the cases, reviewed by Puri and Shinkai,[2] pregnancy was terminated after ultrasonography detected MMIHS. Eight cases of dystocis delivery due to abdominal distention were reported and Cesarean section was required in four cases.

In four cases, paracentesis was needed because the bladder was so distended that the baby could only be delivered vaginally after removal of 250, 500, 650, and 500 mL of urine, respectively, from fetal bladder.[39,44,53,54] The mean birth weight was found to be normal (3 kg) for gestational age.

Clinical symptoms of MMIHS are similar to other neonatal intestinal obstructions. Abdominal distension is a constant and early finding. It is a consequence of the enlarged, unobstructed urinary bladder with or without upper urinary tract dilatation. The majority of patients were not able to void spontaneously. However, a distended, non-obstructed urinary bladder could be easily relieved by catheterization. Of 182 infants, 61 had bilious vomiting and 23 failed to pass meconium.[2] Other symptoms include bile-stained vomiting and absent or decreased bowel sounds.

Nineteen sets of siblings affected with MMIHS have been reported to date. Eighteen families had two affected siblings and one had three. Four sets of affected siblings occurred to consanguineous parents (Table 67.2). In another case, an affected child was born to a member of the family reported by Penman and Lilford,[32] and consanguinity was also present in these parents. In three further cases, an elder sibling of the affected child died just after birth because of intestinal obstruction or multiple abnormalities. In another case, a sibling of the patient was affected by prune belly syndrome.[2]

Table 67.1 Prenatal ultrasound findings.

Ultrasound findings	%
Enlarged bladder	88
Hydronephrosis	57
Normal amniotic fluid volume	59
Increased amniotic fluid volume	33
Decreased amniotic fluid volume	7
Dilated stomach	5
Oligohydramnion (2nd, 3rd trimester)	5

Data from Puri and Shinkai.[2]

bowel loops or a gasless abdomen with evident gastric bubble in the vast majority of 182 reported cases.[2] An enlarged urinary bladder was present in all patients who had cystography or ultrasonography (Fig. 67.2). Vesicoureteral reflux was found in eight patients and in 84 patients i.v. urography or ultrasonography detected unilateral or bilateral hydronephrosis.[29,55–58]

Barium enema showed microcolon in all 71 patients in whom this study was performed and in 39 cases malrotation was associated (Fig. 67.3).

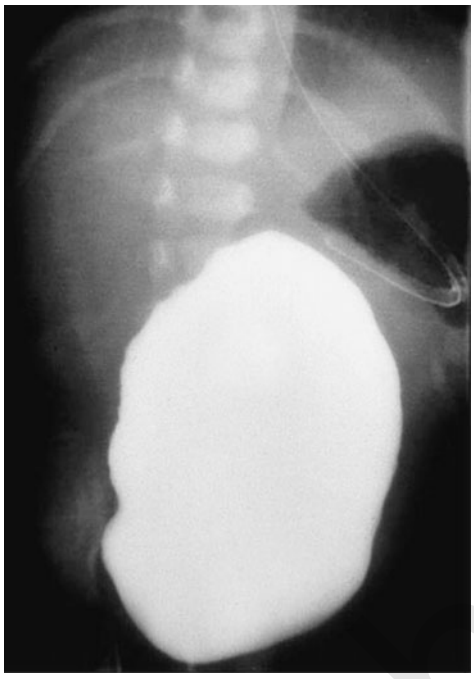

Figure 67.2 Voiding cysturethrogram showing massively enlarged bladder in a megacystis microcolon intestinal hypoperistalsis syndrome patient.

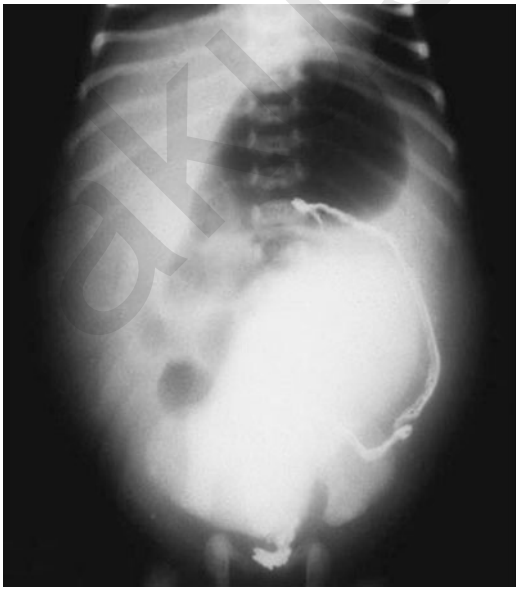

Figure 67.3 Contrast enema showing microcolon in a megacystis microcolon intestinal hypoperistalsis syndrome patient.

In patients who underwent an upper gastrointestinal series, both before and after laparotomy constantly revealed hypo- or aperistalsis in stomach, duodenum, and small bowel. Reverse peristalsis from small bowel into the stomach was observed in three cases, in two cases hypoperistalsis was associated with gastro-esophageal reflux and in one case the esophagus was aperistaltic.[2]

SURGICAL OR AUTOPSY FINDINGS

Megacystis and microcolon were the two most frequent findings at surgery or autopsy and were present in all patients (Fig. 67.4). Puri and Shinkai reported malrotation in a total of 81 cases.[2] Short bowel syndrome was found in 37 cases, dilated proximal small bowel in 19, segmental stenosis of the small bowel in 3, duodenal web in 1, and Meckel's diverticulum in 1.

Surgical management was not mentioned in several reports. Nevertheless, 70% of the reviewed patients underwent one or more surgical procedure. Various surgical interventions have been performed, such as gastrostomy, jejunostomy, ileostomy, cecostomy, segmental resections of jejunum and ileum, lysis of adhesions, and internal sphincter myectomy. In most patients, surgical manipulation of the gastrointestinal tract generally has been unsuccessful and in most patients total parenteral nutrition was required. Thirty-seven patients underwent vesicostomy to decompress the urinary tract and to preserve renal function.

HISTOLOGICAL FINDINGS

Histologic studies of the myenteric and submucosus plexuses were reported in 93 out of 182 cases. Ganglion cells were normal in appearance and number in 72 cases (77%). In the

Figure 67.4 Operative photograph of a massively dilated urinary bladder in megacystis microcolon intestinal hypoperistalsis syndrome.

remaining 21 cases (23%), various neuronal abnormalities included hypoganglionosis, hyperganglionosis, and immature ganglia.[2,30,37,38,40,41,46,59]

The majority of reports do not mention histologic findings in the muscle layers of bowel and bladder wall. However, some authors found significant abnormalities in SMCs, such as thinning of the longitudinal muscle, seen in light microscopy.[2]

Vacuolar degeneration in the center of the smooth muscle of bowel (11 cases) and bladder (eight cases) was shown in electron microscopy (Fig. 67.5). Furthermore, connective tissue proliferation was found in the bowel (nine cases) and bladder (eight cases). In three cases, the bladder showed elastosis. Electron microscopy revealed vacuolar degeneration of smooth cells in muscle layers of bowel and bladder in addition to neuronal abnormalities in two more patients.[2]

Other investigators have reported absence or marked reduction in α-smooth muscle actin and other contractile and cytoskeletal proteins in smooth muscle layers of MMIHS bowel.[43,45]

OUTCOME

Management of patients with MMIHS is frustrating. A number of prokinetic drugs and gastrointestinal hormones have been tried without success. Surgical manipulations of the gastrointestinal tract have generally been unsuccessful. The outcome of this condition remains generally fatal with a survival rate of 19.7%.[60] The majority of the surviving patients are maintained by total or partial parenteral nutrition.[2]

In the recent literature, 12 cases of multivisceral organ transplant are described with various outcomes. Long-term survivors (50% at three years post-transplant) are reported to be free from total parenteral nutrition and seem to show adequate gastric emptying via Mikulicz stomata.[11,12,16,17,20,21,24]

The decision for surgical intervention should be made carefully, individualized and in most cases restricted to supportive interventions (such as feeding enterostomy and decompressing ostomy), since most explorations have not been helpful and probably are not necessary.

Biliary atresia

MARK DAVENPORT

INTRODUCTION

There is still much to learn about biliary atresia (BA); why it happens and how it happens being good examples of areas where there is too much speculation and not enough hard evidence. What is only too obvious is that if it is untreated it progresses to end-stage cirrhosis and is potentially fatal within the first 12–18 months. A treatment strategy has evolved, which in the best hands will give a 90% chance of long-term survival for all infants born with the disease, but, even in these survivors there is still significant morbidity and problems to overcome. Nonetheless, it is compatible with normal life.

HISTORY

The first documented case of biliary atresia was reported in English in 1891 by John Thompson.[1] He was a physician in Edinburgh and his newborn patient developed jaundice, passed only white-colored stool from an early age and ultimately died of liver failure with ascites at about six months. Her post-mortem showed a normally formed but empty gallbladder and an absence of the common hepatic duct.

Further reports followed, but no real treatment could be offered until surgeons began to operate on some of these infants. The most significant series published was that of Ladd in 1928, who reported his experience in ten cases of surgical jaundice – some of which were BA.[2] Fairly quickly afterwards, it was realized that only a small proportion (having 'correctable' BA) were suitable as surgical candidates as at exploration a patent part of the biliary tree could be found and a hepaticojejunostomy performed. The remainder, those with 'uncorrectable' BA, had an entirely solid biliary tract, certainly nothing that could be anastomosed to.

An alternative operation for the latter group was advocated by Morio Kasai (1922–2008), a surgeon working in Sendai, Japan.[3] He showed that a higher, more radical dissection was needed and if the entire extrahepatic biliary tract was removed, then even if it looked solid, still it would contain microscopic biliary ductules which connect to the intrahepatic biliary tract. If enough of these were uncovered then bile flow could be restored. The reconstruction advocated was termed a portoenterostomy to reflect this higher level of anastomosis. Once again, this proved not to be the complete answer with unpredictable results and a significant proportion that showed no effect whatsoever. Such was the skepticism that its value was only really recognized in North America and Europe during the 1970s. Most post-Kasai adult series as a consequence are therefore Japanese,[4] with some rare exceptions.[5] The alternative, if yet more radical, treatment for a terminally damaged liver also appeared in the 1960s – liver transplantation. Tom Starzl's first, albeit unsuccessful, attempt at human liver transplant took place in 1963 in Denver, Colorado in a three-year-old girl with end-stage liver disease due to BA.[6] During that period, the science of immunosuppression was in its infancy and transplant programs shut down having failed to come to terms with inevitable cellular rejection. The key discovery in the 1980s was an effective immunosuppressive agent – cyclosporine – which allowed transplant programs to flourish once more. From the 1990s, in most of the developed world and still today, the strategy for management has been an attempt to resuscitate the native liver with a Kasai portoenterostomy and if that fails – transplantation.[7]

ETIOLOGICAL HETEROGENEITY

Biliary atresia is not one disease, certainly not one with a single cause (Fig. 68.1). In all probability it is a phenotype resulting from a number of different etiologies. Three, perhaps four, groups can be defined clinically:

1. isolated BA
2. biliary atresia splenic malformation (BASM) syndrome[8,9]
3. cystic BA[10]
4. cytomegalovirus-associated BA.

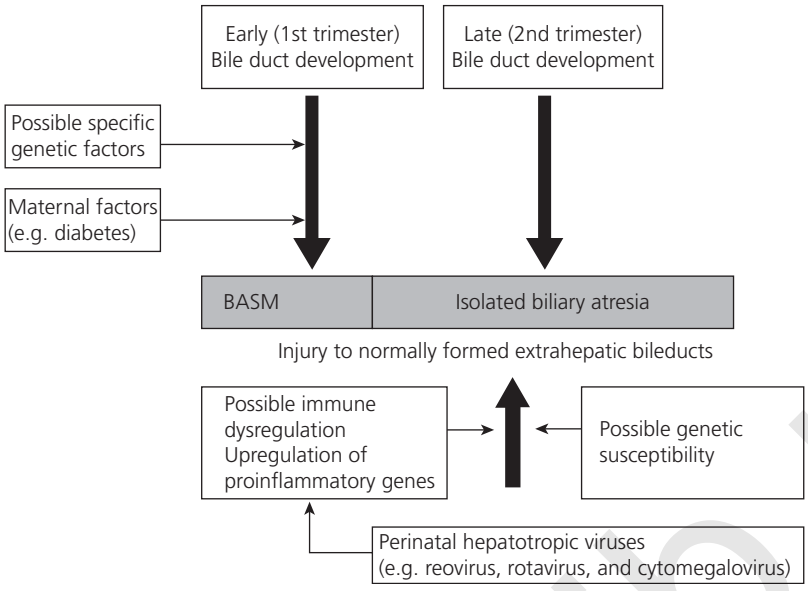

Figure 68.1 Schematic illustration of possible causes of biliary atresia: etiological heterogeneity.

There are other relationships, although these are much rarer. Some cases appear to have an association with other gastrointestinal anomalies, such as esophageal atresia and jejunal atresia (<2% of large series), and we have recently reported those with a defined chromosomal abnormality (e.g. cat-eye syndrome and chromosome 22 aneuploidy).[11]

We have now begun to use the term 'developmental biliary atresia'[12] for those cases where there is almost unequivocal evidence for a prenatal onset, and obstruction is evident by the time of birth. This would therefore include (2) and (3). The onset of occlusion in (4) is probably perinatal with occlusion of a patent biliary system by virally-mediated mechanism a possibility. The most prevalent group, isolated BA (1), is more difficult to categorize etiologically as it is simply defined by absence of anything else. Some could still be developmental in origin and others perinatal in timing.

BILIARY ATRESIA SPLENIC MALFORMATION SYNDROME

We first reported what became known as BASM in 1993,[8] recognizing that splenic anomalies (not just polysplenia) were related in some way to biliary atresia and that there was also a peculiar but consistent association with cardiac defects, situs inversus, pre-duodenal portal vein, and absence of the vena cava (Table 68.1). The reasons for this are still obscure, but it has been suggested that the common factor is simply an embryonic 'insult' in a critical window of the developing viscera – perhaps at 30–35 days' gestation. Whether this affects single specific genes or an array of developmental genes or proteins is not known.

There are genes that appear to be important in both bile duct development (e.g. *JAG1, HNF-6*[13] and visceral and somatic symmetry (e.g. *INV, CFC-1*[14,15]), although most work has been done in the mouse and actual correlation with mutations in humans is not that good. A possible genetic link was recently reported by Davit-Spraul *et al.*,[16] who found an increased frequency of mutations in the *CFC-1* gene (on chromosome 2) in patients with BASM, compared to controls.

A further interesting observation is that there is a definite link between maternal diabetes and BASM, in the same way that this condition can cause transposition of the great vessels, double outlet right ventricle and sacral agenesis (although these do not form part of the usual spectrum of BASM).[8,9]

Table 68.1 Spectrum of anomalies in biliary atresia splenic malformation syndrome.

Organ system	Malformation
Splenic	Polysplenia, double spleen (95%)
	Asplenia (5%)
Situs determination	Inversus (50%)
Venous	Preduodenal portal vein (40%)
	Portosystemic shunt (<2%)
	Vena cava (absence) (50%)
Intestinal development	Malrotation (60%)
Cardiac	Atrial septal defect, ventricular septal defect, Fallot's tetralogy, etc. (~40%)
Liver	Normal, 'mirror-image', or symmetrical in situs inversus
Biliary appearance	Solid and scanty gallbladder, may be absent. Gallbladder often a midline structure with solid, symmetrical proximal biliary ducts
Pancreas	Annular (<5%)
Miscellaneous	Immotile cilia syndrome (Kartagener's syndrome)
	Sacral agenesis

Finally, a small number of infants with BASM have immotile cilia syndrome (also known as Kartagener's syndrome) and this provides an interesting speculation as to mechanism. Certainly, dysfunctional cilia could be incriminated in determination of visceral situs – leaving it essentially to chance. But how cilial dysfunction interacts with the developing biliary tree is not known. Normally, only rats and squirrel monkeys have ciliated intrahepatic bile ducts, although there may be chemosensory cilia on cholangiocytes in humans. Cilia may occur in certain forms of biliary pathology – thus perhaps recapitulating its philogeny.

The macroscopic appearance of the biliary tree and liver is also somewhat different to isolated BA, with frequently absence of the common bile duct and a miniscule gallbladder and small proximal remnant. The liver is also usually symmetrical, whatever the nature of the abdominal situs.

PATHOLOGY OF BILIARY ATRESIA

This is best-described as an 'occlusive pan-ductular cholangiopathy' affecting both intra- and extrahepatic bile ducts.

The most common classification divides BA into three types based on the most proximal level of occlusion of the extrahepatic biliary tree (Fig. 68.2). In types 1 and 2, there is a degree of preservation of structure in the intrahepatic bile ducts but they are still irregular, deformed, and pruned – and do not dilate, even when obstructed. The most common variant, type 3, occurs where there is typically a solid, dense fibro-inflammatory proximal remnant at the porta hepatis. The distal duct may be atrophic, absent, or relatively well preserved. The latter typically seen in association with a mucocele of the gallbladder containing clear fluid. Type 3 intrahepatic bile ducts are usually grossly abnormal with myriad small ductules coalescing at the porta hepatis. Sometimes this can be visualized radigraphically as a 'cloud'.

Extrahepatic cyst formation may be evident and contains clear mucus or bile depending on preservation of the connection with intrahepatic bile ductules. We prefer the name 'cystic biliary atresia' for this entity, but the important thing is to distinguish it from simple obstruction in a cystic choledochal malformation.[10] The key to this is the cholangiogram which will show a distorted, deformed non-dilated intrahepatic duct system (if anything) in the former and a well-preserved and 'tree-like' dilated intrahepatic duct system in the latter. There should also be preservation of a decent epithelial lining in the latter on histology.

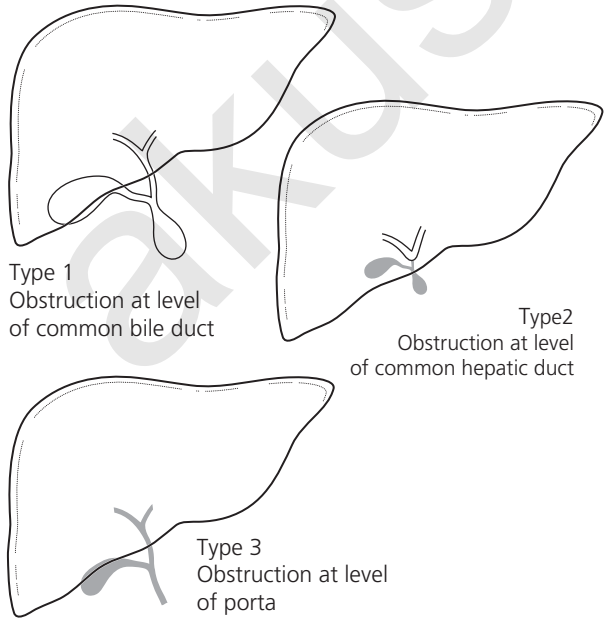

Figure 68.2 Classification of extrahepatic morphology in biliary atresia.

CELLULAR KINETICS AND INFLAMMATION IN BILIARY ATRESIA

That BA is not simply a mechanical obstruction of the biliary tree has been obvious for some time now. There is a marked inflammatory process that is present in most types (possibly with the exception of BASM) as evidenced by an obvious mononuclear infiltrate and expression of a variety of adhesion molecules on intrahepatic biliary and vascular epithelial surfaces.[17] Whether this is a primary or secondary phenomenon (to presence of bile outside biliary canaliculi for instance) is arguable but there is certainly evidence to support the former as a workable hypothesis.[17,18]

The infiltrate is largely composed of $CD4^+$ T-lymphocytes (specifically Th1)[19] and $CD56^+$ (natural killer) NK cells,[17,20] which exhibit markers for proliferation ($CD71^+$) and activation (particularly LFA-1^+ but also $CD25^+$). There is a distinct subset of $CD8^+$ cells, but many studies suggest these may be less important and lack various markers of activation, such as perforin, granzyme B, and Fas ligand.[21]

There is abnormal expression of cell adhesion molecules (proteins involved in cell–cell binding) with both ICAM-1 and VCAM-1 (but not E-selectin) being identifiable on epithelial structures in both liver, and to a lesser extent, the biliary remnant.[17,22]

We also identified increased levels of the soluble adhesion molecules ICAM-1 and VCAM-1 in the circulation at the time of Kasai together with rising levels of these and inflammatory cytokines (e.g. IL-2, TNFα) postoperatively.[23,24] After about six to nine months post-Kasai, these tend to come back down to more normal values (unpublished observation).

The resident (Kupffer cells) or recruited macrophages/monocytes appear to have a crucial role in the development of fibrosis seen in established BA. This may be as both the presenters of antigenic material in the first place and later as the initiating force for fibrosis in the development of chronic liver disease. Tracy *et al.*,[25] in 1996, first showed increases in resident macrophages ($CD68^+$) with marked expression of the lipopolysaccharide receptor $CD14^+$. Increased levels of both $CD68^+$ cells and its circulating markers (TNFα and IL-18) have been shown to impair prognosis post-Kasai.[24,26]

VIRUSES AND BILIARY ATRESIA

There have been a number of studies based on serology in infants with BA which initially suggested a causal link with perinatal viral infection (originally reovirus type 3[27]) but this was later disputed.[28] However, actual viral footprints within the bile ducts have been much harder to demonstrate and a causal link is still controversial.[29,30] Rauschenfels *et al.*,[31] in Germany, looked at wedge liver biopsies obtained from 74 infants at the time of Kasai portoenterostomy for a panel of DNA and RNA hepatotropic viruses. At least one virus was detected in about one-third of infants with the detection rate increasing with infant age. In some, multiple viruses could be found. They suggested this showed that viral infection was a secondary finding and unlikely to be the specific cause of BA. We have recently shown that it can be possible to distinguish clinically infants with cytomegalovirus IgM positivity with BA from other causes and that they do appear to have worse outcome (unpublished observation). Other series have suggested the opposite however.[32]

There is a mouse model of BA where just-born mice can be inoculated with rotavirus (or reovirus or cytomegalovirus) and who developed jaundice with intrahepatic histology similar to that of BA.[33,34] The nature of the cholangiodestructive pathway can be examined relatively easily and it can be shown that there is early upregulation of interferon inducers Irf7 and Irf9 genes (proinflammatory genes) with IFN-γ having greater expression at the time of bile duct obstruction.[35–37]

If no actual virally mediated damage, then it may be that we have to postulate another way of cholangiolar damage by suggesting that the virus acts as a trigger and that in some way there is an immune-mediated destructive process.[18] It could be speculated that this process would continue post-portoenterostomy, and that no native livers would ever drain bile in the long term. There is no real observational evidence that liver loss is inevitable though.

An interesting and novel mechanism of immune damage has been recently suggested based on the observation that male infants with BA have a three-fold increase in maternal-origin cells in their livers.[38] These have later been shown to be maternal-origin chimeric $CD8^+$ T cells and CD45 NK cells and certainly appear capable of initiating immune cholangiolar damage.[39] This is termed 'maternal microchimerism' and it may be the reason that the destructive process is time-limited.

EPIDEMIOLOGY

Given that BA appears a diverse disease, it is not surprising that its epidemiology also varies. Infants with developmental BA have a marked female predominance not seen in the isolated BA group.[8,9,12] Historically, there has been a suggestion of a seasonal variation in incidence,[40,41] though when examined in large national studies this has never been confirmed.[12,42] The implication is that if there were more infants with BA born during the winter months this might be related to the usual prevalence of viruses during this season.

The incidence of BA varies dramatically according to geography. Highest incidences are reported from Asia, with the highest from Taiwan (1 in 5000 live births).[43]

In the UK and Ireland (and much of Europe) there is an incidence of about 1 in 17 000–18 000.[12,42,44] We have recently reported significant regional differences within the UK with some areas having incidences usually seen in Japan for instance. We speculate that this may be as a reflection of the multiracial nature of the UK currently and variation of the different strands of BA (developmental BA was found to be more common in infants of Caucasian origin).[12]

CLINICAL FEATURES

Infants with BA are born smaller at birth (both developmental and isolated) and fail to thrive thereafter due to fat malabsorption.[12] Antenatal detection is possible in cystic biliary atresia and some syndromic cases may present very early because of their other malformations (e.g. malrotation).[45]

Otherwise, the key features are conjugated jaundice together with pale, unpigmented stools, and dark urine (bilirubinuria) in an otherwise healthy neonate. Liver fibrosis and cirrhosis are later developments even in infants with intrauterine BA and evident at birth,[45] and ascites and marked hepatosplenomegaly, are rare features not usually seen until about three months.

Some infants will present with a bleeding tendency which may be catastrophic, detectable with an elevated INR or prothrombin time, and caused by fat-soluble vitamin K deficiency.

LABORATORY FINDINGS

Liver biochemistry will show a conjugated jaundice (variable, but rarely $>250\,\mu mol/L$), modestly raised transaminases (AST >100 IU/L), and significantly raised γ-glutamyl transpeptidase (GGT >200 IU/L). None of this is specific.

The usual differential of a conjugated jaundice is medical and includes TORCH infections (e.g. toxoplasma, rubella, cytomegalovirus, hepatitis, etc.), genetic conditions (e.g. α-1-antitrypsin deficiency, Alagille's syndrome, progressive familial intrahepatic cholestasis (PFIC) disorders), metabolic conditions (e.g. cystic fibrosis, galactosemia), parenteral nutrition together with something termed 'neonatal hepatitis' which is fairly non-specific but none of the above.

The surgical differential is less common, and includes obstructed choledochal malformation, inspissated bile syndrome (usually preterm), and spontaneous perforation of the bile duct.[46] The key feature in these is that they all dilate their intrahepatic bile ducts when obstructed and should be distinguishable simply on ultrasound.

ULTRASONOGRAPHY

Ultrasound typically shows a shrunken, atrophic gallbladder with no evidence of filling between feeds. About 20% will show a 'normal' gallbladder – which turn out to be a

mucocele of the gallbladder in continuity with a relatively preserved common bile duct (CBD) and often absence of common hepatic duct (CHD).

Some centers appear able to actually diagnose BA, simply on ultrasound findings. A specific finding is said to be the 'triangular cord sign' described initially in Korean centers[47] and representing the proximal solid biliary remnant lying in front of the bifurcation of the portal vein. Accuracy rates of >80% have been reported.[48]

MISCELLANEOUS DIAGNOSTIC TECHNIQUES

In the author's unit, the pre-laparotomy diagnosis of BA is usually made by percutaneous liver biopsy showing histological features characteristic of large duct obstruction, and this is perhaps all that is needed in >80% of cases. It is less accurate the younger the liver though and does require an experienced and confident liver pathologist to distinguish these very subtle features.

Other investigations have been reported but are not necessarily essential in every case. Radio-isotope (technetium (Tc)-labeled iminodiacetic acid derivatives) hepatobiliary imaging has a role in some centers in showing the need for laparotomy by demonstrating absence of excretion, recognizing that severe forms of medical cholestasis also show this appearance.[49] A far simpler test is placement of a nasoduodenal tube and aspiration over 24 hours and is used in many Asian centers with undeniable accuracy, but has never really been used in UK centers.

Direct cholangiography is possible and is becoming more popular in those larger centers able to justify the small side-viewing endoscope necessary for infantile endoscopic retrograde cholangiopancreatography (ERCP).[49,50] Failure to cannulate the bile duct is a feature of BA but also may be the result of an inexperienced operator.[51]

Diagnostic laparoscopy and cholangiography (± liver biopsy) is a more widely available alternative to ERCP. Direct puncture of the gallbladder is straightforward to show the presence or absence of bile and a catheter or needle can then be used to outline the biliary tree. If an atrophic gallbladder is present without a lumen, this in itself is evidence of biliary atresia.

SURGERY – KASAI PORTOENTEROSTOMY

The preoperative management includes correcting the coagulopathy and may be an antibacterial bowel preparation. Perioperative antibiotics should be effective against aerobic and anaerobic bowel flora. The various stages in this operation can be broken down as follows below (Figs 68.3 and 68.4).

Cholangiogram

The diagnosis is always confirmed initially through a limited right upper quadrant muscle-cutting incision, allowing access

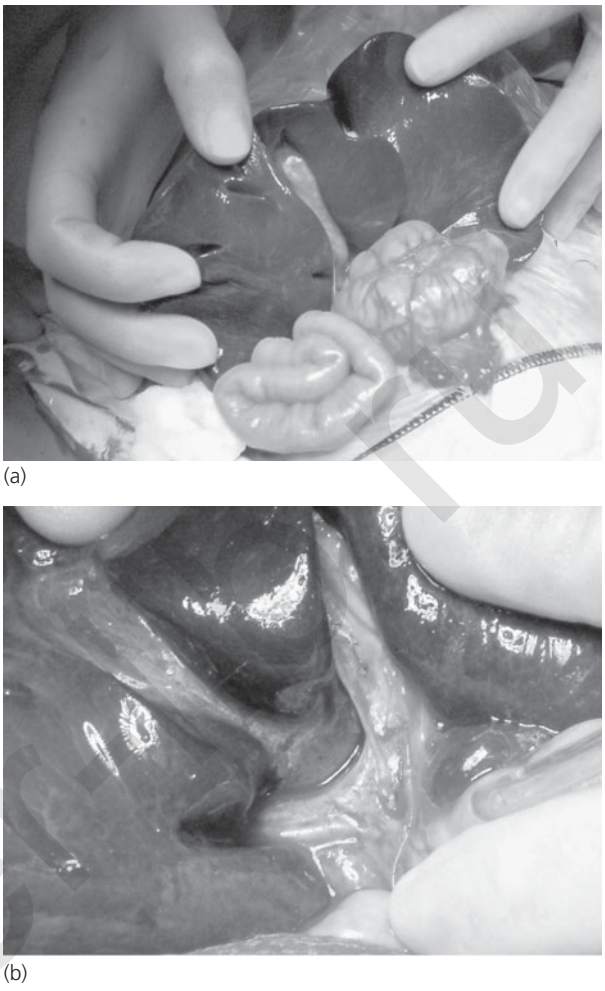

Figure 68.3 Operative appearance of liver in biliary atresia (BA). (a) The liver has been mobilized and is laid out on the anterior abdominal wall. The gallbladder is collapsed and contains no bile, consistent with a type 3 BA. (b) The biliary remnants and gallbladder have been removed, leaving a proximal transection of the portal plate flush with liver capsule.

to the gallbladder. To reiterate, the key observation, confirmed by needle aspiration, is the presence or absence of bile. Practically, the former can only be caused by a type 1 BA, but more likely it indicates one of the 'medical' causes of a conjugated jaundice listed above under Laboratory findings. A cholangiogram should be done to confirm. This may not be possible in some cases simply because the gallbladder has no lumen – but this in itself is indicative of BA. A 'normal' cholangiogram for completeness should show proximal intrahepatic ducts and sometimes this can be difficult; so a small vascular or 'bulldog' clamp on the CBD should aid reflux into the more proximal ducts. Neonatal sclerosing cholangitis and various hypoplastic biliary syndromes can then be detected.

Mobilization and eversion of liver

At this stage, portal venous pressure (via the umbilical ligament) is directly measured, as this may have prognostic

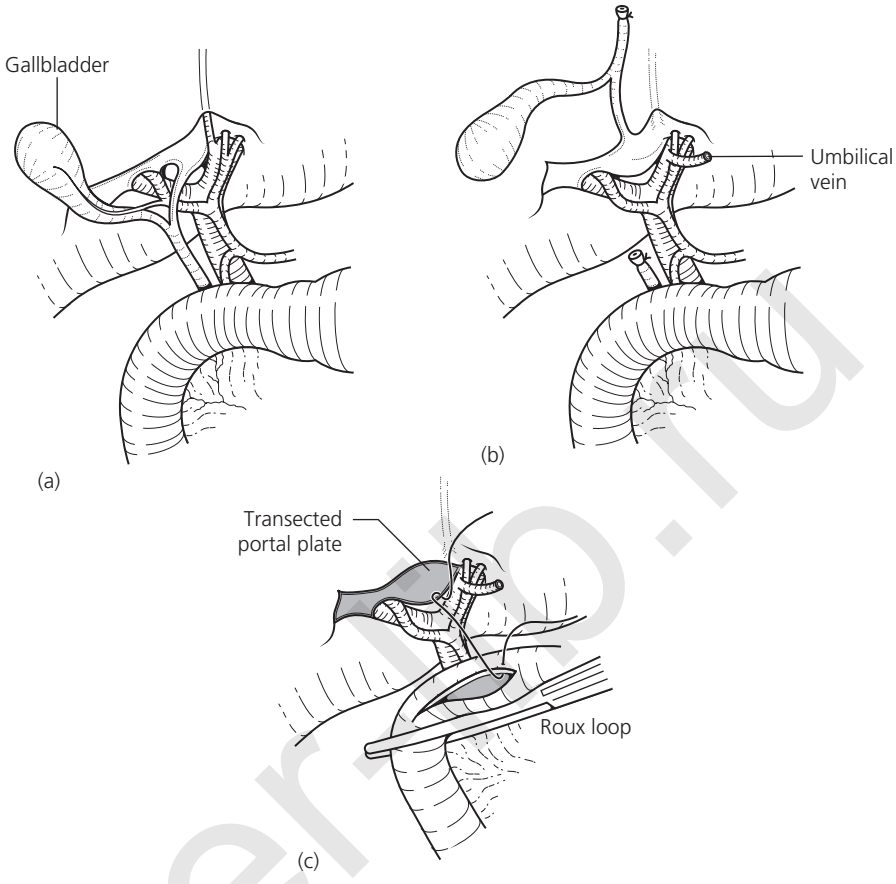

Figure 68.4 Schematic illustration of Kasai portoenterostomy. (a) Type 3 biliary atresia. (b) Mobilization of gallbladder and division of distal common bile duct. Elevation of biliary remnants and separation from vascular structures at level of porta hepatis (portal vein confluence, right and left hepatic arteries). (c) Transection of portal plate from 'umbilical point' on left, to around right portal pedicle. Portoenterostomy with 40–45 cm retrocolic Roux loop.

implications.[52] Then, the liver is mobilized fully by dividing the falciform, right and left triangular, and superior and inferior coronary ligaments. This allows the entire organ to be everted onto the anterior abdominal cavity, facilitating the portal dissection – the key part of the surgery. Care should be taken to warn the anesthetist as this maneuver kinks the cava and reduces venous return.

Portal dissection

The gallbladder should be mobilized off its bed and the distal CBD divided. This allows the more proximal biliary remnant to be dissected free from the vascular elements of the porta (right hepatic artery and bifurcating portal vein). Ligate or coagulate portal lymphatics to facilitate exposure. There are always small veins passing from the superior part of the U-shaped portal vein to the portal plate – these also need careful ligation – and then the liver tissue of the caudate lobe should be seen, opposite the undersurface of segment IV. The limit of the left-sided dissection is within the recessus of Rex where the umbilical vein joins the left portal vein**.** If this fossa is not open then the isthmus can be coagulated and divided. The right vascular pedicle divides into right anterior (base of gallbladder bed) and posterior (in a small innominate fossa) branches each with an accompanying bile duct remnant. All remnant biliary tissue needs excision and there is a definite plane of dissection which can be accessed using scissor dissection. Deeper dissection into liver parenchyma does not seem to achieve anything useful, possibly because of subsequent scarring and occlusion. Coagulation on the portal plate itself should be avoided; any bleeding from the edge should be tolerated as it will stop once the Roux loop is sutured in place.

Roux loop and portoenterostomy

Construct a retrocolic Roux loop measuring 40–45 cm with the jejunojejunostomy about 10–15 cm from the ligament of Treitz (to get mobility and reduce anastomosis tension). The portoenterostomy must incorporate all the denuded portal plate and should be quite wide (~2 cm). The author prefers an end-to-side arrangement using fine (e.g. 6/0 PDS) sutures, although other authors argue for an end-to-end arrangement.[53] A second layer can be added at the end posteriorly using adjacent periportal tissue.

Wound closure needs care as postoperative ascites can test its integrity and strength to the limit. A small drain may help to minimize ascites retention and allow the wound layers to heal. Significant bile leaks do not happen in Kasai operations –almost certainly because there is not that much bile around to leak!

CAVEATS TO SURGERY

Although a visible bile-containing duct may be evident in type 1 or 2 BA and a hepaticojejunostomy performed, it is

better that further proximal tissue is resected to the level of (and therefore needing) a portoenterostomy.

Sometimes on-table evidence of cirrhosis may seem to make a portoenterostomy futile. However, this is rarely absolutely predictable, although in infants of >100 days more likely.[54] A primary transplant may be a better option but is arguable.

At times it has been suggested that frozen section of the resected portal plate is useful to determine whether ductules are large enough (Fig. 68.5). In practice, the aim is to resect all visible bile duct remnant down to, but not encroaching on, parenchyma – thus there is nothing further to resect whatever the pathologist reports.

Portoenterostomy in BASM has a worse long-term outcome, and the outcome can be related to the age at which the surgery is performed.[8,55] The extrahepatic bile ducts are rarely florid, often non-inflammatory and atrophic in appearance. Great care should be taken with the preduodenal portal vein and any aberrant arterial vessels. A malrotation may require a Ladd's procedure and influence the construction of the Roux loop.

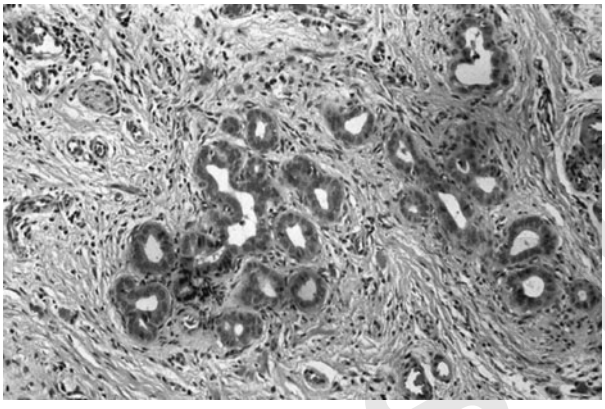

Figure 68.5 Hematoxylin and eosin microphotograph of transected biliary remnant showing multiple biliary ductules lined with relatively normal epithelium; within a fibrous stroma infiltrated by inflammatory mononuclear cells.

POSTOPERATIVE MANAGEMENT

Nasogastric drainage and i.v. fluids are required for 2–4 days before starting feeds. There is no clear advantage from continuing antibiotics beyond one month.

All infants require fat-soluble vitamin supplementation (both enteral and parenteral). All, even those rendered anicteric, will have a degree of fat malabsorption. They should also have an appropriate formula milk (e.g. containing medium-chain rather than long-chain triglycerides). Failure to thrive should be aggressively attended to with nasogastric overnight feeds if necessary. The medical management of the infant or child with serious underlying liver disease is complex, demanding, and absolutely crucial. Most centers achieve this successfully using a multidisciplinary team approach.

Pharmacological improvement in bile flow is possible, by ursodeoxycholic acid for instance but only when a degree of flow has been established by surgery and is one of the postulated mechanisms for steroids.[56] There is not much evidence for other medications, although a number of Japanese and Chinese centers use the Chinese herb, inchinko-to.[57]

The use of steroids is controversial, but appealing given the possible role of inflammation in the etiology of BA. Actual evidence beyond inevitably biased published small series is weak though[58,59] and a recent Cochrane review came to no great conclusions.[60] Our randomized, placebo-controlled trial of oral prednisolone (2 then 1 mg/kg/day in the first month) showed definite improvements in early clearance of jaundice but a lack of real effect on final results and need for transplant.[56] We have not been able to show any sustained effect on more subtle markers of the inflammatory response (e.g. sICAM-1) (unpublished observation). The only other prospective (but not randomized) trial of steroids (starting at 10 mg/kg/day) showed no difference whatsoever.[61]

OUTCOME FOLLOWING PORTOENTEROSTOMY

The actuarial five- and ten-year survival in England and Wales for infants born this century is about 90%.[7,62] There will still be deaths: most awaiting transplantation, some as postoperative complications due to transplant and some due to the effects of other anomalies (e.g. cardiac).

We would expect to restore enough bile flow to clear jaundice and achieve normal values for bilirubin in about 50–60% of infants with isolated BA.[7,55,56,62] Most (>90%) of these infants can expect to survive long term with a relatively normal childhood, but regular outpatient attendance to monitor progress. Their livers will however seldom be 'normal'; in fact, if ever biopsied they will be highly likely to show histological cirrhosis.[63] The five- and ten-year native liver survival will be about 45–50% therefore.[7,62,64] Care should be taken in the interpretation of such figures if they are from countries with no transplant option as their native liver survival equates to true survival.[65]

Effect of age at surgery

Cirrhosis and fibrosis are time-dependent phenomena and it is very reasonable to surmise that the earlier in the disease the cirrhotic process is abbreviated (by restoration of bile flow) then the better the outcome. However, as stated earlier, BA is a heterogenous disease and especially in isolated BA the time of onset is not known and trying to identify a real effect of age on a large series can be difficult.[7,64,66] This hypothesis is supported by the observation that in those where there is definite evidence of intrauterine pathology (i.e. developmental BA) a marked relationship can be seen while in those described as isolated (presumably much more chronologically heterogenous) this relationship is not seen (within 100 days at least).[55]

Large multicenter series with multiple surgeons have been unable to show a real statistically significant relationship.[7,66,67] Figure 68.6 illustrates this problem for isolated

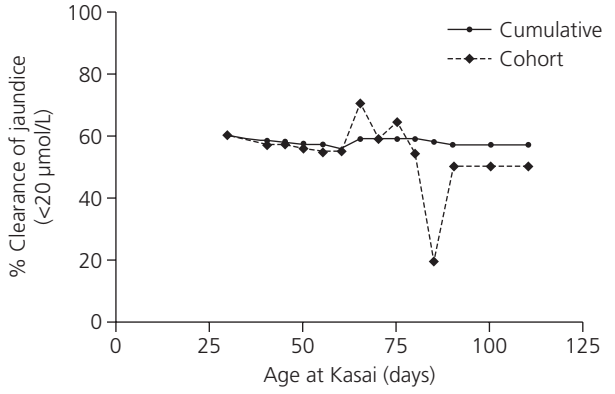

Figure 68.6 Relationship of age at surgery to clearance of jaundice in infants with isolated biliary atresia ($n = 177$). [Reprinted with permission from Ref. 55.] Note: the percentage to clear jaundice in each age-defined (e.g. 31–40 days) cohort is plotted as a solid diamond. The cumulative plots (black circles) are from 30 days and work from left to right, calculating percentage to clear jaundice for successive time points (<30, <40, <50 days, etc.). An essentially flat black line implies no real relationship with age at surgery. [Davenport M *et al.*, *Ann Surg* 2008; 247: 694–8.]

BA and is derived from a single center with two surgeons using the same technique and outcome measured with defined endpoints (clearance of jaundice). Statistically, as the compendium solid black line is virtually flat, implies no 'cut-off' and no effect of age within pragmatic limits. There is actually a gradual decline implying the truth of the original postulate (age worsens outcome) but statistically will require many more numbers to prove it.

Is there any benefit of surgery to those infants who come to surgery at >100 days? Though this is now relatively infrequent in developed countries it still occurs. That they are much more likely to have established cirrhosis is true and their prognosis is certainly less good. Nevertheless, a Kasai as the first step seems reasonable and has been associated with long-term jaundice-free survival in our series.[54] The alternative, of course, is a primary liver transplant.

COMPLICATIONS

Apart from end-stage liver disease in those where there is failure to restore bile flow with development of ascites, malnutrition, and deepening jaundice and which clearly can only be treated by transplantation, there are two major areas of complication.

Cholangitis

This probably occurs in relation to ascending organisms from within the Roux loop, as cholangitis is rare in those who never show any degree of bile flow post-Kasai. It is reported in up to 50% of large series, but seems only to be problematic in the first year postsurgery. It may be characterized by pyrexia, pale stools, increasing jaundice, and other signs of sepsis. Culture of organisms from blood or from liver biopsy is uncommon and judicious use of early, broad-spectrum antibiotics is advised (e.g. ceftazidime, gentamicin, etc.).

Recurrent cholangitis may occur possibly due to the formation of dilated biliary channels or cystic change within the liver and is detectable on ultrasound. In some cases, it occurs because there is a mechanical obstruction to bile drainage within the Roux loop and is detectable using radio-isotope scan.[68] The former is probably best treated by prolonged i.v. antibiotics via a Hickman line and the latter by laparotomy and Roux loop exploration. In older children, newer enteroscopes are now able to visualize the Roux loop directly and this may be an alternate mode of diagnosis.

Portal hypertension

The majority of infants at the time of Kasai will have portal hypertension (PHT), but whether this persists will probably depend upon degree of restoration of bile flow and other dynamic factors.[69] Esophagogastric varices take time to develop but will do so given sustained periods of PHT. The majority of long-term survivors will have endoscopic evidence of varices, although only a proportion will ever bleed. Surveillance endoscopy is recommended in these, although evidence is lacking for the role of prophylactic treatment (e.g. banding). Nonetheless, this is a possible option.

For those who have bled, they will require some form of endoscopic intervention initially, either sclerotherapy or banding. The former technique is well established but not without complications, such as ulceration, stenosis, and stricture formation, and currently should probably be reserved for infants and smaller children where it is not possible to actually pass the banding attachment. There will be a small proportion who have variceal bleeding of such magnitude to require immediate placement of a Sengstaken tube – this is fortunately unusual. Following endoscopic control of the varices an assessment needs to be made about overall liver reserve. There will be some with excellent restoration of liver function and clearance of jaundice where obliteration of varices is all that is needed; there will be others (typically infants and young children of less than two years) where this is simply one part of a failing system and these need to have an expedited transplant.

ROLE OF LAPAROSCOPIC KASAI PORTOENTEROSTOMY

The tsunami of minimally invasive surgery in the 1990s swept along pediatric as well as general surgeons and soon more and more adventurous operations were being described through smaller multiple port incisions, including the Kasai operation. Small series have been reported but none with good results and most with only limited outcomes.[70–72] At the present time, this operation may be the limit, and a number of enthusiasts are returning to the conventional open approach.[73] The reason may be self-evident – the dissection is unforgiving and meticulous precision is required and

therefore even with a robot the operations are simply not comparable. Others have suggested that it may be the effect of the paraphernalia of minimally invasive surgery. For example, Mogilner *et al.*[74] in an experimental model showed that the higher intra-abdominal pressures of the pneumoperitoneum may increase damage through effects on liver blood flow. A definitive answer has yet to be delivered but in its absence, practitioners should be cautious – this surgery has a high enough 'failure' rate without making it more difficult and promises of a better cosmetic result and short hospital stays are fatuous in the context of biliary atresia. The only person benefiting is the transplant surgeon who has a reduced number of adhesions to deal with!

LIVER TRANSPLANTATION IN BILIARY ATRESIA

This has now been available in North America and Western Europe for 'failed' Kasai children since the 1980s. It is still a major undertaking with a consistent risk of postoperative mortality of 6–15%.[75–77] The risk diminishes beyond the first year and an actuarial plateau is then reached, although the vast majority still require oral immunosuppression. A few do develop tolerance (perhaps up to 20%) with the possibility to withdraw medication.[78] Longer-term issues, such as Epstein–Barr-related post-transplant lymphoproliferative disease (up to 10% of some series) and chronic rejection, are still a cause of morbidity and potential mortality.

There are, within all countries and societies, problems coming to terms with ethical attitudes to both cadaveric and living-donor transplantation. Despite efficient use of donor organs, there are never enough of them. As a consequence, waiting-list deaths are still a major issue. There are also lingering technical issues related to size discrepancy, although organ reduction and split liver transplants ameliorate this in the larger centers.

In conclusion, biliary atresia in many respects remains a mysterious disease with its origins cloaked and obscure; in others, though the need for surgical intervention is straightforward, the outcome may be somewhat capricious and unpredictable.[79] Future needs include better pharmacological options to improve bile flow post-Kasai and modify or at least abbreviate the invariable tendency to liver fibrosis (and hence portal hypertension) – a characteristic that can be a real risk to the small infant on a transplant waiting list.

Congenital biliary dilatation

HIROYUKI KOGA AND ATSUYUKI YAMATAKA

INTRODUCTION

Congenital biliary dilatation (CBD), or choledochal cyst, is a cystic or fusiform dilatation of the common bile duct that is uncommon in Caucasians. There is little doubt that CBD is a congenital lesion with a strong hereditary component, which may explain the higher incidence seen in Asia, and its familial occurrence in siblings and twins.[1–3] Traditionally, approximately half become symptomatic in infancy, and neonatal cases have been uncommon. However, with advances in diagnostic imaging techniques, its incidence is increasing, particularly in neonates.[4–11] In our series, about 20% of patients were detected either neonatally or antenatally, and interestingly, the ratio of cystic to fusiform-type CBD neonatally or antenatally is 20:1, in contrast to an overall ratio of 5:3.[12]

The treatment of CBD in early infancy has unique aspects that must be considered in relation to the risks of surgery itself and the size and physiological/immunological immaturity of the patient. Because CBD is commonly associated with pancreaticobiliary malunion (PBMU) involving concurrent anomalies of the common channel, pancreatic duct, and intrahepatic bile duct (IHBD), the importance of cholangiography both preoperatively and intraoperatively cannot be overemphasized. If these anomalies go unnoticed by surgeons, they may be injured during surgery and cause serious postoperative morbidity. Primary cyst excision (CE) with biliary reconstruction to avoid two-way reflux of bile and pancreatic secretions is now the standard procedure of choice.

ETIOLOGY

Various theories have been proposed for the etiology of CBD, but two factors are known to be causal: weakness of the wall of the common bile duct, and obstruction distal to it. Spitz[13] stressed an obstructive factor that appears early in development based on his experimental study in sheep, in which cystic dilatation of the common bile duct could be induced by ligation of the distal end of the choledochus only in neonatal lambs and at no other stages of development. The authors' animal research has confirmed this hypothesis,[14–18] and our radiologic and histologic studies on patients with CBD clearly demonstrate that distal stenosis is closely associated with cystic dilatation of the common bile duct, and that the site of stenosis is related to an abnormal choledochopancreatic ductal junction.[15–19] Jona *et al.*[20] purported that the pathogenesis of CBD-associated PBMU may be related to faulty budding of the primitive ventral pancreas. Wong and Lister[21] conducted research on human fetuses and demonstrated that the choledochopancreatic junction lies outside the duodenal wall before the eighth week of gestation, whereupon it moves inward towards the duodenal lumen, suggesting that an anomalous junction may be caused by arrest of this migration, while Tanaka[22,23] proposed that regression of the terminal choledochus and canalization of the ventral pancreatic duct (W1) caused by sinistral dislocation of the ventral pancreas are responsible for PBMU.

In recent years, cholangiography has identified anomalies of the pancreaticobiliary ductal system in association with CBD, which may allow reflux of pancreatic enzymes and subsequent dissolution of duct walls. This is known as the long common channel theory and was first proposed by Babbitt in 1969.[24] Since then, numerous abnormal arrangements of the pancreaticobiliary junction associated with CBD have been reported by others based on the results of endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiography (PTC), and intraoperative cholangiography (IC). This theory is further supported by the high amylase content of fluid aspirated from dilated ducts in patients with CBD. A dilated common channel and anomalous pancreatic duct are also frequently observed, which may be responsible for the formation of protein plugs or pancreatic stones, often associated with pancreatitis. It is generally recognized that a number of patients with an anomalous long common channel and high amylase level in the gallbladder, show no dilatation of the choledochus, although some had gallbladder carcinoma.[25] However, the authors' research in which choledochopancreatostomy was performed

in puppies to allow regurgitation of pancreatic fluid into the common bile duct, found that the chemical reaction of refluxed pancreatic fluid on the bile duct was extremely mild.[26] Interestingly, in this animal model, fusiform rather than cystic dilatation of the common bile duct was induced.

Although Babbitt[24] stressed that pancreatic fluid is the most likely factor causing edema and eventual fibrosis of the distal common bile duct as well as weakness of the choledochal wall, a diagnosis of CBD can be made antenatally as early as 15–20 weeks' gestation.[9–11,27] at which time pancreatic acini are only just beginning to appear, zymogen granules are immature, and there is no evidence of secretion seen on electron microscopy.[28] Thus, the chemical reaction of pancreatic fluid on the bile duct has not been clarified in the antenatal period, and even in the neonate, the pancreas has not matured enough to produce functional enzymes,[29] so the role of pancreatic fluid in CBD formation may be overrated.

In spite of these findings, controversy surrounds the cause of the stenosis distal to the dilated common bile duct. The authors believe that an anomalous choledochopancreatic duct junction combined with congenital stenosis are the basic causative factors of CBD at least in perinatal and young infants rather than weakness of the duct wall caused by reflux of pancreatic fluid. Both PBMU and stenosis are associated with abnormal development of the ventral pancreatic duct and biliary duct system.

CLASSIFICATION

Alonso-Lej *et al.*,[30] Todani *et al.*,[31] and Komi *et al.*[32] have described classifications for CBD based on anatomy and cholangiography of the hepatobiliary duct system or PBMU. Classification based on the association with PBMU is presented in Fig. 69.1.

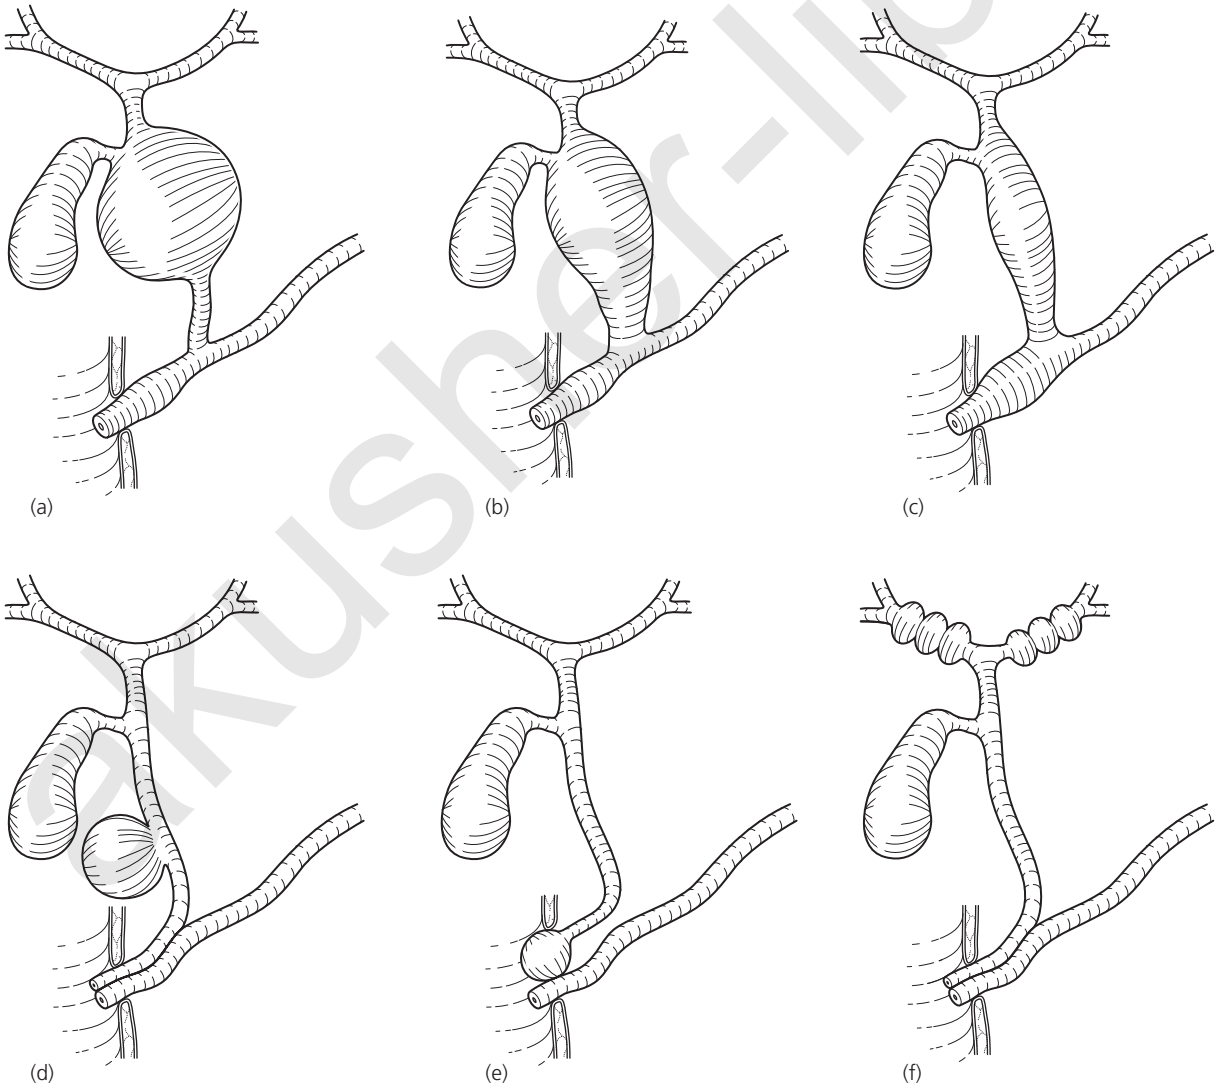

Figure 69.1 Classification of choledochal cysts with pancreaticobiliary malunion (PBMU): (a) Cystic dilatation of the extrahepatic bile duct. (b) Fusiform dilatation of the extrahepatic bile duct. (c) Forme fruste choledochal cyst. Without PBMU: (d) Cystic diverticulum of the common bile duct. (e) Choledochocele (diverticulum of the distal common bile duct). (f) Intrahepatic bile duct dilatation alone (Caroli's disease).

CLINICAL SIGNS AND SYMPTOMS

Clinical manifestations of CBD differ according to age. Neonates and young infants usually present with an abdominal mass, or obstructive jaundice, and acholic stools, depending on the degree of obstruction. Some present with a huge upper abdominal mass with or without jaundice. Some cases can even resemble correctable biliary atresia except that with CBD, there is a patent communication with the duodenum and a well-developed IHBD tree. In older children, the classical triad of pain, mass, and jaundice may be present. Fever and vomiting may also occur. The pattern of pain has been described as being similar to that of recurrent pancreatitis, in which a high serum amylase level is often present. However, in our series, there was little clinical evidence of pancreatitis in the neonate and amylase levels were not found to be elevated. CBD should always be considered in the differential diagnosis of a child with abdominal signs and symptoms; the essentials of management are the same.

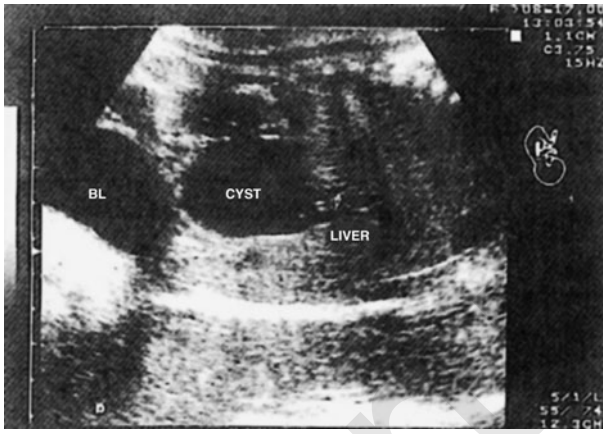

Figure 69.2 Antenatal ultrasound at 32 weeks' gestation. Sagittal view. A cystic structure is seen to be connected to the liver via a short duct (arrow). Bl, bladder.

DIAGNOSIS

Currently, abdominal ultrasonography (US) is the best method for detecting CBD, even though it does not permit visualization of the entire duct system and it is not sensitive enough to demonstrate an undilated common channel and pancreatic duct. However, routine antenatal US performed mainly for dating purposes has been of increasing value for detecting fetal anomalies,[4–11,27] and the number of neonates detected as having incidental CBD has increased significantly (Fig. 69.2).[33] CBD has been detected at routine prenatal ultrasound examinations as early as 15 weeks' gestation[9,10] and may be confused with duodenal atresia, biliary atresia, ovarian cysts, duplication cysts, and mesenteric cyst.

For thorough assessment of CBD, it is important to investigate for coexisting PBMU, anomalies of the pancreatic duct, intrahepatic ducts, and extrahepatic duct. ERCP can accurately delineate the configuration of the pancreaticobiliary duct system in detail, and is unlikely to be replaced by other investigations, especially in cases where fine detail is required preoperatively. ERCP is routinely performed for the diagnosis of biliary malformations in infants and neonates in many centers in Japan, with a reasonable success rate.[34] However, it is an invasive procedure and therefore is unsuitable for repeated use, and is contraindicated during acute pancreatitis.

The authors and others[35,36] have shown that magnetic resonance cholangiopancreatography (MRCP) can provide excellent visualization of the pancreaticobiliary ducts in patients with CBD allowing narrowing, dilatation and filling defects of the ducts to be detected with medium to high degrees of accuracy (Fig. 69.3). Because MRCP is non-invasive, it can partially replace ERCP as a diagnostic tool for the evaluation of anatomic anomalies of the pancreaticobiliary tract, where it is available, but there are limitations of patient size, weight, and age for the use of MRCP. Another advantage of MRCP over ERCP is that the pancreatic duct can be visualized upstream to an obstruction or area of stenosis. Once the quality of MRCP improves, ERCP may become optional.

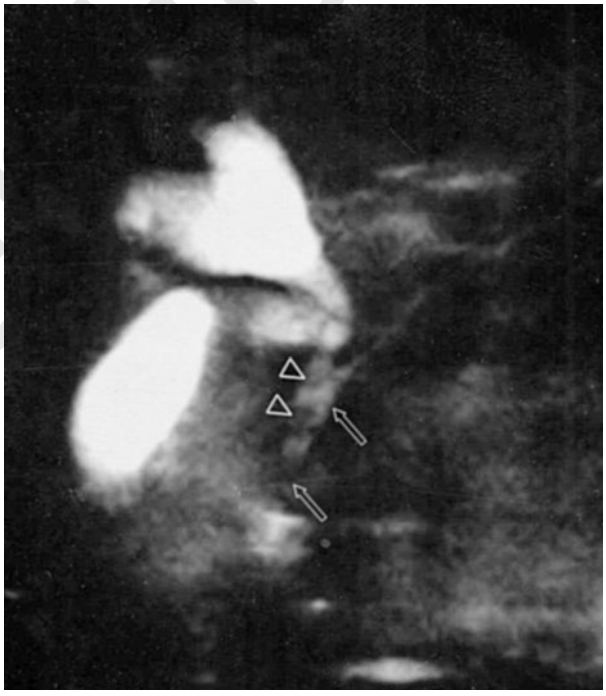

Figure 69.3 Magnetic resonance cholangiopancreatography in a patient with a choledochal cyst showing fusiform dilatation of the extrahepatic bile duct, long common channel (between arrows), protein plugs (arrowheads), and pancreatic duct.

If preoperative imaging can allow clear visualization of the entire biliopancreatic ductal system, including the intra- and extrahepatic bile ducts, and pancreatic duct in detail, intraoperative cholangiography is unnecessary; however, if sufficient information is not obtained, it must be performed. Furthermore, if the cyst is too large, intraoperative cholangiography via the gallbladder or directly via the common bile duct is useless. In such cases, intraoperative cholangiography should

be performed separately for the IHBD and distal common bile duct by a selective technique during excision of the cyst.

SURGERY

Choice of operative procedures

Cyst excision with Roux-en-Y hepaticoenterostomy (HE) is currently the definitive treatment for CBD regardless of age or symptomatology because internal drainage, a commonly used treatment in the past, is associated with high morbidity and high risk for carcinoma. Basically, the only difference between operative procedures available is the type of biliary reconstruction performed, although the level of transection of the common hepatic duct and the level of excision of the intrapancreatic bile duct are controversial. Although most surgeons use a Roux-en-Y hepaticojejunostomy, some[37,38] recommend a wide anastomosis at the level of the hepatic hilum to allow free drainage of bile in order to prevent postoperative anastomotic stricture and stone formation. The authors[39] recommend conventional hepaticojejunostomy, while others prefer hepaticoduodenostomy. Whatever type of biliary reconstruction is used, satisfactory surgical outcome with low early morbidity is to be expected, but postoperative complications after cyst excision, especially in the long term, generally occur more often if dilated IHBD are present. In our experience, hepaticoduodenostomy is not ideal for biliary reconstruction because of a high incidence of complications due to duodenogastric bile reflux.[39] Todani *et al.*[40] encountered a case of hilar bile duct carcinoma that developed 19 years after primary cyst excision and hepaticoduodenostomy. Although Todani's team preferred hepaticoduodenostomy because they believed it was more physiologic, they have since abandoned hepaticoduodenostomy after CE and now perform hepaticojejunostomy. Hepaticoenterostomy at the hepatic hilum is indicated in specific cases only, such as in patients with dilated IHBD with stenosis in the common hepatic duct, or adolescent patients with severe inflammation of the common hepatic duct.

Timing of surgery

Some pediatric surgeons recommend primary cyst excision soon after diagnosis.[6,8,10,41,42] In the authors' experience,[12,43] cyst excision need not be performed hastily if jaundice is not present. Rather, patients should be thoroughly assessed and surgery planned and performed by experienced, well-trained pediatric surgeons. In cases of bile peritonitis following perforation, severe cholangitis, poor general condition, or huge dilated CBD in neonates, external biliary drainage is recommended by either percutaneous transhepatic cholangiodrainage or direct percutaneous cyst drainage. Subsequently, delayed primary excision may be carried out three to six months later.

Neonates with choledochal cysts should receive standard medical management and nutritional support pre- and postoperatively; the importance of thorough preoperative assessment cannot be overemphasized. However, the timing of surgery for neonates is highly controversial because there are very few reports about the management of asymptomatic CBD detected in the antenatal or neonatal period. The authors believe that neonates should be treated by early surgery, particularly if they are jaundiced; for example, Dewbury *et al.*[4] reported that a laparotomy at 10 days of age confirmed a prenatally diagnosed CBD associated with severe hepatic fibrosis. Early surgery provides the opportunity to exclude biliary atresia, prevent biliary and hepatic complications, such as liver fibrosis which can progress rapidly in cases with biliary obstruction,[4,10,41] reverse fibrosis, reduce the risk for cholangitis, prevent accumulation of biliary sludge, relieve obstructive jaundice, as well as prevent cyst perforation.[6] The results of surgical treatment at this age are generally excellent.[42]

Complete excision

Complete (full-thickness) excision of the cyst is much easier in neonates and young infants, because the wall of the dilated common bile duct is generally thin and there are few adhesions to surrounding structures, such as the portal vein.[44,45] Aspiration of the cyst prior to dissection makes surgery easier if the cyst is large. The cyst should be incised in the middle portion close to the duodenum, because there is often an anomalous opening of the hepatic duct, i.e. a separate opening or opening into the distal part of the cyst. The cyst is then transected after careful circumferential dissection from the hepatic artery and portal vein. Subsequently, the distal portion is dissected and excised, taking care to completely remove the dilated segment at the level of the caliber change in order to prevent malignant transformation of the remaining cyst epithelium. If the cyst has no distinct caliber change (i.e. fusiform), the cyst should be excised just above the choledochopancreatic junction, and the stump double-sutured, ligated, and transected (Fig. 69.4). If protein plugs are found in the common channel, intraoperative endoscopy should be used to wash them towards the duodenum to avoid postoperative stone formation and pancreatitis. Finally, the common hepatic duct is transected at the level of distinct caliber change to leave an adequate length for HE.

Mucosectomy/biliary reconstruction

If CE of the distal portion is difficult due to inflammation or adhesions, mucosectomy[42,43] of the distal portion of the cyst is recommended, in order to avoid damage to the pancreatic duct, hepatic artery, and portal vein, and also to prevent the residual epithelium of the distal portion of the cyst from undergoing malignant transformation (Fig. 69.5). However, in neonates, mucosectomy is rarely indicated because there is little inflammation around the cyst wall. Biliary reconstruction in neonates and young infants is technically involved because anastomoses are often small and so should only be undertaken by experienced pediatric surgeons. Some surgeons overcome this problem by partially incising the mouth of the stoma of the anastomosis to widen it. On occasions,

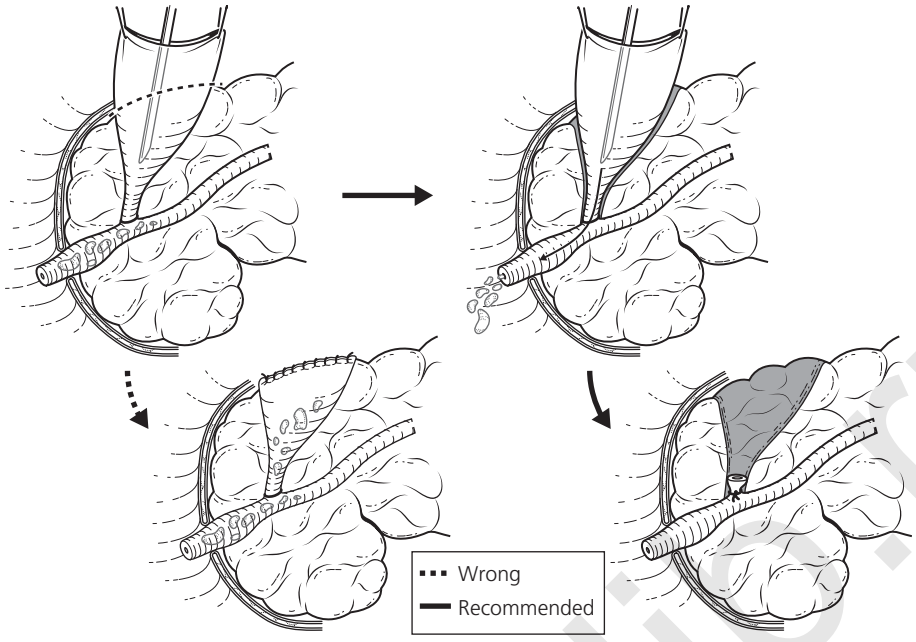

Figure 69.4 Diagram of intraoperative endoscopy of the bile duct distal to a cyst with debris and protein plug. If the distal common bile duct is resected along the dashed line, over time, a cyst will reform around the distal duct left within the pancreas, leading to recurrent pancreatitis, stone formation in the residual cyst, or malignant changes in the residual cyst. In contrast, if the distal duct is resected along the solid line, that is, just above the pancreaticobiliary ductal junction, cyst reformation due to residual duct within the pancreas is unlikely.

Figure 69.5 Mucosectomy of distal portion of choledochal cyst.

the authors have encountered luminal stenosis of macroscopically normal common hepatic ducts at the time of CE, which was considered to be secondary to fibrosis, probably as a consequence of inflammation associated with previous perforation.

Although an end-to-side anastomosis was initially used, the authors now prefer end-to-end anastomosis during Roux-en-Y hepaticojejunostomy, because drainage is more streamlined, with less possibility of bile stasis (Fig. 69.6). With end-to-side anastomosis, there was overgrowth of the blind end, causing adhesive bowel obstruction between the blind pouch and jejunum in one case, and stone formation in the blind pouch in another (Fig. 69.7).[46] Bile stasis in the blind pouch can also cause stone formation in the IHBD dilatation at the porta hepatis. If end-to-side anastomosis is unavoidable, the common hepatic duct should be anastomosed as close as possible to the closed end of the blind pouch so there will be no blind pouch at the anastomosis site; if an end-to-side anastomosis is performed far from the closed end of the blind pouch, elongation of the blind pouch will occur later in life as the child grows.

The authors have seldom performed other procedures, such as HE at the hilum or valved jejunal interposition hepaticoduodenostomy to prevent reflux of digested food into the IHBD.[38] Although these procedures are appealing theoretically, there is no significant difference in morbidity. HE at the hepatic hilum is more difficult than conventional HE, particularly in neonates and young infants without IHBD dilatation, and valved jejunal interposition hepaticoduodenostomy is a complicated procedure.

ASSOCIATED ANOMALIES REQUIRING TREATMENT

Intrahepatic bile duct dilatation

Recently, more attention has been paid to the treatment of IHBD anomalies, such as dilatation with downstream stenosis, which is strongly associated with late postoperative

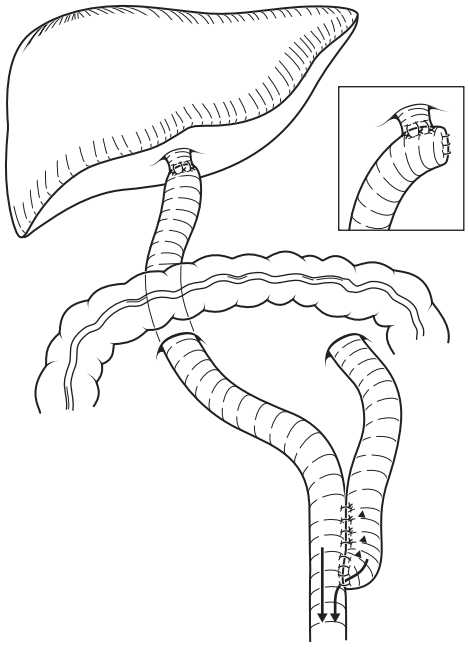

Figure 69.6 Adequate Roux-en-Y (RY) hepaticojejunostomy at the time of cyst excision. Arrowheads indicate approximated native jejunum and distal Roux-en-Y limb. Arrows indicate smooth flow without reflux of small bowel contents.

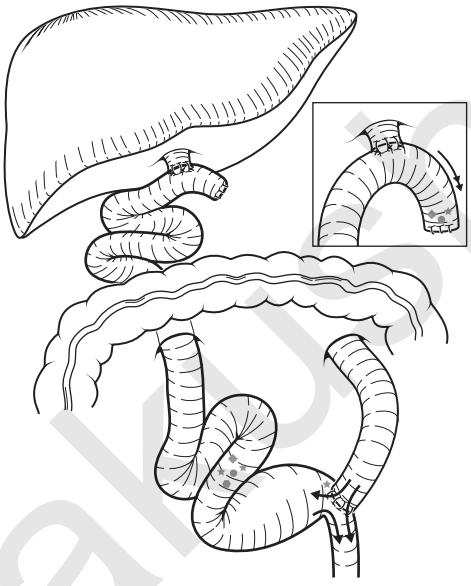

Figure 69.7 Inadequate Roux-en-Y (RY) hepaticojejunostomy at the time of cyst excision. Note hepaticojejunostomy far from the closed end of the blind pouch (arrowhead). Double arrowheads in the inset indicate elongation of the blind pouch. Arrow with an asterisk indicates reflux of jejunal contents into the RY limb through a T-shaped RY jejunojejunostomy.

complications.[31,38,46–52] In our series,[12] eight of 21 neonatal patients (38.1%) had IHBD dilatation (in one it was severe, and was still persistent at follow up 14 years later), which is remarkably less than the incidence in older children (53.3%).[46] IHBD dilatation can be treated by segmentectomy of the liver, intrahepatic cystoenterostomy, or balloon dilatation of the stenosis at the time of CE.[31,49,50] The authors have treated stricture of the IHBD at the hepatic hilum by intrahepatic ductoplasty and cystojejunostomy or hepaticojejunostomy at the hepatic hilum in three cases, [46,51]creating a wide stoma by incising along the lateral wall of the hepatic ducts following excision of the narrowed segment of the common hepatic duct (Fig. 69.5). By using intraoperative endoscopy, the ideal level of resection of the common hepatic duct can be safely determined without injuring the orifices of the hepatic duct or leaving a redundant duct.

Anomalies of the pancreatic duct and common channel

Anomalies of the pancreatic duct and common channel are only rarely symptomatic in neonates and young infants, and can include pathology such as stenosis of the papilla of Vater, stricture of the pancreatic ducts, protein plugs, or even a septate common channel.[32,52–54] Stone debris in the common channel and IHBD can also be responsible for postoperative abdominal pain, pancreatitis, stone formation, or jaundice and should be removed at the time of radical surgery. The authors have found intraoperative endoscopic examination of the common channel and intrahepatic duct to be of enough value to include it as a routine procedure during standard surgical treatment of CBD, because it is extremely efficient for examination and irrigation, and allows all distal pancreatic duct stone debris and stone debris in the common channel to be removed. If stenosis of the major papilla with a dilated common channel is found, a transduodenal papilloplasty or endoscopic papilloplasty should be performed.[52]

INTRAOPERATIVE ENDOSCOPY

Since 1986, the authors have routinely performed intraoperative endoscopy of the common channel, pancreatic duct, and IHBD to examine the duct system directly for stone debris and duct stenosis, and to remove stone debris by irrigation with normal saline (Fig. 69.8).[46] The authors use a pediatric cystoscope or fine fiberscope with a flush channel to view the pancreatic and biliary duct systems directly at the time of cyst excision.[51,52] In other cases, a neonatal cystoscope, a fine flexible scope (1.9–2.0 mm) with a flush channel is required. Recently, we found there was a high incidence of IHBD debris not detected by preoperative radiographic investigations,[55] and some cases where IHBD debris identified on preoperative radiography was overlooked when the case was reviewed retrospectively. These facts indicate that intraoperative endoscopy is necessary at the time of CE even if preoperative radiography does not indicate the presence of IHBD debris. Another striking finding was that debris can be present in the absence of IHBD dilatation, although debris was more common when the IHBD were dilated. Thus, we believe inspection using intraoperative endoscopy is mandatory even when there is no IHBD dilatation. In a recent

Figure 69.8 Massive debris in the common channel observed through the pediatric cystoscope.

review of the long-term follow up of our intraoperative endoscopy patients, the incidence of postoperative stone formation was lower than reported in the literature,[56] evidence of the clinical benefit of performing intraoperative endoscopy during CE.

LAPAROSCOPIC SURGERY

Recent advances in laparoscopy technology have enabled pediatric/hepatobiliary surgeons to perform minimally invasive surgery for CBD.[57] In 1995, the first laparoscopic CE in a child was reported.[58] Since then, several authors have reported the safety and feasibility using minimally invasive techniques for advanced hepatobiliary surgery in children.[59–62] Although technically more challenging, the general concepts are the same as for open surgery. The authors' approach is to use conventionally placed trocars (right upper quadrant, left paraumbilical, left upper quadrant; scope in the umbilicus) to free the cyst and transect it at mid level. An additional 3.9 mm trocar in the left epigastrium is used for a fine ureteroscope. Under laparoscope guidance, the tip of the scope is inserted into the common channel through the distal cyst to remove any protein plugs (Fig. 69.9).[63] Another two trocars are added for the hepaticojejunostomy; lateral right subcostal, and between the lateral right subcostal and right upper quadrant trocars. Hepaticojejunostomy is then performed using 5/0 absorbable sutures with the right upper quadrant trocar as a needle holder in the right hand; a 5 mm trocar between the lateral right subcostal and right upper quadrant trocars for the scope; and the 3 mm subcostal trocar as a needle receiver in the left hand. Both the right and left edge sutures are exteriorized and used as traction sutures during anastomosis of the anterior wall.

Although long-term follow-up results have yet to be collated, experienced laparoscopic surgeons would appear

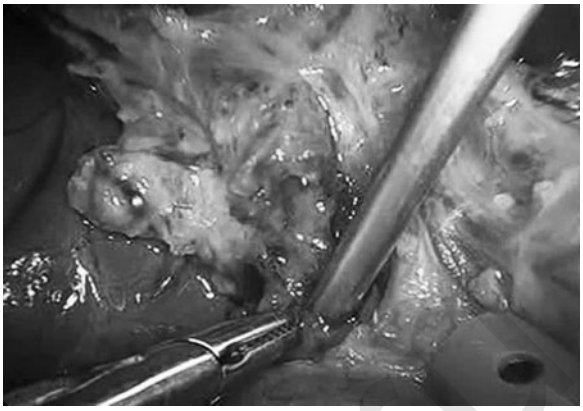

Figure 69.9 Under laparoscope guidance, the tip of the scope is inserted into the common channel through the distal cyst to remove any protein plugs.

to obtain results as good as those for open surgery. In a report comparing laparoscopic CE and Roux-en-Y reconstruction with open surgery in children,[64,65] operating time was found to be longer, and overall costs higher, but there was significantly less blood loss and duration of hospitalization was shorter. There were no significant differences for the incidence of bile leakage or wound infection rates.

Most recently, robot-assisted laparoscopic resection of CBD has been reported.[66,67]

POSTOPERATIVE COMPLICATIONS AND MANAGEMENT

Surgical outcome is better and early morbidity lower in younger children than in older children. The authors[68] reviewed 200 children and 40 adults who underwent CE and HE cyst excision hepaticoenterostomy (CEHE) and found that 18 out of 200 (9.0%) children developed complications post-CEHE. No stone formation was seen in the 145 children who had CEHE before the age of five years in our series, and there were 18 children who had 25 episodes of complications post-CEHE including cholangitis, IHBD stone formation, pancreatitis, stone formation in the intrapancreatic terminal choledochus or pancreatic duct, and bowel obstruction. There were no complications in the 70 children who had intraoperative endoscopy in our series.[68] Stones developed in seven (12.7%) of 55 children who had CEHE when they were more than five years old. For management of complications, reoperation was required in 15 children – revision of HE in four, percutaneous transhepatic cholangioscopic lithotomy in one, excision of intrapancreatic terminal choledochus in two, endoscopic sphincterotomy of the papilla of Vater in one, pancreaticojejunostomy in one, and laparotomy for bowel obstruction in six.

Careful long-term follow up is required, particularly in patients with IHBD dilatation and also dilatation of the remaining distal bile duct, pancreatic duct, and common channel, because there is a risk for chronic inflammation, stone formation, as well as the possibility of carcinoma arising at a later stage.

Hepatic cysts and abscesses

STEPHANIE A JONES, FREDERICK M KARRER, AND DAVID A PARTRICK

INTRODUCTION

Cysts and abscesses of the liver in the neonatal period are uncommon. Hepatic cysts presenting in infants are usually simple, unilocular cysts, with polycystic liver diseases presenting later in childhood or in adults. Most abscesses in infants are pyogenic with parasitic infections occurring in older children or adults. Cross-sectional imaging studies (ultrasound, computed tomography, magnetic resonance imaging) can typically make work up and localization relatively straightforward. Antenatal diagnosis of liver cysts is now more common with improving scanning technology. Treatment, however, still requires experience and judgment to prevent recurrences or complications.

SIMPLE HEPATIC CYST

Simple or solitary cysts in infants can be congenital or acquired in origin. Parasitic cysts (from hydatid disease) are rare in children and have never been reported in infancy.

Congenital cysts probably arise from defective fusion or obstruction of intrahepatic bile ducts during development, or possibly originate from peribiliary glands.[1,2] These cysts are usually single and unilocular, but septation has been reported.[3] Although one or two thin septa are regarded as normal for a simple cyst, more septae should prompt consideration of other pathologies. Simple cysts are well encapsulated with a smooth surface. There is a 2:1 female preponderance.[4] Most common in the right lobe, they abut or hang down from the liver edge.[5] The liver almost never completely covers the cyst, especially the pedunculated cysts, so the presenting portion has a bluish hue. The internal cyst wall is lined by simple cuboidal or columnar epithelium.[6] Most contain clear fluid, but it may be brownish because of remote hemorrhage. Bilious cyst fluid indicates communication with a biliary radical.

Acquired or post-traumatic cysts may result from blunt trauma or birth trauma causing an intrahepatic hematoma. The hematoma reabsorbs leaving behind a cyst cavity. These cysts are lined by granulation tissue and fibrosis and rarely communicate with the biliary tree.

Differential diagnosis of complex cystic structures in the liver

Cystic structures in the neonatal liver also include ciliated hepatic foregut cysts, choledochal cysts, and mesenchymal hamartomas, and cystadenomas.[2,4,7,8] Simple, ciliated and choledochal cysts usually are unilocular, whereas mesenchymal hamartomas and cystadenomas are multilocular. Ciliated hepatic foregut cysts (CHFC) are rare cystic structures in the neonatal liver thought to originate from remnants of embryonic foregut buds that are trapped in the liver during development. They are most often seen in the left lobe of the liver. Common imaging characteristics of CHFC are uni- or bilocular, sediment containing cysts with calcifications in the cyst wall. Fine needle aspirate of the cyst will show ciliated columnar epithelial cells in a mucoid background.[4] Mesenchymal hamartoma (MH) is an uncommon tumor of the liver usually presenting before two years of age. A characteristic finding in MH are cysts of different sizes, with a variable solid component to the mass. MH may thus be cystic, solid, or mixed in presentation. Although MH is pathologically benign, reports of malignant generation to angiosarcoma and progression to an aggressive clinical course have been described.[8] Complex cysts should be completely excised because of the reported risk of malignant degeneration of these structures.[2]

Choledochal cysts are described in Chapter 69 of this textbook.

Presentation

Most congenital cysts do not have any clinical manifestations in infancy and are not diagnosed until an older age (fourth or fifth decade of life). Some are discovered prenatally or incidentally during work up of unrelated problems.[9] When they are symptomatic in infancy, it is usually because of a

visible or palpable upper abdominal mass.[10–12] They rarely cause symptoms from compression of other structures, but infants can present with abdominal distension, feeding difficulties, respiratory distress, and duodenal obstruction secondary to a large cyst.[2] Hemorrhage, secondary infection, rupture, or torsion can lead to an acute abdominal condition, but such complications are extremely rare.[13]

Diagnosis

Cysts large enough to be detected on physical examination are easily distinguished from solid tumors by ultrasonography. Liver function is typically normal in spite of the impressive size of these cysts. Plain x-rays may show diaphragmatic elevation or a soft tissue mass displacing the gas pattern in the abdomen. Computed tomography (CT) is useful to identify the exact location and number of cysts. Other preoperative imaging techniques (cholangiography, angiography, nuclear scans) may provide additional information but are usually unnecessary. With improving imaging technology, many hepatic cysts are being discovered antenatally. In some series, small asymptomatic simple cysts comprised the majority of the prenatal hepatic findings, and these regressed spontaneously. Only one in seven required postnatal surgery secondary to increasing size or symptoms.[2] On prenatal ultrasound, placental pathology in conjunction with hepatic cysts has been linked to mesenchymal hamartomas.[14] If such a finding is noted prenatally, early resection of the liver cyst should be considered.

Treatment

Small asymptomatic cysts (<5 cm) discovered incidentally should be left alone. Large or symptomatic cysts should be treated surgically. Percutaneous cyst aspiration may rule out biliary communication or abscess, but is not definitive therapy because of a high recurrence rate.[15] Complete resection is optimal and can be accomplished easily when the cyst is pedunculated. Many of these may be amenable to minimally invasive surgical techniques. If complete excision cannot be accomplished by simple enucleation, formal lobectomy is not typically indicated. These are benign lesions, therefore the risk of treatment should not exceed the risk of the disease. Under these circumstances, partial excision is preferred. By unroofing at least one-third of the cyst cavity, any serous drainage will be reabsorbed by the peritoneal cavity.[16] The edges of the cyst can be managed by oversewing with a running absorbable suture or by electrocautery. If the cyst contains bile and cholangiography confirms communication of the cyst with the biliary tree, then internal drainage via Roux-en-Y cystojejunostomy is indicated. Infected cysts should be drained externally (see below under Treatment, p. 646).

Prognosis

The prognosis for infants with simple hepatic cysts is excellent. Mortality and cyst recurrence should approach zero.[9,17,18]

POLYCYSTIC LIVER DISEASE

When liver cysts develop throughout the liver in high number, it is usually in association with an inherited polycystic disease. The two main variants of polycystic disease are autosomal dominant (adult type) and autosomal recessive (childhood type).[19] Both are associated with polycystic disease of the kidney. Autosomal dominant polycystic kidney disease (ADPKD) is the most common form (90%). Symptoms of renal involvement (pain, hypertension, renal failure, urinary tract infection) usually do not develop until adulthood. Liver cysts in autosomal dominant polycystic disease are exceptionally rare in childhood and have not been seen in infancy.

Autosomal recessive polycystic kidney disease (ARPKD) presents in childhood. There are four subgroups (perinatal, neonatal, infantile, juvenile), with varying degrees of involvement of the kidneys and liver.[20] The most severe cases present perinatally with oligohydramnios, Potter's syndrome, pulmonary hypoplasia, and usually die shortly after birth. Patients with lesser degrees of renal involvement present at an older age with renal failure and hypertension. In some children, renal involvement is minor and they do not present until adolescence with symptoms of portal hypertension such as variceal bleeding.[21]

In all forms of ARPKD, the liver is not usually grossly cystic. The liver abnormality is termed congenital hepatic fibrosis. Microscopically, there is bile duct proliferation with irregular broad bands of fibrous tissue containing multiple microscopic cysts formed by disordered terminal bile ducts, chiefly in the portal areas. The incidence of portal hypertension in ARPKD increases with longevity and appears to be inversely related to the severity of the renal disease. Treatment for portal hypertension is not required in infancy since it takes time for esophageal varices with the tendency to bleed to develop. If portal hypertension leads to esophageal bleeding, endoscopic treatment or portosystemic shunting is preferred. Hepatic synthetic function is usually preserved and the portal hypertension may improve in adolescence as other collaterals develop. Therefore, liver transplantation is usually not needed. Rarely, fibrosis is accompanied by cystic dilation of intrahepatic biliary ducts like Caroli's disease. This rare variant does not require treatment in infancy.[22]

The named subgroups of ARPKD aid discussion but are far from distinct. There is, in fact, considerable overlap among individuals and within families. In infancy, the treatment of ARPD only addresses the renal and consequent pulmonary insufficiency. No treatment is required for the hepatic lesion.

HEPATIC ABSCESSES

Incidence and etiology

The most common source of hepatic abscess in children has historically been perforated appendicitis (Fig. 70.1), but the incidence in this population has decreased since the introduction of antibiotics. It is now more commonly seen in

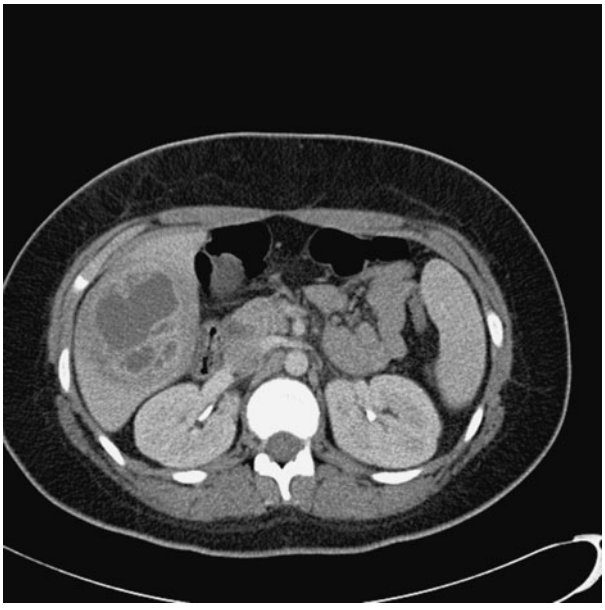

Figure 70.1 Computed tomography abdomen of a 12-year-old girl with a post-appendicitis right lobe liver abscess.

children with an underlying immune deficiency.[23] Although approximately 50% of children with pyogenic hepatic abscess are less than six years old, neonatal hepatic abscesses are rare. One study reported only three cases of hepatic abscesses out of 11403 neonatal admissions.[24] Even though rare, they can definitely be lethal in this vulnerable population. In this review, only 18 neonatal cases of solitary hepatic abscess were identified in the English literature from 1900.[24] In an earlier review, 24 cases were identified historically (including cases of multiple abscesses), to which the authors added an additional 13.[25] Neonatal liver abscess seems to differ considerably from the disease in older children. The patent umbilical vein in neonates provides ready access for bacteria to the liver, and umbilical vessel catheterization is a significant predisposing factor in hepatic abscess formation.[26,27] In hospitalized infants, umbilical vein catheters allow bacteria colonizing the umbilical stump a direct route to the liver. Less common sources of liver abscesses are inoculation via the portal vein from necrotizing enterocolitis,[28] isolated bowel perforations, and other intra-abdominal infections of the newborn. Bacteremia from meningitis or another septic insult can also result in hepatic abscesses via the hepatic artery.[29] Multiple pyogenic hepatic abscesses can complicate neonatal sepsis. Hepatic abscess has also been reported as a rare complication of ventriculoperitoneal shunts (six cases have been reported in the literature, primarily in older patients).[30] More recently, the majority of neonatal cases of hepatic abscess have occurred in premature neonates who are relatively immunosuppressed and have undergone umbilical vessel catheterization (Box 70.1).[24,31] There are reported associations of hepatic abscesses in infants exposed to HIV from the mother, misplaced umbilical catheters (right-sided abscesses), or the use of hypertonic glucose solutions via an umbilical catheter.[31]

The infecting organisms in neonates are more often Gram-negative than Gram-positive. Kays[18] reviewed the infectious causes of pyogenic liver abscesses, and in 22 neonates (less than one month of age) Gram-positive aerobes accounted for only 27% of abscesses whereas Gram-negative aerobes were responsible for 73%. Fungus was the infectious source in 5% (one patient, although an additional case has since been reported[24]), and anaerobic organisms have not been isolated from any neonatal liver abscess reported in the literature. This is in contrast to older children with hepatic abscess where up to 50% of infecting organisms isolated are Gram-positive, 25% are Gram-negative, 10% are anaerobic, 6% are fungus, and the remainder are unknown (cryptogenic). Others have noted polymicrobial infections in up to 50% of hepatic abscesses.[32]

Box 70.1 Predisposing factors for neonatal hepatic abscess

- Prematurity (immunocompromised)
- Umbilical vein catheterization (colonizing organisms, hypertonic glucose solution, misplaced catheter)
- Omphalitis
- Intra-abdominal infection (necrotizing enterocolitis, bowel perforation)
- Bacteremia (meningitis)

Presentation and diagnosis

The clinical diagnosis of neonatal hepatic abscess remains difficult. The classic findings of fever, hepatomegaly, and right upper quadrant pain are seldom obvious in the neonate. Signs and symptoms of sepsis may be present, but many infants are simply noted to be irritable with only mild abdominal distention or tenderness. A rapidly enlarging and tender liver is characteristic for a hepatic abscess, but this is not commonly found on clinical examination. Fever, leukocytosis, elevation of the sedimentation rate, as well as the C-reactive protein may be present. In the majority of patients, liver function tests are normal, but direct and indirect hyperbilirubinemia, elevation of the alkaline phosphatase, elevation of serum transaminase, anemia, and hypoalbuminemia have all been reported.[23] Therefore, to make the diagnosis in neonates, a high index of suspicion is necessary in conjunction with appropriate imaging techniques.

Radiographic evaluation

Plain films may suggest the diagnosis of hepatic abscess by the presence of an elevated right hemidiaphragm and right pleural effusion. Sometimes, a gas shadow can be visualized in the liver itself corresponding to the abscess cavity. Improvements in abdominal ultrasound and CT scanning now allow for a more rapid and accurate diagnosis in neonates.[33] Ultrasound has the advantage of lower cost, no radiation exposure, relative convenience, and ease of repeating the examination (no sedation, portable).[34,35] A hepatic abscess typically shows low or variable echogenicity by ultrasound, and cystic lesions as small as 1 cm can be

identified separate from liver parenchyma. A pyogenic abscess may have more irregular margins on ultrasound compared with an amebic liver abscess, which may be round and well-defined.[36] CT scanning has demonstrated increased sensitivity compared with ultrasound and it gives a clearer definition of the abscess.[23] The abscess margins variably enhance with the use of i.v. contrast. Figure 70.2 demonstrates the appearance on CT scan of a large hepatic abscess in a 5-day-old full-term baby. This neonate had an umbilical venous catheter in place with progressive hepatomegaly on physical examination. Included in the differential diagnosis of this cystic mass were hepatoblastoma, infantile hemangioendothelioma, mesenchymal hamartoma, and other rare liver tumors. Any neonate with persistent fever and suggestion of upper abdominal tenderness or an enlarged liver should undergo radiographic examination, especially if risk factors are present. If the ultrasound appears normal but clinical suspicion remains high, CT scanning should be performed. Specific diagnosis requires aspiration of the lesion with Gram stain and culture leading to subsequent identification of the infecting organism.

Figure 70.2 Computed tomography scan of a large hepatic abscess in a 5-day-old neonate.

Treatment

Systemic antibiotic therapy remains the mainstay of therapy for neonatal hepatic abscess. Initial antibiotic treatment should be started aggressively and include broad coverage. In neonates, empiric treatment should specifically be directed against Gram-negative bacilli and *Staphylococcus aureus*, although anaerobic abscesses have been reported and specific antibiotics covering anaerobes should be considered if the patient does not respond to initial therapy. After cultures identify the infecting organism, antibiotics can be narrowed according to the reported sensitivities. Percutaneous aspiration of smaller neonatal hepatic abscesses can be done for diagnostic purposes,[37] but larger abscesses require therapeutic drainage of the purulent fluid collection for adequate treatment.[38] Percutaneous drainage techniques have been demonstrated to be safe and efficacious in children with hepatic abscesses,[39] and recent experience in neonates has shown similar good results.[24,40] If indicated, an open abdominal exploration allows investigation and possible treatment of an intra-abdominal source of the infection. Laparoscopy may have a role in these patients in this regard. The neonate depicted in Figure 70.2 was treated aggressively with open surgical drainage and i.v. antibiotics (vancomycin to cover coagulase negative staphylococcus species cultured from the abscess cavity). This aggressive treatment resulted in nearly complete resolution of the process, documented by CT within 6 weeks (Fig. 70.3). Investigators have variably recommended 2–3 weeks of drainage with a total antibiotic course of 3–6 weeks.

Once drained and treated with antibiotics, follow up should include serial ultrasound examination. Most cases should have complete resolution, but chronic, partially calcified foci in the abscess site and portal vein thrombosis have been described after treatment.[40] Prevention of hepatic abscesses may not be possible in neonates given the many potential risk factors they may encounter. According to a recent Cochrane review,[41] there is no evidence to support the use of prophylactic antibiotics for umbilical vein catheterization to prevent sepsis or liver abscess.

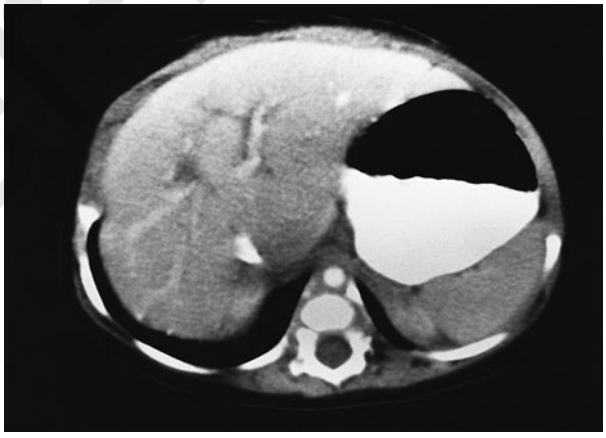

Figure 70.3 Repeat computed tomography scan 6 weeks following open surgical drainage and i.v. antibiotic treatment demonstrating complete radiographic resolution of the hepatic abscess.

AMOEBIC LIVER ABSCESS

The parasite *Entamoeba histolytica* is generally considered a possible causative organism in older children with hepatic abscess,[42,43] but it has rarely been documented to occur in newborns.[44] Hepatic abscesses due to *E. histolytica* usually follow a one- to two-month course of amoebic dysentery.[36] Due to non-specific signs and symptoms, the diagnosis again rests on clinical suspicion. Serologic testing via indirect hemagglutination or complement fixation assays can be a useful diagnostic tool. Even though investigators have tried to differentiate the radiographic appearance of amoebic versus pyogenic liver abscesses,[36,45] fine needle aspiration of the

abscess cavity is typically required. Return of characteristic 'anchovy paste' appearing material is suggestive of amoebic infection. Presence of trophozoites in stool and positive amoebic serology confirm the diagnosis.[45] Rather than drainage as the standard of therapy, amoebic liver abscesses can often be treated successfully with metronidazole and iodoquinal over a 30-day course.[46,47]

71

Omphalocele and gastroschisis

STEVEN W BRUCH AND JACOB C LANGER

INTRODUCTION

Omphalocele (also known as exomphalos) consists of a central abdominal wall defect that permits herniation of abdominal viscera into the umbilical cord. A membrane that is made of Wharton's jelly, from which the umbilical cord emerges (Fig. 71.1), covers the viscera. Pare provided the first description of an omphalocele in 1634. Hey reported the successful treatment of an omphalocele by primary repair in 1803, and Ahlfeld described the escharotic treatment using alcohol in 1899. In 1814, Scarpa observed that omphaloceles were often associated with other congenital anomalies.

Gastroschisis is a smaller abdominal wall defect to the right of a normally positioned umbilical cord, which permits herniation of intestine (Fig. 71.2), as well as occasionally liver, testis, or ovary. There is never an associated sac, and other than non-rotation and intestinal atresia, there are few associated congenital anomalies. Gastroschisis was first described by Calder in 1733, and the first surgical treatment for gastroschisis was described by Fear in 1878.

The surgical repair of abdominal wall defects has evolved over many years, with advances in diagnostic ability, neonatal intensive care, and anesthetic techniques. Although Gross popularized the skin flap closure of large omphaloceles in 1948,[1] it was Olshausen who first described this technique in 1887.[2] In 1966, Izant *et al.*[3] introduced manual stretching of the abdominal wall to make more room for primary closure. Schuster created the first mesh silo in 1967 to temporarily house the herniated viscera until primary closure could be accomplished.[4] Recently, a spring-loaded silo was developed which permits placement of the silo without the need for fascial sutures.[5]

Two additional advances in the medical management of infants with abdominal wall defects have had a significant impact over the past 30 years. Raffensperger and Jona[6] were

Figure 71.1 Omphalocele. The viscera (in this case liver and small bowel) are covered by a sac that is composed of Wharton's jelly, and the umbilical cord enters the top of the sac.

Figure 71.2 Gastroschisis. The defect is to the right of the umbilical cord and the entire intestinal tract is exteriorized. There is no sac. The bowel wall and mesentery are thickened and foreshortened.

the first to use postoperative paralysis and ventilator support in the neonatal intensive care unit to hasten abdominal wall closure, either primarily or after silo placement. Filler *et al.*[7] introduced the use of total parenteral nutrition (TPN) to the neonatal population, which has become a crucial component in the high survival rate of infants with abdominal wall defects.

EMBRYOLOGY AND ETIOLOGY

During the 6th week of embryonic development, the intestines begin to grow rapidly and migrate out of the umbilical ring into the umbilical cord.[8] By the tenth week, the intestines return to the abdominal cavity, rotating 270° counter-clockwise to attain their normal position. An omphalocele results from failure of the bowel to return to the abdomen, possibly due to delayed closure of the lateral folds with persistence of a large umbilical ring. The defect is centrally located on the abdomen, varies in size, and has a sac covering the abdominal contents that consists of peritoneum, Wharton's jelly, and amnion. Because the process of intestinal rotation normally occurs after return of the viscera to the abdomen, infants with omphalocele usually have non-rotation or malrotation. In addition to the intestine, some or all of the liver may also be present in the sac. The liver is often round and globular in appearance, central in location, and has an abnormal fixation to the diaphragm. The hepatic veins appear tortuous and wander close to the skin edge at the superior aspect of the defect. The spleen and ovaries or testes may also be found in the sac. Failure of the cephalic fold to close leads to lower sternal abnormalities and an epigastric omphalocele, which is commonly associated with cardiac defects, pericardial absence, and an anterior diaphragmatic defect, together known as 'pentalogy of Cantrell'. Failure of the caudal fold to close leads to a hypogastric omphalocele often associated with bladder or cloacal exstrophy.

Gastroschisis results in bowel herniation through a small defect to the right of the normally formed umbilical cord. There are several hypotheses to explain the development of the gastroschisis defect. In 1980, DeVries hypothesized that abnormal involution of the right umbilical vein results in adverse effects on the surrounding mesoderm and eventual body wall rupture.[9] One year later, Hoyme *et al.*[10] proposed that disruption of the omphalomesenteric or vitelline artery supplying the yolk sac near the umbilicus results in infarction and necrosis at the base of the umbilical cord followed by rupture of the abdominal wall. In 2007, Feldcamp *et al.*[11] theorized that defective closure of one or more of the embryonic body wall folds results in the gastroschisis defect. In 2009, Stevenson *et al.*[12] proposed that failure of the yolk sac and related vitelline structures to be incorporated into the umbilical stalk results in perforation of the abdominal wall that acts as an egress point for the intestine. Although a small number of cases may result from rupture of an omphalocele *in utero*, the exact mechanism for the development of gastroschisis remains unclear.[13] Despite this, the clinical scenario is well described. The entire intestinal tract is usually eviscerated, floating free in the amniotic cavity without an enveloping sac. Ovary, testis, and liver are less often involved. The intestines may develop a thick inflammatory peel, are foreshortened, and have a thickened mesentery – findings that correlate with functional impairment of motility and nutrient absorption. These changes result from a combination of factors, including contact with the amniotic fluid and constriction at the abdominal wall defect.

The cause of both omphalocele and gastroschisis is unknown. Omphalocele may have a genetic component, as suggested by the high incidence of structural and chromosomal anomalies, and also by the high incidence of omphalocele in several knockout models in mice.[14] Although gastroschisis is thought not to have a genetic component to its origin, Torfs *et al.*[15] described four gene polymorphisms associated with an increased risk for gastroschisis: intracellular adhesion molecule 1 (ICAM 1), endothelial nitric oxide synthase (eNOS), atrial naturetic peptide (NPPA), and alpha adducin (ADD1).[15]

INCIDENCE

The incidence of gastroschisis has been increasing worldwide over the past two decades. During that same time, the incidence of omphalocele has remained relatively constant. The EUROCAT working group reported that the incidence of gastroschisis increased from 0.60 per 10000 births in 1980–4 to 2.33 per 10000 births in 2000–2.[16] From 1987 to 2003, the overall birth prevalence for gastroschisis increased 3.2-fold in a population-based study from California.[17] The reason for this increase in gastroschisis, but not in omphalocele, is not well understood. Rasmussen and Frias[18] reviewed the currently available literature on non-genetic risk factors for gastroschisis, including sociodemographic factors, maternal therapeutic and non-therapeutic drug exposures, chemical exposures, and other factors. They found that the only factor to be definitively identified as a risk factor for gastroschisis is young maternal age. Other factors that require further confirmation include maternal exposure to certain medication including, aspirin and pseudephedrine, cigarette smoking, and illicit drugs, maternal nutritional factors, recent change in paternity, and short cohabitation time.

ASSOCIATED ANOMALIES

Omphalocele is associated with other anomalies up to 74% of the time.[19–21] Of these anomalies, 20% are cardiac, with tetralogy of Fallot and atrial septal defects being the most common.[22] Other common anomalies include:

- chromosomal anomalies (trisomy 13, 14, 15, 18 (most common), and 21), which occur in 20% of omphaloceles, and are more common in those without liver in the sac;
- Beckwith–Wiedemann syndrome (omphalocele, macroglossia, gigantism, pancreatic islet cell hyperplasia, and predisposition to Wilms' tumor and other pediatric solid tumors), which occurs in 12% of omphaloceles;
- pentalogy of Cantrell (epigastric omphalocele, anterior diaphragmatic hernia, sternal defect, pericardial defect, cardiac anomaly);

- lower midline syndrome (bladder or cloacal exstrophy, imperforate anus, colonic atresia, sacral vertebral anomalies, and meningomyelocele);
- multiple congenital anomalies, with malformations of the musculoskeletal, urogenital, cardiovascular, and central nervous systems being most common.

Gastroschisis occurs in association with other abnormalities much less frequently. The majority of the associated abnormalities involve the gastrointestinal tract. Intestinal atresia occurs in 10–15% of cases, and is thought to be secondary to a vascular accident or from constriction of the blood supply to the intestine at the defect. Meckel's diverticulum and intestinal duplications have also been noted.

FUNCTION OF EXTERIORIZED VISCERA

Because of the presence of a sac in most omphaloceles, the exteriorized viscera usually function normally. In infants with gastroschisis, however, the exteriorized intestine becomes thickened and shortened, and suffers from impaired motility and nutrient absorption.[23] A number of experimental studies have been done to investigate the etiology of this bowel damage. The results of these studies suggest that:

- intestinal damage arises from both amniotic fluid exposure and constriction of the bowel at the abdominal wall defect;[24,25]
- the damage occurs late during gestation;[26]
- amniotic fluid exposure causes injury because of meconium, rather than urine, in the fluid;[27]
- amniotic fluid exposure results in changes in collagen composition and in the production of mucosal enzymes;[28–30]
- levels of inflammatory cytokines in the amniotic fluid of fetuses with gastroschisis are elevated.[32]

Although there is a significant amount of variability in the severity of these abnormalities, intestinal transit and absorption tend to return to normal by six months in most infants.

PRENATAL DIAGNOSIS AND MANAGEMENT

The unique anatomic characteristics of omphalocele and gastroschisis allow them to be identified and differentiated using prenatal ultrasound. The diagnosis of omphalocele cannot be made definitively prior to the tenth gestational week, as the intestines are normally located in the umbilical cord up until that time. Although it is usually possible to sonographically differentiate omphalocele from gastroschisis, prenatal rupture of an omphalocele may make this more difficult. An abdominal wall defect is often suspected on routine screening because of elevation of the maternal serum alphafetoprotein (MSAFP), which is elevated in 90% of mothers carrying fetuses with omphalocele and 100% of those with gastroschisis.[33] Using a combination of maternal serum screening and ultrasound, the sensitivity and specificity for prenatal diagnosis of abdominal wall defects should approach 100%.[34]

Once an abdominal wall defect is identified, a search for additional anomalies should be carried out. If the problem is clearly gastroschisis, this can be limited to a careful anatomic ultrasound. For fetuses with omphalocele, both structural and chromosomal problems should be sought. Karyotype analysis by amniocentesis or chorionic villous sampling, and an anatomic ultrasound, including fetal echocardiography, should be completed. In most series, approximately two-thirds of associated abnormalities are detected prenatally in these fetuses.[35]

Currently, *in utero* repair is not recommended for either gastroschisis or omphalocele. Based on the principle that amniotic fluid exposure results in intestinal damage, several authors have advocated amniotic fluid exchange or amnioinfusion for the fetus with gastroschisis. Animal experiments suggest that bowel damage may be ameliorated with this technique,[36] and preliminary clinical experience was encouraging.[37–39] However, Midrio *et al.*[40] evaluated the effectiveness of serial amnioexchange in eight fetuses and failed to show reduced concentrations of inflammatory mediators and digestive substances in the amniotic fluid. In cases of gastroschisis with severe oligohydramnios, amnioinfusion may be lifesaving.

Serial ultrasound examination of herniated bowel in fetuses with gastroschisis is standard. Although prenatal ultrasound findings including bowel wall thickening, bowel dilation, presence of an associated peel, matting of the bowel, loss of peristaltic activity, changes in bowel wall echogenicity, attenuation of mesenteric blood flow, and changes in stomach position have been correlated with postnatal outcomes in some studies,[41–43] more recent studies have suggested that none of these findings predicted a worse postnatal course.[44,45] A large systematic review by Tower *et al.*[46] suggested that prenatal bowel dilation does not predict an increased risk of adverse postnatal outcome.

The timing, location, and mode of delivery may impact the outcome of infants with omphalocele and gastroschisis. Most infants with omphalocele should be delivered at term. In contrast, infants with gastroschisis may benefit from early delivery to minimize the damage from exposure of the bowel to amniotic fluid. Many centers choose to deliver at 37 weeks' gestation after documenting lung maturity, although this remains controversial.[47–49] Most studies looking at this question use historical controls to compare early to spontaneous delivery, and report both improved[50,51] and worse[52] outcomes for early delivery. Hadidi *et al.*[53] reported outcomes from two obstetric groups delivering infants into the same neonatal intensive care unit over the same time period, one preferring early Cesarean delivery at 36 weeks and the other preferring later spontaneous vaginal delivery. The results were mixed. They found that infants with gastroschisis born by early elective Cesarean delivery had a higher incidence of primary closure, fewer complications, mostly septic in nature, and they began enteral feeds sooner. However, they reported no difference in ventilator days, or overall length of stay in the two groups.[53] Early delivery does not necessarily need to be done by Cesarean section, as it has been shown that the average gastroschisis pregnancy goes into spontaneous labor around 37 weeks.[54]

Use of routine Cesarean delivery for both omphalocele and gastroschisis also remains controversial. There is general agreement that infants with a very large omphalocele should be delivered in this manner to prevent injury to the exteriorized liver; however, infants with smaller defects should probably be delivered vaginally unless there are obstetric indications for Cesarean section.[55] Many retrospective studies have been carried out comparing Cesarean and vaginal delivery for infants with gastroschisis, with most demonstrating no benefit of Cesarean delivery.[55–58] In most of the studies in which a benefit was found, the delivery was carried out before term, suggesting that it was the early delivery rather than the Cesarean section which conferred the benefit.[49,59,60]

With very few exceptions, all infants with an abdominal wall defect should be delivered at a perinatal center, where immediate neonatal and surgical expertise is available.[47,61]

NEWBORN MANAGEMENT

The initial treatment of a newborn with omphalocele or gastroschisis consists of fluid resuscitation, nasogastric decompression, avoidance of hypothermia, and local care of the exteriorized viscera. In infants with gastroschisis, the bowel should be inspected to ensure its blood supply is not compromised by twisting of the mesentery or constriction at the abdominal wall defect. If the size of the abdominal wall defect in gastroschisis is causing vascular compromise, the defect should be enlarged immediately. The bowel should be wrapped in warm saline-soaked gauze and covered with a waterproof dressing (Fig. 71.3). A bowel bag or cellophane works well for this purpose. Children with gastroschisis should be transported and nursed on their right side to avoid kinking of the mesenteric vessels. In infants with omphalocele, the sac should be inspected for leaks before placing the dressing.

Newborns with abdominal wall defects should be placed in a temperature-controlled environment, as they lose a great deal of heat through the exposed bowel. Babies with gastroschisis require up to two to three times the amount of fluid a normal term infant would require. Isotonic solutions should be used for resuscitation, and the child should be well hydrated prior to going to the operating room for repair. Once fluid resuscitation has been accomplished, parenteral nutrition, preferably through a central venous catheter, should be initiated.

Figure 71.3 Appropriate dressing of an abdominal wall defect in the delivery room. The viscera are covered with warm saline-soaked gauze, supported on the anterior abdominal wall and covered with a waterproof dressing.

All infants should be carefully examined clinically and radiologically to ensure adequate pulmonary, cardiac, and renal function are maintained. Associated anomalies must be diligently searched for, particularly in those infants with omphalocele.

SURGICAL MANAGEMENT

The goal of surgical management for both omphalocele and gastroschisis is to place the herniated viscera back into the abdomen and to close the fascia. In many cases, this can be done in a single operation. Strategies to help accomplish this include: (1) stretching of the abdominal wall; (2) using normal saline or *N*-acetylcysteine enemas to clear the meconium from the colon; and (3) milking the small bowel contents toward the stomach and aspirating with a nasogastric tube. For omphalocele, the sac is usually removed after ligating the umbilical arteries and vein. Areas of the sac that are firmly adherent to a portion of the liver must be left in place to avoid hepatic injury. Careful dissection is required at the superior aspect of the omphalocele to avoid the malpositioned hepatic veins which are often very superficial. In some cases, the abdominal wall defect may require enlargement in order to fit the viscera back inside the abdomen. In all cases of abdominal wall defects, the bowel should be inspected to look for associated atresias and for evidence of a rotation abnormality. If an atresia is identified and the bowel appears to be healthy, the atresia should be repaired with a primary anastomosis. If the bowel is too thickened or inflamed, a stoma may be performed or the abdominal wall defect repaired with the plan for repair of the atresia at another laparotomy several weeks later.[62,63] Ideally, the intestine should be arranged in a position of non-rotation, although in most cases of gastroschisis it is difficult to assess for the presence of malrotation at the time of abdominal wall closure. In infants with omphalocele, the diaphragm should be inspected to ensure there is no defect that would only become apparent after the intestines are placed back into the abdomen.

If the viscera do not fit into the abdomen without a significant increase in intra-abdominal pressure, a silastic 'silo' can be placed and the herniated contents gradually reduced back into the abdomen over the next 1–10 days (Fig. 71.4). Parenteral antibiotics should be continued until the silo is removed. The contents of the silo should be reduced every 12–24 hours as tolerated by the baby. The bowel in the silo needs to be carefully observed during the reduction to avoid mechanical injury usually due to pushing a large amount of bowel through a small defect leading to vascular compromise and bowel necrosis.[64] When the viscera have been successfully returned to the abdomen, the infant is taken to the operating room, the silo is removed, and the fascia is closed along with the overlying skin.

The decision whether to do a primary repair or to place a silo can be difficult. Excessive intra-abdominal pressure may result in abdominal 'compartment syndrome', with intestinal

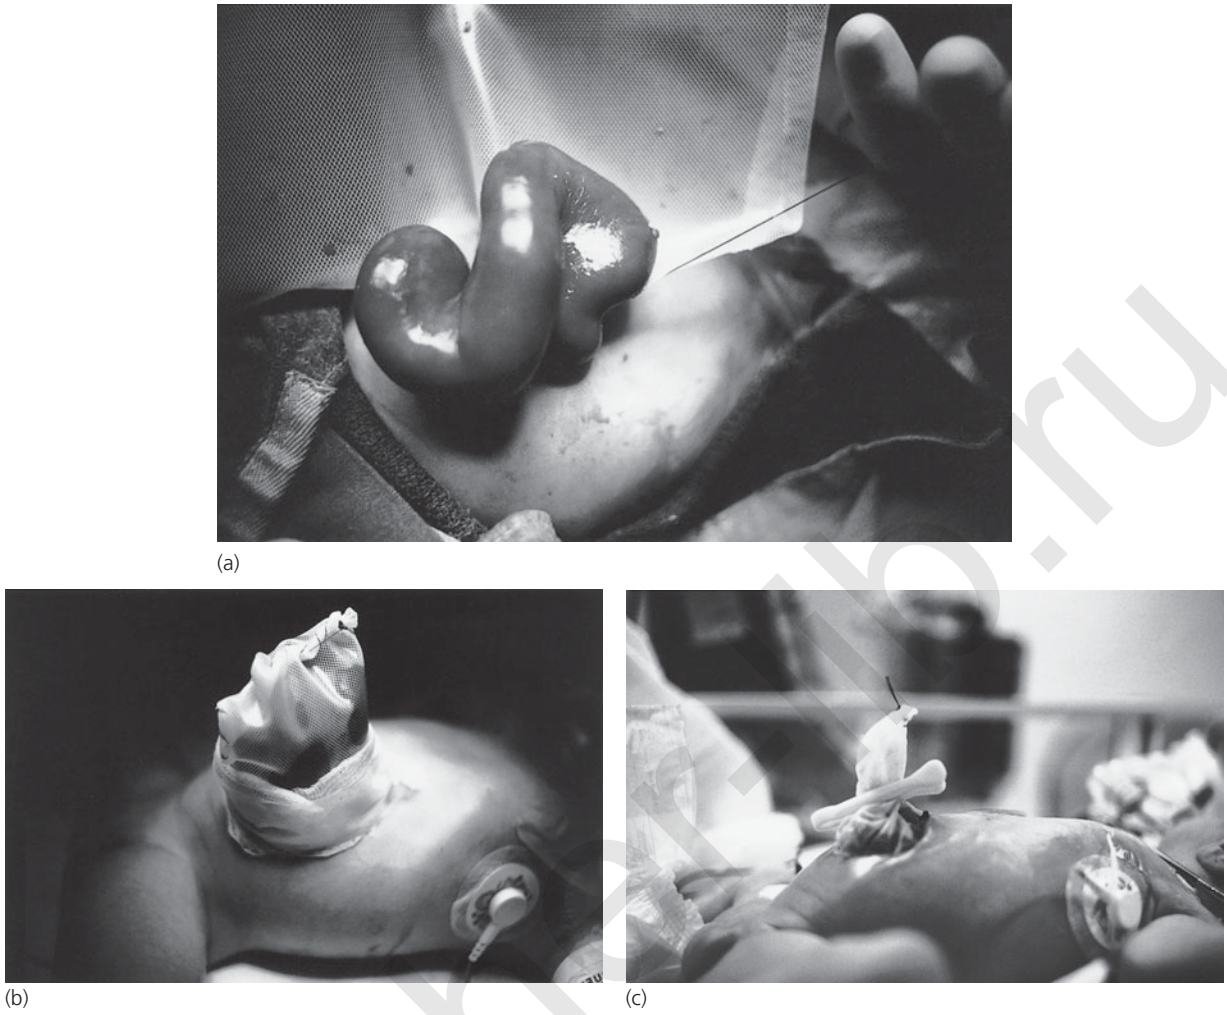

Figure 71.4 The use of a silo in a child with gastroschisis. (a) The silo is sewn to the abdominal wall, over the bowel. (b) The bowel is slowly reduced once or twice per day. (c) The abdominal wall is ready to be definitively closed.

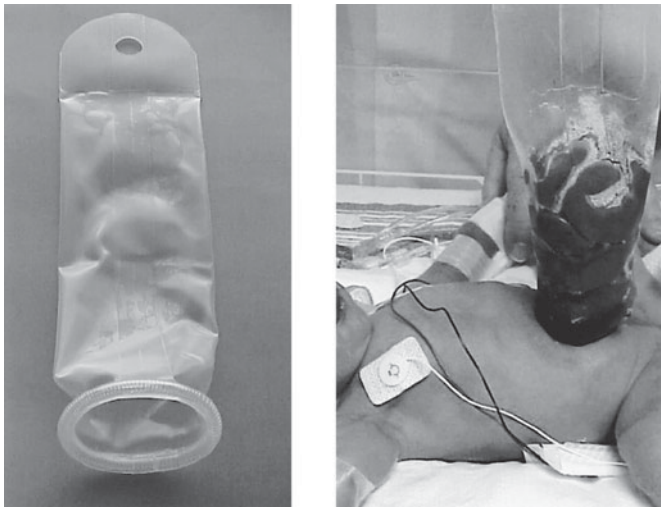
ischemia leading to perforation and fistulization, reduced hepatic and renal blood flow, and reduced circulation to and from the lower extremities. Peak airway pressures have been used for many years as an indicator of excessive intra-abdominal pressure. Experimental and clinical studies have demonstrated that intravesicular or intragastric pressures of <20 mmHg, in combination with a rise in central venous pressure of <4 mmHg correlate with a lower incidence of abdominal compartment syndrome.[65–68] These parameters may also be followed postoperatively, and during silo reduction. Elevation of pressures would suggest that the abdomen should be reopened and a silo placed.

Several innovations have been introduced that may improve the outcome for infants with gastroschisis. Immediate repair in the delivery room, as initially reported by the Detroit group[69] and now practiced by some South American surgeons, is thought to allow easier abdominal wall closure, earlier extubation, less time to initiation of feeds, and a shorter hospital stay. However, this approach has not been validated in any prospective studies. Bianchi and Dickson[70] reported a technique for closure of gastroschisis at the bedside without the use of anesthesia or a silo. Although this approach may be useful in selected patients with relatively healthy bowel, some authors have reported poor results using the Bianchi approach.[71] Several groups have advocated routine bedside placement of a spring-loaded silo, which can be introduced into the defect without the need for a general anesthesia (Fig. 71.5). After gradual reduction of the viscera over the next 0–7 days, closure of the fascia is accomplished either in the operating room, or by placing a dressing and allowing the wound to granulate.[72] In retrospective studies, this technique was associated with improved outcomes when compared to the standard approach.[5,73] However, a recent multicenter randomized controlled trial of 54 infants with gastroschisis, and a recent review of 99 cases of gastroschisis by the Canadian Pediatric Surgery Network both failed to reveal any association between abdominal wall closure technique and functional outcome.[74,75]

Occasionally, an omphalocele is so large that it is unlikely that the abdominal cavity will accept the herniated contents over a reasonable period of time, even with the use of a silo. In other cases, the infant may have severe pulmonary hypoplasia or prematurity, or associated anomalies that preclude an attempt at closure. In these cases, the omphalocele sac may be left intact and allowed to slowly granulate and eventually epithelialize.[76] In the past, this was accomplished by painting



(a) (b)

Figure 71.5 (a) Spring-loaded silo. (b) This device can be placed at the bedside without an anesthetic and permits gradual reduction of the viscera in every case, with only one trip to the operating room.

with mercurochrome or iodine,[77] but mercury or iodine poisoning was reported in some cases and these agents have been largely abandoned. The use of OpSite has also been described.[78] The authors currently advocate the use of silver sulfadiazine for this purpose, which forms an eschar on the sac. The eschar begins to granulate, then epithelializes, and eventually a pseudo-skin forms from the edges of the wound and covers the entire sac (Fig. 71.6). The resulting ventral hernia is ultimately repaired electively when the child's other medical problems have improved. Newborns with omphalocele associated with life-threatening structural or chromosomal anomalies have a poor prognosis, and a frank discussion with the neonatologists and parents should precede any aggressive treatment.

POSTOPERATIVE MANAGEMENT

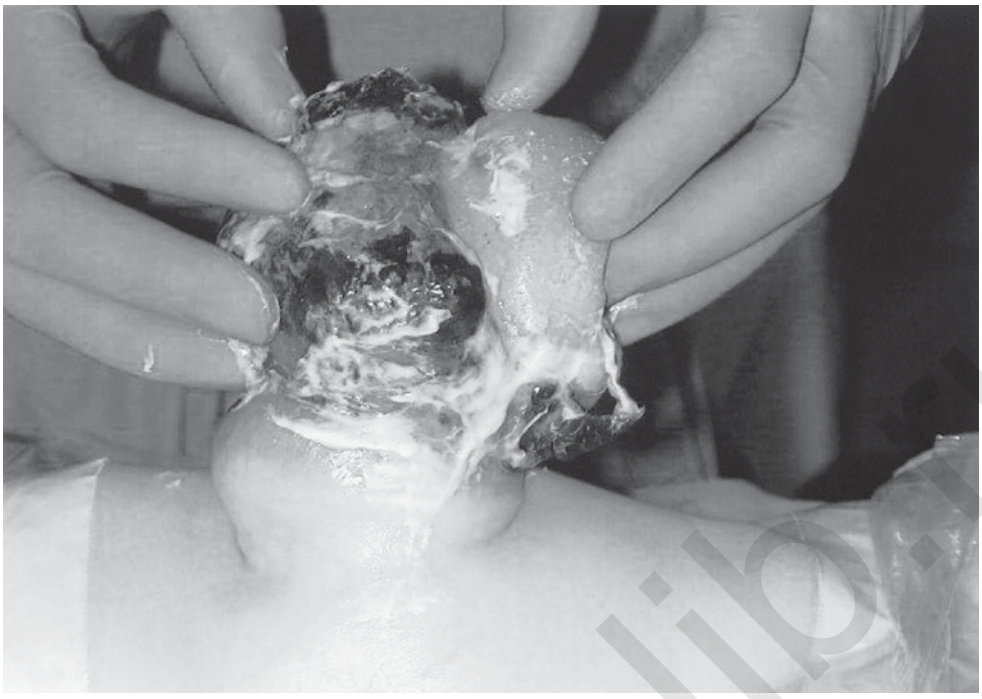
Postoperatively, feeding is started when gastrointestinal function returns; this usually takes much longer for infants with gastroschisis than with omphalocele, and can take weeks to months. If feeding is not proceeding well, the possibility of a missed atresia must be considered, and both upper and lower intestinal contrast studies should be carried out. Prokinetic agents are often used in this situation. Cisipride, which is no longer available, has been shown experimentally and clinically to improve intestinal motility.[79] Erythromycin, another prokinetic agent, however, has been shown not to have an effect on motility in infants with gastroschisis.[80]

Necrotizing enterocolitis is relatively common in infants with gastroschisis,[81] but the risk may be decreased by prevention of excessive intra-abdominal pressure during reduction of the viscera.[5,82] In addition, both omphalocele and gastroschisis are accompanied by an increased incidence of gastro-esophageal reflux, especially in the first year of life.[83] Although this can often be managed medically, some children require fundoplication or jejunostomy tube placement.[84] For many infants with an abdominal wall defect, long-term TPN must be used through a central venous catheter, which may be accompanied by complications related to line infections, metabolic disturbances, and liver injury.[85]

Functional bowel issues may be exaggerated in the subset of infants with gastroschisis who have intestinal atresia. In a review by Phillips *et al.*,[86] 12% of their gastroschisis population had an intestinal atresia. Of these, 29% did well following repair, 28% died of short bowel syndrome, necrotizing enterocolitis, or midgut infarction. The remaining 43% developed massive intestinal dilation and stasis despite having adequate bowel length. The majority of these infants required additional operations aimed at rescuing their dysfunctional bowel. These included tapering enteroplasties, diverting stomas for decompression, and anastomotic revisions.

LONG-TERM OUTCOME

The outcome of infants born with gastroschisis depends on the condition of the intestine. In uncomplicated cases of gastroschisis, the overall survival is greater than 90%.[87–90] However, the group of infants with gastroschisis that require home TPN due to loss of bowel length or inability to tolerate enteral feeds despite normal bowel length have a 50% mortality rate in the first two years of life.[90] A significant number of these patients require additional surgery, usually for adhesive intestinal obstruction, and a small group of children suffer from short bowel syndrome or long-term motility disorders which ultimately require small bowel transplantation.[91] In fact, gastroschisis is the most frequent indication for pediatric small bowel transplantation.[92] The outcome for infants with omphalocele is more dependent on the presence and severity of associated malformations. In the absence of chromosomal abnormalities, or severe pulmonary or cardiac anomalies, the majority of these children survive to live normal lives.[87,88] Henrich *et al.*[93] looked at several aspects of long-term quality of life in children with gastroschisis and omphalocele. These are depicted in Table 71.1. The results are



(a)

(b)

Figure 71.6 Escharotic management of a large omphalocele. The sac is covered with silver sulfadiazine (a). This results in granulation tissue and ultimately in epithelialization. The resulting ventral hernia (b) can be repaired at any time, when the child's medical condition improves.

Table 71.1 Long-term quality of life.

		Gastroschisis (%)	Omphalocele (%)
Gastrointestinal issues	Frequent	7	10
	Rarely or never	77	75
Physical limitations		9	7
Cosmetic results	Good or excellent	82	73
	Umbilical reconstruction	23	35
	Troubled by lack of umbilicus	24	11
Abdominal wall hernia		14	20

Omphalomesenteric duct remnants

KENNETH KY WONG AND PAUL KH TAM

INTRODUCTION

The omphalomesenteric duct is a long narrow tube that joins the yolk sac to the digestive tube in the human embryo. Normally, the duct undergoes complete obliteration during the 7th week. Incomplete obliteration results in omphalomesenteric remnants, which may be apparent in the newborn infant.[1]

ETIOLOGY

Development of the midgut in the embryo is characterized by elongation of the gut at the end of the 4th week of gestation. At the apex, the intestinal loop remains connected and open to the yolk sac via the omphalomesenteric (vitelline) duct.[2] In some people, the duct persists due to incomplete obliteration and resorption, thus giving rise to various anatomical anomalies.

PATHOLOGY

Omphalomesentric remnants can be classified into various types according to the underlying anomaly (Fig. 72.1):

- persistent omphalomesenteric duct (patent or obliterated);
- omphalomesenteric duct cyst;
- Meckel' diverticulum;
- umbilical mucosal polyp/umbilical cyst.

HISTORY, PRESENTATION, AND DIAGNOSIS

Persistent omphalomesenteric duct

The omphalomesenteric duct may be patent and present as an omphalo-ileal fistula. The fistula may contain ectopic gastric, colonic, or pancreatic tissue. After birth, the infant presents with umbilical discharge, which resembles small bowel content. An umbilical 'polyp' consisting of intestinal mucosa may also be present. In the newborn, the discharge can often result in peri-umbilical excoriation. The diagnosis is confirmed by passing a catheter through the fistula into the small intestine and aspirating small bowel content, or by injecting radiographic contrast medium into the fistula.

Rarely, the ileum may even prolapse through the omphalo-ileal fistula, giving rise to the so-called 'steer-horn' abnormality.

For obliterated omphalomesenteric duct, it may persist as a fibrous cord attaching the ileum to the umbilicus internally. The infant who has this anomaly is usually asymptomatic. However, there is a risk of small bowel volvulus occurring around such a band.

Omphalomesenteric duct cyst

The obliterated omphalomesenteric duct may contain one or more cysts. The clinical presentation of this is similar to obliterated duct, with a risk of small bowel volvulus. Sometimes, the cyst can become infected and the child may present with pain and fever.

Meckel's diverticulum

The most common omphalomesenteric remnant seen is the Meckel's diverticulum, which is the persistence of the enteral end on the anti-mesenteric side of the small intestine (Fig. 72.2). This anomaly occurs in around 2% of the population, with its location usually within 60 cm of the ileocecal. Complications of the diverticulum include bleeding, diverticulitis, and intussusception. Asymptomatic ones are usually found incidentally at laparotomies for other conditions. A recent study showed that resection of incidentally detected Meckel's diverticulum had a significantly higher postoperative complication rate than leaving it *in situ*, and that 758 resections would need to be performed to prevent

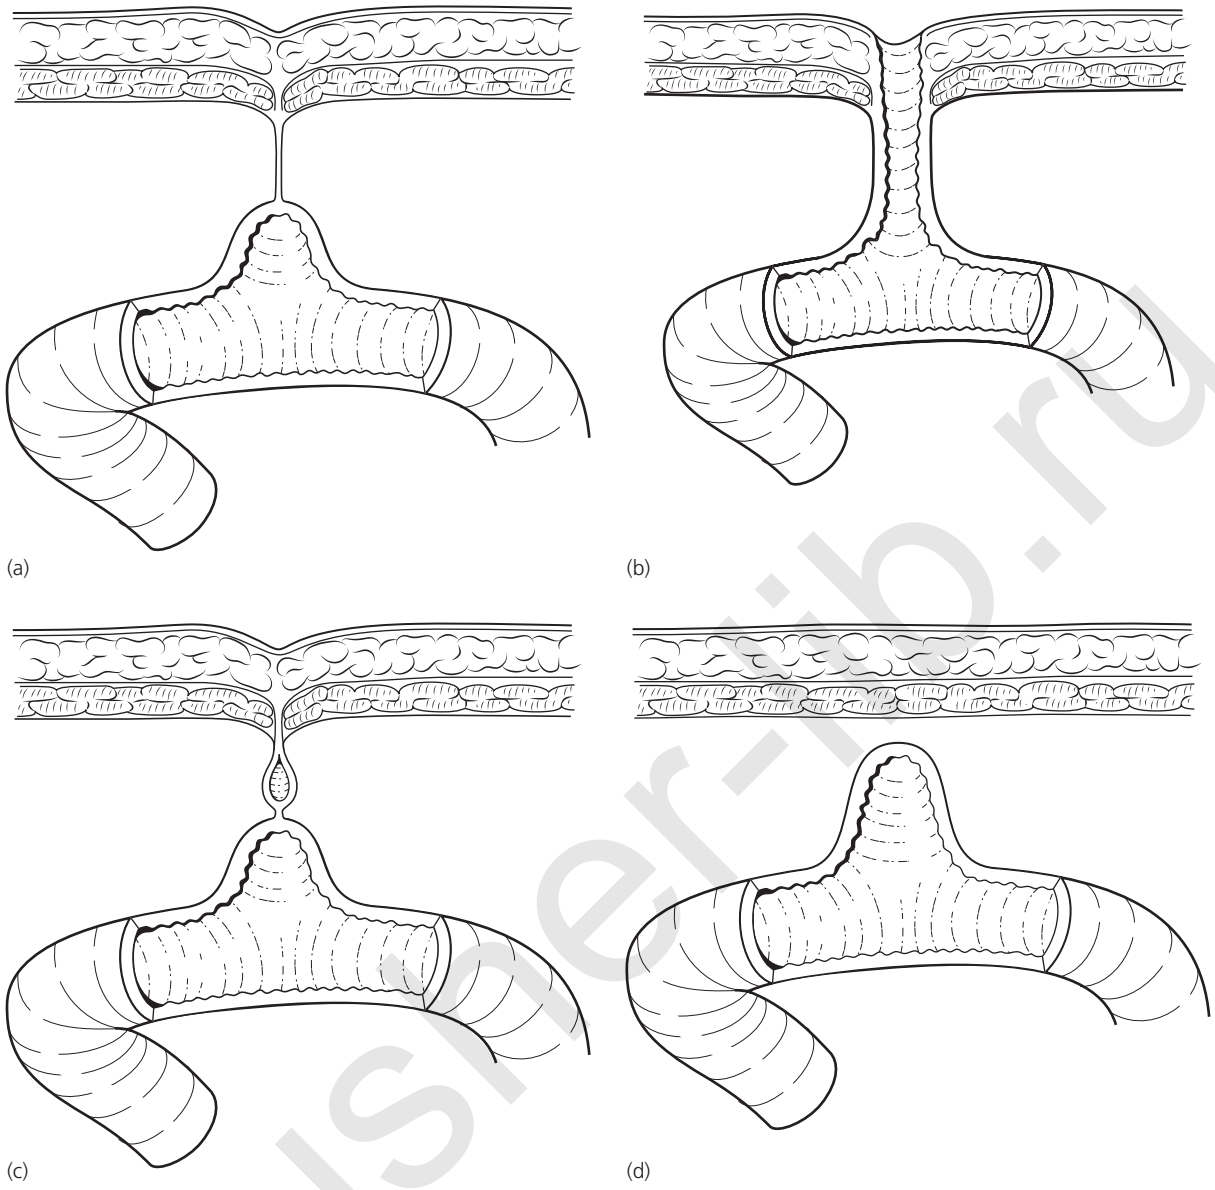

Figure 72.1 Schematic diagrams showing the various anatomical variations of omphalomesenteric remnants: (a) obliterated omphalomesenteric duct; (b) patent omphalomesenteric duct; (c) a cyst in an obliterated omphalomesenteric duct; (d) Meckel's diverticulum.

one death from the condition. As a result, there is no evidence to support the resection of incidentally detected Meckel's diverticulum.[3]

For diagnosis, the presence of ectopic gastric mucosa with the secretion of gastrin can be detected using Tc-99 radioisotope scanning (Fig. 72.3), although a negative result does not exclude the presence of Meckel's diverticulum (sensitivity of Tc-99 around 80–85%).[4]

Umbilical polyp

An umbilical polyp is a remnant of intestinal mucosa at the umbilicus. The pink, polypoid tissue produces a persistent discharge which may be blood-stained. The other differential diagnosis is an umbilical granuloma, which should respond to simple cauterization treatment. The diagnosis of an umbilical polyp may be confirmed by biopsy to look for the presence of intestinal or gastric mucosa.

OPERATIVE MANAGEMENT

Omphalomesenteric remnants are best managed operatively[5] and the approaches for the various anomalies are described below.

Excision of a patent omphalomesenteric duct

The orifice of the fistula is mobilized using a circumferential incision, preserving the surrounding umbilical skin (Fig. 72.4).

Figure 72.2 An intraoperative photograph showing a Meckel's diverticulum delivered out through an umbilical incision.

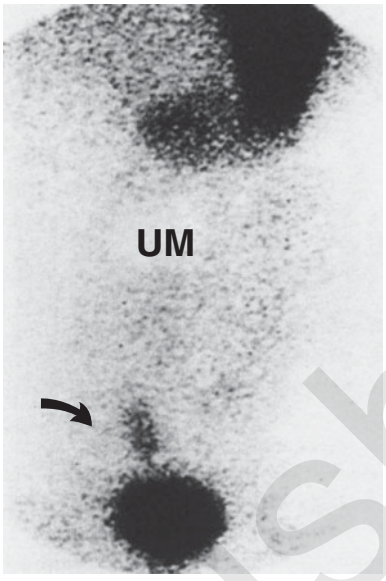

Figure 72.3 A photograph of a Tc-99 radio-isotope scan taken at 20 minutes, showing the presence of gastrin secreting mucosa in a Meckel's diverticulum.

Figure 72.4 An intraoperative photograph taken after dissection of a patent omphalomesenteric duct.

A separate skin-crease incision is made below the umbilicus. The superior skin flap, which includes the umbilicus, is elevated and the fistula is brought out through the subumbilical incision. The abdominal wall fascia is incised transversely on either side of the fistula. The umbilical vessels and the urachus are individually ligated and divided and the peritoneal cavity is entered. The fistula is traced to its termination on the distal ileum.

The blood supply to the fistula runs across the ileum, and should be ligated and divided near its origin on the mesentery. The fistula is excised with a margin of ileum using a transverse elliptical incision. The ileal defect is repaired transversely with a single interrupted layer of absorbable 4-0 sutures. The linea alba is then repaired and the subumbilical incision closed with subcuticular 5-0 suture. The circular defect in the center of the umbilicus may be left to heal by secondary intention if small, or may be loosely closed with a purse-string suture. The healed wound should resemble the umbilicus.

Meckel's diverticulectomy

Symptomatic and confirmed Meckel's diverticulum should be excised. For those patients who are asymptomatic, it is not essential to remove them. Nowadays, the procedure is assisted or even performed wholly laparoscopically in many centers. Laparoscopy is also useful in helping to diagnose symptomatic patients with negative isotope scans. The principles of laparoscopic resection remain the same as open surgery and it is the authors' preference to resect a short segment of ileum together with the diverticulum to ensure that all abnormal mucosa is removed.[6,7] For open surgery, a 2-cm peri-umbilical incision is used to gain access to the peritoneal cavity. This will ensure an excellent cosmetic result postoperatively.

The Meckel's diverticulum is situated on the anti-mesenteric border of the distal ileum, and may be bound to the adjacent small bowel mesentery by a covering of peritoneum. These adhesions are divided to mobilize the diverticulum. Occasionally, the diverticulum is attached to the umbilicus, from which it must be separated. The blood vessels on the mesenteric side are ligated and divided. Ileal resection with primary end-to-end anastomosis with single-layer, interrupted absorbable 4-0 sutures is carried out. This ensures the removal of all ectopic tissue. The fascia of the subumbilical incision is closed using 3-0 absorbable sutures, and the skin is approximated with subcuticular 5-0 sutures reinforced with adhesive strips.

Excision of an umbilical polyp

A circumferential incision is made around the polyp, preserving as much of the normal umbilicus as possible. The skin defect is repaired using an absorbable purse-string suture. Because of the possibility of an underlying connection to the ileum by a remnant of the omphalomesenteric duct, limited exploration of the peritoneal cavity is advisable. A subumbilical incision is made as described above. The abdominal wall is opened transversely and the peritoneal cavity entered. If an omphalomesenteric duct remnant is present, it is resected.

COMPLICATIONS

For conditions which involve peritoneal access (either open or laparoscopic) and intestinal resection, early postoperative complications include anastomotic leak, adhesion formation, postoperative ileus and wound infection. These are, however, rare (<5%). Intestinal obstruction from adhesions may present as a late event.

Bladder exstrophy: considerations and management of the newborn patient

ANDREW A STEC AND JOHN P GEARHART

INTRODUCTION

In this chapter, the techniques for managing the newborn with classical bladder exstrophy are discussed based on the authors' experience and data derived from more than 940 patients with bladder exstrophy, epispadias, and cloacal exstrophy from an institutional approved database at the authors' institution.

The primary objectives of modern surgical management of classic bladder exstrophy are: (1) a secure abdominal closure, (2) reconstruction of a functional and cosmetically acceptable penis in the male and female external genitalia in the female, and (3) urinary continence with the preservation of renal function and volitional voiding.

Currently, several techniques exist to reconstruct the newborn with bladder exstrophy. Regardless of the technique chosen, placing the posterior vesico-urethral unit into the pelvis combined with a successful primary closure gets the child in the best position for bladder growth and eventual voided continence. In the authors' experience, these objectives can best be achieved with newborn primary bladder and posterior urethral closure, early epispadias repair, and finally, bladder neck reconstruction when the bladder reaches an appropriate volume for an outlet procedure. This chapter will be limited to discussion on the early management and initial primary closure of these infants.

INCIDENCE AND INHERITANCE

The incidence of bladder exstrophy has been estimated to be between one in 10 000 and one in 50 000 live births.[1] However, data from the International Clearinghouse for Birth Defects monitoring system estimated the incidence to be 3.3 in 100 000 live births.[2] Two series have reported a 5:1 to 6:1 ratio of male-to-female exstrophy births.[1,2] The risk of recurrence of bladder exstrophy in a given family is approximately one in 100.[2] Shapiro *et al.* determined that the risk of bladder exstrophy in the offspring of individuals with bladder exstrophy and epispadias is one in 70 live births, a 500-fold greater incidence than that in the general population.[3] In reviews of exstrophy patient cohorts, three interesting trends have been found: (1) bladder exstrophy tended to occur in infants of younger mothers; (2) an increased risk at high parity was seen for bladder exstrophy and epispadias;[2] (3) an increased incidence occurs with *in vitro* pregnancies.[4]

EMBRYOLOGY

Bladder exstrophy, cloacal exstrophy, and epispadias are variants of the exstrophy–epispadias complex. The etiology of this complex has been attributed by Muecke to the failure of the cloacal membrane to be reinforced by ingrowth of mesoderm.[5] The cloacal membrane is a bilaminar layer situated at the caudal end of the germinal disk, which occupies the infra-umbilical abdominal wall. Mesenchymal ingrowth between the ectodermal and endodermal layers of the cloacal membrane results in formation of the lower abdominal muscles and pelvic bones. After mesenchymal ingrowth occurs, downward growth of the urorectal septum divides the cloaca into a bladder anteriorly and rectum posteriorly. The paired genital tubercles migrate medially and fuse in the midline cephalad to the dorsal membrane before perforation. If the cloacal membrane is subject to premature rupture, its stage of development when membrane rupture occurs determines if epispadias, bladder exstrophy, or cloacal exstrophy, will result.[6]

While multiple explanations have been presented, Marshall and Mueke maintain that the basic defect is an abnormal overdevelopment of the cloacal membrane, preventing medial migration of the mesenchymal tissue and proper lower abdominal wall development. Classic exstrophy accounts for

60% of patients born with this complex.[7] Of these patients, 30% are epispadias variants and 10% are cloacal exstrophies or minor variants, such as superior vesical fissure, duplicate exstrophy, and pseudoexstrophy.

ANATOMIC CONSIDERATIONS

Exstrophy of the bladder is part of a spectrum of anomalies involving the urinary tract, genital tract, musculoskeletal system, and sometimes the intestinal tract. In classic bladder exstrophy, most anomalies are related to birth defects of the abdominal wall, bladder, genitalia, pelvic bones, rectum, and anus (Fig. 73.1).

Figure 73.1 Newborn male infant with classic bladder exstrophy.

Musculoskeletal defects

Patients with classic bladder exstrophy have a characteristic widening of the pubic symphysis caused by malrotation of the innominate bones, in relation to the sagittal plane of the body along both sacroiliac joints. In addition, they display an outward rotation or eversion of the pubic rami at their junction with the iliac bones. Recently, new data by Sponseller *et al.*[8] utilizing computer tomography of the pelvis with three-dimensional reconstruction, have further characterized the bony defect associated with both classic bladder exstrophy and cloacal exstrophy. Sponseller *et al.* found that patients with classic bladder exstrophy have a mean external rotation of the posterior aspect of the pelvis of 12° on each side, retroversion of the acetabulum, and a mean 18° of external rotation of the anterior pelvis, along with a 30% shortening of the pubic rami. These rotation deformities of the pelvic skeletal structures contribute to the short, pendular penis seen in bladder exstrophy. Additionally, this rotation also accounts for the increased distance between the hips, waddling gait, and the outward rotation of the lower limbs in these children, which in itself causes little disability and usually corrects to some degree over time.

The most recent study using three-dimensional computed tomography (CT) has further increased our understanding of the pelvic anatomy in patients with bladder exstrophy.[9] In this paper, Stec *et al.*[9] showed that the sacroiliac joints are externally rotated, the pelvis is rotated inferiorly, and the pelvic volume in exstrophy patients is larger than normal controls. These new findings will hopefully serve to improve our understanding and surgical approach to pelvic osteotomy in these patients. One study was performed on fetal bony pelves with the exstrophy complex to determine histologic patterns and growth potential. Despite the abnormal gross architecture, histologically the exstrophic bones were identical to controls and completely normal; bone development was occurring at an expected rate with the potential for continued normal growth.[10]

In addition to the bony structures of the pelvis being laterally rotated, the large muscle groups constituting the pelvic floor are also flattened and laterally splayed. A fundamental tenet of bladder exstrophy repair is proper pelvic floor mobilization and placement of the vesicourethral complex deep within the pelvis. In 2001, Stec *et al.*[11] published the initial description using three-dimensional CT characterizing the pelvic floor in unclosed neonates with bladder exstrophy. This study found four primary findings that characterize the pelvic floor musculature in classic bladder exstrophy: (1) the pelvic floor covers a two-fold greater surface area in the exstrophy complex; (2) each levator ani half is outwardly rotated 38° from midline; (3) the levator ani is 31° flatter in the exstrophy complex thereby, forming much less of a supportive sling than controls; and (4) only 32% of the puborectal sling is located anterior to the rectum for pelvic support as compared to 50% in controls. Magnetic resonance imaging (MRI) studies on the pelvic floor musculature created more advanced three-dimensional models of the abnormal character of the pelvic floor muscle, demonstrating one additionally important caveat: the degree of pubic and bony diastasis does not account for all of the derangements in the pelvic floor anomaly in exstrophy.[12]

Abdominal wall defects

The triangular defect caused by the premature rupture of the abnormal cloacal membrane is occupied by the exstrophied bladder and posterior urethra. The fascial defect is limited inferiorly by the intrasymphyseal band, which represents the divergent urogenital diaphragm. This band connects the bladder neck and posterior urethra to the pubic ramus on anatomical study. The anterior sheath of the rectus muscles has a fan-like extension behind the urethra and bladder neck that inserts into the intrasymphyseal band. At the upper end of the

triangular fascial defect is the umbilicus. In bladder exstrophy, the distance between the umbilicus and the anus is always foreshortened. Although an umbilical hernia is usually present, it is usually of insignificant size. The umbilical hernia is repaired at the time of the abdominal wall closure. In a review of 181 children with bladder exstrophy, Connolly *et al.*[13] reported inguinal hernias in 81.8% of boys and 10.5% of girls.

Anorectal defects

The perineum is short and broad, with the anus situated directly behind the urogenital diaphragm, displaced anteriorly, and corresponding to the posterior limit of the triangular fascial defect. The divergent levator ani and puborectalis muscles and the distorted anatomy of the external sphincter contribute to varying degrees of anal incontinence and rectal prolapse. Anal continence is usually imperfect at an early age, but typically improves. Prolapse virtually always disappears after bladder closure. If the infant develops prolapse after closure, a bladder outlet obstruction must be ruled out.

Male genital defects

The male genital defect is severe and the most troublesome aspect of the surgical reconstruction, independent of the decision as to whether to treat by modern staged closure, combined closure, or by some form of urinary diversion. Formerly, it was thought that the individual corpus cavernosum was of normal caliber, but appeared to be shorter because of the wide separation of the crural attachments, the prominent dorsal chordee, and the shortened urethral groove. However, data by Silver *et al.*[14] have described the genital defect in bladder exstrophy in much greater detail. Utilizing MRI in adult men with bladder exstrophy and comparing this to age- and race-matched controls, it was found that the anterior corporal length in male patients with bladder exstrophy is almost 50% shorter than that of normal controls. A functional and cosmetically pleasing penis can be achieved when the dorsal chordee is released, the urethral groove lengthened, and the penis somewhat lengthened by mobilizing the crura in the midline. Potency is preserved in almost all exstrophy patients. Testis function has not been studied in a large group of post-pubertal exstrophy patients, but it is generally believed that fertility is not impaired by testicular dysfunction.

Female genital defects

Reconstruction of the female genitalia presents a less complex problem than in the male (Fig. 73.2). The vagina is shorter than normal, hardly greater than 6 cm in depth, but of normal caliber. The vaginal orifice is frequently stenotic and displaced anteriorly; the clitoris is bifid. The labia, mons pubis, and clitoris are divergent. The uterus enters the vagina superiorly so that the cervix is in the anterior vaginal wall. The Fallopian tubes and ovaries are normal. Female patients

Figure 73.2 Female infant with classic bladder exstrophy.

are typically able to bear children. Most adolescents and young adults will undergo a vaginoplasty procedure in order to wear tampons and have intercourse.

Urinary defects

At birth, the bladder mucosa may appear to be normal, however, ectopic bowel mucosa or an isolated bowel loop or more commonly, a hamartomatous polyp may be present on the bladder surface. The size, distensibility, and neuromuscular function of the exstrophied bladder, as well as the size of the triangular fascial defect to which the bladder muscles attach, affects the decision to attempt repair. When the bladder is small, fibrosed, inelastic, and covered with polyps, functional repair may be impossible. The more normal bladder may be invaginated or may bulge through a small fascial defect, indicating the potential for satisfactory capacity after successful initial closure. It is not until examination under anesthesia that the true defect can be adequately evaluated, as bladders which appear to be small in the nursery may have a substantial amount of bladder sequestered below the fascial defect.

The upper urinary tract is usually normal, but anomalous development does occur. Horseshoe kidney, pelvic kidney, hypoplastic kidney, solitary kidney, and dysplasia with megaureter are all encountered in these patients. The ureters have an abnormal course in their termination. The peritoneal pouch of Douglas between the bladder and the rectum is enlarged and unusually deep, forcing the ureter down laterally in its course across the true pelvis. The distal segment of ureter approaches the bladder from a point inferior and lateral to the orifice, and it enters the bladder with little or no obliquity. Therefore, reflux in the closed exstrophy bladder occurs in 100% of cases and subsequent surgery is usually required at the time of bladder neck reconstruction.

PRENATAL DIAGNOSIS AND MANAGEMENT

Reports have indicated that it is possible to diagnose classic bladder exstrophy prenatally.[15,16] The absence of a normal fluid-filled bladder on repeat examinations suggested the

diagnosis, as did a mass of echogenic tissue on the lower abdominal wall.[16] In a retrospective review of 25 prenatal ultrasound examinations with the resulting birth of newborn classic bladder exstrophy, several observations were made: (1) absence of bladder filling, (2) a low-set umbilicus, (3) widening of the pubic ramus, (4) diminutive genitalia, and (5) a lower abdominal mass which increased in size as the pregnancy progressed and as the intra-abdominal viscera increased in size.[17] Prenatal diagnosis of bladder exstrophy allows for optimal management including delivery in a pediatric center and appropriate prenatal counseling of the parents.

DELIVERY ROOM AND NURSERY CARE

At birth, while the bladder mucosa is usually smooth, pink, and intact, it is also sensitive and easily denuded. In the delivery room, the umbilical cord should be tied with 2-0 silk sutures close to the abdominal wall so that the umbilical clamp does not traumatize the bladder mucosa and cause excoriation of the bladder surface. The bladder may be covered with a non-adherent film of plastic wrap (i.e. saran wrap (cling film)) to prevent the mucosa from sticking to clothes or diapers. In addition, each time the diaper is changed the plastic wrap should be removed, the bladder surface irrigated with sterile saline, and a new square of plastic wrap put in place.

The parents should be educated by a surgeon with a special interest and experience in managing cases of bladder exstrophy. An exstrophy support team should be available, which includes a pediatric orthopedic surgeon, pediatric anesthesiologists, social workers, nurses with special interests in bladder exstrophy, and a child psychiatrist with experience and expertise in genital anomalies. It is important to note that the need for changing the sex of rearing in classic bladder exstrophy is almost non-existent in the male child.

Cardiopulmonary and general physical assessment can be carried out in the first few hours of life. Radionuclide scans and ultrasound studies can provide evidence of renal structure, function, and drainage, even in the first few hours of life before the patient undergoes closure of the exstrophy defect. A thorough neonatal assessment may have to be deferred until transportation to a major children's medical center can be arranged. In these days of modern transportation, no child should be more than a few hours away from a neonatal center with full diagnostic and consultative services. During travel, the bladder should be protected by a plastic membrane to prevent damage to the delicate newborn bladder mucosa.

Occasionally, preoperatively, it may become evident that a small fibrotic bladder patch that is stretched between the edges of a small triangular fascial defect without elasticity or contractility cannot be selected for the usual closure procedure. Figure 73.3 shows a bladder that is too small for closure. Examination with the patient under anesthesia may at times be required to assess the bladder adequately, particularly if considerable edema, excoriation, and polyp formation has developed between birth and the time of assessment. Decisions regarding the suitability of bladder closure or the need for waiting should only be made by surgeons with a great deal of experience in the bladder exstrophy condition. A recent review by Dodson *et al.*[18] at one institution, found on initial judgment that the bladder was too small for closure in 20 patients. After a period of time, when the bladder had grown sufficiently, closure was undertaken. Long-term follow up revealed that 50% of these patients remained dry after bladder neck reconstruction and 50% required other adjunctive procedures.

Figure 73.3 Patient with a small fibrotic bladder patch deemed too small for neonatal closure. Note the polypoid nature of the bladder mucosa.

PRIMARY BLADDER CLOSURE

Over the past two decades, modifications in the management of functional bladder closure have contributed to a dramatic increase in the success of the procedure. The most significant changes in the management of bladder exstrophy have been: (1) early bladder, posterior urethra, and abdominal wall closure; (2) the widespread use of pelvic osteotomy along with appropriate pelvic immobilization; (3) early epispadias repair at six to ten months of age; (4) reconstruction of a competent bladder neck and reimplantation of the ureters; and (5) most importantly, defining strict criteria for the selection of patients suitable for this approach.

The primary objective of functional closure is to convert the patient with bladder exstrophy into one with complete epispadias with incontinence and balanced posterior outlet resistance that preserves renal function. Typically, epispadias repair is now performed between six and ten months of age, after testosterone stimulation. Bladder neck reconstruction occurs when the child is four to five years of age, has an adequate bladder capacity, and is ready to participate in a postoperative voiding program.

Another type of staged exstrophy repair is the Kelly repair, or radical soft tissue mobilization. In this repair, the bladder and abdominal wall are closed without osteotomy after birth. Several months later, a radical soft tissue mobilization and the urogenital diaphragm and its periosteal attachments are dissected and used to allow closure of the pelvis and pelvic floor. The penis is made hypospadiac and later penile repair is

performed. Osteotomy is never used in this repair and so far continence results are modest with up to 71% of patient achieving either complete or partial continence in the largest cohort of patients reported in the literature.[19]

This offering will deal with the most common issue seen by the pediatric surgeon, that of obtaining a secure primary closure. Chan *et al.*[20] have shown that a successful closure of a good quality bladder template in a newborn is the single most important predictor of eventual voided continence.

Pelvic osteotomy

Pelvic osteotomies performed at the time of closure confer several advantages, including (1) easy re-approximation of the symphysis with diminished tension on the abdominal wall closure, eliminating the need for fascial flaps; (2) placement of the urethra deep within the pelvic ring enhancing bladder outlet resistance; and (3) bringing the large pelvic floor muscles near the midline, where they can support the bladder neck and aid in eventual urinary control.

After pubic approximation with osteotomy, some patients show the ability to stop and start the urinary stream, experience dry intervals, and in some cases become completely continent.[21] In a review article of a large number of patients referred to the authors' institution with failed exstrophy, a majority were referred with partial or complete dehiscence of the bladder, or major bladder prolapse, and had not undergone osteotomy at the time of initial bladder closure.[22]

The authors' recommendation is to perform bilateral transverse innominate and vertical iliac osteotomy when bladder closure is performed after 72 hours of age.[23] In addition, if the pelvis is not malleable or if the pubic bones are >4 cm apart at the time of initial examination under anesthesia, osteotomy should be performed, even if closed before 72 hours of age. A well-coordinated surgical and anesthesia team can perform osteotomy and proceed to bladder closure without undue loss of blood or risk of prolonged anesthesia in the child. However, one must realize that osteotomy, posterior urethral and bladder closure, along with abdominal wall closure, is a 5–7-hour procedure in these infants.

Combined osteotomy is performed by placing the patient in the supine position, preparing and draping the lower body below the costal margins and placing soft absorbent gauze over the exposed bladder. The pelvis is exposed from the iliac wings inferiorly to the pectineal tubercle and posteriorly to the sacroiliac joints. The periosteum and sciatic notch are carefully elevated and a Gigli saw is used to create the transverse innominate osteotomy, exiting anteriorly at a point halfway between the anterosuperior and anteroinferior spines (Fig. 73.4). This osteotomy is created at a slightly more cranial level than that described for a Salter osteotomy, in order to allow placement of fixator pins in the distal segments.

In addition to the transverse osteotomy, the posterior ileum may be incised from the anterior approach in an effort to correct the deformity more completely. This is important because anatomical studies have shown that the posterior portion of the pelvis is also externally rotated in patients with exstrophy, and as patients age they lose the elasticity of their sacroiliac ligaments. For this part of the osteotomy, an osteotome is used to create a closing wedge osteotomy vertically and just lateral to the sacroiliac joint. The proximal posterior iliac cortex is kept intact and used as a hinge. This combination of osteotomies easily corrects the abnormalities in both the anterior and posterior aspects of the pelvis.

Two fixator pins are placed in the inferior osteotomized segment and two pins are placed in the wing of ileum superiorly. Radiographs are obtained to confirm pin placement, the soft tissues are closed, and the urologic procedure is then performed. At the end of the procedure, external fixators are then applied between the pins to hold the pelvis in a corrected position. Light longitudinal skin traction is used to keep the legs still. The patient remains in the supine position in traction for approximately 4 weeks to prevent dislodgement of tubes and destabilization of the pelvis. The external fixator is kept on for approximately 6 weeks until adequate callus is seen at the site of osteotomy. Postoperatively, in newborns who undergo closure without osteotomy in the first 48–72 hours of life, the baby is immobilized in modified Bryant's traction in a position in which the hips have 90° flexion. When modified Bryant's traction is used, the traction is employed for 4 weeks.

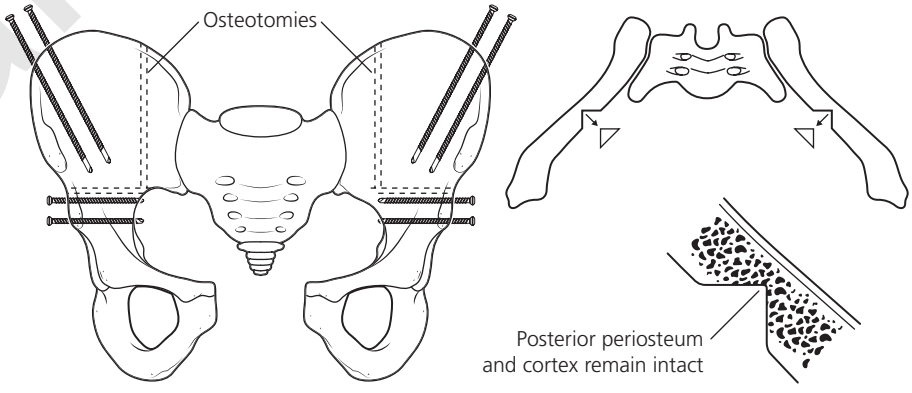

Figure 73.4 Combined transverse anterior innominate and anterior vertical iliac osteotomy with pin placement and preservation of the posterior periosteum and cortex.

Bladder, posterior urethral, and abdominal wall closure

The various steps in primary bladder closure are illustrated in Fig. 73.5. A strip of mucosa 2 cm wide, extending from the distal trigone to below the verumontanum in the male and to the vaginal orifice in the female, is outlined for prostatic and posterior urethral reconstruction in the male and adequate urethral closure in the female. The male urethral groove length is typically adequate and no transverse incision of the urethral plate needs to be performed for urethral lengthening. The diagrams in Fig. 73.5a–c show marking of the incision with a blue marker pen from just above the umbilicus down around the junction of bladder and the paraexstrophy skin to the level of the urethral plate. The approximate plane is entered just above the umbilicus and a plane is established between the rectus fascia and the bladder (Fig. 73.5c,d). The umbilical vessels are doubly ligated and incised allowing them to fall into the pelvis. The peritoneum is taken off the dome of the bladder at this point so that the bladder can be placed deeply into the pelvis at the time of closure. The plane is continued caudally down between the bladder and the rectus fascia until the urogenital diaphragm fibers are encountered bilaterally. The pubis will be encountered at this juncture and a double-pronged skin hook can be inserted in this bone and pulled laterally to accentuate the urogenital diaphragm fibers and help the surgeon radically incise these fibers between the bladder neck, posterior urethra, and the

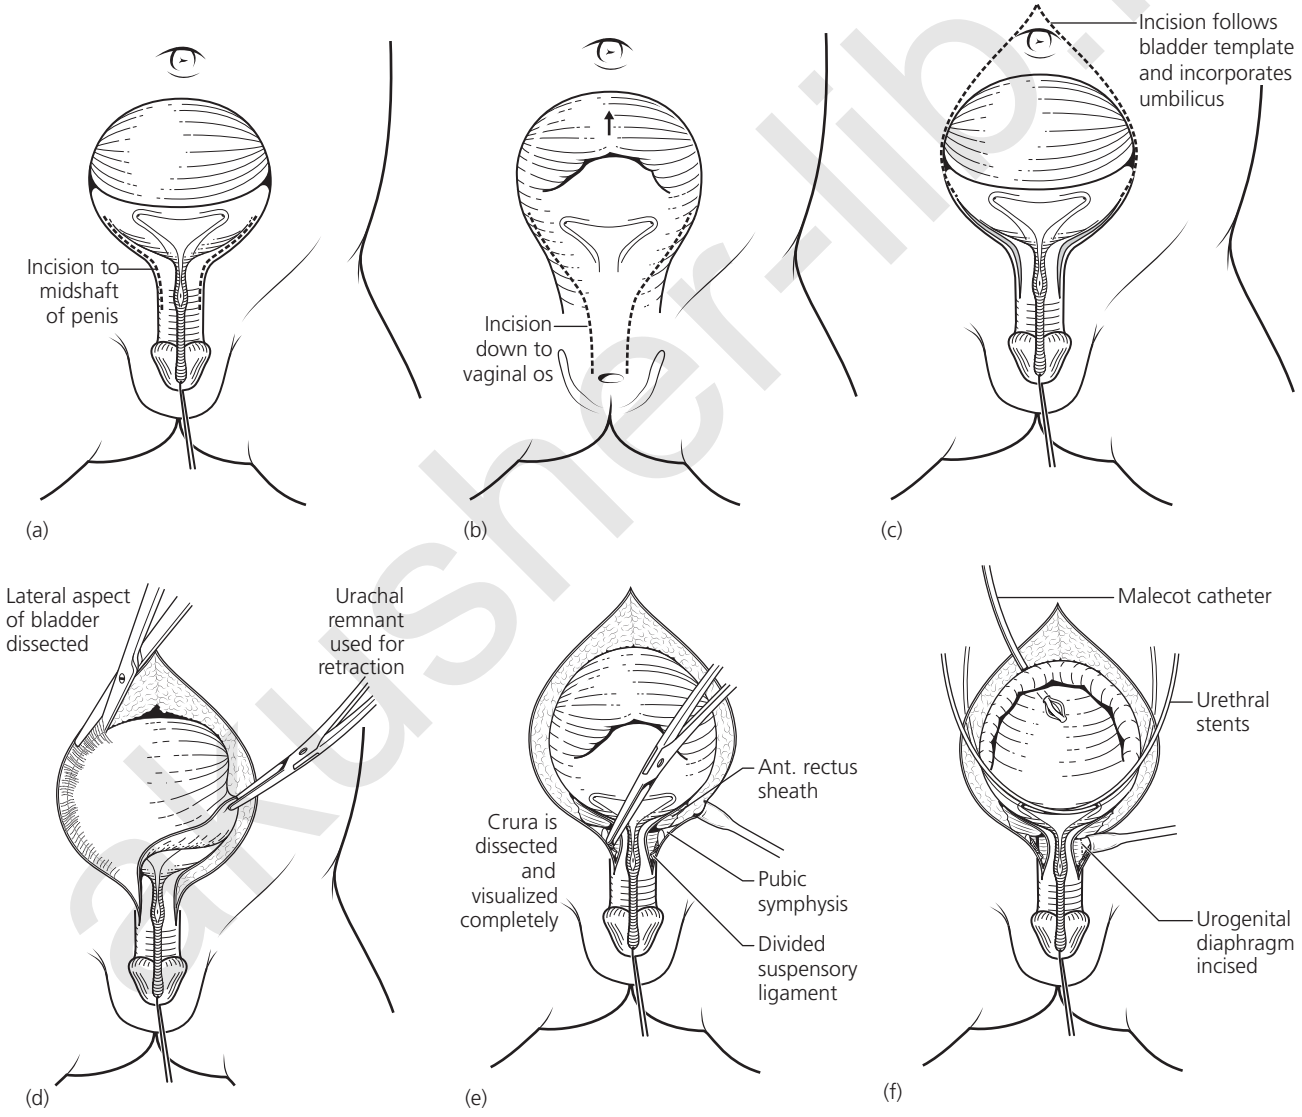

Figure 73.5 (a) Marking of the initial incisions for a male exstrophy patient from trigone around urethral plate. (b) Marking of comparable incisions for closure of a female exstrophy patient down to vaginal os. (c) Marking of the subsequent incision around the umbilicus and bladder, joining the initial dissection. (d) Development of the retropubic space and division of the lateral bladder attachments. (e) The urogenital diaphragm and anterior corpora are freed from the pubis in a subperiosteal plane. (f) Final deep incision of the remnant urogenital diaphragm fibers and insertion of a suprapubic tube. (g) Exit of the ureteral stents from the lateral sidewall of the bladder and the first layer of the bladder wall closure. (h) Closure of fascia is performed after placement of a No. 2 nylon horizontal mattress suture to approximate the pubis.

pubic bone. Gentle traction on the glans of the penis at this point will show the insertion of the corporal body on the lateral inferior aspect of the pubis. These urogenital fibers are taken down sharply with the electrocautery down to the pelvic floor in their entirety. If this maneuver is not performed adequately, the posterior urethra and bladder will not be placed deeply into the pelvis. Therefore, when the pubic bones are brought together, the posterior vesico-urethral unit will be brought anteriorly in an unsatisfactory position for later reconstruction.

The corporal bodies are not brought together at this juncture, as later Cantwell–Ransley epispadias repair will require the urethral plate to be brought beneath the corporal bodies. If the urethral plate is left in continuity, it must be mobilized up to the level of the prostate in order to create as much additional urethral and penile length as possible. Further urethral lengthening can be performed at the time of epispadias repair, at around six months of age.

Apparent penile lengthening is achieved by exposing the copora cavernosa bilaterally and freeing the corpora from their attachments to the suspensory ligaments on the anterior part of the inferior pubic rami. However, since Silver *et al.*[14] have shown that there is a 50% shortage of length in the corporal bodies in exstrophy patients versus normal controls, any penile lengthening that is obtained is more correction of chordee and changing the angulation of the penis, rather than true penile lengthening.

After their incision, the wide band of fibers and muscular tissue representing the urogenital diaphragm is detached subperiostally from the pubis bilaterally (Fig. 73.5e,f). Reluctance to free the bladder neck and urethral wall from the inferior ramus of the pubis moves the neobladder opening cephalad if any separation of the pubis occurs during healing. The mucosa and muscle of the bladder, and the posterior urethral wall on to the penis are then closed in the midline anteriorly. This orifice should accommodate a 12–14-Fr urethral catheter comfortably. The size of the opening should allow enough resistance to aid in the bladder adaptation and to prevent prolapse, but not enough outlet resistance to cause upper tract changes. The posterior urethra and bladder neck are buttressed to the second layer of local tissue if possible (Fig. 73.5g,h). The bladder is drained by a suprapubic non-latex Malecot catheter for a period of 4 weeks. The urethra is not stented in order to avoid necrosis with accumulation of secretions in the neourethra. Ureteral stents provide drainage for 10–14 days after closure, when swelling due to the presence of closure of a small bladder may obstruct the ureters and give rise to obstruction and transient hypertension. If there are no problems with the stents during healing, the current authors leave the stents in for as long as 2–3 weeks.

When the bladder and urethra have been closed and the drainage tube placed, pressure over the greater trochanters bilaterally allows the pubic bones to be approximated in the midline. Horizontal No. 2 mattress sutures are placed in the pubis and tied with a knot away from the neourethra (Fig. 73.5h). Often in a good closure, the author is able to use another stitch of No. 2 nylon at the most caudal insertion of the rectus fascia onto the pubic bone. This maneuver will add to the security of the pubic closure. A V-shaped flap of abdominal skin at a point corresponding to the normal position of the umbilicus is tacked down to the abdominal fascia and the drainage tubes exit this orifice. The method described by Hanna[24] is the author's most commonly performed procedure. Before and during the procedure, the patient is given broad-spectrum antibiotics in an attempt to convert a contaminated field into a clean surgical wound. Non-reactive sutures of polyglycolic acid (Dexon/Vicryl) and nylon are used to avoid an undesirable stitch reaction or stitch abscess.

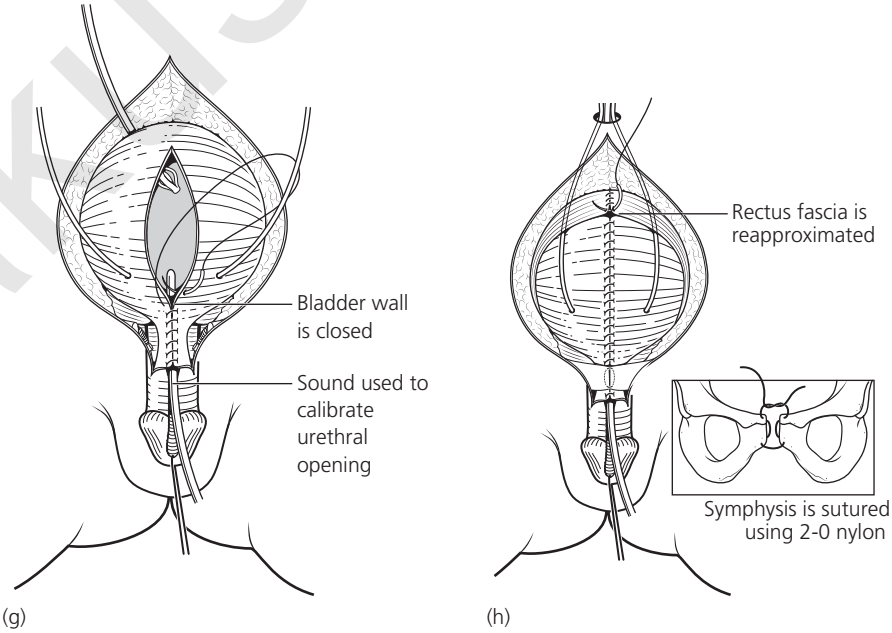

Figure 73.5 *Continued*

Combined bladder closure and epispadias repair

The modern staged closure of bladder exstrophy has yielded consistently good cosmetic and functional results, and the utilization of osteotomy has improved the potential for successful initial closure and later continence. In an effort to decrease costs, the morbidity associated with multiple operative procedures, and possibly to effect continence, there is current interest in performing single-stage reconstruction or combining procedures in appropriately selected patients. This technique was first described by Lattimer and Smith[1] for primary closures and Gearhart and Jeffs[25] in 1991 for failed exstrophy closures. Grady and Mitchell[26] have renewed interest in its use in newborn patients and results have now been reported in groups of boys undergoing single-stage reconstruction (bladder closure and epispadias repair) in infancy.

The complete primary repair of bladder exstrophy is now being performed in neonates at several centers worldwide. The basics steps of the procedure have been outlined by Grady and Mitchell.[26] The initial dissection begins superiorly and is carried inferiorly to isolate the bladder template. This is carried down in a continuous fashion to then begin the penile dissection ventrally. The penile dissection will progress medially with care being taken to preserve the urethral plate for later tubularization. As previously described by Mitchell and Bagli,[27] the penis will be completely dissembled into individual corporal bodies and urethral plate with supporting spongiosum tissue. Deep proximal dissection is undertaken to free the vesco-urethral unit from the intersymphyseal ligaments to provide deep placement of the unit into the pelvis. Once the dissection is complete, the bladder is closed, the penis is reassembled anatomically with a hypospadiac urethra and the abdominal wall and skin closure is completed.[26]

Long-term results of 39 children have been published that show in experienced hands, this procedure produces comparable success rates.[28] Of children aged four years or older who underwent complete primary repair, 74% are continent in daytime with volitional voiding. Importantly, only 20% of boys and 43% of girls achieved primary urinary continence without the need for bladder neck reconstruction. Complication rates were comparable at 18%, with five urethrocutaneous fistulae and two patients with fascial dehiscence. However, there are published reports of significant complications from the complete primary repair. At least two cases of complete loss of a corpora and hemiglans have been reported, as well as several cases of prolapse and dehiscence.[29]

In the authors' opinion, this technique should be limited to boys of older age (older than six months of age) because recent experimental evidence indicates that newborn exstrophy bladders differ from bladders in older infants in the level of maturity of the muscle and connective tissue components. The senior author believes that these patients should be carefully selected, especially newborns, because of the reasons given earlier. Otherwise, boys presenting after failed initial closure and/or older than six months of age, may be candidates for a combination of epispadias repair with bladder closure. Children should be carefully selected based on phallic size, length, and depth of the urethral groove, size of the bladder template, and perivesical and urethral plate scarring in children who have undergone a previous failed closure.

CONCLUSION

The modern staged approach to treatment in patients with bladder exstrophy is able to provide a satisfactory outcome both cosmetically and functionally in most cases. This approach consists of: (1) initial bladder closure, (2) repair of epispadias, and (3) bladder neck reconstruction. Bladder neck reconstruction is the recommended management based on the authors' and institutional experience with over 941 cases of the exstrophy–epispadias complex. Recent reports of a single-stage repair by other authors have proposed successful outcomes, however follow up is limited and numbers of patients in these series is small. In the modern staged repair, the continence rate for males with exstrophy voiding per urethra is 80.6%, with 70% dry around the clock and 10.6% dry during the day, but damp at night.[30] In females, 74% were voiding per urethra and continent 24 hours a day with an additional 10% being continent during the day while wet at night.[31] While recent developments in tissue engineering hold promise to improve outcomes for patients requiring genitourinary reconstruction in the future, staged functional closure remains the gold standard for patients with class bladder exstrophy at the turn of the millennium.

Cloacal exstrophy

DUNCAN WILCOX AND MORITZ M ZIEGLER

INTRODUCTION

Cloacal exstrophy is the most severe anomaly in the exstrophy–epispadias spectrum. It is a rare and complex malformation that affects between one in 200 000 and one in 400 000 live births, with a male to female ratio of 1:2.[1] Despite its complexity, survival is expected, with nearly 100% of patients now surviving. Management has become focused on patient outcomes and the achievement of an optimal quality of life. This has been born out in the last three decades where the shift for improving the quality of life has included appropriate gender assignment, urinary and fecal social continence independent from stoma appliances, improved physical and social independence, and mobility.[2–5]

HISTORY

Cloacal exstrophy, also known as vesico-intestinal fissure, ileovesical fistula, or extrophia splanchnica, was first described by Littre in 1709 and again by Meckel in 1812.[1] The era of operative correction began with Rickham's 1960 report of a three-stage procedure performed over eight months.[6] Although only 17 of 34 patients survived correction during the years 1968–76, survival of 13 of 15 patients at a single institution was reported in the early 1980s;[1] and since that time, survival has ranged from 90 to 100% in a variety of reported series.[3–5]

Today, survival from cloacal exstrophy is nearly universal, mortality being a product of associated renal or cardiac disease and occasionally secondary to short bowel syndrome. The focus of care has now shifted to urinary, gastrointestinal, and genital reconstruction, designed to render the patient appliance-free. Considerable attention is now paid to appropriate gender assignment.

EMBRYOGENESIS

The classic description of cloacal exstrophy is that it results from incomplete coverage of the infra-umbilical wall by the secondary mesoderm of the primitive streak, resulting in a 'rupture' of the midline structures during the 5th embryonic week.[7] Were this developmental defect to occur after fusion of the genital tubercles in the 7th week, bladder exstrophy would result. If, however, the rupture occurs before the 5th week, the genital tubercles will have not fused and the urorectal septum will have not descended to separate the future bladder from the future large bowel. The result is a large midline defect with exposure of both bowel and bladder elements and separation of the genitalia. Furthermore, the absence of the urorectal septum may cause a marked retardation in the development of the colon, resulting in the blind-ending, foreshortened distal hind gut typically seen in these patients.

However, challenge to this classic explanation has occurred from three fronts: studies in twins,[8] the diagnosis of cloacal exstrophy in the fetus,[9] and the development of a chick model that simulates this anomaly.[10] Twin studies include reports in which cloacal exstrophy was present in one of two monozygotic twins, while the twin sibling was normal. This same finding has occurred in a set of conjoined twins. In two additional reports of the fetal diagnosis of cloacal exstrophy, rupture of the cloacal membrane occurred as late as 18–24 weeks and 22–26 weeks, a contrasting observation that may account for the broad scope of anatomic variations seen in this anomaly.[9,11] The chick studies suggest a role for space occupation by the swollen dorsal aorta that produces a widening of pelvic structures and a secondary stretching or thinning of the infra-umbilical abdominal wall before eventual rupture.[12]

SPECTRUM OF ANATOMIC VARIABILITY

Cloacal exstrophy is the most severe form of abdominal wall defect (Fig. 74.1). An omphalocele of variable size is present. Inferior to the omphalocele is a complex midline lesion with exposed mucosal surfaces. Laterally are the right and left hemi-bladders, and typically a ureteral orifice is present and identifiable in the lower portion of each, and the rudimentary

(b)

Figure 74.1 (a) A patient with cloacal exstrophy and (b) a diagram depicting the component parts of the deformity: a prolapsing terminal ileum (elephant trunk deformity), a cephalad membrane-covered omphalocele, two separated bladder halves, orifices depicting an appendiceal lumen and two ureteral orifices. It can also be observed that the pubic rami are separated and along their superior margin can be seen bifid corporal bodies.

trigone can often be seen. The central mucosal plate is composed of intestinal epithelium and represents an open ileocecal plate. Up to five orifices may be present on this surface. The most superior orifice belongs to the terminal ileum, which may be prolapsed as an 'elephant trunk' deformity. In the middle of the bowel plate is one or two orifices, representing the single or duplicated appendix. Finally, the most inferior orifice, which may also be single or duplicated, represents the distal colon or hind gut, and it is almost always of shortened length and ends blindly.

Genital abnormalities are usually present. For male infants, testes are often undescended and located intra-abdominally and an inguinal hernia is frequently seen. The penis is bifid with one corporal body each laterally positioned on the separated pubic rami, the urethra is epispadic, and the vas deferens may be normal, absent, or duplicated. In the female, the clitoris is bifid and separated or it may be absent, the vagina is typically duplex, although it too could be exstrophied or even absent, and the uterus is bicornuate in type.

The pelvis is also affected with the pubic symphysis widely separated and the hips are externally rotated and somewhat abducted. Additionally, within the anatomic spectrum, between 30 and 75% of patients also present with an associated spina bifida.[13]

PREOPERATIVE MANAGEMENT

Associated anomalies

Anomalies of organ systems remote from the basic cloacal exstrophy defect are common, occurring in as many as 85% of cases.[14,15]

Genitourinary anomalies

Abnormalities include the upper urinary tract (42–60%): hydronephrosis, hydroureter, ureteral atresia, ureteral duplication, pelvic kidney, renal agenesis, multicystic kidney, and crossed fused renal ectopia. These anomalies are often associated with, or can lead to, renal function impairment.

Frequently, in boys, the testicles are undescended and there are known vasal anomalies with the vas being normal, absent, or duplicated. In girls, there is frequently duplication of the whole or all of the internal genitalia, and in postpubertal girls there is an association of ovarian cysts, and secondary severe pelvic pain or urinary obstruction has been reported.[16]

Gastrointestinal anomalies

Associated gastrointestinal anomalies include malrotation, duodenal atresia, Meckel's diverticulum, and intestinal duplications.[17,18] Congenital short bowel syndrome has been noted in nearly 25% of patients; therefore, ileal as well as colon preservation is a very important strategy for long-term intestinal rehabilitation.[17]

Spinal–orthopedic anomalies

Vertebral anomalies occur in 48–75% of cases, with myelodysplasia syndromes present in 30–75%.[15] The tethered cord anomaly must also be excluded. Associated orthopedic anomalies (26–30%) include club foot, congenital dislocation of the hips, and other potentially severe deformities.[13]

Cardiac anomalies

Cardiac anomalies are frequently seen in patients with cloacal exstrophy and need to be evaluated with an echocardiogram

prior to surgical reconstruction. Cardiac anomalies are a common cause of death in these patients.[19]

Prenatal diagnosis

Prenatal ultrasound has become commonplace for the diagnosis of cloacal exstrophy. Major diagnostic criteria include the following: non-visualization of the bladder, a large midline infra-umbilical anterior abdominal wall defect or cystic abdominal wall structure, the protruding proboscis (ileum), an omphalocele, or myelomeningocele.[20] Less frequently defined minor criteria include lower extremity defects, renal anomalies, ascites, widened pubic arches, a narrow thorax, hydrocephalus, and a single umbilical artery. This diagnostic prepartum information allows appropriate education of the parents, planning for the pregnancy, timing, and location of the delivery, as well as optimal newborn management, preferably in a center experienced in the multidisciplinary medical and surgical care of this complex anomaly.

Postnatal management

At birth, immediate management is stabilization of the baby, protection of the exposed omphalocele, bladder, and bowel, and if present, protection of the myelomeningocele. After a screening physical examination, baseline laboratory studies include an evaluation of renal function and serum electrolytes (although initially this will be a more accurate indicator of the mother's renal function), as well as chromosomes and blood to assist in future cross-matching. An ultrasound of the genitourinary tract and spine along with chest/abdominal radiographs is done to complete the initial screening for associated anomalies. A cardiac echo is also recommended. Normal body temperature is maintained either by covering the exposed mucosa and membranes with a plastic wrap, or by enclosing the lower half of the torso in a plastic saline-containing bag warmed to ideal body temperature. A prenatal or postnatal chromosome study would be useful in determining the genetic sex of the baby.

At this time, it is imperative to assemble the team of pediatric surgeon and urologist, and if other organ system involvement has been identified, e.g. myelomeningocele, the appropriate additional consultants.[3,4,20,21] It is also prudent to add an endocrinologist to the evaluative team, as well as a psychiatrist/psychologist versed in gender assignment issues.[22] At that time, a team meeting with the family, if not done prenatally, must be arranged, and the magnitude of the problems and their potential solutions discussed. It is then important to prioritize and define a step-wise management plan that defines all of the issues, including gender (Table 74.1). All parties should be in agreement with the plan.

This complex anomaly requires the combined efforts of both pediatric surgeon and pediatric urologist. The team leader must also coordinate input from a variety of ancillary personnel, including a stoma therapist, physical therapist, social worker, psychiatrist or psychologist, and endocrinologist. A neurosurgeon or orthopedic surgeon may also need to be involved if indicated.

Table 74.1 Step-wise management plan for cloacal exstrophy.

Management phase	Patient age	Therapeutic procedures
Phase 1	Newborn	Meningocele coverage Closure/coverage of omphalocele Separation of bowel/bladder plates Ileal reconstruction End colostomy Hemi-bladder approximation/closure Pubic bone approximation
Phase 2	1–6 months	Feeding access Manage short bowel syndrome
Phase 3	6 months–2 years	Bladder closure if not done Phase 1: Iliac osteotomy First-stage genital reconstruction Tethered cord release Midline sagittal anorectoplasty
Phase 4	2–8 years	Bladder augmentation Construction of catheterizable urinary reservoir Second-stage genital reconstruction/gender decision
Phase 5	5–18 years	Completion of genital reconstruction Exogenous hormone therapy

Gender assignment

Gender assignment is frequently a complex and controversial decision. In 46,XX patients there is no debate, since all of these children should be raised as females. The problem occurs in 46,XY patients. When the phallic structures are of adequate length, and clearly this is a subjective data point, then most pediatric urologists would recommend that the child be raised as male; however, when the phallic structures are very diminutive, the decision is more difficult. Historically, the majority of these children were gender reassigned and raised as female. However, with increasing evidence of the potential of testosterone imprinting of the brain and the more frequent use of free flap phallic reconstruction, the contemporary trend is to raise these children as males, a strategy agreed to by two-thirds of polled pediatric urologists. If, however, it is decided to change the sex of rearing to female, then most surgeons would advocate early gonadectomy prior to the infant testosterone surge to minimize further brain imprinting.[23]

This decision involves many complex problems that include fertility, psychological, sexual ability, and gender-specific problems. Consequently, it is important that this

decision is made as part of a multidisciplinary team with significant family input.

OPERATIVE MANAGEMENT

The sequence

The successful therapy of this complex anomaly requires an orderly approach of both sequential and simultaneous steps.[13,14] If a myelomeningocele is present, it must first be covered, and attention to a possible tethered cord can be delayed. The next focus is a multistep procedure that includes coverage/closure of the omphalocele, take-down of the exposed ileal plate and exstrophied hemi-bladders, establishment of gastrointestinal continuity by tubularizing the bowel plate and salvaging all of the small and large bowel length, including the appendices, and creation of an end-colostomy that should exit the left upper abdomen. The hemi-bladders are connected in the posterior midline, and if possible tubularized into a reservoir. The separated pubic rami are approximated in the midline, a maneuver that facilitates both omphalocele closure, as well as bladder closure. The gonads and external genitalia are often addressed as the final step or at a subsequent procedure. Attention to the undescended and typically intra-abdominal testes can also be delayed until a time of further reconstruction. The subsequent phases of therapy are individualized and planned in a discussion with the family led by the care team.

STEP 1. OMPHALOCELE CLOSURE

In cases with a huge omphalocele, it is practical to consider leaving the intact membrane in place as a barrier for a potential staged closure. However, since in dissecting out the exstrophied bladder and bowel the peritoneal cavity will be entered, the usual approach is to open the abdomen extending the incision vertically with removal of the omphalocele membrane. This will facilitate eventual primary fascial closure of the omphalocele, aided by approximation of the pubic rami. This same exposure is optimal for staged closure techniques, including the application of a prosthetic silo. Newer approaches to abdominal wall coverage and closure include application of an expanded thoraco-epigastric myocutaneous flap or application of an absorbable matrix on which a mobilized skin flap can be laid.

STEP 2. BOWEL RECONSTRUCTION

The central bowel plate is then separated from the two lateral hemi-bladders. Intestinal reconstruction including the blind-ending colon segment should emphasize bowel conservation. The exstrophied ileocecal junction should be tubularized to restore continuity of the ileocolonic lumen. Appendices, single or duplicated, should always be considered as potential catheterizable conduits for achieving urinary dryness and thus should not be sacrificed. Similarly, duplicated colon segments, even though blind ending, can be used as interposed properistaltic and anti-peristaltic colon conduits to potentially prolong intestinal transit time. This is especially beneficial in the usual circumstance of a foreshortened colonic length or in the unusual circumstance of a concomitant limited small bowel length. An extra colon may also prove to be useful in urinary conduit reconstruction later in the child's life, and for these reasons it should never be sacrificed. After mobilizing the blind-ending colon, the tubularized bowel must then be exited as an end colostomy. The placement of this fecal stream stoma will optimally be exited more lateral and more cephalad than is usual, especially if a prosthetic pouch is used to close the omphalocele.

STEP 3. BLADDER RECONSTRUCTION

The free hemi-bladders are then reapproximated into a single midline posterior bladder wall plate by suture technique, taking care to identify and protect the ureteral orifices. If sufficient bladder surface exists from which to construct an adequate capacity reservoir, then the bladder is also closed anteriorly, forming a closed bladder. The tubularized bladder is then positioned behind the approximated pubic rami. The bladder neck and/or the reconstructed rudimentary urethra will drain inferiorly onto the perineum.

Primary abdominal closure is possible in most patients. Such primary closure can be performed most easily in the first 48 hours of life, with the benefit of circulating 'relaxin' and permanent high-tensile strength suture material placed into either end of the separated pubis. However, if the abdomen is too tight to allow for complete primary closure, a number of options is available. If the skin is sufficient but the muscle wall will not close then a material (mesh, durabond) can be inserted between the two recti to allow abdominal closure and the skin is then closed over the top. If the skin cannot be closed, then two options may be considered. First, close the bladder and bowel and then place a silo. This has the advantage that closure can be performed slowly in the neonatal intensive care unit as the abdominal cavity enlarges, but it also raises concerns about the fecal stream contaminating the silo. The second option is to approximate the bladder only posteriorly and then use the bladder plate to create a bladder exstrophy, hence using the plate to provide extra-abdominal space. The main problem with this is that it can cause damage to the bladder mucosa and it will require a significant later operation.

STEP 4. GENITAL RECONSTRUCTION

For genetic XY babies with a microphallus or a bifid phallus, gender conversion would previously have been accomplished at the neonatal procedure by assigning a female phenotype. However, current practice would not proceed to that decision until exploration of the options had occurred with a team that would include a urologist, endocrinologist, psychologist, and the baby's parents.[24–26] The discussion would include the role of prenatal as well as pubertal genetic male imprinting, as well as the options for phallic reconstruction that even might include total replacement phalloplasty.[27,28] Corporal and glandular tissue should always be preserved for eventual reconstruction, and the separated hemi-scrota should be

preserved and reapproximated in the midline. Completion orchiopexy should be delayed until a definitive gender decision is made. Vaginal reconstruction should be deferred to a later age for genetic XX babies to permit full evaluation and correction of double systems, potential vaginal atresia, or potential vaginal exstrophy, the latter located caudal to the exstrophied bladder mucosa. This will also allow an informed decision to be made about which tissue might best be used to augment any deficiency in vaginal tissue.[29,30]

POSTOPERATIVE CARE

Postoperatively, the patient should receive fluid and electrolyte management which takes into account a potentially diminished renal reserve. Many methods are available to minimize tension at the closure by preventing lower extremity movement that include: maintaining muscle relaxation and having the baby ventilated for a number of days; placement of a circumferential wrap that encircles the lower extremities from ankles to mid-abdomen to 'strap' together the upper thighs, minimizing pelvic tension and possible distraction of the closed pubic rami;[31] suspension in a modified Bryant's traction can also be done; and in some centers modified Salter osteotomies are performed to help with pelvic closure.[32] Staged closure of the omphalocele should follow in those cases with an applied prosthetic silo. The fecal and urinary stream should be isolated, either by temporary bladder or ureteral catheters or by permitting free drainage of urine onto the bladder exstrophied plate. An appliance should cover the colostomy.

After completion of the newborn repair, the associated anomalies should be prioritized and addressed. Orthopedic assessment of extremity, pelvis, and spinal deformities is necessary, and a long-range treatment plan should be outlined. If the pelvis was not primarily reapproximated, the eventual plan for pelvic osteotomy can be made so that at the time of reoperation, pelvic closure becomes a reality.[32]

LONG-TERM MANAGEMENT

Gender assignment/genital reconstruction

Although there is a genetic male predominance in cloacal exstrophy, the commonly found inadequate corporal structures associated with a bifid penis make adequate penile reconstruction difficult. Historically, therefore, most such patients underwent a female gender assignment. Despite their genetic sex, they were reared as a girl, and an eventual reconstructive operation was designed to develop phenotypic female anatomy complemented by female hormonal replacement.[3,23] However, in recent years, there has been a call to re-examine genotypically congruent sex assignment, even in those newborns with an inadequate phallus, both because of a high frequency of sexual dysfunction in gender-converted children and adolescents, as well as a realization of the potential for penile reconstruction.[23,29,33,34] Certainly, genetic males with adequate bilateral or even unilateral phallic structures should receive a male gender assignment. In any case where gender reassignment or conversion is considered, there is a considerable need for parental counseling, endocrinology input, and input on a longitudinal basis from a trained psychiatrist/psychologist for both the parents and child. All corporal and scrotal/labial tissue needs to be preserved. The corporal tissue, typically bifid, becomes critical whether reconstructing a penile shaft or a clitoris. In the phenotypic male, penile reconstruction and orchidopexy will be the two steps of significance, and they can be delayed beyond the neonatal period. In genotypic males with cloacal exstrophy, the testes are often located intra-abdominally. If a genotypic congruent sex assignment is maintained, orchidopexy will be needed. Fortunately as a group, the testes, despite their location, retain near-normal histology. In contrast, when gender conversion to the female phenotype is considered, orchiectomy should be performed early to prevent further masculinization of the brain. Penile reconstruction will likely need to be deferred to an older age if the bifid phalli are inadequate for simple reapproximation.

In genetic females, the bifid clitoris and labia are initially preserved and reapproximated in the midline. As the child grows, staged operations are used to create an adequate appearance. Failure of midline fusion, a key characteristic of cloacal exstrophy, is frequently manifested in the female reproductive system by duplication of the vagina, uterus, and Fallopian tubes. Atresia and exstrophy of the vagina are also possible. The latter is difficult to distinguish in the newborn period, due to the large exstrophic bladder above or anterior to the exposed vaginal tissue. However, diagnosis of this entity is important in planning the eventual staged vaginal reconstruction. An atretic vagina will require reconstruction with a combination of perineal skin flaps and a small or large bowel pull-through. Increasingly, a buccal mucosa free graft is instead being done (Baker L, personal communication).[30] An intact vagina may contain a septum or be duplicated, and it is most prudent to resect the more rudimentary of the two, attaching the remaining uterus to the vaginal vault. Other than the propensity for cyst formation, the ovaries should be normal.[16]

Continence and stomas

The goal for most children with cloacal exstrophy is a stoma-free existence. At a delayed interval, we prefer to use pelvic magnetic resonance imaging or computer tomographic imaging, coupled with electrical stimulation of the perineum, to define the presence of an anorectal pelvic muscle complex. If such muscle is present, a midline sagittal anorectoplasty is feasible in selected patients who also have an adequate small and large bowel length and sacral spinal structures for establishing a continent anorectum. Others have advocated a primary rectal pull-through procedure performed in the newborn period following the anterior approach used for abdominal wall reconstruction. Although anorectal reconstruction is an attractive and preferred outcome, those children amenable to this plan who also have a good outcome are few.[3,4,17] As a result, either a permanent colostomy or a colostomy or pull-through aided by an antegrade continent enterostomy (ACE) procedure may be preferred.[35] More

recently, a catheterizable continent stoma system has been described that may remove the need for a stoma appliance.[36]

Urinary 'dryness' is frequently accomplished utilizing the principle of a catheterizable stoma in a urinary reservoir. Using a 'continent nipple valve' of the Mitrofanoff principle with an appendix or a tubularized portion of small bowel, a catheterizable conduit is attached to the reservoir. The reservoir itself could be bowel or bladder augmented with stomach, small or large bowel. These procedures are typically deferred until the child has grown out of infancy.[21,22]

PATIENT OUTCOMES

With the progressively improving survival of cloacal exstrophy patients, attention has shifted to optimizing bowel, bladder, and sexual function. Historically, these children were at best committed to a chronic bowel as well as a chronic urinary stoma, and when that was coupled with a degree of genital ambiguity, short-bowel syndrome, or spinal dysraphism, the quality of life was best described as unfortunate. What has now been realized is that the majority of such children have a preserved intellect, and also an anatomy that lends itself to imaginative but real 'continent' outcomes.

A bowel pull-through procedure is feasible in selected patients, and only in the face of an absent gluteal cleft, poor response of muscle to perineal stimulation, severe sacral deformity, a lipomeningocele, or a 'rocker-bottom' should a permanent bowel stoma be considered. The remainder of the patients can undergo a pull-through procedure, and if a degree of incontinence exists, a bowel management program or application of the ACE procedure will be an adjunct.[4,35] The most challenging of the group are those children who also have a short small bowel, and in that circumstance various nutritional, pharmacologic, and operative manipulations may be in order.[17] In one series of 26 patients with cloacal exstrophy, four had colon duplication, one a duodenal web, and one had malrotation. Of six patients with short bowel syndrome, five were eventually weaned from parenteral nutrition. Interestingly, two of the four patients who underwent abdominal–perineal colon pull-through were continent of stool.[16] In another series of 22 patients, ten had an ileostomy, seven a colostomy, three were stoma free, and two had died. In this series, an association of spinal dysraphism increased intestinal morbidity, and the presence of an ileostomy, as opposed to a colostomy, increased dependence on parenteral nutrition and its inherent morbidity.[16] In a third series of 50 patients, 25 had a colon pull-through, and of these, four were failures, two were continent, and 19 were managed by a colon wash-out regimen.[3]

The reconstructed urinary reservoir is typically of small volume and it is non-dynamic. Bladder augmentation has been a process in evolution and includes the use of stomach, large and small bowel, or a potential combination thereof, that include ileal urinary conduits. To enhance bladder continence mechanisms, the bladder neck can be tightened, a bowel nipple valve can be added, bladder neck bulking agents can be injected, and these changes coupled with intermittent catheterization can render the majority of patients dry.[3,5] A catheterizable conduit attached to the urinary reservoir has also been proven to be effective. Spontaneous voluntarily controlled perineal voiding is currently an unrealistic outcome expectation. The magnitude of urinary reconstruction is indicated in one series of 50 patients, where 21 had narrowing of the bladder neck, 7 had a bowel nipple constructed, 12 a Mitrofanoff procedure, 4 a ureterostomy, and 35 had a bladder augmentation. Dryness was achieved 75% of the time.[3]

The outcomes from genital reconstruction in females are satisfactory, but the ability of a bifid uterus and reconstructed vagina to permit fertility has, as of yet, not been reported.[23,29] The greater controversy arises in a genetic male who has a penile reconstruction. Since the testes, even if located intra-abdominally, appear to be histologically normal, fertility may be preserved; however, to date, a fertile male has also not been reported.[23] More than 30% of males have a diminutive or absent penis. If an inadequate phallus is the result of a series of failed operative reconstructions, reported emotional disasters are common. More controversial yet are those genetic males who have undergone reassignment to the female phenotype. Acting-out male behavior imprinted genetically or hormonally has been witnessed. At adolescence, such 'phenotypically assigned females' have declared their 'maleness' and have emotionally struggled with their sexual identity. This has been reported to be improved if the testicles are removed early in the first year of life to prevent further masculinization.[23] In one assessment of quality of life, child behavior, and social cognition, no difference was reported for the gender-ambiguous children who underwent a gender reassignment when they were compared to the control exstrophied group who had no gender issue.[37] However, in another series of 29 genetic males with cloacal exstrophy reassigned to the female phenotype, all patients in adolescence had declared themselves male.[26]

Although staged management has the inherent difficulty of multiple operative procedures, the expectations for an excellent outcome should remain high. Many of these children can be rehabilitated to have a meaningful and functional quality of life through a careful, individualized, staged reconstruction accomplished by a team experienced in the care of this complex anomaly.

Prune belly syndrome

PREM PURI AND HIDESHI MIYAKITA

INTRODUCTION

Prune belly syndrome is characterized by a triad of abnormalities, including an absence or deficiency of abdominal wall musculature, cryptorchism, and anomalies of the urinary tract. The characteristic deficiency of the abdominal wall musculature was first described by Frohlich in 1839.[1] Parker first reported the association of the genitourinary anomalies with the deficient abdominal musculature.[2] The term 'prune belly syndrome' was coined for this complex by Osler in 1901.[3] In 1950, Eagle and Barrett further defined the triad of absent abdominal wall musculature, undescended testes, and urinary tract abnormalities.[4] The incidence of prune belly syndrome is estimated to be one in 29 000 to one in 50 000 live births.[5–13] This syndrome occurs almost exclusively in boys.[13] It is very rare in females;[13] only 5% of cases described in the world literature have been reported to occur in females.[4–6,14]

ETIOLOGY

The pathogenesis of prune belly syndrome remains controversial and many theories have been proposed to explain it.[3,4] One theory proposes that prenatal obstruction or dysfunction of the urinary tract causes urinary tract dilatation, fetal abdominal distension, and subsequent muscle wall hypoplasia and cryptorchism in males.[5,6,15–17] An embryological theory proposes that failure of primary mesodermal differentiation leads to defective muscularization of both the abdominal wall and the urinary tract.[6,15–17] Although both theories explain some elements of the syndrome, they fail to explain others. Reinberg *et al.*[18] recently suggested that the two theories should be regarded as complementary mechanisms, both operating in any given case. They theorized that teratogenic agents produce abnormal development of derivatives of the lateral plate mesoderm and abnormal epithelial–mesenchymal interactions, resulting in abnormal organ development and mechanical or functional obstruction of the urinary tract. Recently, Stephens and Gupta proposed a theory of abnormal development of the intermediate mesoderm as a key factor in the pathogenesis of prune belly syndrome.[5,19] This theory has two features: the first is that the terminal part of the Wolffian duct is incorporated into both the prostatic and membranous urethra, and the second is that during incorporation, the ducts including their ureteric buds overexpand. Abnormal ectasia of the terminal Wolffian duct occurring between 6 and 10 weeks' gestation may produce saccular dilatation of the prostatic urethra, prostatic hypoplasia, and the valve-like obstruction in the membranous urethra. The ectasia could explain the attenuated bladder trigone and laterally placed wide ureteric orifices. Involvement of ureteric buds may also produce irregular megaureters. Renal dysplasia can be explained as a result of primary dysplasia of the metanephros or secondary to ureteric ectopia.

A single-gene abnormality or chromosomal defect has been suggested as the cause of this syndrome. There is an especially high incidence of prune belly syndrome associated with trisomy 21,[20] trisomy 13,[21,22] and trisomy 18.[23,24] Ramasamy *et al.*[25] reviewed 11 cases of familial prune belly syndrome and suggested a sex-influenced autosomal recessive mode of inheritance. Reports of prune belly syndrome in siblings and cousins, and reports of the syndrome associated with the 45X0 karyotype of Turner syndrome, support this proposal.

PATHOLOGY

Abdominal wall

Prune belly syndrome represents a spectrum of disease severity, ranging from those that die within the first few days of life to those that survive with relatively stable renal function in childhood. The most obvious defect in newborns with the syndrome is the shriveled prune-like appearance of the abdominal wall due to a deficiency in the abdominal wall musculature (Fig. 75.1). The affected muscles in decreasing order of frequency are the transversus abdominus, rectus abdominus below the umbilicus, and internal oblique,

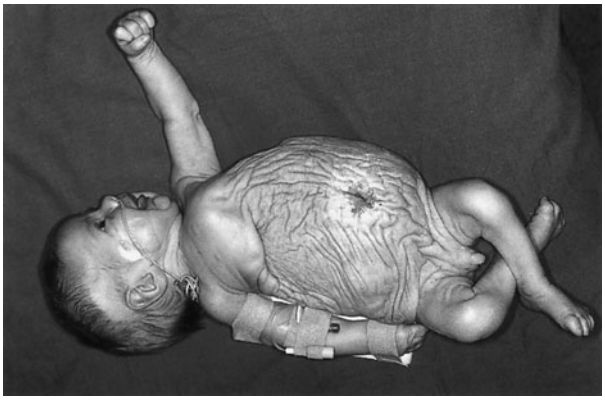

Figure 75.1 A newborn with typical features of prune belly syndrome. Note the shriveled prune-like appearance of the abdominal wall and patent urachus.

external oblique, and rectus abdominus above the umbilicus.[26–28] Biopsy from the abdominal musculature shows that major functioning or recoverable muscle exists in the lateral and upper sector of the abdomen, but that little or no muscle exists in the lower central abdomen.[29] Light microscopy shows a thin mass of muscle tissue with an irregular pattern of fatty infiltration interdigitated with the muscle. Electron microscopy shows a loss of coherence and internal orientation.[30] Z-bands are shattered and disarranged, and glycogen granules are clumped in various areas. The abdominal wall defect may result in chronic constipation and respiratory infection. In addition, this defect increases the risk of postoperative pulmonary complications in patients who undergo general anesthesia. It is also impossible for the patient with a complete manifestation of the triad syndrome to raise himself from the supine position to the sitting position without using the arms or rolling over and pushing up. However, the defect itself does not have prognostic significance.

Urinary tract

Abnormalities of the urinary tract are the major factors affecting the prognosis of patients with prune belly syndrome. Patients are at high risk for developing renal failure in infancy and childhood. As many as 30% of patients, typically those with impaired renal function at initial evaluation, develop chronic renal failure in childhood or adolescence.[6]

Kidney

The kidney in prune belly syndrome has many ranges of disorders from total agenesis (rare) or dysplasia, to no significant aberration.[6,31–38] Patients who have severe renal dysplasia usually have severe abnormalities of the bladder and urethra at birth and may even have another malformation, such as imperforate anus.[39] The degree of renal dysplasia or hydronephrosis does not appear to be related to the degree of abdominal wall deficiency.

Ureter

The ureters are characteristically markedly elongated, dilated, and tortuous. This is the most common urinary tract abnormality, and is present in 81% of patients with prune belly syndrome.[32] The lower end of the ureter is more severely affected than the upper one, and there are occasional saccular dilatations of the middle segment. The orifices are usually patent and obstruction is rare. Vesico-ureteral reflux is common and present in up to 85% of patients (Fig. 75.2).[32] The ureteric smooth muscle is replaced by fibrous tissue in the affected areas and there is scarcity of muscle bundles on histologic examination.[33] Ehrlich and Brown[34] studied the structure by electron microscopy and reported a marked decrease in nerve plexuses with irregularity and degeneration of non-myelinated Schwann fibers. These findings are in keeping with the poor peristalsis of the affected ureters.

Figure 75.2 Micturating cystourethrogram showing grade V vesico-ureteral reflux into left dilated tortuous ureter.

Bladder

Bladder abnormalities are common in prune belly syndrome. The typical bladder is large, irregular in shape and thick walled. Although the bladder wall is thickened, trabeculation is rare. Histologically, the intrusion of fibrous tissue between sparse muscle layers is similar to the ureters.[31] Commonly, there is a patent urachus or urachal cyst in prune belly syndrome. The trigone is surprisingly large, with very widely spaced, usually large and abnormal-appearing ureteric orifices which can be expected to reflux.[35] The bladder neck is often wide and ill-defined. Pelvic innervation and bladder ganglion cell distribution has been found to be normal.[6]

Urethra

The prostatic urethra is usually wide and elongated at the bladder neck (Fig. 75.3). It tapers to a narrow point at the level of the urogenital diaphragm, even though most patients do not demonstrate true obstruction at this point.[36] Often there is a posterior urethral diverticulum formed by a large prostatic utricle. The reduced musculature and prostatic hypoplasia cause a 'functional obstruction' to bladder outflow.[37] The membranous and anterior urethra are sometimes atretic or extremely hypoplastic. There are also reports of abnormalities of the penis, including ventral and dorsal chordee, hypospadias and hypoplastic, or absent corpora cavernosa. Other urethral lesions occur with hypospadias, and ventral and dorsal chordee.[36] Ejaculation is possible, but usually is retrograde due to the open bladder neck.

In females, the prune belly syndrome triad consists of lax, aplastic, or hypoplastic abdominal musculature, urinary tract anomalies, and genital anomalies, most commonly bicornuate uterus and vaginal atresia. Six of the seven female cases reported by Reinberg *et al.*[18] had vaginal atresia or uterine duplication and frequently coexisted in the same patient. Other urogenital anomalies include urogenital sinus and ambiguous genitalia.

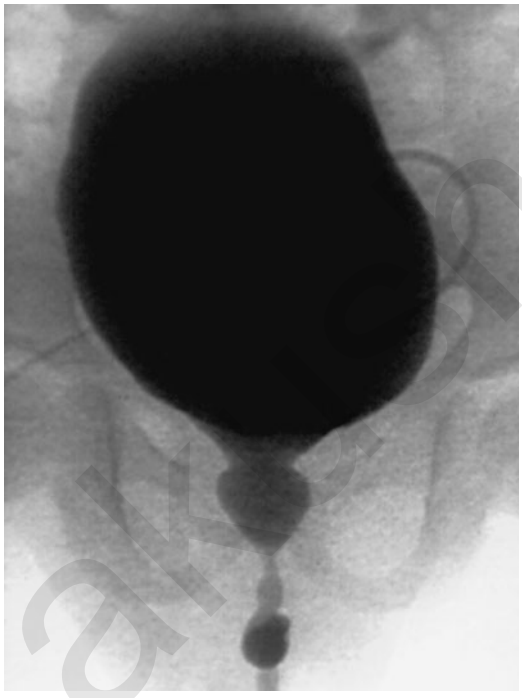

Figure 75.3 Micturating cystourethrogram showing ill-defined bladder neck with enlarged prostatic urethra. No urethral obstruction was demonstrated in the 2-week-old infant.

Testes

Bilateral cryptorchidism is an essential characteristic of prune belly syndrome. The testes may be located anywhere from just inferior to the lower pole of the kidney to near the ureterovesical junction.[31,38] Maldescent of the testes is believed to be related to absence of the abdominal muscles and the gubernaculum. In fetuses with prune belly syndrome, testicular histology revealed reduced spermatogonia and Leydig cell hyperplasia.[40,41] Testicular biopsy samples of infant testes in prune belly syndrome demonstrate atypical germ cells with large nuclei and prominent nucleoli and intense alkaline phosphatase staining localized to the cytoplasmic membrane.[41] The similarity of histological appearance of these testes to those in intratubular germ cell neoplasia suggests that long-term follow up of these patients for the development of invasive germ cell tumors is important. A few cases of malignancy in the testes of patients with prune belly syndrome have been reported.[42–44]

ASSOCIATED ANOMALIES

There is a high incidence of associated anomalies in patients with prune belly syndrome. Non-urological-associated anomalies in patients with prune belly syndrome occur in 65–73% of patients.[6,45–50]

Gastrointestinal anomalies are observed in about 30% of patients. Malrotation of the gut with a single mesentery and the occasional sequelae of volvulus and obstruction is the most common gastrointestinal anomaly. The other gastrointestinal anomalies are gastroschisis and omphalocele, imperforate anus, Hirschsprung's disease, and duodenal atresia.[39,48,49]

Cardiovascular anomalies, such as atrial and ventricular septal defects and tetralogy of Fallot, have been reported in about 10% of cases.[50] Pulmonary anomalies are common, the most severe of which is hypoplasia of the lungs associated with *in utero* oligohydramnios.

Orthopedic problems have frequently been reported in patients with prune belly syndrome.[39] The most common abnormalities are talipes deformities, congenital dislocations of the hip, and compression deformities of the limbs.

Antenatal diagnosis

With improved quality of antenatal scans, major renal tract abnormalities are being diagnosed as early as 13 weeks' gestation.[51] Differentiating between posterior urethral valve and prune belly syndrome could be difficult. Unfortunately, fetal detection of prune belly syndrome has not led to an improved outcome.[52,53] Fetal vesico-amniotic shunts have been used in the hope of preventing renal parenchymal damage in children with enlarged bladder and upper renal tract dilatation.[54–56] However, studies have failed to document a beneficial effect of fetal intervention on subsequent renal function or pulmonary development.

Newborn assessment and investigations

The prune belly appearance of the abdominal wall together with bilateral undescended testes allows easy diagnosis of this condition in a newborn. When antenatal oligohydramnios is

evident, pulmonary complications should be anticipated, and an immediate chest x-ray to exclude pneumothorax and pneumomediastinum is necessary.

Initial creatinine measurements reflect maternal renal function and repetitive sampling is necessary. A serum creatinine >1.0 mg/dL in a term infant or >1.5 mg/dL in a preterm infant after 72 hours indicates poor renal function and poor overall outcome. On the other hand, if initial creatinine is <0.7 mg/dL, then subsequent renal failure is unlikely. Urine should be checked for any infection and antibiotic prophylaxis to prevent urinary tract infection started. Renal ultrasound will provide information regarding kidneys, cortical thickness, renal tract dilatations, and bladder volume and post-micturition residue. A micturating cystourethrogram (MCUG) will provide information regarding vesico-ureteric reflux and rare presence of posterior urethral valve. However, contrast medium should be sparingly used in the presence of poor renal function and impaired glomerular filtration rates to avoid a rapid rise in serum osmolality and subsequent intraventricular hemorrhage. Mercaptoacetyltriglycine (MAG3) and dimercaptosuccinic (DMSA) studies are requested as indicated to assess the differential renal filtration and drainage.

Management

Based on the severity of renal disease, patients with prune belly syndrome could be classified into three groups:[57]

- Group 1 is characterized by oligohydramnios, pulmonary hypoplasia, possible urethral obstruction or patent urachus. These children also have very poor renal function and will usually die in the immediate postnatal period due to pulmonary complications. Aggressive surgical approach in these children should be avoided.
- Group 2 children have mild impairment of renal function and may progress to renal failure. During early infancy, a cutaneous vesicostomy may improve drainage of urine and allow time for definitive reconstructive surgery later. Definitive surgery is better postponed until one year of age.
- Group 3 consists of the majority of children with prune belly syndrome with normal renal function and dilated renal tracts. Surgical intervention is not necessary, as long as the renal function is maintained and no infection is seen. When problems are encountered, a urodynamic study is needed to evaluate bladder emptying and unbalanced voiding. When deterioration is noted, these children should be managed as the children in group 2, with early vesicostomy.

Definitive surgery includes abdominoplasty, bilateral orchidopexies and a suitable antereflux procedure around one year of age. Abdominoplasty for the cosmetic improvement should be performed around one year of age.[58–60] The surgical management strategy of the urinary tract should be tailored to suit individual cases. Surgical options include internal urethrotomy (when obstruction to outflow is evident on urodynamics study), ureteral tailoring and ureteric reimplantations, reduction cystoplasty with concomitant excision of a dilated urachal diverticulum, and/or intermittent catheterization. Approximately 30% of the long-term survivors will develop renal failure as a result of renal dysplasia, recurrent pyelonephritis or obstructive nephropathy. These children go on to have renal transplantation and are reported to have a graft survival rate of 66.7% at five years. However, good bladder emptying must be achieved prior to transplantation to avoid the significant risk of infection in the presence of immunosuppressant therapy.

Conjoined twins

JUAN A TOVAR

INTRODUCTION

Genetically identical individuals joined by a part of their anatomy and often sharing one or more organs are known as 'conjoined twins'. This event occurs in 1:50 000 to 1:100 000 live births[1] and it is one of the more difficult challenges of pediatric surgery.

Mythologic creatures like two-faced Jano or multiple-headed Hydra were probably inspired by observation of conjoined twins.[2] Although representations of conjoined twins from ancient cultures were relatively frequent, they became popular after the original siamese twins Chang and Eng Bunker were sent to the United States in the nineteenth century for exhibition in a circus.[3] The complexity of the technical problems involved in separations of conjoined twins explains why the first attempts are relatively recent (seventeenth century).[4]

ETIOLOGY

Conjoined twinning is due to incomplete division of a primitive embryonal disk destined to produce identical twins. These are, of course, monozygotic, monochorionic, isosexual, and share the same genome and fingerprints.[5,6] The causes for this incomplete division are unknown but, interestingly, two-thirds of the cases are females. Spencer[7] pointed out in her monography that the twins are always joined by central parts of their anatomies and that they are always homologous in the sense that they never have the head or the lower limbs on opposite sides. This seems to confirm that the mechanism is a missed cleavage of the primitive embryonal disk along the longitudinal axis.

Some ancient experiments in amphibians and a few modern molecular genetic observations suggest that fusion of two originally separated embryos may be the explanation for some rare cases in which there is sex discordance.[8–10]

CLASSIFICATION

The location, extent, and nature of the bridge between both twins varies widely and this complicates description of the anatomy of each set. Several classifications attempt at simplifying description. Conjoined twins were divided into ventrally and dorsally joined and subdivided according to the level of fusion.[7,11] They are divided by taking into account their asymmetric or symmetric nature and the level of the fusion which followed by the suffix 'pagus'.

Asymmetric twins include 'fetus *in fetu*', acardius acephalus, and heteropagus parasitic twins. The description of the first variety of organoid teratomata to the family of conjoined twins is only acceptable when they are 'organoid' and contain a more or less rudimentary spine.[12] Acardius acephalus is a variety of parasitic twin devoid of heart and head that is connected by marginal placental vessels with the healthy twin (the 'autositus') who is in charge of the circulation and nutrition of both.[13] Heteropagus twins are usually attached to the abdominal wall of an anatomically normal autositus twin, without or with exomphalus, as organoid parasitic masses containing various organs and limbs unable to sustain independent circulation by themselves.[14,15]

Symmetric conjoined twins may be joined by the head (craniopagus), the thorax (thoracopagus), the abdomen (omphalopagus), the spine (rachiopagus), or by the caudal pole (ischiopagus and pygopagus). Occasionally, they are laterally fused along the body axis (parapagus).[16,17]

CLINICAL PRESENTATION

Nowadays, most conjoined twins are prenatally diagnosed by ultrasound in the advanced countries preventing serious obstetric problems. Except in thoracopagus with a common heart and in asymmetric twins, both fetal heart tones can be identified as in regular twins. The heads and limbs of

conjoined twins are on the same side ('homologous') in contrast with regular twins which are usually arranged in opposite directions. This allows fetal ultrasonographic diagnosis that leads to detailed ultrasound (US) and/or magnetic resonance imaging (MRI) studies aimed at defining the anatomy of the fusion and the chances of separation.[18,19]

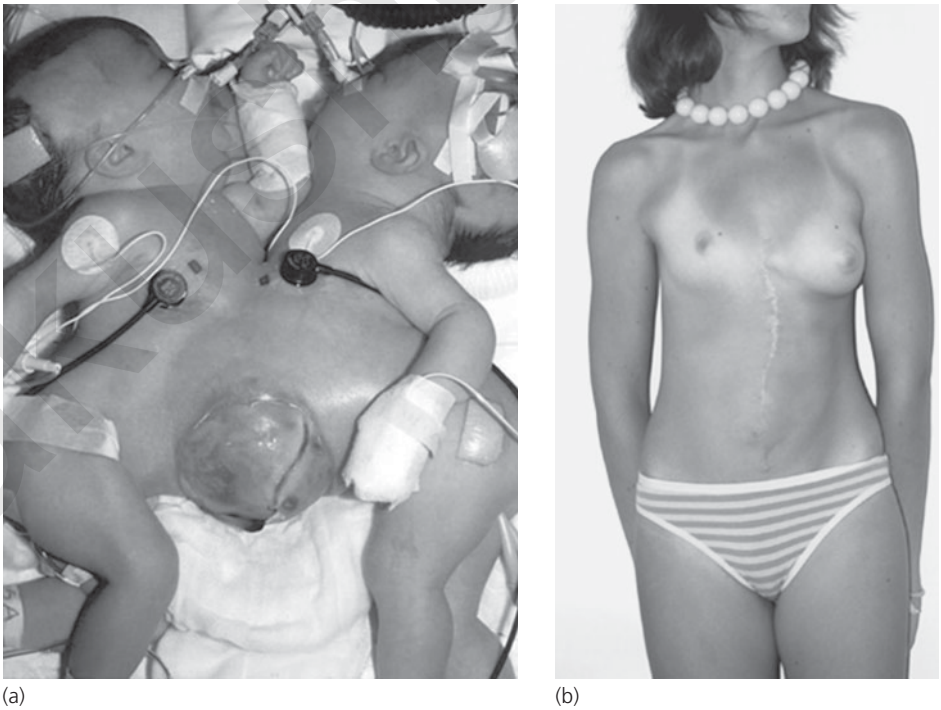
Most sets of twins are delivered by Cesarean section and can be taken care of by interdisciplinary teams from the beginning. In cases delivered vaginally, it is frequent for signs of obstetric trauma to be present at birth: long bone fractures, rupture of exomphalos, etc. The anatomy varies widely according to the modality of joining. Thoracopagi with common hearts have almost constantly severe cardiovascular and arterial anomalies that produce early symptoms and may be rapidly lethal.[20,21] The most frequent forms, omphalopagi and thoracopagi, often have an omphalocele membrane as part of the joining bridge (Figs 76.1 and 76.2). The livers are often fused and the intestines are usually connected or shared. The bladder may be common and sometimes opens at the lower part of the bridge as an exstrophy (Fig. 76.3). In cases joined by the rump (Figs 76.4 and 76.5, pages 690 and 691), the anatomical varieties in terms of gastrointestinal and urogenital openings are multiple.

Serious malformations or trauma suffered by only one of the twins may create difficult clinical situations because crossed circulation creates a single internal environment which is hard to manipulate: the healthier twin can compensate in part for the problems of the diseased one, but the latter may expose the former to disbalances, toxins, or medications.[22]

DIAGNOSIS

A comprehensive understanding of the anatomy of the organs and the distribution of their functions is necessary for planning viable separation strategies. Plain x-rays, gastrointestinal or urogenital tract contrast studies may depict the points of junction and other features of the corresponding organs but, due to the atypical anatomy,[23] incomplete understanding leads to unexpected surprises. Ultrasonography helps at every diagnostic step.[19,24] Angiography, that was widely used in the past for depicting the nature of the blood supply of the shared organs[25] is being replaced by computed tomography (CT) or magnetic resonance angiography.[26] CT angiography is the best way for depicting the vascular arrangement. MRI better depicts the fused neural and meningeal tissues in craniopagus, rachiopagus, ischiopagus, pygopagus, or parapagus.[27] Both CT and MRI are crucial for imaging the anatomy of conjoined hearts.[28] Helical CT reconstruction of the bony junctions may help in preparing strategies of skeletal separation (Figs 76.4 and 76.5, pages 690 and 691).[29] Nuclear imaging may help to define the functional anatomy of the liver, kidney, or other organs.[30]

Hematologic and biochemical studies are often misleading due to cross-circulation. When the vascular channels are large, parabiosis is complete, but when only minor territories are in connection, both twins maintain some internal environmental differences that can be relevant in cases in which blood tests are necessary for diagnosis. Other tests, like electrocardiogram (ECG), are challenging when the hearts are



(a) (b)

Figure 76.1 (a) Set of omphalopagus twins. Severe brain hemorrhage in twin on the right after vaginal delivery prompted neonatal separation. Only the twin on the left survived. Fourteen years later (b), she is a bright, normal girl whose only concern is breast asymmetry.

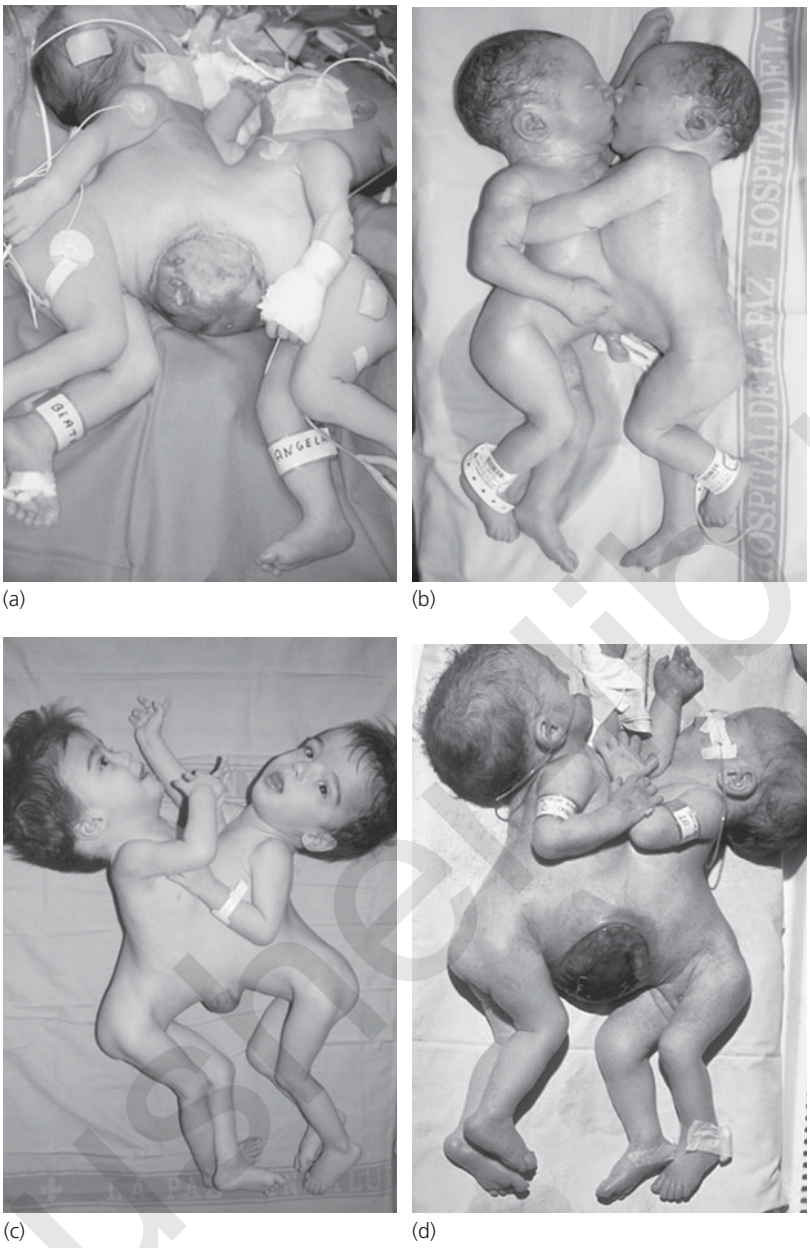


Figure 76.2 Four sets of thoracopagus twins with common hearts. Separation was undertaken only in set shown in panel (a) because they were joined only by a narrow atrial bridge. Unfortunately, the twins did not survive.

connected.[31] Metabolic rate may show considerable differences between twins upon calorimetry.[32]

TREATMENT

Preoperative ethical issues

The principles that regulate the medical profession are particularly difficult to respect in conjoined twins and serious ethical dilemmas are to be expected:[18,33,34]

- **Autonomy**. The principle of autonomy (the decisions of the patient should be respected), is usually exerted by proxy by the parents in children, and this may be a source of conflicts among them or with doctors or the courts if unanimous decisions are not agreed upon.
- **Justice**. The principle of justice (similar chances for both patients) is obviously at risk when it comes to separation that may involve mutilation or sharing of organs.
- **Beneficence and non-maleficence**. The principles of beneficence and non-maleficence (the benefit of the patients should be sought and no harm should be inflicted to them), that are considered as the ethical backbone of the medical decision-making process, are also difficult to

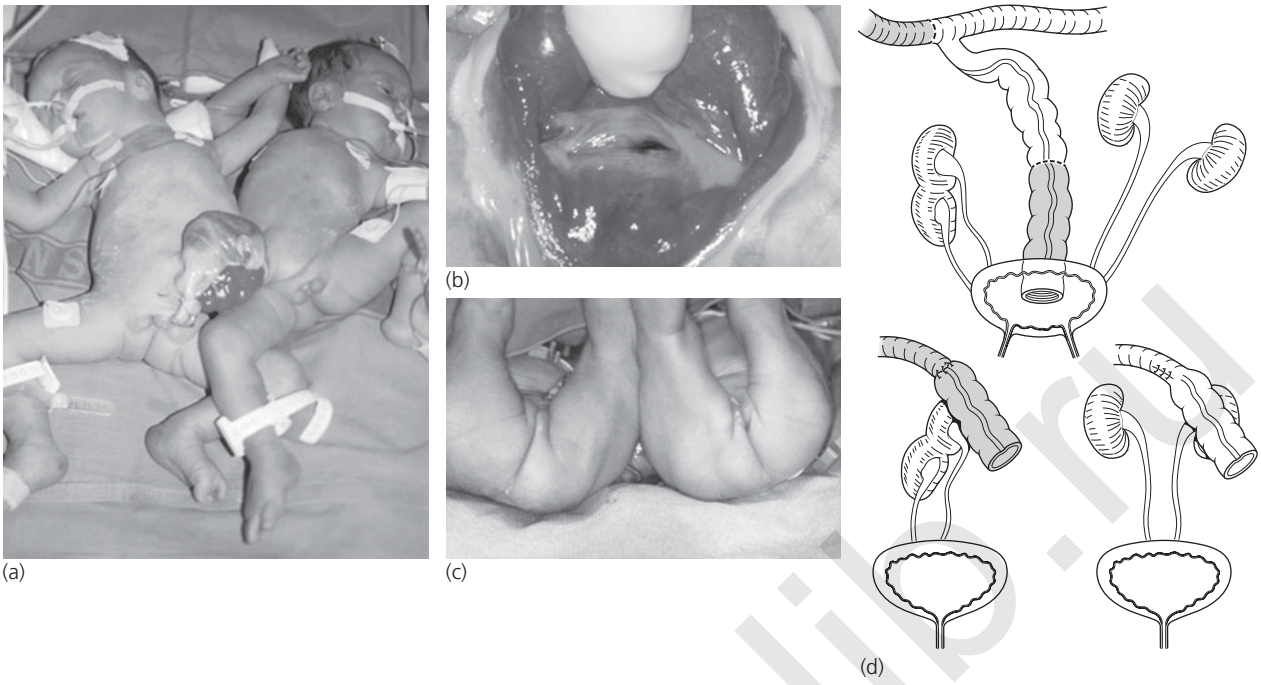

Figure 76.3 Omphalopagus twins with incomplete cloacal exstrophy. The single bladder opened under the exomphalos (a). A single colonic opening was visible in the middle of the bladder plate (b). Both had anorectal agenesis with one single urogenital canal and double uterus and vaginas (c). Separation involved division of the colon with colostomies and bladder closure (d). Later on, sagittal anorectoplasty with colonic and vaginal pull-through were performed.

apply if separation is necessary for the survival of only one twin, if distribution of organs is uneven, and if separation involves, as is usually the case, loss of some functions that might be preserved without separation.

When separation of conjoined twins is considered, the patients are usually too young for deciding by themselves, the parents are heavily influenced by information delivered by doctors and the team involved is usually so large and often ethically discordant, that keeping a unified line of decision becomes difficult. Acknowledgement of a strong moral leadership after open discussion of every issue is required before providing the parents with information about the chances and the consequences of separation. In case of serious discrepancies among all participants in the process of decision, the courts might be involved.

Furthermore, new difficulties may be created by the media (whose interference is difficult to avoid due to the large number of people involved). The twins and their family should be protected from these agents and, if possible, the entire process of decision-making and even the separation should be kept private.

Preoperative meetings

When separation has been decided upon, one or more meetings with scrub nurses, nurses, anesthesiologists, and surgeons of the required specialties (general pediatric, orthopedic, plastic, urologic, neurologic, and cardiovascular surgery) should be scheduled.[35] Technical aspects should be discussed and the operation itself should be rehearsed, because installation of the set of twins on the table, skin prep and draping, and transport of one twin with the corresponding anesthetic equipment to another table for reconstruction after separation should be carried out according to a previously established protocol. The expected order and extent of the participation of each specialist team in the separation should also be scheduled. The surgeon in charge of the direction of the operation acts as an orchestral conductor and his/her coordinating activity extends well beyond the end of the separation itself.

Separation

Anesthesia is a serious challenge not only because of the obvious anatomical difficulties for intubation, insertion of lines, and invasive monitoring, but mainly because of the previously mentioned situation of parabiosis, in which one single internal environment is shared to variable extents by the twins. The drugs administered to one pass on into the other one and biochemical and gas monitoring may be confusing.[36–38]

In general, asymmetric conjoined twins represent surgical challenges that are not unlike other ones met in this specialty. The acardius-acephalus parasitic twin is unviable and dies upon clamping the umbilical cord of the host (autositus) twin. The fetus *in fetu* is treated as a tumor and heteropagus asymmetric parasitic twins are removed with attention at preserving as much tissue as possible in order to respect the organs and allow wall reconstruction of the host.

The separation of craniopagus may be extremely difficult or even impossible, given the complexity of the neural,

arterial, and venous connections involved. Modern imaging and sophisticated neurophysiologic monitoring are particularly useful in these cases. The final amount and nature of the brain tissue and the vascular network shared by the twins set the limits for separation.[39–41]

Separation of omphalopagus twins involves variable difficulties depending on the extent of organ sharing. These twins more often have fused livers and gastrointestinal tracts. A small liver bridge without major vascular connections is relatively easy to take down, but a large mass of anatomically atypical liver with wide arterial, venous, and biliary connections[42] may be a serious undertaking. Perioperative ultrasonography and parenchyme-dividing devices used for liver resection are very useful for this purpose. The most common form of gastrointestinal tract connection involves fusion of the small bowel from the upper jejunum down and divergence near the distal ileum. Separation consists in most cases of allocating half the available gut to each twin. Additional problems may be met when atresia of one of the tracts or a common cystic dilatation of the mid bowel are present.[16–18,43,44]

Thoracopagus twins without connected hearts are separable in contrast with those with common myocardium. Only a few of them are amenable to surgery under cardiopulmonary bypass. In addition, these twins often have cardiovascular defects that may further complicate or preclude the separation. The aorta and the pulmonary arteries may be hypoplastic and the infradiaphragmatic aortas are often largely connected by thick collaterals. Of those who cannot be separated, most die of the associated heart dysfunctions in the first months or years of life.

Rachiopagus, ischiopagus, pygopagus, and parapagus twins share to different extents parts of the spine, central nervous system, gastrointestinal and genitourinary tracts and they may represent formidable challenges. The separation of the bony parts requires highly skilled orthopedic surgeons. In some cases, the reconstruction of the pelvic rim requires bilateral iliac osteotomies and pubic fixation (Fig. 76.4). In some cases, even refashioning a bony pelvis is impossible and the subsequent prosthetic treatment is difficult (Fig. 76.5).[45,46] The spine often has some malformations at other levels, and scoliosis has to be taken into account during follow up.[47,48]

Neurosurgical separation may involve dividing a common spinal cord with reconstruction of the dural sacs on each side.[46] Since fusion of neural tissue is usually distal, the motor and sensitive effects tend to be limited.

The distribution of a common lower gastrointestinal tract between both twins entails the loss of continence for one or both of them. In frontally joined twins, there is usually ileal confluence near the ileocecal valve and a single colon. The functional reconstruction of the pelvic organs is therefore

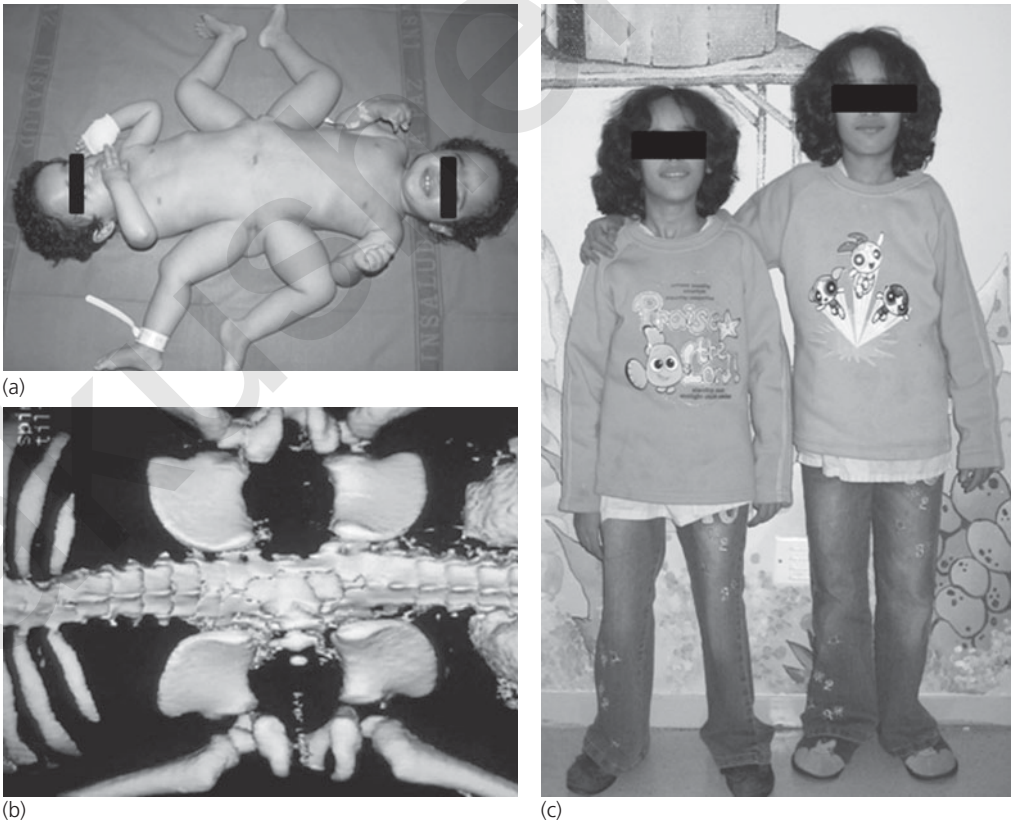

Figure 76.4 (a) Ischiopagus tetrapus (four legs) twins. (b) The spines and the spinal cords were joined at the caudal end as shown by helicoidal computed tomography reconstruction. During separation, the spines were divided, the meningeal sacs were reconstructed, a quadruple iliac osteotomy was performed for joining both pubic bones in each twin, the urogenital system was reconstructed, and colostomies were fashioned. (c) Patients at the age of 12 years. They deambulate normally and enjoy relatively normal lives with permanent colostomies and intermittent bladder catheterization.

(a)

(b)

(c)

(d)

Figure 76.5 (a) Caudal parapagus twins with an extrathoracic limb irrigated from the abdominal aorta of twin A. (b) There was a single pelvis with two lower limbs and two spines with communicating spinal canals and joined cords. Separation involved two surgical steps. First, the spinal cords and meningeal sacs were separated and subcutaneous expanders were inserted (c). Second, the sacrum, the gastrointestinal and genitourinary tracts were divided and the parietal defects were closed. In twin A, the skin and muscle of the additional limb were used as a vascularized flap. In twin B, a synthetic mesh was used for this purpose. Colostomies were fashioned. Both twins are able to deambulate with braces (d).

rarely possible. Occasionally, the rectal function can be preserved in one twin, but more often this is impossible, and ostomies have to be fashioned at some stage. All refinements of advanced bowel management are necessary to obtain subsequent adaptation of these patients to a more or less normal life.[45]

The same can be said about distributing the urogenital tract structures between the twins. Keeping a bladder and urethra for one twin is rarely possible in most frontally united sets. Again, all refinements of reconstructive urology, bladder augmentation, clean intermittent catheterization, and continent urinary diversion may help to readapt these

patients.[49,50] The native genital tract can be reconstructed if duplicated, but sometimes vaginal replacement is necessary.

One of the major technical problems posed by separation of conjoined twins is the coverage of the huge parietal defects left. When only one survives, part of the wall of the other one can be used to bridge the defects, but in other cases, the skin can be expanded with subcutaneous expanders prior to separation[51–53] and various flaps or biologic[54] or synthetic materials[55,56] may be necessary. Since they have to be inserted in contaminated operative fields, the risks of bacterial colonization and infection are increased.

COMPLICATIONS

The nature of these risky operations involves a large number and variety of possible complications. Perioperative hemorrhage and damage to vital structures is always possible due to the often atypical anatomy. Bone division or meningeal membrane opening simultaneous to gastrointestinal or the genitourinary procedures increase the risk of serious infection. Wound closure avoiding compartment syndrome may necessitate synthetic materials that are also exposed to contamination. Wound disruption and infection are therefore not rare. Finally, a wide range of complications not unlike those seen after other major operations may occur: internal hemorrhage, abscesses, vascular thromboses, or postoperative intussusception among others are possible.

EARLY AND LONG-TERM RESULTS

Overall mortality in conjoined twinning is high. When diagnosis is made during early pregnancy, interruption of gestation is common practice in developed countries, particularly for the forms with bad prognosis.[1] Fetal mortality or stillbirths are also frequent. Obstetric mortality or severe birth trauma remain a real risk when prenatal diagnosis is missed and this happens more often in undeveloped countries in which pregnancies are not monitored. A considerable proportion of twins have multiple malformations that cause demise in the first hours or days of life.[39] When separation is deemed possible, it must be reminded that neonatal operations involve higher mortality not only because they are better performed later when most anatomical and functional features of the set have been ascertained, but also because neonatal separation is only indicated for life-threatening reasons (for instance, one twin may be very ill or develop intestinal obstruction).[57]

Thoracopagus twins with a common heart rarely survive because most have severe malformations. Of those sets in which separation is attempted, only a few individual twins survive.[58,59] However, thoracopagus without shared heart can be successfully separated.

Most omphalopagus twins can be separated and survive if no obstetric trauma or severe associated malformation are present (Fig. 76.1). In all other forms of conjoined twinning, a high proportion of the twins can be separated and survive, although with more or less extensive deficits that require follow up for life and often additional operations.

In the long term, separation of conjoined twins rarely produces independent individuals without sequelae. Some cases of asymmetrical twins and omphalopagi may survive separation facing a normal life. Most other cases have orthopedic or neurologic sequelae or have fecal and urinary continence problems that become predominant problems with the passage of time. Orthopedic and motor deficits may require prolonged rehabilitation and/or prosthetic appliances. Permanent enterostomies are not rare and the most sophisticated procedures for obtaining urinary continence or dryness are necessary.[16,60,61]

It is particularly discouraging that these pregnancies are often terminated in advanced medical and social environments able to provide lifelong assistance for rehabilitation and social integration, whereas twins from less privileged countries that are diagnosed at term are eventually separated and lack all the necessary facilities.

Separation of conjoined twins is a major test for the quality of pediatric surgical care. Only institutions with highly sophisticated pediatric surgical specialties can undertake these operations with a reasonable chance of success.

Epidemiology and genetic associations of neonatal tumors

SAM W MOORE AND JACK PLASCHKES

INTRODUCTION

Fifty percent of childhood cancer occurs under the age of five years[1] and clear evidence of inheritability exists in many childhood tumors. Although benign tumors and masses are not uncommon, malignant tumors are rare during the perinatal period.[2] Their behavior is variable and certain apparently benign neonatal masses (e.g. teratomas) may undergo malignant change if untreated. On the other hand, others (e.g. neuroblastoma) may behave relatively benignly and even mature in the neonatal period. Many of these tumors respond to therapy and have a good prognosis, but the mortality rate is estimated to be 6.26 per million live births.[3,4]

The hypothesis that tumors (and even adult cancer) may be linked to or even initiated during fetal development[5–7] is supported by an ever-increasing number of animal experimental studies. This makes the study of neonatal tumors particularly interesting as a possible explanation of their early (as opposed to later) appearance may lie in the developmental processes still active in the host. Possible reasons for this are based on the hypothesis that either genetic or environmental (e.g. nutrition and exposures to environmental toxins) factors (or both) may act as oncogenic promotors during gestation.[8]

This hypothesis is currently supported by an ever-increasing body of evidence and places the emphasis firmly on the developmental period as a focus of disease prevention and intervention. In this context, tumors occurring in the developmental and perinatal period can be regarded as a 'window of opportunity' in cancer research,[9,10] and may lead to the identification of potential therapeutic molecular targets.

INCIDENCE OF NEONATAL TUMORS

Neonatal tumors (NNT) or perinatal tumors comprise 2% of childhood malignancies, but from an epidemiological point of view, there is little clarity as to the real prevalence, sites of origin, and pathological nature of neonatal tumors and reported series vary from unit to unit (Table 77.1) varying from 17 to 121 per million live births (Table 77.2).[11–17] The reported incidence in the UK and United States, respectively, is approximately one in every 12 500–27 500 live births.[2] The Manchester Children's Registry estimated the incidence to be 121.29 per 10^6 child-years when all children under one year of age, including those with leukemias and lymphomas, are counted.[13] Overall, the highest incidence has been reported in Japanese children and the lowest in black children in the United States.[1]

AGE AND SEX

The majority of tumors are diagnosed when the infant is between 1 and 4 weeks of age. Fewer malignant tumors are diagnosed at birth, although benign or potentially malignant tumors are frequently encountered then.

The male-to-female ratio is equal in the majority with the exceptions of retinoblastoma (male preponderance) and teratoma (female preponderance).

PRENATAL DIAGNOSIS

With the advent of routine prenatal ultrasonographic screening and the considerable recent advances in technology, many neonatal tumors are now diagnosed antenatally. This is particularly true of patients with mixed germ cell tumors of the sacrococcygeal region and patients with renal tumors.

One of the difficulties in assessing the true incidence of neonatal tumors is the non-reporting of tumors occurring in stillborn babies and babies dying in the neonatal period.

The advent of neuroblastoma screening programs has brought more to light, but does not appear to affect the prognosis. The biological characteristics of neuroblastomas

detected by screening in Japan have been shown to be mostly favorable.[18] Few of these tumors have N-myc amplification, although 10–20% have unfavorable histological features.

CLINICAL PRESENTATION

Although many NNT present with benign masses, 34% of 192 patients reported by the International Society of Pediatric Oncology from 12 different centers presented with metastatic disease.[13] Some may be incidental findings and some larger masses may be diagnosed with antenatal ultrasonography.

PATHOLOGY

A particular problem exists in classifying neonatal tumors in that histological features of malignancy do not always correlate with clinical behavior. As a result, there are at least four clinical groupings of neonatal tumors:[19,20]

1. Tumors that are clearly malignant by all the usual criteria, but:
    a. behave more like those occurring in older children;
    b. behave better than expected;
    c. behave worse than expected;
    d. demonstrate unpredictable or uncertain behavior.
2. Tumors that show local invasiveness, but have no metastatic potential.
3. Benign tumors that are either:
    a. life threatening because of size and location;
    b. have a known tendency towards malignant transformation.
4. Extreme rarities, e.g. malignant carcinomas which are similar to adult-type tumors.

TUMOR TYPES

The distribution of the various histological types of tumors appears to be relatively constant when compared to other published series (Table 77.3). In a study of 192 cases collected from 12 different countries by the International Society of Pediatric Oncology 1987–91, 33 different types of tumor were reported to occur within the neonatal period.[20] Teratoma was the most frequently encountered type in our own,[21] as well as other large series,[20,22] and is followed by neuroblastoma, leukemia, and soft-tissue tumors. Certain tumors (e.g. retinoblastomas and brain tumors) vary in incidence, depending on hospital referral patterns. Renal and liver tumors occurred less frequently in the neonatal period.[13] Other types of tumor tend to be largely rarities. True carcinoma as seen in adults remains extremely rare in childhood, making up only 1–2% of patients.[23]

ETIOLOGY AND CARCINOGENESIS

The etiology of cancer in children is multifactorial and includes both genetic and environmental factors. It seems likely that genetic factors predominate in heritable tumors, whereas a more involved multistep process is involved in those occurring spontaneously.

Genetic factors in neonatal tumors

Following the first report of the Philadelphia or Ph1 chromosome,[24] in affected cells of patients with chronic myeloid leukemia (CML), genetic mechanisms have been implicated in the etiology of many cancers, thus opening new areas for diagnosis and prognosis. Tumors are accepted as being a largely genetically based disorder at the cellular level and have been implicated in both non-hereditary and hereditary forms of malignancy in children and adults.[25] This is particularly true of neonatal tumors where most cancer cells are monoclonal, have a high incidence of chromosomal changes and some specific genetic mutations, as well as a clear inherited predisposition to malignancy.

As such, neonatal tumors provide a unique opportunity to study familial and genetic associations because minimal interactions between genetic and environmental factors have occurred that soon after birth. Modern genetic surveillance techniques offer potential opportunities for prevention, in contrast to most malignancies encountered in older patients.

Apart from explaining how tumors may present in the perinatal period, genetic control may also partly explain the variable behavior of certain tumors within the perinatal period.[10]

There are essentially three groups of genetic abnormalities involved in the epidemiology of neonatal tumors:

1. Genes resulting in a high risk of malignancy (e.g. in retinoblastoma)
2. Genetically determined syndromes, where an increased risk of malignancy exists
3. Genes which confer a higher risk by conferring an increased susceptibility to environmental factors.

The incidence will be influenced by the incidence of these abnormalities in the population/family at risk.

GENES RESULTING IN A HIGH RISK OF MALIGNANCY

Accumulating research over the past two decades have seen many significant advances in understanding the mechanisms of the heritability of cancer (5–10% of all cancers). This is of particular interest in the field of neonatal tumors.

The best example of this group is the *RB1* gene, which confers a risk of retinoblastoma. Other examples include Li–Fraumeni syndrome, where there is an association of rhabdomyosarcoma, soft tissue tumors, breast carcinoma adrenocortical carcinoma, brain tumors, and leukemia.

As many of the genetic mutations associated with malignancy in children appear to occur spontaneously, a double 'hit'[26] is a likely mechanism.

THE 'TWO-HIT' OR MULTISTEP MODEL OF TUMOR DEVELOPMENT

Whereas it is generally recognized that tumors are a genetically related disease, tumorigenesis can mostly be attributed to a multistep process whereby each step probably correlates with one or more distinct genetic variations in the major regulatory genes. Knudson,[26] in an attempt to understand the pathogenesis of neonatal retinoblastomas, proposed that the tumor resulted from a combination of a prezygotic (germinal) mutation, as well as a postzygotic (somatic) event on the basis of extrapolated statistical data. This so-called 'two-hit' theory, was later confirmed by Comings[27] who suggested that both of these events could apply to mutations of the *RB1* gene. It is now widely accepted that inherited or *de novo* chromosomal mutations or deletions may result in a susceptibility to cancer.

Knudson's 'two-hit' model is particularly applicable to inherited cancer models (and possibly neonatal tumors), whereby an inherited susceptibility occurs on the basis of an identified germline mutation. The tumor development then rests on the further inactivation of a second allele (often tumor suppressor genes) which gives rise to early activation of the oncogenic pathway.

This theory provides the basis for understanding the pathogenesis of a number of tumors occurring in the neonatal period and has since been validated for a number of other tumor types (e.g. retinoblastoma, Wilms' tumor (WT), neuroblastoma, and other tumors).

In sporadic tumors (as opposed to hereditary tumors), a multistep process is more likely and the mutational activation of oncogenes is often correlated with non-mutational inactivation of tumor suppressor genes. As this is probably an early event, it is then followed by a number of independent mutations in other genes to allow neoplastic growth.

How this applies to special circumstances, such as neonatally occurring tumors, beyond these known examples is still unclear. These tumors feature a number of host-specific features which include the potential of spontaneous regression in some, a greater capacity for cell repair, as well as a comparatively good prognosis when compared to histologically similar tumors occurring later in childhood. It is therefore reasonable to assume that further study of the genes controlling childhood cancer and particularly cancer occurring early in life, warrants further attention.

Genetically determined high-risk syndromes

The identification of a genetic association of a specific tumor may be hampered due to the fact that the precise genetic mechanisms may not be recognized by the current genetic testing methods. Etiological factors involved in the pathogenesis of certain tumors (e.g. Wilms' tumor) appear to be more complicated than those of others (e.g. retinoblastoma). Increases in familial occurrence or an increased risk in monozygotic twins may be present and an association between a specific malignancy and a set of alleles at a specific locus thus identified. This may not be exclusive to the particular tumor under study and may be associated with the pathogenesis of other types of tumors. Examples of this are the associations between leukemia, lymphomas, central nervous system (CNS) neoplasms, and soft-tissue tumors, as well as the *RB1* and *WT1* genes among others. The evaluation of clinical associations and syndromes linked to specific tumor types is therefore of considerable importance.

Mendelian single gene-related syndromes

Syndromes arising from defects in chromosomal breakage or disorders of sexual differentiation may lead to malignancy. A number of examples of Mendelian single-gene malignancy-related syndromes are described in Box 77.1.

These may be autosomal dominant, recessive, or X-linked. In addition, certain disorders of sexual differentiation may

Box 77.1 Inherited syndromes and childhood malignancy

- Chromosome breakage syndromes

  - Turcot's syndrome
  - Multiple mucosal neuroma syndrome
  - Basal cell nevus syndrome
- Metabolic disorders
  - Tyrosinemia (hereditary)
  - Alpha-1 antitrypsin deficiency
  - Glycogenolysis (type 1)
- Immune deficiency disorders
  - Sex-linked lymphoproliferative syndrome
  - Wiskott–Aldritch syndrome
  - Severe combined immunodeficiency
  - Bruton's agammaglobulinemia

also be associated with cancer in the pediatric age group. Autosomal dominant syndromes include familial colonic polyposis, neurofibromatosis, and the nevoid basal cell carcinoma syndrome (Gorlin syndrome), as well as the blue rubber bleb and Sotos syndromes. Skeletal abnormalities, such as multiple exostoses, polyostotic fibrous dysplasia, and Mafuccis syndrome are also associated with a higher incidence of tumor formation. These tumors do not normally present in the neonatal period and are added for completeness, but are extremely interesting from a genetic point of view (i.e. in tracing the affected individuals in family groups).

Autosomal recessive syndromes associated with tumors include xeroderma pigmentosum, Fanconi's anemia, Bloom syndrome, and ataxia telangiectasia syndromes. Bloom syndrome includes a sensitivity to ultraviolet light, growth retardation, and immunodeficiency which is associated with a higher rate of associated malignancy occurring at an earlier age,[28] e.g. leukemias and gastrointestinal malignancies. Fanconi's anemia is also linked to leukemia and liver tumors. Tumors associated with an autosomal recessive familial inheritance, as well as those associated with immunodeficient X-linked recessive syndromes occur outside the neonatal period, suggesting some degree of an initiating environmental influence.

The Epstein–Barr virus has been suggested as a possible pathogenetic factor[29] in the X-linked lymphoproliferative syndrome. Of particular interest are the fragile chromosomal syndromes, where fragile sites associated with breakage and repair of chromosomal defects are transmitted through families. A high percentage of the inheritable and constitutive fragile sites have been mapped to genetic sites associated with human cancer.[30] These chromosomal rearrangements have been associated with malignancy in at least six out of the 16 inheritable fragile chromosome sites and have also been identified in other non-inherited fragile chromosome sites.[30] As a result of the chromosome fragility in these cases, deletions and chromosomal fragments may occur. Should the fragile sites break close to a proto-oncogene location, the activation of the oncogene may result in the malignant transformation of the cells. In several disorders in sexual differentiation, the incidence of gonadal tumors has been increased.

Familial associations with cancer

Although loss of a chromosome segment of a specific chromosome pair (heterozygosity) may be involved in the pathogenesis of certain tumors,[31,32] a specific chromosome from one of the parents appears to be given preference in particular situations.[31] Examples of this are the loss of a maternally derived gene on chromosome 11 in sporadic Wilms' tumor[32] and the successive loss of function of both alleles of RB (retinoblastoma susceptibility gene) in the development of retinoblastoma, as well as certain sarcomas such as osteosarcoma.[31] Genetic processes other than chromosome anomalies may also be involved in the familial transmission of a tendency to develop certain tumors.

Large cohort studies of the offspring of parents with cancer have failed to show an overall increased risk for tumors.[33] There is also little evidence to suggest that cancer treatment confers an additional risk. In a separate study of 36 survivors of 82 neonatal tumors, the authors found no familial increase in the incidence of malignancy, although chromosomal abnormalities were identified in three patients.[34] One patient had a chromosome 21 abnormality, one had trisomy 13, and in the other a distinctive familial translocation pattern was located on the 9th chromosome in a girl with a neuroblastoma.[35] The lack of increase in incidence agrees with the findings of previous studies,[11,36,37] where no inherited effects of childhood tumors or tumor therapy were identified in survivors of childhood neoplasms.

Other syndromes associated with an increased genetic risk of cancer

Although a family history may be observed in the group of neurocristopathies associated with neural crest abnormalities, the associated tumors appear outside the neonatal period. Examples of this are pheochromocytoma, von Recklinghausen's disease, Sturge–Wreber syndrome, tuberous sclerosis, and von Hippel–Lindau disease, as well as the MEN II tumor syndrome.

Other congenital syndromes which confer an increased risk of malignancy include the WAGR and Denys–Drash syndromes in Wilms' tumors, the Beckwith–Wiedemann and Down syndromes, and neurofibromatosis (*NF1* gene). There is an increased risk of leukemia and other tumors in patients with Down syndrome.[38] Leukemoid reactions may be more difficult to distinguish in the neonatal period.[39] Abnormalities of the neurofibromatosis 1 gene (*NF1*) have been identified in patients with von Recklinghausen's disease and a number of different mutations on the tumor suppressor gene have been described in chromosome 17q. An additional NF2 suppressor gene has been identified on chromosome 22q, leading to tumors such as acoustic schwannomas and other neural tumors.

There is a certain amount of overlap in phenotypic expression in syndromes such as the Beckwith–Wiedemann, Denys–Drash, Simpson–Golabi–Behmel, and Perlman, as well as other overgrowth syndromes. Nephroblastomatosis may be a feature of a number of these syndromes and long-term survey is required as these could put patients at risk for embryonic tumors.

There are additional associations between Wilms' tumor, aniridia, urogenital malformations, and mental retardation (WAGR) and the Denys–Drash syndrome.[40] This latter syndrome includes features of intersex disorders, nephropathy, and Wilms' tumor. Although initially described only in males with pseudohermaphroditism,[40,41] this syndrome has been extended to include female children with ambiguous genitalia, nephropathy, and Wilms' tumor.[42] An observed constant association with genetic mutations located at chromosome 11p13 (*WT1* or Wilms' tumor gene) and the Denys–Drash syndrome indicates a possible molecular marker for this syndrome. The exact site of the point mutation which was identified in the majority of cases was located on the *WT1* exon 9, which affects the amino acid residue 394 arginine.[42] There is also an association between other tumors, such as hepatoblastoma or adrenocortical

carcinoma and Wilms' tumor, which may coexist in 6–10% of patients.

Genetic factors which are involved in an increased risk of tumors include tyrosinosis, the MEN II and III syndromes, congenital adrenal hyperplasia, the basal cell nevus and Li–Fraumeni syndromes.[43] Genetic mutations predisposing to malignant disease include the Wilms' tumor 1 gene. In this instance, an 11p13 chromosomal defect is often typical. A further example is the neurofibromatosis type 1 gene, which is common in certain tumors. Gene amplifications have been reported in certain tumors. Amplified N-myc and N-ras oncogenes have been observed in neuroblastomas. This N-myc amplification has been shown to be associated with the more severe form of the malignancy.

Association with congenital malformations

There is also a fairly clear relationship to congenital abnormalities which have been reported to occur in as much as 15% of neonatal tumors. The role of genetic factors in development and the link between congenital malformation and tumors (e.g. neuroblastoma[44]) is also becoming clearer. In one recent study, 15 out of 72 patients with a neonatal tumor had associated congenital abnormalities.[45]

Increased susceptibility to environmental factors

In addition to genetic factors, environmental exposure is also a strong contender for promoting oncogenesis. Although it is true that neonates have a limited exposure to environmental toxins having just been 'born', so to speak, but environmental influences which affect the mother (e.g. environmental exposure to ionizing radiation, drugs taken during pregnancy, infections and tumors in the mother, and congenital malformations) may also affect the unborn baby. As a result, events occurring during pregnancy could be of key significance in the development of neonatal tumors. Both the environmental and genetic factors may thus influence the development of a neonatal tumor in the offspring. It is therefore conceivable that both genetic and environmental factors may be operating (possibly in tandem) at this stage giving rise to a 'unifying hypothesis' linking ontogeny to oncogenesis.

Environmental exposure quite possibly influences vital signaling cascades which occur during development. These noxious influences would, however, have to occur during a period when normal developmentally specific mechanisms are influenced by multiple genetic and environmental factors which may influence the epigenetic processes taking place during that period.[6] Such influences on epigenetic factors have already been identified from patients exposed to certain environmental toxins in certain adult tumors.[6] More recently, the importance of disturbances in epigenetic programming which regulate both normal and neoplastic growth and development have been explored.[46,47]

It stands to reason, therefore, that a study of those genetic and environmental factors with the potential to influence this process has the potential to provide considerable information about both cancer etiology and the natural history of tumors, including their development and progression.

This molecular epidemiological approach in investigating childhood tumors is enhanced by the current available technology which may permit the characterization of connections between exposure and subsequent health effects in newborns by means of biomarkers (e.g. mutations in cord blood DNA).[48]

Radiation-induced tumorigenesis

Ionizing radiation has been clearly implicated in the etiology of a number of tumors in children. This may involve prenatal, as well as postnatal exposure. There is a dose-related increase in tumor incidence or a tendency for tumors to occur at a younger age following prenatal or neonatal radiation exposure.[49] This is also true of internally deposited radionucleotides administered in the prenatal or neonatal periods.[50] It is clear from experimental evidence that deletions, point mutations, translocations, and other genetic abnormalities occur as a result of ionizing radiation. As a result a state of genomic instability may occur, which may in turn result in malignant transformation. There does appear to be an increased susceptibility to ionizing radiation in the Li–Fraumeni syndrome mouse model (p53-deficient mice), which suggests some environmental influence in the development of tumors.[51]

Effect of drugs in pregnancy

It is becoming clearer that fetal exposure to endocrine disruptors and hormonally active substances (e.g. diethylstilboestrol) affect the prevalence of reproductive abnormalities, metabolic disorders and thus influence cancer.[52]

Drugs may act as carcinogens or co-carcinogens in association with other agents or a particular genetic background. There is also clear evidence that tumors may arise in the children of mothers taking medication. One of the best examples of this is the fetal hydantoin syndrome.[53] There is some evidence of tumors arising from estrogens taken during pregnancy, and sacrococcygeal tumors have also been associated with maternal intake of acetazolamide.[54] This may be a greater problem than was initially thought. Satge *et al.*[55] showed a history of medications being taken in 39 out of 89 (44%) neonatal tumor patients. Out of the 39 tumors, nine were malignant, of which the main types were neuroblastomas and teratomas. Three groups of drugs were identified: IARC group 1 diethylstilboestrol and oral contraceptives, IARC group 2 possibly carcinogenic to humans, and IARC group 3, where no association has been proven. To date the association of vitamin K with carcinogenesis remains unproven.[56]

Environmental exposure

Results of epidemiological studies are inconsistent as far as environmental exposure is concerned, but only weak

associations with risk factors such as smoking have been identified.[57] Other environmental factors such as exposure to electromagnetic radiation have proved to be difficult to determine from an epidemiological point of view.

SPECIFIC CLINICAL ASSOCIATIONS OF NEONATAL TUMORS

Retinoblastoma

Much of the understood relationship between genetics and tumors of childhood really lies in the seminal work of Knudson[26] who in 1971 developed the 'two-hit theory' of oncogenesis in retinoblastoma based on an analysis of the age of presentation of hereditary as opposed to the non-hereditary cases. Knudson's hypothesis that these tumors resulted from two separate genetic events was extended to suggest that these events could be mutations of the same *RB1* gene. It has subsequently been shown that 90% of individuals with the *RB1* gene will develop a retinal tumor. A small number of these patients (5%) have additional associated genetic disturbances (e.g. deletions or translocations at 13q14).

Retinoblastoma remains the most common intraocular tumor of childhood, with the average age of diagnosis being at 11–12 months of age for bilateral disease and 23 months for unilateral tumors. In cases with a strong family history and a high index of suspicion, diagnosis may be made in the perinatal period.

The retinoblastoma protein (pRB) is part of the control of genes involved in the cell cycle and, as such, interacts with a number of transcriptional factors by modulating their activity. Inactivation of the *RB1* gene can therefore also be involved in the development of other malignancies and patients with *RB1* mutations carry a risk of developing other tumors, such as osteogenic sarcomas, fibrosarcoma, and melanomas in early adult life. The cloning of the *RB1* gene[58] indicated an association with other tumors such as osteosarcoma and breast carcinoma, in addition to retinoblastoma. Deregulations and/or mutations of the retinoblastoma protein (RB/RB1) pathway have been observed in many human cancers suggesting a fundamental role in oncogenesis.

To date, deregulated expression in more than 260 genes has been associated with retinoblastoma. An understanding of the function of these genes, not only provides valuable insights into oncogenesis in retinoblastoma but has yielded possible therapeutic target sites (e.g. MCM7 and WIF1) currently under investigation.[59]

Wilms' tumor

Wilms' tumor is the most common pediatric renal tumor with a peak age of incidence of three to four years. Although rare in the neonatal period, patients with synchronous bilateral Wilms' tumor, familial cases, and those with abnormalities are noted to be significantly younger. Predisposing associations with aniridia, congenital abnormalities of the genitourinary tract, and hemihypertrophy may be associated with nephroblastomatosis, which may lead to an early Wilms' tumor (Box 77.2).

The genetic factors involved in Wilms' tumor are much more complex than those involved in other tumors, such as retinoblastoma. The familial associations have been shown to be part of an autosomal dominant trait and are of the order of 1% with a somewhat slight female preponderance, particularly in multicentric and bilateral tumors.

Wilms' tumor has been associated with at least two genetic variations (11p13 and 11p15). Associations between Wilms' tumors and aniridia, urogenital malformations and mental retardation (WAGR) and the Denys–Drash syndromes[40,41] led to the identification of a constitutional chromosomal deletion in the short arm of one copy of chromosome 11 p13 (the *WT1* gene). The *WT1* gene appears to act as a tumor suppressor gene with its deletion resulting in development of a Wilms' tumor.[60] The gene encodes a zinc finger transcription factor which binds GC-rich sequences and acts as either an activator or repressor of transcription for a number of growth factors (including Igf-2) which may be a possible explanation of its mechanism of action. In addition to the *WT1* gene at 11p13, there is evidence of a second WT gene at 11p15 (*WT2* gene). A high reported frequency of LOH at 1p35–p36 (DIS247) suggests that this may be involved in the pathogenesis of Wilms' tumor.[61] The Knudson and Strong model for Wilms' tumor has been validated through molecular identification of the *WT1* gene.[62,63]

The *WT1* gene variations are only present in approximately 20% of Wilms' tumors, however, suggesting further genetic associations. Further genes (e.g. *WT3* and *WT4*) also appear to be implicated in the oncogenesis of Wilms'

Box 77.2 Syndromes associated with Wilms' tumor

       - Adrenocortical carcinoma

tumors as are gains of 1q and deletions of chromosome 22 associated with a worst prognosis. The 11p15 variation is also associated with the Beckwith–Wiedemann syndrome. More recently, the *WTX* gene (Xq11.1) was reported to be mutated in Wilms' tumors. It is of interest that these two genes appear to occur with similar regularity and despite some overlap with the *WT1* gene, a combination could account for up to a one-third of Wilms' tumors.[64] An association between the WNT/beta-catenin signaling pathway (the *CTNNB1* gene encoding beta-catenin) and the *WTX* gene is also known. This and other reports[65,66] of beta-catenin mutations in Wilms' tumors suggests that Wnt signaling pathway dysregulation also plays an oncogenic role in certain Wilms' tumors.

As the most critical factor in the Wnt signal transduction pathway, beta-catenin appears to be involved in the development of a number of malignant tumors. This is not surprising as the Wnt signaling pathway is involved in kidney development and pathway activation being involved in beta-catenin protein stabilization, intracellular accumulation, and nuclear translocation. It is clear that beta-catenin gene mutations (identified in $\pm$15% of Wilms' tumors) may lead to nuclear beta-catenin accumulation in cells.[65] One recent report observed a highly significant ($p = 3.6 \times 10^{-13}$) association between *WT1* and beta-catenin mutations in Wilms' tumors.[66] Further studies have reported overexpression of beta-catenin/TCF target genes in *WT1*-mutant tumors with gain-of-function mutations of the *CTNNB1* gene being identified elsewhere in the gene on complete sequencing, increasing the overall mutation rate to 75%.[67]

In addition, a loss of heterozygosity (LOH) for 16q is a structural alteration identified in 20–30% of Wilms' tumors. p53 alteration also appears to be required for the progression to the anaplastic subtype. Further associations with p53 analogs (p73 and p63/KET) suggests that association with the p53 family may be important to cell growth and differentiation.[68] Haploinsufficiency in the *PAX6* gene is also strongly associated with aniridia.[69] Familial Wilms' tumor does not, however map to the 11th chromosome as FWT1 is on 17q12-q21 and FWT2 on 19q13. Other susceptibility genes still remain to be identified.

Neuroblastoma

Neuroblastoma is one of the most commonly occurring malignant solid tumors in childhood which is often being advanced at diagnosis, commonly metastasizing widely to bone marrow, bone cortex, liver, lymph nodes, and lung. The tumor arises from the neural crest origin and can originate from any site along the distribution of the sympathetic chain. More than 90% are active in secreting biochemical substances which helps in diagnosis as catecholamine metabolites may be measured in the urine.

Genetic factors play a major role in development and the link between maldevelopment and tumors. A positive association between congenital malformation and neuroblastoma has been reported in at least one recent study (odds ratio (OR) = 2.2, 95% confidence interval (95% CI): 1.1–4.5),[44] being particularly linked to those tumors presenting at under one year of age (OR = 16.8, 95% CI: 3.1–90), as opposed to those presenting at over one year of age.

Neuroblastomas demonstrate a unique clinical behavior within the perinatal period. Certain tumors, although malignant in appearance, may undergo spontaneous regression whereas others metastasize widely and aggressively. Studies have shown a favorable outcome for neuroblastoma in the majority of mass-screened perinatal patients[18,70] suggesting either a better biological profile or operative developmental signaling pathways which still function in the perinatal period. In addition, stage IVS neuroblastomas although widely spread (including a massively enlarged liver and extensive subcutaneous (blueberry muffin) lesions), have a relatively good clinical prognosis.

Neuroblastoma tumor cells are associated with molecular genetic features in up to 80% of cases, many of which are of biological and clinical significance as prognostic factors and are currently of value in directing treatment.

The most important of these are MYCN amplification, deletion of chromosome 1p, ploidy, additional copies of chromosome 17q, and the expression of the gene for the neurotrophin nerve growth factor gene *TRKA*. Multiple areas of LOH and copy number gain were seen. In many cases, the defect is found to be on chromosomes 1, 11, and 17. Gain of copy number on 17q has recently been reported in 95% of cases studied and one of the most consistent changes being a deletion on the short arm of chromosome 1 (1p36.1–1p36.3). Whereas 1p LOH is encountered in one-third of cases,[71] inactivation of the tumor suppressor gene at 11q23.3 has been found to be an even more frequently encountered element of malignant progression being identified in up to 68%.[72] LOH on both chromosomes 11q and 1p were mostly accompanied by copy number loss, indicating homozygous deletion. It is also highly associated with occurrence of chromosome 3p LOH.

Additional chromosomal abnormalities have been identified at 4p, 6q, 9q, 10q, 12q, 13q, 14q, 16q, 22p, and 22q.[73] Amplification of the n-Myc oncogene (usually found on chromosome 2) has been associated with a more advanced form of the malignancy and is a poor prognostic sign. Few of the perinatal neuroblastomas have n-myc amplification, although 10–20% have unfavorable histological features. Recent research into high-risk neuroblastomas without MYCN amplification has shown that other oncogenic genes may deregulate MYC via altered beta-catenin signaling (a transcriptional target of beta-catenin) indicating some degree of interdependence with other signaling pathways.[74] Recent reports of the downregulation of activin-A by MYCN offers an explanation for this as deprived neuroblastoma cells experience a decrease in growth-inhibitory signal transduction leading to excessive cell growth.[75] In addition, the expression of TrkA has recently been shown to inhibit angiogenesis and tumor growth in neuroblastomas suggesting possible new treatment options.[76] It is also interesting to note that *p53* gene mutations are absent in neuroblastomas,[77] although present in other tumors of childhood.

The association of the Wnt signaling cascade with cancers in young children, provides a further potential candidate

signaling pathway with the potential for therapeutic down-regulation and indicates the existence of an underlying mechanism which may result in dysregulation of the Wnt/beta-catenin transcription pathway.

TERATOMA

Germ cell tumors account for approximately 3% of pediatric malignancies worldwide and occur in gonadal (male and female) and extragonadal sites. Epidemiology should include abortions and stillbirths, as the related mortality rate is high. The majority of teratomas are located in the sacrococcygeal region and gonads in childhood. Sacrococcygeal tumors are mostly benign at birth and the majority do not develop to malignancy if adequate surgical removal is carried out before the infant is three months of age. After this time, the risk of malignancy increases if residual tumor is present and older children may require chemotherapy along with delayed surgical excision.

Teratomas are thought to arise from the primordial germ cells as the result of an early event. A genetic tendency towards spontaneous gonadal teratomas is seen in a specific strain of experimental mice (strain 129).[78] An association with autosomal dominant familial recurrence has been reported and there also appears to be a Mendelian dominant genetic predisposition to the development of a presacral mass in association with anorectal, sacral, and urogenital abnormalities.[79] Patients with an imperforate anus and a hemisacrum have a high incidence of presacral masses which are teratomas and may occasionally be malignant.[79] Recent evidence points to an association with the long arm of chromosome 7 and Currarino's triad.[80] Mediastinal teratomas have been shown to develop in the second trimester.[81] Their sensitivity to chemotherapy and the existence of reliable tumor markers are important prognostic factors.

SOFT-TISSUE TUMORS

Soft-tissue tumors (STS) are not uncommon in childhood and whereas the majority are benign lesions of connective tissue, a number of extremely aggressive tumors exist. There are arguably three separate clinical groups of soft-tissue tumors encountered in childhood (that is, congenital fibrosarcoma (CFS), rhabdomyosarcoma (RMS), and non-rhabdomyosarcoma (NRSTS)).[82]

Spicer[83] classified congenital fibrosarcoma separately to differentiate it from the more aggressive-type fibrosarcomas with similar histopathologic features seen in adults as they mostly have a favorable outcome and metastasize rarely. Classifying STS on prognosis and outcome, he considered that tumors of intermediate prognosis included rhabdomyosarcomas, peripheral neuroectodermal tumors (PNET), undifferentiated sarcomas, and malignant melanomas, whereas tumors with a uniformly bad prognosis included Kaposi sarcoma, malignant schwannoma, Triton tumors, and juvenile hyaline fibromatosis, as well as visceral fibromatosis.

Rhabdomyosarcoma

Rhabdomyosarcoma accounts for 10% of neonatal malignancies,[84] being the most common malignant STS even in the perinatal period.[20] It has a number of genetic associations which differentiate the histological subtypes and is associated with a number of genetic syndromes (Beckwith–Wiedemann, Li–Fraumeni, and WAGR syndromes, and neurofibromatosis (type 1)). This suggests a genetic basis for its early appearance in the neonatal period.

Associated genetic variations include loss of heterogeneity of the short arm of chromosome 11 (11p15 locus 12) in embryonal tumors which leads to an overexpression of the insulin growth factor II (*IGFII*) gene. Equally, a subset of alveolar RMS has a unique chromosomal translocation between chromosomes 2 and 13, that is, (t[2;13]) (q35;q14)).[85,86] This is close to the junction of the *PAX3* gene which controls neuromuscular development[87] and the *PAX/FKHR* fusion gene is found in as many as 60% of alveolar RMS. A further 10% of patients with particularly poor prognosis may also carry the Ewing's sarcoma (*EWS/ETS* fusion genes (occasionally along with the *PAX/FKHR* gene)).

Numerous other genetic variations have been reported, including frequent gains of chromosomes 2, 7, 8, 11, 12, 13q21, and 20, as well as losses of 1p35–36.3, 6, 9q22, 14q21–32, and 17.[88] A further loss of 1p36[89] corresponds to the locus for the paired home box PAX 7 which is characteristically altered in alveolar RMS tumors. The 1p region is interesting as it is also associated with neuroblastomas. Additional associations between mutations in the p53 tumor suppressor gene are also associated with adverse outcome.

STS and the Beckwith–Wiedemann syndrome

The Beckwith–Wiedemann syndrome (macrosomia, macroglossia, omphalocele, and hemihypertrophy) is associated with genetic and/or epigenetic alterations that modify imprinted gene expression on chromosome 11p15.5. There is an increased risk of soft tissue sarcomas (approximately 7.5%), especially if hemihypertrophy is present. Oncogenesis is associated with the detection of abnormal myogenic transcription factors (MyoD, Myogenin, and Myf5) and the PAX/FHKR chimeric transcription factors. Detection of other fusion genes, such as EWS/WT1, in desmoplastic small round cell tumors, EWS/ATF in clear cell sarcoma, SSX/SYT in synovial cell sarcoma, or the TLS/CHOP in liposarcoma have also been described. An overexpression of MyoD in RMS is thought to inhibit the development of muscle cells and characteristically marks these tumors.[90]

The increased tumor risk in the Beckwith–Wiedemann overgrowth syndromes (BWS) and the associated Wilms' tumor, hepatoblastoma, and hemihypertrophy, are probably due to the complex genetic/epigenetic abnormalities of

the imprinted 11p15 region.[91,92] A specific cancer risk is associated with specific areas of the gene[93] with the most common constitutional abnormalities currently appearing to be epigenetic, with aberrant methylation occurring at H19 or LIT1. As a result, untranslated RNAs are recorded on the gene at 11p15. Variations in H19DNA methylation were found to be significantly increased in at least one report (that is, 56% (9/16) versus 17% (13/76; $p = 0.002$), but not LIT1 alterations.

Ewing's family tumors

Although the cell of origin of Ewing's sarcoma is unknown, the Ewing's family of tumors most frequently has a specific translocation that results in expression of the EWS/FLI1 fusion protein responsible for malignant transformation.[94] Although a number of EWS/FLI1 downstream targets have been identified, the exact details of the oncogenic mechanism remains uncertain. It is currently thought that the *FLI*, *ERG*, *FEV*, *ETV1*, and *ETV4* genes appear to be involved in chimera formation which all upregulate EAT-2 (a previously described EWS/FLI1 target). EWS/FLI1 dysfunction appears to then result in functional activation of the retinoblastoma (pRB) family proteins which are key mediators of the resulting probable oncogenic transformation.[95]

HEPATOBLASTOMA

Hepatoblastoma (HB) is the most common malignant liver tumor particularly in the younger child. Although up to one-third of hepatoblastomas are associated with congenital abnormalities, familial recurrence is extremely rare with the exception of families with adenomatous polyposis coli.[96] There is also considerable support for associations with trisomies 2, 8, and 20 in the development of HB.[97] It has also been associated with a low birth weight in the neonate.[98]

Congenital hepatoblastomas appear to have a poorer prognosis than those occurring in the older child with metastatic lesions being reported at unusual sites (brain,[99] iris and choroid,[100] and placenta[101]). The latter may indicate tumor seeding during pregnancy via the fetal circulation.

There is relatively little known about the molecular basis of hepatoblastoma in infancy and the common tumor markers, such as CTNNB1, APC,[102] and IGF-2, are variable, particularly in the sporadic tumors. Some support exists for associations with trisomies 2, 8, and 20.[103] Multiple deletion or point mutations have been described in hepatoblastoma, but gains on chromosomes 1q and 2 are typical with 2q24 being viewed as the critical chromosomal band. In addition, gains on 8q and 20 have been shown to have a significantly higher association with poor outcome.[103]

There is a clear association with the Beckwith–Wiedemann syndrome[104] and hemihypertrophy. It has been postulated that the mechanism of tumorigenesis is similar to that of Beckwith–Wiedemann syndrome-associated tumors, such as Wilms' tumor, RMS, and hepatoblastoma, which suggests a common genetic pathway involving LOH at the 11p site.[105]

The chief APC gene function is to downregulate beta-catenin by phosphorylation sites on exon 3. Beta-catenin is a transcription-activating protein with the potential to promote tumorigenesis. APC mutation and dysregulation has been shown to lead to accumulation of beta-catenin protein in the cellular nucleus, thus activating a number of tumor-related events.[102] Current data suggest that activation of beta-catenin signaling may be an important step in hepatoblastoma pathogenesis. In a separate study, mutations in beta-catenin were only detected in 19% of cases, although beta-catenin protein accumulation was identified in 67% and microsatellite instability in 81% confirming that beta-catenin dysfunction is involved in sporadic hepatoblastoma;[106] chromosomal variations were observed in 88% of cases in a genome-profiling study.[107] Gains in chromosomes 1q, 2 (or 2q), 8, 17q, and 20, and losses in chromosomes 4q and 11q occurred frequently, as well as high-grade amplifications at 7q34, 14q11.2, and 11q22.2. LOH at 11p15 was identified in a subgroup and is of considerable interest due to the location of the insulin-like growth factor II (*IGFII*) and *H19* genes within this region.[107]

OTHER TUMORS

Other genetic aberrations associated with tumors, such as the loss of heterozygosity on chromosome 5q, in identifying the gene for familial polyposis of the colon, defects in tumor-suppressive genes on 17q (p53) and 18q (DCC) in carcinoma of the colon, and translocation of the end of the long arm of chromosome 8 with chromosome 14, or an alteration in C-myc regulation or p53[108] in Burkitt's lymphoma, are interesting associations with pediatric tumors, but are not particularly associated with the neonatal period.

ANTENATALLY DIAGNOSED TUMORS

Clinical approach to antenatally diagnosed tumors

The reasons for highlighting neonatal tumors are manifold, but include the following:

- increased diagnosis of neonatal tumors due to routine ultrasonography during pregnancy brings to light tumors whose natural history and optimal management is unclear;
- increased knowledge and understanding of pathophysiology and biological behavior of tumors may reduce unnecessary harmful forms of therapy;
- molecular genetics in these tumors identifies risk factors and provides models for understanding carcinogenesis in other tumors;
- environmental and teratogenic factors may be identified.

All evidence points toward the fact that the natural history of neonatal tumors is different (mostly better) than that of comparable tumors in older children. The basis of this

behavior is largely unknown and hard epidemiological and etiological data in this group are lacking.

It is important that the identification of the genetic associations of these tumors continues and the cancer-producing genes to identify the genetic alleles associated with malignancy are investigated further. In addition, it is important that families with a genetic susceptibility to malignant tumors be investigated in order to identify specific genetic loci which may or may not be related to a specific allele. Because of the rarity of these tumors, it is clear that international collaborative studies and research projects are necessary to achieve this goal.

THERAPEUTIC CONSIDERATIONS

There is a paucity of objective information on the optimal treatment and long-term outcome of neonatal tumors[11] and the impact of therapeutic measures to be taken into consideration.[12,109–111]

Hemangiomas and vascular malformations

ARIN K GREENE AND STEVEN J FISHMAN

INTRODUCTION

Vascular anomalies are disorders of the endothelium that usually present during childhood. These lesions affect all parts of the vasculature: capillaries, veins, arteries, or lymphatics. Although nearly always benign, vascular anomalies may involve any location. In addition to disfigurement, local complications include obstruction, bleeding, infection, and pain. Systemic sequelae can include thrombocytopenia, pulmonary embolism, congestive heart failure, sepsis, and even death.

A biologic classification of vascular anomalies has clarified the difference between vascular anomalies based on physical findings, natural history, and cellular characteristics.[1] Vascular anomalies are broadly divided into two groups: tumors and malformations (Table 78.1). Vascular tumors are characterized by endothelial cell proliferation (Fig. 78.1). Vascular malformations, in contrast, arise from dysmorphogenesis and have normal endothelial cell turnover (Fig. 78.2).

Table 78.1 Biological classification of vascular anomalies.

Tumors	Malformations	
	Slow flow	Fast flow
Infantile hemangioma (IH)	Capillary (CM)	Arteriovenous (AVM)
Congenital hemangioma (CH)	Venous (VM)	
Kaposiform hemangioendothelioma (KHE)	Lymphatic (LM)	
Pyogenic granuloma (PG)		

VASCULAR TUMORS

Infantile hemangioma

CLINICAL FEATURES

Infantile hemangioma (IH) is a benign tumor of the endothelium that affects approximately 4–5% of Caucasian infants.[1–3] It is more frequent in premature children and females (3:1 to 5:1).[4] IH typically is single (80%) and involves the head and neck (60%), trunk (25%), or extremity (15%).[2] The median age of appearance is 2 weeks, although 30–50% of lesions are noted at birth as a telangiectatic stain or ecchymotic area.[5] IH grows faster than the rate of the child during the first nine months of age (the proliferating phase).[6] When IH involves the superficial dermis it appears red. A lesion beneath the skin may not be appreciated until three to four months of age when it has grown large enough to cause a visible deformity; the overlying skin may appear bluish. By 9–12 months of age, the growth of IH plateaus to approximate that of the infant.[6] After 12 months of age, the tumor begins to shrink (the involuting phase); the color fades and the lesion flattens. Involution stops in approximately 50% of children by five years of age (the involuted phase).[5] After involution, one-half of children will have an abnormality: residual telangiectasias, scarring, fibrofatty residuum, redundant skin, or destroyed anatomical structures.

DIAGNOSIS

Ninety percent of IH are diagnosed by history and physical examination. Diagnosis is facilitated using a hand-held Doppler device showing fast-flow. Ultrasonograpy (US) is the first-line confirmatory study to differentiate IH from other lesions. IH appears as a soft-tissue mass with fast-flow, decreased arterial resistance, and increased venous drainage.[7] On magnetic resonance imaging (MRI), IH is isointense on T_1, hyperintense on T_2, and enhances during the proliferating phase.[8] Involuting IH has increased lobularity and adipose tissue; the number of vessels and flow is reduced.[8] Rarely,

Figure 78.1 Vascular tumors of childhood. (a) Infantile hemangioma (IH) in a three-month-old female. The lesion was noted 2 weeks after birth and subsequently enlarged. It was treated with corticosteroid injection. (b) Rapidly involuting congenital hemangioma (RICH) in a 3-week-old male. The lesion was fully grown at birth and rapidly involuted over the first year of life. (c) Non-involuting congenital hemangioma (NICH) in a 2.5-year-old male; the vascular mass had not changed since birth. (d) Pyogenic granuloma in an eight-year-old female with a three-month history of a bleeding lesion. (e) Kaposiform hemangioendothelioma (KHE) in a 5-week-old neonate treated with vincristine.

biopsy is indicated if malignancy is suspected or if the diagnosis remains unclear following imaging studies. Because an erythrocyte-type glucose transporter (GLUT1) is specifically expressed in proliferating IH, immunostaining for GLUT1 can differentiate IH from other lesions.[9]

CLINICAL CONSIDERATIONS

Head and neck hemangiomas

Ten percent of proliferating IH cause significant deformity or complications, usually when located on the head or neck.[10]

Ulcerated lesions may destroy the eyelid, ear, nose, or lip. IH of the scalp or eyebrow can result in alopecia. Periorbital hemangioma can block the visual axis or distort the cornea causing amblyopia. Subglottic hemangioma may obstruct the airway; tracheostomy rarely may be necessary.

Multiple hemangiomas

Although 20% of infants will have more than one IH, occasionally a child will have five or more small (<5 mm), dome-like lesions termed 'hemangiomatosis'.[5] These children are at increased risk for IH of internal organs. The liver is most commonly affected; the brain, gut, or lung are rarely involved. US should be considered to rule out hepatic IH.

Hepatic hemangiomas

The liver is the most common extracutaneous site for IH, which may be focal, multifocal, or diffuse (Fig. 78.3).[11] Although most hepatic IH are non-problematic and discovered incidentally, some tumors can cause heart failure, hepatomegaly, anemia, or hypothyroidism. Ninety percent of fast-flow hepatic lesions are hemangioma; arteriovenous malformation, hepatoblastoma, and metastatic neuroblastoma are less common and do not demonstrate significant shunting on imaging.[11] Focal hepatic IH are usually asymptomatic unless they have associated direct macrovascular shunts (hepatic artery to hepatic vein and/or portal to hepatic vein). These direct shunts can lead to high output cardiac failure. Focal hepatic lesions are not associated with cutaneous lesions. They are not typical infantile hemangiomas, but rather the hepatic presentation of rapidly involuting congenital hemanangioma (RICH). Multifocal hepatic IH are typical infantile hemangioma, immunopositive for GLUT1, and may be associated with cutaneous lesions. Although usually asymptomatic, multifocal lesions can also have associated macrovascular shunts which can cause high-output cardiac failure. In either focal or multifocal variants, shunts may close with tumor involution, which may be hastened pharmacologically. Embolization of the shunts, although technically demanding, will quickly control cardiac failure.[12] Diffuse hepatic IH can cause massive hepatomegaly, respiratory compromise, or abdominal compartment syndrome. Infants are also at risk for hypothyroidism and subsequent irreversible brain injury because the tumor expresses a deiodinase which inactivates thyroid hormone.[13] Patients require thyroid-stimulating hormone monitoring and, if abnormal, thyroid replacement, often in massive doses, until the IH undergoes involution.

Lumbosacral hemangioma

Large, superficial, plaque-like, or reticular IH may rarely be associated with underlying spinal, urogenital, or anorectal malformations when it is located in the lumbosacral midline (tethered spinal cord, anorectal and genital malformations, renal anomalies, lipomyelomeningocele).[14,15] US is obtained to rule out associated spinal anomalies in infants less than four months of age. MRI is indicated in older infants or when US is equivocal.

PHACES association

PHACES association affects 2.3% of patients with IH, and consists of a plaque-like IH in a 'segmental' or trigeminal dermatomal distribution of the face with at least one of the following anomalies: posterior fossa brain malformation, hemangioma, arterial cerebrovascular anomalies, coarctation of the aorta and cardiac defects, eye/endocrine abnormalities, sternal clefting or supraumbilical raphe.[16] Ninety percent of infants are female and cerebrovascular anomalies are the most common associated finding (72%).[17] Because 8% of children with PHACES have a stroke in infancy, patients should have an MRI to evaluate the brain and cerebrovasculature.[18] Infants are referred for ophthalmologic, endocrine, and cardiac evaluation to rule out associated anomalies.[18]

NON-OPERATIVE MANAGEMENT

Most IH are managed by observation because 90% are small, localized, and do not involve esthetically or functionally important areas. During the proliferative phase, 16% of lesions will ulcerate; the lips, neck, and anogenital region are the most common areas to break down.[19] Other complications include bleeding and infection.[19] To reduce the risk of ulceration, the IH is kept moist during the proliferative phase with hydrated petroleum to minimize desiccation, as well as to protect against incidental trauma. IH may be further protected by using a petroleum gauze barrier. If an ulceration develops, it is managed with local wound care.

Topical corticosteroid

Topical corticosteroid has minimal efficacy; especially against IH involving the deep dermis and subcutis. Ultrapotent agents may be effective for small, superficial IH; however, their efficacy is inferior to intralesional corticosteroid. Although lightening may occur, if an underlying mass is present it likely will not be affected.[20] Adverse effects include hypopigmentation, skin atrophy, and possible adrenal suppression.

Intralesional corticosteroid

Small, well-localized IH that obstruct the visual axis or nasal airway, or those at risk for damaging esthetically sensitive structures (i.e. eyelid, lip, nose) are best managed by intralesional corticosteroid. Triamcinolone (3 mg/kg) stabilizes the growth of the lesion in at least 95% of patients, and 75% of tumors will decrease in size.[21] The corticosteroid lasts 4–6 weeks and thus infants may require additional injections during the proliferative phase. Intralesional corticosteroid may cause subcutaneous fat atrophy. Blindness has been reported following injection of periorbital hemangioma, possibly due to embolic occlusion of the retinal artery.[22,23]

Systemic corticosteroid

Problematic IH that is too large to treat with intralesional corticosteroid is managed by daily oral prednisone. The patient

is started on 3 mg/kg per day for one month which then is tapered every 2–4 weeks until it is discontinued between 10 and 12 months of age when the tumor is no longer proliferating. Recently, propranolol has been described for the treatment of IH, but its efficacy and safety, compared to corticosteroid, has not been studied.[24,25] Corticosteroid, in contrast, has been used to treat IH for over 40 years and has proven to be very safe and effective.[26–29] Overall, 84% of patients treated with different doses of corticosteroid will have (1) stabilization of growth or (2) accelerated regression.[28] Almost all patients, however, will respond to 3 mg/kg per day.[28] Treatment response is usually evident within 1 week of therapy by signs of involution: decreased growth rate, fading color, and softening of the lesion. The location of the hemangioma does not affect the response rate.[30] For the rare lesion that fails to stabilize with corticosteroid, the dose may be increased up to 5 mg/kg per day which may improve treatment response.[31] Alternatively, the child may be switched to vincristine; interferon is not advocated in children less than 12 months of age because it may cause spastic diplegia.[32,33]

Complications of systemic corticosteroid for the management of IH have been studied and no adverse effects on neurodevelopment have been found.[29] Short-term morbidity includes: cushingoid face (71%), personality change (29%), gastric irritation (21%), fungal (oral or perineal) infection (6%), myopathy (1%), decreased gain in height (35%), and decreased gain in weight (43%).[27] These findings resolve after the completion of therapy. For example, over 90% of children return to their pretreatment growth curve for height by 24 months of age.[27] Long-term complications of corticosteroid, such as aseptic necrosis of the femoral head, diabetes, osteoporosis, long-term adrenal insufficiency, cataracts, and glaucoma, have not been noted in patients treated with corticosteroid for IH.[27,34,35]

Embolic therapy

High-output congestive heart failure may be caused by macrovascular shunts seen with focal or multifocal hepatic lesions, or very rarely large non-hepatic IH. Embolization may be indicated for the initial control of heart failure, while the therapeutic effects of systemic corticosteroid are pending. Cardiac failure can recur even after initial improvement, and continued drug therapy after embolization may be indicated until the child is approximately 12 months of age when natural involution begins.

Laser therapy

Pulsed-dye laser treatment for proliferating IH is contraindicated. The laser penetrates only 0.75–1.2 mm into the dermis and thus only affects the superficial portion of the IH. Although lightening may occur, the mass of IH is not affected and accelerated involution does not occur.[36,37] Instead, patients have an increased risk of skin atrophy and hypopigmentation.[37] The thermal injury delivered by the laser to the ischemic dermis increases the risk of ulceration, pain, bleeding, and scarring.[38] The pulsed-dye laser is indicated, however, during the involuted phase to treat residual telangiectasias. Destructive laser therapy may be useful in airway hemangioma to avoid tracheostomy while awaiting successful response to pharmacotherapy.

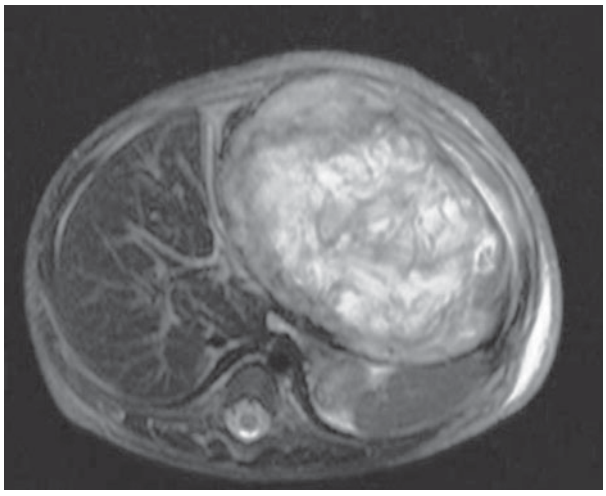
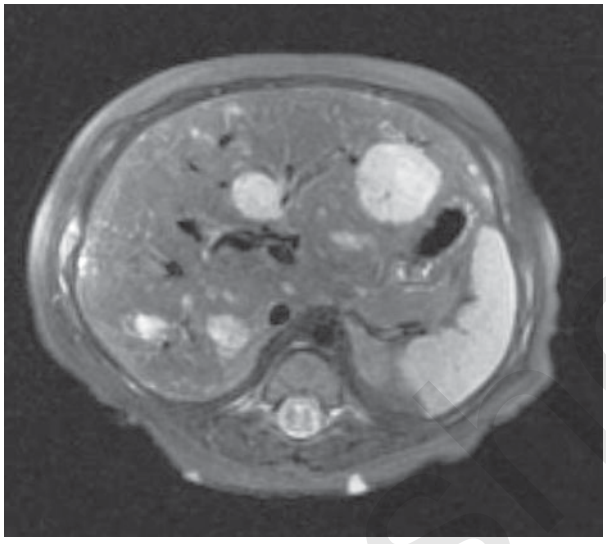
OPERATIVE MANAGEMENT

Proliferative phase (infancy)

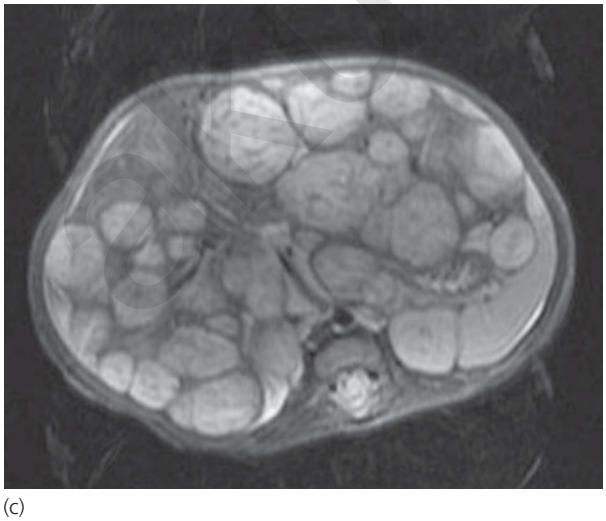
Operative treatment in infancy is generally not recommended. The tumor is highly vascular during this period and the patient is at risk for blood loss, iatrogenic injury, and an inferior esthetic outcome, compared to excising residual tissue after the tumor has regressed.[30] Factors that lower the threshold for resection of a problematic proliferating IH include (1) failure or contraindication to corticosteroid, (2) well localized in an anatomically safe area, (3) complicated reconstruction is not required, (4) resection will be necessary in the future and the scar will be the same. Circular lesions located in visible areas, particularly the face, are best treated by circular excision and purse-string closure.[39] This technique minimizes the length of the scar, as well as distortion of surrounding structures. A lenticular excision of a circular hemangioma will result in a scar as long as three times the diameter of the lesion, while a two-stage circular resection followed by lenticular excision 6–12 months later will leave a scar approximately the same length as the diameter of the original hemangioma.[39]



(a)



(b)



(c)

Figure 78.3 Types of hepatic hemangioma in infancy. Axial T_2 MRI showing three patients with focal (a), multifocal (b), and diffuse (c) hepatic hemangiomas.

Involuting phase (early childhood)

While operative management of IH is generally avoided during the proliferative phase, resection during involution is much safer because the lesion is less vascular and smaller. Because the extent of the excision and reconstruction is reduced, the esthetic outcome is superior. Approximately 50% of IH leave behind fibrofatty tissue or damaged skin after the tumor regresses, causing a deformity.[5] Less often, children require reconstruction of damaged structures (i.e. nose, ear, lip). Staged or total excision should be considered during this period, rather than waiting for complete involution if (1) it is clear that the patient will require resection (i.e. post-ulceration scarring, destroyed structures, expanded skin, significant fibrofatty residuum), (2) the length of the scar would be similar if the procedure was postponed to the involuted phase, (3) the scar is in a favorable location. Advantages of operative intervention during this period, compared to late childhood, is that reconstruction is performed prior to the child's development of memory or awareness of body differences.

Involuted phase (late childhood)

Waiting until IH has fully involuted prior to resection ensures that the least amount of fibrofatty residuum and excess skin is resected, giving the smallest possible scar. Allowing full involution to occur, however, must be weighed against the psychosocial morbidity of maintaining a deformity until late childhood. Allowing full involution is advocated for lesions when it is unclear if a surgical scar would leave a worse deformity than the appearance of the residual hemangioma.

Congenital hemangioma

CLINICAL FEATURES

Congenital hemangioma (CH) is fully grown at birth and does not illustrate postnatal growth.[40–42] CH has a different appearance to IH: it is red-violaceous with coarse telangiectasias, central pallor, and a peripheral pale halo. Unlike IH, CH is more common in the extremities, has an equal sex distribution, and is almost always solitary with an average diameter of 5 cm.[40–42] Two types of CH exist: rapidly involuting congenital hemangioma RICH and non-involuting congenital hemangioma (NICH). RICH involutes rapidly after birth and 50% of lesions have completed regression by seven months of age.[40,42] RICH affects the head or neck (42%), limbs (52%), or trunk (6%).[40–42] RICH does not leave behind a significant adipose component, unlike IH.[42] NICH, in contrast, does not undergo involution.[41] It involves the head or neck (43%), limbs (38%), or trunk (19%).[41]

MANAGEMENT

RICH does not require operative management in infancy because it undergoes accelerated regression; tumors are observed. Occasionally, RICH is complicated by congestive heart failure which is treated by corticosteroid or embolization

as the lesion involutes. Since RICH undergoes such rapid natural involution, it is not clear whether corticosteroid hastens involution. After regression, RICH may cause a residual deformity, usually atrophic skin and subcutaneous tissue. Operative intervention for RICH must not create a more obvious deformity than the lesion. Reconstruction with autologous grafts (fat, dermis) or acellular dermis may be indicated. NICH is rarely problematic in infancy and is observed. Because NICH is benign, asymptomatic tumors do not require excision. Symptomatic lesions in infancy are managed with embolization or resection. Resection may be indicated to improve the appearance of the affected area, as long as the surgical scar is less noticeable than the lesion. Pulse-dye laser therapy may improve the late appearance of CH by eliminating telangiectasias.

Kaposiform hemangioendothelioma

CLINICAL FEATURES

Kaposiform hemangioendothelioma (KHE) is a rare vascular neoplasm that is locally aggressive, but does not metastasize.[43,44] Although one-half of lesions are present at birth, KHE may develop during infancy (58%), between the ages of one and ten years (32%), or after 11 years of age (10%).[45] KHE has an equal sex distribution, is solitary, and affects the head/neck (40%), trunk (30%), or extremity (30%).[45] The tumor is often greater than 5 cm in diameter, and thus larger than the typical IH.[44] KHE causes a visible deformity, as well as pain. In addition, 50% of patients have Kassabach–Merrit phenomenon (KMP) (thrombocytopenia $<25\,000/mm^3$, petechiae, bleeding).[43,44] KHE partially regresses after two years of age, although it usually persists long term, causing chronic pain and stiffness.

DIAGNOSIS

KHE is diagnosed by history and physical examination. Unlike IH, it is usually present at birth as a flat, reddish-purple, edematous lesion that does not exhibit rapid postnatal growth; it is also associated with KMP. MRI is indicated for diagnostic confirmation or to evaluate the extent of the tumor. MRI shows poorly defined margins, small vessels, and invasion of adjacent tissues.[8] KHE shows T_2 hyperintensity and postgadolinium enhancement; signal voids may also be present.[8] Histologically, KHE has infiltrating sheets or nodules of endothelial cells lining capillaries.[43] Hemosiderin-filled slit-like vascular spaces with red blood cell fragments, as well as dilated lymphatics, are present.[43]

MANAGEMENT

Most lesions are large and involve multiple tissues preventing complete extirpation. Patients with KMP require systemic treatment to prevent life-threatening complications. Large, asymptomatic tumors are also managed with pharmacotherapy to minimize fibrosis and subsequent long-term pain and stiffness. KHE responds best to vincristine (90%), which is the first-line therapy.[46] KHE does not respond as well to second-line drugs, interferon (50%), or corticosteroid (10%).[44,46] Thrombocytopenia will not be significantly improved with platelet transfusion because the platelets are trapped in the lesion. Transfusion can worsen swelling and should be avoided unless there is active bleeding or a surgical procedure is planned. By two years of age, the tumor often undergoes partial involution and the platelet count normalizes. Excision rarely may be indicated for symptomatic patients with well-localized lesions or who have failed chemotherapy. Resection is not required for large lesions that are not causing functional problems because KHE is benign. The risks of the resection and the resulting deformity should be weighed against the appearance of the tumor.

Pyogenic granuloma

Pyogenic granuloma (PG) has been called 'lobular capillary hemangioma'.[47] PG is a solitary, red papule that grows rapidly, forming a stalk. It is small, with an average diameter of 6.5 mm; the mean age of onset is 6.7 years.[48] The male:female ratio is 2:1. PG is commonly complicated by bleeding (64.2%) and ulceration (36.3%). PG primarily involves the skin (88.2%), but can involve mucous membranes as well (11.8%). PG is distributed on the head or neck (62%), trunk (19%), upper extremity (13%), or lower extremity (5%). Within the head and neck, affected sites include: cheek (28.8%), oral cavity (13.5%), scalp (10.8%), forehead (9.9%), eyelid (9.0%), or lips (9.0%).[48] PG should be treated after diagnosis to prevent likely ulceration and bleeding. Numerous treatment methods have been described for PG: curettage, shave excision, laser therapy, or excision. Because the lesion can involve the reticular dermis, it may be out of the reach of the pulsed-dye laser, cautery, or shave excision. Consequently, these modalities have a recurrence rate of 43.5%.[48] Definitive treatment requires full-thickness skin excision.

VASCULAR MALFORMATIONS

Capillary malformations

CLINICAL FEATURES

Capillary malformation (CM) consists of dilated capillaries in the superficial dermis. CM is most often solitary, but can be small or extensive. It may occur in any location and over time darkens and develops fibrovascular overgrowth. It can be associated with soft tissue and skeletal hypertrophy. Sturge–Weber syndrome consists of CM in the ophthalmic (V1) trigeminal dermatome associated with ipsilateral ocular and leptomeningeal vascular anomalies.[49] Leptomeningeal anomalies can lead to seizures, contralateral hemiplegia, and delayed motion and cognition. Patients are at risk for retinal detachment and glaucoma and should be followed by an ophthalmologist.[5]

MANAGEMENT

Pulse-dye laser (585 nm) therapy can improve the appearance of CM by lightening the color; the head and neck region has a better response compared to the extremities.[50] Outcome is also superior for smaller lesions and those treated at a younger age.[51] Fifteen percent of patients achieve at least 90% lightening, 65% improve 50–90%, and 20% respond poorly.[52] Multiple treatments, spaced 6 weeks apart, are often required until the CM fails to improve with additional treatments. After laser treatment, CM often redarkens over time.[53] CM can also be associated with soft-tissue and skeletal overgrowth.[49] Enlargement of the maxilla or mandible can result in an occlusal cant and malocclusion. CM of the trunk or extremity may be associated with fatty overgrowth causing asymmetry. Because overgrowth may be progressive, most patients do not require contouring, usually labial, until adolescence or adulthood. Malocclusion may be corrected in adolescence with orthodontic manipulation. If orthodontics is insufficient, an orthognathic procedure is considered when the jaws are completely grown. Severe cutaneous thickening and cobblestoning can be resected and reconstructed by linear closure, skin grafts, or local flaps. Facial asymmetry caused by overgrowth of the zygoma, maxilla, or mandible can be improved by contour burring.

Lymphatic malformation

CLINICAL FEATURES

Lymphatic malformation (LM) results from an error in the embryonic development of the lymphatic system. LM is characterized by the size of the malformed channels: microcystic, macrocystic, or combined.[1,2] Macrocystic lesions are defined as cysts large enough to be treated by sclerotherapy.[54] Because the lymphatic and venous systems share a common embryological origin, lymphatic-venous malformation (LVM) can also occur. LM is usually noted at birth or within the first two years of life. LM is most commonly located on the head and neck; other frequent sites include the axilla, chest, and perineum. Lesions are soft and compressible. The overlying skin may be normal, have a bluish hue, or contain pink-red vesicles.

LM typically causes a deformity and psychosocial morbidity, especially when it involves the head and neck. The two most common complications associated with LM are bleeding and infection. Intralesional bleeding occurs in up to 35% of lesions causing bluish discoloration, pain, or swelling.[55] Infection complicates as many as 71% of LMs and can progress rapidly to sepsis.[55] Cutaneous vesicles can bleed, cause malodorous drainage, as well as wounds. Swelling due to bleeding, localized infection, or systemic illness may obstruct vital structures. Two-thirds of patients with extensive cervicofacial LM require tracheostomy to maintain the airway.[55] Secondary bony overgrowth is another complication; the mandible is most commonly involved and patients can develop a malocclusion. Jaw contouring or orthognathic procedures may be required.[55] Oral lesions can cause macroglossia bleeding, pain, poor oral hygiene, and caries.[56] Thoracic or abdominal LM may lead to pleural, pericardial, or peritoneal chylous effusions. Periorbital LM leads to a permanent reduction in vision (40%) and 7% become blind in the affected eye.[57] LM may be diffuse or multifocal; patients can have splenic or osteolytic bone lesions.

DIAGNOSIS

Ninety percent of LM are diagnosed by history and physical examination.[1,2] Small, superficial lesions do not require further diagnostic work-up. Large or deep lesions are evaluated by MRI to (1) confirm the diagnosis, (2) define the extent of the malformation, and (3) plan treatment. LM appears as a cystic lesion (macrocystic, microcystic, or combined) with septations of variable thickness.[58] It is hyperintense on T_2-weighted sequences and does not show diffuse enhancement.[58] Although US is not as accurate as MRI, it may provide diagnostic confirmation or document intralesional bleeding. US findings for macrocystic LM include anechoic cysts with internal septations, often with debris or fluid-fluid levels.[58] Microcystic LM has ill-defined echogenic masses with diffuse involvement of adjacent tissues. Histological confirmation of LM is rarely necessary. LM shows abnormally walled vascular spaces with eosinophilic, protein-rich fluid, and collections of lymphocytes.[59] Immunostaining with the lymphatic markers D2-40 and LYVE-1 are positive.[59]

MANAGEMENT

LM is a benign condition and intervention is not mandatory; small or asymptomatic lesions may be observed. Often, an infected LM cannot be controlled with oral antibiotics and i.v. antimicrobial therapy is usually required. Intervention for LM is reserved for symptomatic lesions that cause pain, significant deformity, or threaten vital structures.

Sclerotherapy

Sclerotherapy is first-line management for large or problematic macrocystic/combined LM. It involves aspiration of cysts followed by the injection of an inflammatory substance which causes scarring of the cyst walls to each other. Sclerotherapy has superior efficacy and a lower complication rate than resection.[60] Resection of macrocystic LM is generally not necessary unless (1) the lesion is symptomatic and sclerotherapy is no longer possible because all of the macrocysts have been treated, (2) resection may be curative because the lesion is small and well-localized, or (3) the lesion is so massive or has a large microcystic component, such that a significant mass will remain after sclerotherapy.

Several scleroscants may be used to treat LM: doxycycline, sodium tetradecyl sulfate (STS), ethanol, bleomycin, and OK-432. We prefer doxycycline because it is very effective (83% reduction in size) and safe (less than 10% risk of skin ulceration).[58,61] STS is our second-line agent. Ethanol is an effective scleroscant, but has the highest complication rate. It can be used for small lesions but large volumes should be

avoided to reduce the risk of local and systemic toxicity. Ethanol can injure nerves and thus should not be used in proximity to important structures. The use of OK-432 is limited because it is not widely available in all countries.[60]

The most common complication of sclerotherapy for LM is skin ulceration (10%).[58,61] Ethanol is associated with additional systemic toxicity: central nervous system (CNS) depression, pulmonary hypertension, hemolysis, thromboembolism, and arrhythmias.[58] Extravasation of the sclerosant into muscle can cause atrophy and contracture.[54] LM often re-expands over time; 9% recur within three years following OK-432 treatment and most will re-expand with longer follow up.[60,62] Consequently, patients often need repeat sclerotherapy over the course of their lifetime. If a problematic LM recurs and macrocysts are no longer present in the lesion, then resection is the only treatment.

RESECTION

Extirpation of LM can be associated with significant morbidity: major blood loss, iatrogenic injury, and deformity.[55,56,63] For example, resection of cervicofacial LM can injure the facial nerve (76%) or hypoglossal nerve (24%).[55] Excision is usually subtotal because LM involves multiple tissue planes and important structures; 'recurrence' is thus common (35–64%).[62,64] Consequently, sclerotherapy is the preferred treatment for macrocystic/combined lesions. Nonproblematic microcystic lesions can be observed. Resection is reserved for (1) symptomatic microcystic LM causing bleeding, infection, obstruction/destruction of vital structures, or significant deformity, (2) symptomatic macrocystic/combined LM that no longer can be managed with sclerotherapy because all macrocysts have been treated, (3) small, well-localized LM (microcystic or macrocystic) that may be completely excised for cure. When considering resection, the postoperative scar/deformity following removal of the LM should be weighed against the preoperative appearance of the lesion.

For diffuse malformations, staged resection of defined anatomic areas is recommended. Subtotal resections of problematic areas, such as bleeding vesicles or an overgrown lip, should be carried out rather than attempting 'complete' excision of a benign lesion which would result in a worse deformity than the malformation itself. Macroglossia may require tongue reduction to return the tongue to the oral cavity or to correct an open-bite deformity. Bony overgrowth is corrected by osseous contouring and malocclusion may require orthognathic correction, usually at the time of skeletal maturity.

Bleeding or leaking cutaneous vesicles may be managed by resection if they are localized and the wound can be closed by direct approximation of tissues. Vesicles often recur through the scar. Large areas of vesicular bleeding or drainage are best managed by sclerotherapy or carbon dioxide laser; alternatively, wide resection and skin graft coverage is required. Microcystic vesicles involving the oral cavity respond well to radiofrequency ablation.[65] Patients and families are counseled that LM can expand following any intervention, and thus additional treatments may be required in the future.

Venous malformation

CLINICAL FEATURES

Venous malformation (VM) results from an error in vascular morphogenesis; veins are dilated with thin walls and abnormal smooth muscle.[66] Consequently, lesions expand, flow stagnates, and clotting occurs. Lesions are blue, soft, and compressible; hard calcified phleboliths may be palpable. VM may range from small, localized skin lesions to diffuse malformations involving multiple tissue planes and vital structures. VM is typically sporadic and solitary in 90% of patients; 50% have a somatic mutation in the endothelial receptor TIE2.[67,68] Sporadic VM is usually greater than 5 cm (56%), single (99%), and located on the head/neck (47%), extremities (40%), or trunk (13%).[67] Almost all lesions involve the skin, mucosa, or subcutaneous tissue; 50% also affect deeper structures (i.e. muscle, bone, joints, viscera).[67]

Approximately 10% of patients with VM have multifocal, familial lesions; either glomovenous malformation (GVM) or cutaneomucosal venous malformation (CMVM).[67,69] GVM is an autosomal dominant condition with abnormal smooth muscle-like glomus cells along the ectactic veins. It is caused by a loss-of-function mutation in the glomulin gene.[70] Lesions are typically multiple (70%), small (two-thirds <5 cm), and located in the skin and subcutaneous tissue; deeper structures are not affected.[67] GVM involves the extremities (76%), trunk (14%), or head/neck (10%). Lesions are more painful than typical VM. CMVM are small, multifocal mucocutaneous lesions caused by a gain-of-function mutation in the TIE2 receptor.[71] The condition is autosomal dominant and less common than GVM. Lesions are small (76% <5 cm), multiple (73%), and located on the head/neck (50%), extremity (37%), or trunk (13%).[67] Blue rubber bleb nevus syndrome (BRBNS) is a rare condition with multiple, small (<2 cm) VM involving the skin, soft tissue, and gastrointestinal tract.[72] Morbidity is associated with gastrointestinal bleeding requiring chronic blood transfusions or recurrent, usually self-limited, intussusceptions.

Complications of VM include psychosocial morbidity, pain, and swelling. Head and neck VM may present with mucosal bleeding or progressive distortion leading to airway or orbital compromise. Extremity VM can cause leg-length discrepancy, hypoplasia due to disuse atrophy, pathologic fracture, hemarthrosis, and degenerative arthritis.[63] VM of muscle may result in fibrosis and subsequent pain and disability. A large VM involving the deep venous system is at risk for thrombosis and pulmonary embolism. Gastrointestinal VM can cause bleeding and chronic anemia. Stagnation within a large VM results in a localized intravascular coagulopathy (LIC) and painful phlebothromboses.

DIAGNOSIS

At least 90% of VMs are diagnosed by history and physical examination.[1,2] Dependent positioning of the anomaly can help confirm the diagnosis; VM will enlarge because of reduced venous return. Small, superficial VM do not require

further diagnostic work-up. However, large or deeper lesions are evaluated by MRI to (1) confirm the diagnosis, (2) define the extent of the malformation, and (3) plan treatment. VM is hyperintense on T_2-weighted sequences.[58] In contrast to LM, VM enhances with contrast, often shows phleboliths as signal voids, and is more likely to involve muscle. US may be used for some localized lesions; findings include compressible, anechoic–hypoechoic channels separated by more solid regions of variable echogenicity.[7] Phleboliths are hyperechoic with acoustic shadowing.[58] CT is occasionally indicated to assess osseous VM. Histological diagnosis of VM is rarely necessary, but may be indicated to rule out malignancy or if imaging is equivocal.

MANAGEMENT

Patients with large extremity lesions are prescribed custom-fitted compression garments to reduce blood stagnation in the lesion and thus the risk of expansion, LIC, phlebolith formation, and pain.[73] Patients with recurrent pain secondary to phlebothrombosis may find relief from prophylactic daily aspirin (81 mg) to prevent thrombosis. Large lesions are at risk for coagulation of stagnant blood, stimulation of thrombin, and conversion of fibrinogen to fibrin. Fibrinolysis results in LIC.[73] The chronic consumptive coagulopathy can cause either thrombosis (phleboliths) or bleeding (hemarthrosis, hematoma, intraoperative blood loss).[73] Low molecular weight heparin (LMWH) is considered for patients with significant LIC or at risk for disseminated intravascular coagulation (DIC).[73] Patients who develop a serious thrombotic event require long-term anticoagulation or a vena caval filter.

Sclerotherapy

Intervention for VM is reserved for symptomatic lesions that cause pain, deformity, or threaten vital structures. First-line treatment is sclerotherapy, which is safer and more effective than resection.[54,58,74] Diffuse malformations are managed by targeting specific symptomatic areas, because the entire lesion is too extensive to treat at one time. Sclerotherapy is continued until symptoms are alleviated or when vascular spaces are no longer present to inject. Although sclerotherapy effectively reduces the size of the lesion and improves symptoms, it does not remove the malformation. Consequently, patients may continue to have a mass or visible deformity after treatment that may be improved by resection. In addition, VM usually re-expands after sclerotherapy, and thus patients often require additional sclerotherapy treatments over the course of their lifetime.

Our preferred scleroscants are STS and ethanol; STS is most commonly used.[58] Although ethanol is more effective than STS, it has a higher complication rate. Most patients, especially children, are managed under general anesthesia using US or fluoroscopic imaging. The most common local complication of sclerotherapy for VM is skin ulceration (10–15%).[54,74] Extravasation of the scleroscant into muscle can cause atrophy and contracture.[54] Post-treatment swelling may necessitate close monitoring. Systemic adverse events from sclerotherapy, including hemolysis, hemoglobinuria, and DIC, are more common if large lesions are treated. Patients with low fibrinogen levels are given LMWH 14 days before and after the procedure.[73] Anticoagulation is held for 24 hours perioperatively (12 hours before and after the intervention) to prevent bleeding complications.[58,73]

RESECTION

Extirpation of VM can be associated with significant morbidity: major blood loss, iatrogenic injury, and deformity. In contrast to sclerotherapy, resection is not favorable because: (1) the entire lesion can rarely be removed, (2) resection may cause a worse deformity than the lesion, (3) the risk of recurrence is high because channels adjacent to the visible lesion are not treated, (4) the risk of blood loss and iatrogenic injury is greater. Resection should be considered for (1) small, well-localized lesions that can be completely removed or (2) persistent mass or deformity after completion of sclerotherapy (patent channels are not accessible for further injection). When considering resection, the postoperative scar/deformity following removal of the VM should be weighed against the preoperative appearance of the lesion. Subtotal resections of problematic areas, such as an overgrown lip, should be carried out rather than attempting 'complete' excision of a benign lesion which would result in a worse deformity than the malformation itself. Patients and families are counseled that VM can expand following excision, and thus additional operative intervention may be required in the future.

Many VMs should have sclerotherapy prior to operative intervention. After adequate sclerotherapy, the VM is replaced by scar and thus the risk of blood loss, iatrogenic injury, and recurrence is reduced. In addition, fibrosis facilitates resection and reconstruction. Because GVM are usually small and less amenable to sclerotherapy, first-line therapy for painful lesions is often resection. Nd:YAG photocoagulation may be an adjuvant to sclerotherapy for the management of difficult airway lesions.[75] Gastrointestinal VM with chronic bleeding, anemia, and transfusion requirements are typically managed by resection. Solitary lesions can be treated by endoscopic banding or sclerotherapy.[76] Multifocal lesions (i.e. BRBNS) require removal of as many lesions as possible through multiple enterotomies, instead of bowel resection, to preserve bowel length.[72,76] Diffuse, problematic colorectal VM may require colectomy, anorectal mucosectomy, and endorectal pull-through.[77]

Arteriovenous malformation

CLINICAL FEATURES

Arteriovenous malformation (AVM) results from an error in vascular development during embryogenesis. An absent capillary bed causes shunting of blood directly from the arterial to venous circulation, through a fistula (direct connection of an artery to a vein) or nidus (abnormal channels bridging the feeding artery to the draining veins).[66] Genetic abnormalities cause certain types of familial AVM. Hereditary hemorrhagic telangiectasia is due to mutations in endoglin and activin receptor-like kinase 1 (ALK-1), which

affect transforming growth factor-beta (TGF-β) signaling.[78] Capillary malformation–arteriovenous malformation (CM-AVM) results from a mutation in RASA1.[79] Patients with PTEN mutations also can develop arteriovenous anomalies.[80]

The most common site of extracranial AVM is the head and neck, followed by the limbs, trunk, and viscera.[5] Although present at birth, AVM may not become evident until childhood. Arteriovenous shunting reduces capillary oxygen delivery causing ischemia; patients are at risk for pain, ulceration, bleeding, and congestive heart failure. AVM also may cause disfigurement, destruction of tissues, and obstruction of vital structures. AVM worsens over time, and can be classified according to the Schobinger staging system (Table 78.2).[81]

Table 78.2 Schobinger staging of arteriovenous malformation.

Stage	Clinical findings
I (quiescence)	Warm, pink-blue, shunting on Doppler
II (expansion)	Enlargement, pulsation, thrill, bruit, tortuous veins
III (destruction)	Dystrophic skin changes, ulceration, bleeding, pain
IV (decompensation)	Cardiac failure

DIAGNOSIS

Most AVMs are diagnosed by history and physical examination.[1,2] If AVM is suspected, the diagnosis should be confirmed by US with color Doppler examination showing fast-flow and shunting. MRI is also obtained to (1) confirm the diagnosis, (2) determine the extent of the lesion, and (3) plan treatment. MRI shows dilated feeding arteries and draining veins, enhancement, and flow-voids on T_2-weighted imaging.[82] If the diagnosis remains unclear after US and MRI, angiography is performed. Angiography is also indicated if embolization or resection is planned to determine the flow dynamics of the lesion. AVM shows tortuous, dilated arteries with venous shunting and dilated draining veins on angiogram.[82] Often, a blush illustrates the nidus of the lesion. Histopathological diagnosis of AVM is rarely necessary, but may be indicated to rule out malignancy or if imaging is equivocal.

MANAGEMENT

Because AVM is often diffuse, involving multiple tissue planes and important structures, cure is rare. The goal of treatment is usually to control the malformation. Intervention is focused on alleviating symptoms (i.e. bleeding, pain, ulceration), preserving vital functions (i.e. vision, mastication), and improving a visible deformity. Management options include embolization, resection, or a combination. Resection offers the best chance for long-term control, but the re-expansion rate is high and extirpation may cause a worse deformity than the malformation itself. Almost all AVM will re-expand after embolization. Consequently, embolization is most commonly used preoperatively to reduce blood loss during resection, or for palliation of unresectable lesions.[83]

Asymptomatic AVM should be observed unless it can be completely removed for cure with minimal morbidity; embolization or incomplete excision of an asymptomatic lesion may stimulate it to enlarge and become problematic. Intervention is determined by (1) the size and location of the AVM, (2) the age of the patient, and (3) Schobinger stage. Although resection of an asymptomatic stage I AVM offers the best chance for long-term control or 'cure', intervention must be individualized based on the degree of deformity that would be caused by excision and reconstruction.[83] For example, a large stage I AVM in a non-anatomically important location (i.e. trunk, proximal extremity) may be resected without consequence, before it progresses to a higher stage where resection is more difficult, and the recurrence rate is greater.[83] Similarly, a small, well-localized AVM in a more difficult location (i.e. face, hand) may be excised for possible 'cure' before it expands and complete extirpation is no longer possible.

In contrast, a large, asymptomatic AVM located in an anatomically sensitive area is best observed, especially in a young child not psychologically ready for major resection and reconstruction. First, resection and reconstruction may result in a more noticeable deformity or functional problem than the malformation itself. Second, although the recurrence rate is lower when stage I AVM is resected, it is still high and thus even after major resection and reconstruction the malformation can recur. Third, some children (17.4%) do not experience significant morbidity from their lesion long term, into adulthood.[83]

Intervention for stage II AVMs is similar to stage I lesions. However, the threshold for treatment is lower if an enlarging lesion is causing a worsening deformity or if functional problems are expected. Stage III and IV AVMs require intervention to control pain, bleeding, ulceration, or congestive heart failure.

Embolization

Embolization involves the delivery of a substance, through a catheter to the AVM, to occlude blood flow and/or fill a vascular space. Reduced arteriovenous shunting and ischemia improves symptoms and may shrink the lesion. Embolization is used either as a preoperative adjunct to resection or as monotherapy for lesions not amenable to extirpation. Because the AVM is not removed, almost all lesions eventually will expand after treatment.[66,81–84] Stage I AVM has a lower recurrence rate than higher-staged lesions. Most recurrences occur within the first year after embolization, and 98.0% re-expand within five years.[83] Despite the high likelihood of re-expansion, embolization can effectively palliate an AVM by reducing its size, slowing expansion, and alleviating pain and bleeding. Preoperative embolization also reduces blood loss during extirpation.

Substances used for embolization may be liquid (n-butyl cyanoacrylate (n-BCA), ethanol, Onyx (ethylene-vinyl alcohol

copolymer)) or solid (polyvinyl alcohol particles (PVA), coils). The goal of embolization is occlusion of the nidus and proximal venous outflow.[82] The embolic material is delivered to the nidus, not the arterial feeding vessels. Occlusion of inflow will cause collateralization and expansion of the AVM; access to the nidus will also be blocked preventing future embolization. For preoperative embolization, temporary occlusive substances (gelfoam powder, PVA, embospheres) that undergo phagocytosis are used. Permanent liquid agents capable of permeating the nidus (ethanol, n-BCA, Onyx) are used when embolization is the primary treatment. The most frequent complication of embolization is ulceration.

Resection

Resection of AVM has a lower recurrence rate than embolization and is considered for well-localized lesions or to correct focal deformities (i.e. bleeding or ulcerated areas, labial hypertrophy).[83] Wide extirpation and reconstruction of large, diffuse AVM should be exercised with caution because (1) cure is rare and the recurrence rate is high, (2) the resulting deformity is often worse than the appearance of the malformation, and (3) resection is associated with significant blood loss, iatrogenic injury, and morbidity. When excision is planned, preoperative embolization will facilitate the procedure by reducing the size of the AVM, minimizing blood loss, and creating scar tissue to aid the dissection. Multiple embolizations, spaced 6 weeks apart, may be required prior to resection. Excision should be carried out 24–72 hours after embolization, before recannalization restores blood flow to the lesion.

Surgical margins are best determined clinically, by assessing the amount of bleeding from the wound edges.[81] Most defects can be reconstructed by advancing local skin flaps. Skin grafting ulcerated areas has a high failure rate because the underlying tissue is ischemic; excision with regional flap transfer may be required. Free-flap reconstruction permits wide resection and primary closure of complicated defects, but does not improve long-term AVM control.[63,81,83–85] Despite subtotal and presumed 'complete' extirpation, most AVMs treated by resection recur.[83] The majority of recurrences occur within the first year after intervention, and 86.6% re-expand within five years of resection.[83] Patients and families are counseled that AVM is likely to re-expand following resection, and thus additional treatment may be required in the future.

PTEN-associated vascular anomaly

The PTEN (phosphatase and tensin homolog) gene encodes a tumor suppressor lipid phosphatase.[86] Patients with PTEN mutations have PTEN hamartoma-tumor syndrome (PHTS). This autosomal dominant condition had previously been referred to as Cowden syndrome or Bannayan–Riley–Ruvalcaba syndrome (BRRS).[80,87] Males and females are equally affected, and approximately one-half (54%) of patients have a unique fast-flow vascular anomaly with arteriovenous shunting, referred to as a PTEN-associated vascular anomaly (PTEN-AVA).[80] Unlike typical AVM, PTEN-AVA may be multifocal, is associated with ectopic adipose tissue, and has disproportionate, segmental dilation of the draining veins.[80,82] Patients with PHTS have macrocephaly, and males have penile freckling.[80] Histopathology shows skeletal muscle infiltration with adipose tissue, fibrous bands, and lymphoid aggregates. In addition, tortuous arteries with transmural muscular hyperplasia and clusters of abnormal veins with variable smooth muscle are present.[80] Genetic testing is confirmative; the mutation is associated with multiple benign and malignant tumors which require surveillance.

COMBINED VASCULAR MALFORMATIONS

Capillary malformation–arteriovenous malformation

The prevalence of CM-AVM is estimated to be 1 in 100 000 Caucasians.[79,88] Patients have atypical capillary malformations that are small, multifocal, round, pinkish-red, and surrounded by a pale halo (50%).[79,88] Thirty percent of individuals also have an AVM: Parkes–Weber syndrome (PWS) (12%), extracerebral AVM (11%), or intracerebral AVM (7%).[88] PWS describes a diffuse AVM of an overgrown extremity with an overlying CM.[5] PWS involves the lower extremity approximately twice as often as the upper extremity.[88] CM-AVM is an autosomal dominant condition caused by a loss-of-function mutation in the *RASA1* gene.[79] A patient presenting with multiple CMs, especially with a family history of similar lesions, should be evaluated for possible AVMs on physical examination. Because 7% of patients with CM-AVM will have an intracranial fast-flow lesion, brain MRI should be considered.[69] Exploratory imaging of other anatomical areas is not necessary because extracranial AVM have not been found to involve the viscera.[88] Although the CM is rarely problematic, associated AVMs can cause significant morbidity.

Klippel–Trenaunay syndrome

Klippel–Trenaunay syndrome (KTS) is an eponym denoting a slow flow, capillary-lymphatico-venous malformation (CLVM) in association with soft tissue and/or skeletal overgrowth.[89] KTS affects the lower extremity in 95% of patients, the upper extremity in 5% of patients, and least commonly the trunk.[89] Leg-length discrepancy is followed by plain radiographs and MRI is used to confirm diagnosis as well as determine the extent of the anomalies. The deep venous system is commonly malformed. The marginal vein of Servelle is often located in the lateral calf and thigh and communicates with the deep venous system.[90] Complications include thrombophlebitis (20–45%) and pulmonary embolism (4–24%).[91] KTS of the lower extremity can involve the pelvis causing hematuria, hematochezia, constipation, and bladder outlet obstruction. Unlike some other hemihypertrophy syndromes, patients with KTS are not at increased risk for Wilms' tumor and screening ultrasounds are unnecessary.[92] Severe enlargement of the foot requires ray, midfoot, or Syme amputation to allow the use of footwear. Management of the VM component of KTS is conservative with compressive

stockings for insufficiency and aspirin to minimize phlebothrombosis. Symptomatic varicose veins may be removed or sclerosed if a functioning deep system is present. Occasionally, sclerotherapy and surgical excision are necessary for the LM component. Staged contour resection of the extremity can be performed.

Congenital nevi

CHRISTINA M PLIKAITIS AND BRUCE S BAUER

INTRODUCTION

Pigmented lesions represent a common congenital diagnosis encountered by the pediatric surgeon. Congenital nevi represent a group of skin lesions occurring at birth or becoming apparent within the first few years of life, and are characterized by ectopic rests of dermal elements. Although most commonly melanocytic in nature (such as the congenital melanocytic nevus, nevi of Ota, nevi of Ito, nevus spilus, café-au-lait spots, and Mongolian spots), nevi can also originate from sebaceous (nevus sebaceous of Jadassohn), neural or epidermal elements. Lesion characteristics vary according to the type of cell involved, location within the skin, and level of cell differentiation. Knowledge of the differential diagnosis and natural history of these lesions can help balance the plan of care, so as to address the potential risk of malignant degeneration while accounting for functional and esthetic concerns encountered during excision and reconstruction.

CONGENITAL MELANOCYTIC NEVI

Congenital melanocytic nevi (CMN) are the most common congenital nevi composed of nevus cells of melanocytic origin that carry a varying amount of pigment. These nevi can be classified based on their expected size at adulthood into small (<1.5 cm), intermediate (1.5–19.9 cm), and large (>20 cm) lesions with some describing a separate giant (>50 cm) classification for very extensive or garment-like lesions.[1,2] These classification groups are important not only when determining treatment options, but when stratifying the potential risk of malignant change. When evaluating a lesion in a baby, body surface area changes between infancy and adulthood can be used to predict if a lesion falls into the large category. As a general rule, a 9-cm lesion on the head or neck or a 6-cm lesion on the body of an infant will grow to meet the large nevi classification.[2] Another cited definition of large congenital nevi includes lesions >2% total body surface area.[3] Incidence of CMN decreases with increasing size of the lesion with the relatively common small lesions occurring in 1:100 births, intermediate lesions in 1:1000, large lesions in 1:20 000 births, and giant lesions in 1:500 000.[3–5]

Etiology

Embryologically, melanocytes originate from neural crest cells as melanoblasts. During early gestation, these melanoblasts migrate to the basal layer of the epidermis at which time they differentiate into dendritic melanocytes and associate into melanosomes that produce pigment for transfer to keratinocytes. Congenital melanocytic nevi result from a disturbance in this migration and differentiation process resulting in ectopic rests of immature cells along their course of migration. Because of this, nevus cells often extend deep into the subcutaneous tissues and can even involve fascia, muscle, periosteum, or the leptomeninges. They usually require excision at the fascial level for adequate removal, while retaining function.

When nevus cells are found within the central nervous system (leptomeninges, brain, or spinal column), the condition is called neurocutaneous melanosis (NCM). The clinical presentation of NCM can range from asymptomatic to progressive, severe neurologic deterioration with developmental delay, hydrocephalus, and seizures often with fatal outcomes. Symptoms are produced by either the benign proliferation of nevus cells within the central nervous system which block the circulation of cerebral spinal fluid and lead to hydrocephalus and increased intracranial pressure, or from their malignant degeneration. If NCM is to become symptomatic, the vast majority of cases will do so before age three years. The prognosis of symptomatic NCM is poor with >90% dying usually within three years of onset of neurologic symptoms.[6] Although it is difficult to know the true incidence of NCM in association with large congenital melanocytic nevi (LCMN) because screening of asymptomatic patients is not universally performed, a study of an internet registry found NCM on magnetic resonance imaging

(MRI) in approximately 5% of cases of LCMN/GCMN (giant congential melanocytic nevi) of which only 5–6% became symptomatic.[7] Large CMN of the posterior midline and those found in association with multiple satellite nevi (>20) have the highest risk of NCM and should be strongly considered for MRI screening (Fig. 79.1a,b).[8]

Pathology

Nevus cells differ from melanocytes histologically as they group together in clusters rather than arrange as individual melanosomes. In addition, nevus cells assume a rounded rather than dendritic shape, and keep their pigment within their cytoplasm instead of transferring it to the surrounding keratinocytes.[9]

Because of the higher risk of malignant transformation found in CMN compared to acquired nevi, efforts have been made to identify histologic characteristics specific to CMN. When nevus cells are found within eccrine ducts, follicular epithelium, or blood vessels, it indicates a congenital lesion; however, not all CMN display this finding.[10] Furthermore, only congenital lesions demonstrate nevus cells within the deeper subcutaneous tissues, fascia, and muscle. Clinically, examination of small CMN with a dermatoscope or under loupe magnification will reveal small pigment granules at the peripheral aspect of the lesion which is another specific finding to CMN.[11] Discovery of more specific markers for

Figure 79.1 (a,b) Giant melanocytic nevus of the perineum and buttocks and multiple satellite nevi, both independent predictors of underlying neurocutaneous melanosis. (c,d) Using serial expansion and excision techniques with transposition-designed flaps, total excision of the lesion was accomplished without loss of urinary or fecal continence with a reasonably normal appearance (e) on long-term follow up.

Figure 79.1 *Continued*

CMN will help to more clearly determine the true rate of melanoma associated with these lesions.

Presentation

CMN can differ greatly in their size and appearance. Although often obvious at birth, some lesions can be quite faint, and seem to appear with time over the first year of life as they increase in pigmentation. Coloration varies from pale tan to a deep bluish black, and may be uniform or extremely variegated. The lesions are often thickened in texture with increased skin markings compared to surrounding normal skin. They often have hair which can range from fine light fuzz to coarse thick follicles. When large lesions are present, they may be accompanied by smaller peripheral satellite lesions of different sizes and numbers which may appear for the first two to three years of life.

Over time, the surface of CMN may change to become verrucous and irregular with darkening of pigmentation, but lightening of color can be seen in as many as 30% of patients with large and giant nevi. Erosion or breakdown is not uncommon in the neonatal period, but may also occur later. This does not necessarily indicate malignant change, but warrants further investigation.

Management

The management strategy of CMN can be stratified based on size of the lesion and potential risk of malignant change.

SMALL CONGENITAL MELANOCYTIC NEVI

Most CMN fall into this small category and can usually be addressed with simple or staged excision. The lifetime risk of melanoma occurring in small CMN has been quoted at 4.9% when based on patient-reported history of a congenital lesion which lowers to 2.6% for lesions determined to be CMN on histologic criteria of melanoma specimens.[12] However, the risk of melanoma arising within small CMN before puberty is extremely unlikely.[13] For this reason, most defer the removal of these lesions until the patient reaches an age at which comfortable excision can be performed under local anesthesia to avoid the associated risks of general anesthesia. However, if the lesion falls in a cosmetically sensitive area or is located in an area that will require general anesthesia regardless of age, consideration should be given to earlier removal to avoid potential psychologic sequelae of delaying treatment. From a practical point of view, these procedures are best performed either before the patient begins toddling or just prior to school entrance in order to avoid potential complications from falls, heightened anxiety, and lack of patient cooperation.

LARGE CONGENITAL MELANOCYTIC NEVI

Management of large CMN is a more complex involved process that again strikes a balance between addressing the risk of malignancy with functional and esthetic concerns of the lesion and its reconstruction.

At this time, large CMN are not able to be diagnosed prenatally. The appearance of dark, extensive, hairy lesions of the face, trunk, or extremities is by nature devastating for parents who have been anxiously awaiting the birth of their child. Because of this, the infant with large congenital melanocytic nevi should be referred early to a dermatologist and surgeon familiar with the management of these lesions to allow parents to be counseled about the nature of these lesions, risks of malignancy, potential for excision, and reconstructive options. If presented in a compassionate manner, even the news of a multiple-stage reconstruction over many years can be well accepted by families. In over 25 years of experience, the senior author has developed treatment plans for the management of these lesions with the tenet that esthetic and functional outcome are as important as removal of the nevus itself.

An immediate concern of the family and doctors involved with the care of these patients is the potential risk of malignancy. Review of the literature reports a wide range for the rate of melanoma occurring in patients with LCMN, anywhere from 2 to 31%.[1–4 14,15] This variance is explained in part by differences in study design and patients (with an increasing number undergoing surgical interventions), and can lead to confusion in how to counsel patients' families. A retrospective study of patients with LCMN defined as $>2\%$ total body surface area (TBSA) found an 8.5% risk during the first 15 years of life.[3] Sandsmark *et al.*[14] quoted a risk of 6.7% in childhood. A more recent prospectively followed patient cohort registry reported a five-year cumulative life-table risk of 2.3%; however $>50\%$ of these patients had undergone partial to complete excision of their nevi, with all reported melanomas arising in extracutaneous locations.[15] The timing of melanoma diagnosis in patients with LCMN has also been studied with a trend towards development of malignancy early in life. It has been reported that 50% of LCMN that develop malignancy do so in the first three years of life, with 60% by childhood and 70% by puberty.[16] Although the true incidence of malignant melanoma arising in untreated LCMN is unlikely to be clearly defined, these numbers encourage early removal.

History and physical examination

On initial history, any changes in the appearance of the nevus or satellite lesions should be elicited along with any family history of melanoma. Documentation of developmental milestones and presence of any neurologic symptoms should be noted. Serial examination of the lesion(s) should be undertaken every three to six months, depending on the character and variability in the appearance of the lesions. Often patches of darker color or raised nodules develop within a large CMN that may represent neural nevus. This is a form of intradermal nevus with melanocytes that appear histologically similar to Schwann cells and contain nerve organelles, such as Meissner's and Pacinian corpuscles. The patches may also represent local areas of proliferation that do not necessarily behave in an aggressive manner. Certainly biopsy of any suspicious raised, ulcerating, or atypical areas can be used to exclude malignancy (Fig. 79.2). Histologic findings of low mitotic rate, lack of necrosis, evidence of maturation in the cell population and lack of high-grade nuclear atypia are clues to a benign course. The best description of these areas is melanocytic tumor of uncertain potential, and these unusual areas are best addressed earlier in the course of reconstruction.

In the case of large nevi in an axial location especially of the posterior midline scalp or back or when numerous satellite lesions (>20) are present, MRI is recommended to document the presence of neurocutaneous melanosis (NCM). Asymptomatic patients can be identified specifically by T_1 shortening on the MRI. For increased sensitivity, the MRI should be obtained before age four months, because after then increasing myelinization of the central nervous system (CNS) can potentially obscure visualization of nevus cells.[17] Foster *et al.*[18] reported that 23% of at-risk patients had NCM on MRI, with only one patient developing neurologic sequelae of hypotonia, developmental delay, and seizures during the five-year follow-up period. More recent studies report a lower 5% incidence of NCM in patients with LCMN.[7]

It is important to convey that the finding of NCM on MRI does not necessarily imply the future development of neurologic symptoms. It does, however, indicate a risk for later development of benign or malignant melanotic tumors. In the cases of symptomatic NCM, the associated poor prognosis should deter the surgeon from aggressive management of the cutaneous lesion. At this point, the low incidence of symptom development reported in asymptomatic patients with a positive screen for NCM would certainly caution against applying that same philosophy to this patient population. Further study will help to fully ascertain the true predicted course of disease in asymptomatic, scan-positive patients and help guide both surgical planning and the role of serial scanning. At this time, if the initial MRI is positive, we proceed with reconstruction as planned and feel that further scans are unnecessary unless neurologic symptoms develop.

Figure 79.2 Sarcoma arising within a giant congential melanocytic nevus at birth.

Other congenital nevi

BLUE NEVI

Blue nevi are smooth, bluish-black lesions that can be present at birth but more likely appear during childhood and puberty (Fig. 79.3). They occur more frequently in females and are usually found on the head or extremities. Two variants exist: common and cellular. The common blue nevus is a relatively small (<1 cm), sharply demarcated, dome-shaped benign lesion. Histologically, it is composed of intradermal and possibly subcutaneous dendritic melanocytes with normal overlying epithelium. The cellular blue nevus is larger (1–3 cm) with less regular borders and is frequently found in the lumbosacral area. The lesion tends to be wider at the surface than the base, and is composed of spindle-shaped melanocytes in aggregates mixed within dendritic melanocytes. Unlike the common form, malignant transformation has been reported within the cellular variant, and therefore excision is recommended.

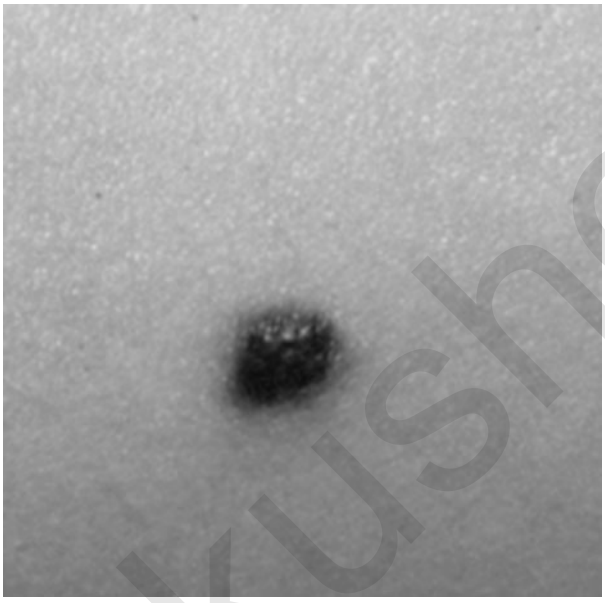

Figure 79.3 Blue nevus.

MONGOLIAN SPOTS

Mongolian spots are blue-gray macules usually overlying the lumbosacral area of otherwise healthy infants (Fig. 79.4). They are more common in Asian and darker-skinned individuals. Mongolian spots are most often present at birth, but may appear within the first weeks of life, and usually regress spontaneously by the age of three to four years. Lesions are made up of widely scattered dendritic melanocytes within the lower two-thirds of the dermis.[19] No treatment of these benign lesions is necessary, however, laser can be effective for management of a persistent lesion.[19]

Figure 79.4 Mongolian spot of the posterior trunk.

NEVUS OF OTA/NEVUS OF ITO

The nevus of Ota is a blue-gray facial discoloration characterized by speckled or mottled coalescing macules appearing at birth or in childhood in the V1–V2 distribution (Fig. 79.5). Unlike Mongolian spots, these lesions do not regress, and can become hyperpigmented in puberty. The lesion may extend to involve the mucosal membranes of the nose and mouth, as well as sclera, conjunctiva, and retina, and occular pathology and glaucoma have been associated. Nevus of Ota displays a female predominance, and is found most commonly in Asian and Indian populations. In 10% of cases, the nevus is bilateral and associated with extensive Mongolian spots.

The nevus of Ito is a blue-gray macular lesion similar to the nevus of Ota that affects the shoulder (scapula, deltoid, supraclavicular) area and is sometimes associated with sensory changes. It is rarer than nevus of Ota, and more common in Asians.

Both of these lesions represent field defects of dermal melanocytosis, histologically characterized by elongated dendritic melanocytes scattered within the collagen bundles

Figure 79.5 Nevus of Ota in its typical V1–2 distribution.

mostly in the upper third of the reticular dermis. They may contain raised areas within the lesion which are indistinguishable from blue nevus.

Although considered benign, there have been a few reported cases of malignant change, especially in areas similar to cellular blue nevus, and may require biopsy to distinguish them from melanoma.[19] Historically, cryotherapy and non-selective destruction with CO_2 laser has been used with mixed esthetic results. Current laser technology allows the surgeon to take advantage of selective photothermolysis to direct laser energy to destroy the melanocytes without damaging the surrounding tissues with excellent cosmetic results. Multiple treatments with a Q-switched ruby laser, Q-switched alexandrite laser, or Q-switched Nd:YAG laser is effective to fade the lesion.[19] For the nevus of Ota, an ophthalmologist should be consulted due to the risk of ocular pathology.

CAFÉ-AU-LAIT SPOTS

Café-au-lait spots are benign sharply demarcated macules of light tan to brown regular pigmentation. They can present in normal individuals or when multiple can be associated with syndromes such as neurofibromatosis. Histologically, lesions are caused by increased pigment in macromelanosomes within the keratinocytes in the basal layer. Laser ablation can be used to successfully treat lesions that are of cosmetic concern, but recurrence is common.[20]

NEVUS SPILUS

Nevus spilus are light tan to brown macules that resemble café-au-lait spots, but with areas of darker speckling within it (Fig. 79.6). On histology, there are both areas of increased pigment within the keratinocytes of the basal layer, as well as an increased number of melanocytes. The specked areas represent a mixture of findings from freckling, to congenital melanocytic nevi, to blue nevi. Suspicious areas within the lesion should be excised for biopsy as the nevocellular areas do carry some malignant potential. If the entire lesion is in a cosmetically sensitive area, it can be removed surgically.

Figure 79.6 Nevus spilus of the lower lip.

SEBACEOUS NEVI

Sebaceous nevi present at birth as a waxy, hairless, yellow-orange plaque usually on the scalp, head or neck (Fig. 79.7). Over time, they can become more nodular, verrucous, and itchy, and are most pronounced at puberty. Sebaceous nevi are hamartomas of sebaceous glands. They carry a risk of malignant transformation (well documented at 15–20%) into basal cell carcinoma, making removal by excision with reconstruction recommended. Sebaceous nevus syndrome is the combination of large sebaceous nevi of the scalp and face associated with developmental delay, seizures, ophthalmologic and bony abnormalities.

Extensive linear sebaceous nevus is mostly seen in the head and neck and presents some unique challenges to the reconstructive surgeon. For the larger lesions involving scalp and face, tissue expansion can be applied in a similar fashion which will be described for LCMN. Narrow linear lesions can be excised in stages, often timed so a partial excision is performed at the same time. A tissue expander is placed elsewhere and further excision done when the expander is removed for distant flap reconstruction. Lesions on the ear are addressed with either staged excision or excision and full-thickness skin graft. Those involving the helical rim should be grafted only after full growth of the ear to avoid distortion of the cartilage. It is not uncommon to see linear nevi involving the lower lip, chin, and adjacent neck. Given the linear orientation, it is important to design the reconstruction to minimize tension on the repair while breaking up the scar line to avoid scar hypertrophy and contracture. The senior author's surgical approach has been described in detail in a previous publication.[21]

Figure 79.7 Extensive sebaceous nevus of the face and scalp.

SPITZ NEVI

Although not usually congenital, Spitz nevi are another commonly encountered pediatric skin lesion. They present as pink, raised, firm lesions that on occasion can be pigmented (Fig. 79.8). At times, they may be confused with pyogenic granulomas because of their appearance and rapid growth at onset. Originally termed 'benign juvenile melanoma', these lesions display a bizarre pathology beneath the microscope, and can be confused with malignancy if the pathologist is not provided with the history of the lesion and patient's age. In fact, these lesions are benign, but do grow rapidly and tend to recur aggressively if not completely excised. Because of that, these lesions should be excised with a generous 3–4-mm border of normal tissue to decrease the chance of recurrence.

Figure 79.8 Spitz nevus of the nose.

MANAGEMENT OF LARGE AND GIANT CONGENITAL MELANOCYTIC NEVI

Treatment for LCMN and GCMN remains controversial to some, as they feel the risk of malignant degeneration within these lesions is too low to warrant the extensive number of surgeries and potential scar burden associated with removal. Others feel the potential for non-cutaneous melanoma to develop in nevus cells not amenable to surgical removal (such as in NCM) represents a remaining risk that negates the effectiveness of cutaneous excision for reduction of melanoma risk.[6] However, the significant deformity and associated psychological impact caused by these lesions often tip the scales toward attempted intervention. Management plans should always strive to balance removal of the nevus with a functional and esthetic reconstruction, and lesions that cannot be effectively addressed in this manner should be considered for conservative management by serial observation by an experienced dermatologist.

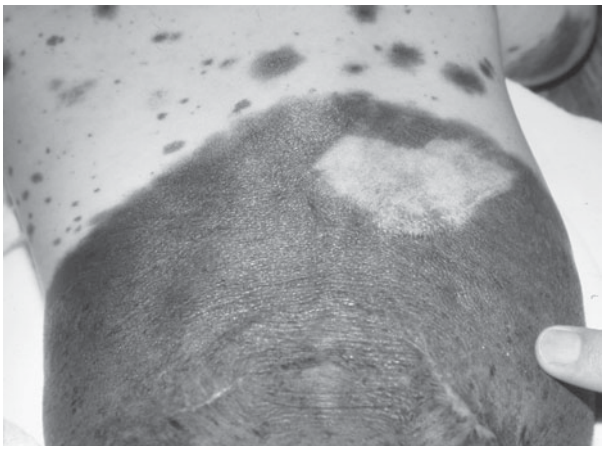
Treatment options are most often surgical with excision and reconstruction using either adjacent or expanded skin or skin grafts/substitutes, but can include dermabrasion, curettage, and laser.

Dermabrasion, curettage, and laser therapy

Non-excisional methods of treatment for CMN, including dermabrasion, curettage, and laser, have been reported as effective methods of reducing the cell burden of the nevus without completely removing it to improve appearance. The success of dermabrasion and curettage relies on the finding that early in infancy, the skin nevus cells lie in a more superficial location histologically within the upper reticular dermis and epidermis. Dermabrasion works to abrade away these surface cells, whereas curettage separates the cells at the natural cleavage plane between the superficial and deep dermis. Using either method, the number of nevus cells within a lesion is reduced, but not eliminated. Therefore, as lesions may be lighter initially, they may darken with time as described in a long-term study (Fig. 79.9a,b).[22] In addition, any associated hypertrichosis is not affected, as hair follicles are found much deeper extending into the subcutaneous fat. Finally, malignant potential theoretically remains for the remaining nevus cells, and scarring from these interventions may make follow-up examination difficult. Nonetheless, good cosmesis has been reported using both methods, despite biopsy-proven persistence of nevus cells within the lesions throughout the field of the original defect. In order to be effective, these treatments must be performed at less than 15 days of life.

Laser offers another potential treatment strategy attractive to both the patient and doctor as a simplified method to reduce the pigmentation of a lesion without scarring. Laser therapy is well suited for the treatment of lesions characterized by superficial dermal pigmentation, such as the nevi of Ota and Ito, persistent Mongolian spots, café-au-lait macules, and some elements of nevus spilus due to their minimal thickness, location of pigment within the dermis, and low potential for malignancy. Effective treatment relies on proper wavelength and pulse-width selection to allow penetration of the skin and photoselective destruction of melanin, while preserving the remaining elements to avoid scarring.[19,20] Serial treatments are required. Scarring can occur with aggressive treatment or improper setting selection. Hypo- and hyperpigmentation have also been reported which may be temporary or permanent. Exposure to sunlight in the perioperative period can cause significant burning, scarring, and hyperpigmentation.

Unfortunately, because CMN display nevus cells within all layers of the skin, as well as within the deeper structures, it is unrealistic to think that a laser could effectively penetrate to the depths necessary to eliminate all pigment-producing nevi cells without significant secondary damage and scarring. In addition, laser treatment vaporizes the specimen, therefore eliminating histologic evaluation of the lesion to determine its nature. Finally, the impact of the exposure of nevus cells to the radiant energy associated with laser therapy is unknown, and may not be apparent for many years into the future.



(a)

(b)

Figure 79.9 (a) The pale area within the nevus was curetted immediately after birth. Seeing this result, the rest of the lesion was curetted. (b) As a toddler, this typical result shows recurrence of pigmentation and scarring, making clinical and histological surveillance of the lesion difficult.

Although dermabrasion, curettage, and laser offer a relatively simple approach to improving the appearance of CMN, they present many drawbacks. Leaving residual nevus cells within CMN imparts a continued risk of malignancy, and scarring may make monitoring the lesions more difficult after treatment. In addition, scarring from these therapies may complicate ultimate excisional treatment options in the future. Finally, the delay of more definitive reconstruction may have its own psychological effects on a child. Although limited use of these therapies may be useful in certain areas of reconstruction (such as lightening of a thin lesion in the cosmetic and functionally sensitive eyelid area), thoughtful consideration is warranted prior to widespread implementation of these modalities in a treatment algorithm for LCMN.

Surgical excision and reconstruction

The benefits of surgical excision of LCMN include complete removal of involved skin and subcutaneous tissue. Although some have focused on skin grafts, skin substitutes, or cultured epithelium for reconstruction, when possible, use of tissue expansion allows the most functional and esthetic result by allowing replacement with full-thickness normal tissue. Goals of treatment include complete excision at an early age, minimization of scarring and functional impact with a low requirement for future procedures. Early excision is emphasized for four reasons: (1) The greatest risk for malignancy is reported in childhood, most notably in the first three years of life. (2) The elasticity and healing capacity of the skin is better the younger the patient. (3) Patients operated on in infancy tolerate surgery better both physically and emotionally than their older counterparts. (4) By completing reconstruction early, the psychological impact of the lesions and surgical interventions can be reduced.

In 1988, Bauer *et al.*[23] presented a coordinated approach to the management of these lesions in 78 patients. This report outlined the spectrum of treatment options from skin graft to tissue expansion, and assessed the effectiveness of excision and reconstruction with each technique in each body region. Since then, further experience with over 300 patients has allowed further development and refinement of approach.[24–28] Although a full discussion of the nuances of management of each of LCMN is beyond the scope of this chapter, the following provides a summary.

SCALP

Scalp reconstruction is complicated by its relatively inflexible quality and the unique esthetics of maintaining hair quality and direction. Because of this, tissue expansion remains the workhorse for scalp reconstruction during excision of LCMN. Scalp lesions are best reconstructed in stages, with placement of one or more tissue expanders in a subgaleal plane beneath the normal scalp skin. Following adequate expansion (generally from 10 to 12 weeks), the expanders are removed, lesions excised, and the defect closed using both advancement and transposition flaps designed to preserve hair direction and hairline.[24] Serial expansions are often necessary, and flaps should be carried out and checked before nevus excision (Fig. 79.10a–g). Safe expansion of the infant scalp can be carried out at six months of age with careful attention given to the fontanel during expander placement and reconstruction. Although temporary cranial molding is common, there were no infants with permanent skull deformities noted with spontaneous correction occurring generally within three to four months.

FACE

LCMN of the face present some of the greatest reconstructive challenges. By dividing the face into esthetic units, tissue expansion of available adjacent areas of normal skin in the neck and forehead can provide skin of excellent quality match, while allowing scars to lie at the junction of esthetic units rendering them less obvious (Fig. 79.10d–e). When advancing tissue from the neck into the cheek area, a

Figure 79.10 (a) Large congential melanocytic nevus of the scalp and forehead after the first round of expansion. (b) Result after first stage. (c) Re-expansion of the forehead. (d–f) Final reconstruction of esthetic units with scars well concealed at hairline and along the browline.

transposition design can help improve flap movement while aligning the scars optimally. Whether transposed with the flap based laterally (most common) or medially, the transposition minimizes the risk of late downward drift of the flap and ectropion of the lower eyelid.[24] Lesions of the nose are best resurfaced by an expanded forehead flap carried on a superficial temporal artery pedicle when possible or with an expanded supraclavicular full-thickness skin graft. The periorbital area is also best addressed with expanded full-thickness skin grafts to allow preservation of the thin nature of the tissue, while decreasing incidence of ectropion.[25] LCMN of up to 75% of the forehead can be managed with tissue expansion (often serial) and requires careful planning to minimize distortion of the eyebrow position and maintain a normal distance from brow to hairline. Nevi extending into the temporal area must be treated by expansion of both scalp

Figure 79.10 *Continued*

and forehead, with flaps designed to establish both normal position and hair direction for the temporal region.[26]

TRUNK

The often extensive involvement of GCMN of the trunk with relative lack of normal donor skin presents a daunting challenge to the reconstructive surgeon, leading many to resort to split-thickness skin graft-based reconstruction. The inferior functional and esthetic results achieved call into question whether excision should have been undertaken at all in favor of conservative observation. With better expanded flap design carried out in series, or use of expanded distant flaps with microvascular transfer, superior trunk reconstruction can be achieved.

The posterior trunk is the most common location of GCMN often extending anteriorly in a dermatome distribution. These lesions are best reconstructed with serial tissue expansion and subsequent transposition flap closure (Fig. 79.1a–e). By utilizing flap transposition over simple advancement, excision and reconstruction of bathing trunk and large thorax nevi previously felt to be treatable only with skin grafting has become possible.[24] Anterior trunk lesions can be treated with an abdominoplasty technique with or without expansion depending on lesion size. When adjacent donor sites are unavailable for expansion, excision and reconstruction of shoulder, upper back, and posterior neck nevi can be accomplished using microvascular transfer of a free expanded TRAM (transverse rectus abdominal muscle) flap (Fig. 79.11a–d). With increased use of expanded flaps over skin grafting for trunk reconstruction, late contour deformities seen at junction points between grafted and ungrafted areas can be significantly reduced. These modified techniques have resulted in esthetic benefits far beyond what could be accomplished with alternative treatments.

EXTREMITIES

LCMN of the extremities continue to present a considerable challenge due to the limitations of local expansion techniques in these areas and the relatively poor esthetic outcome experienced with skin grafting. The current authors' prior approach utilized both split-thickness and expanded full-thickness skin grafts for most lesions, but the long-term soft-tissue contour defect and pigment abnormalities in the grafted skin have led to the use of alternative approaches when possible. In upper extremity lesions, use of transposition flaps from the upper back and shoulder has effectively eliminated contour defects to the proximal upper extremity. In addition, three-stage, expanded pedicled flaps from the abdomen and flank can be designed to provide complete coverage of a circumferential nevus from elbow to wrist with excellent contour and acceptable scarring achieved at both donor and recipient sites (Fig. 79.12a–d).[27] A similar

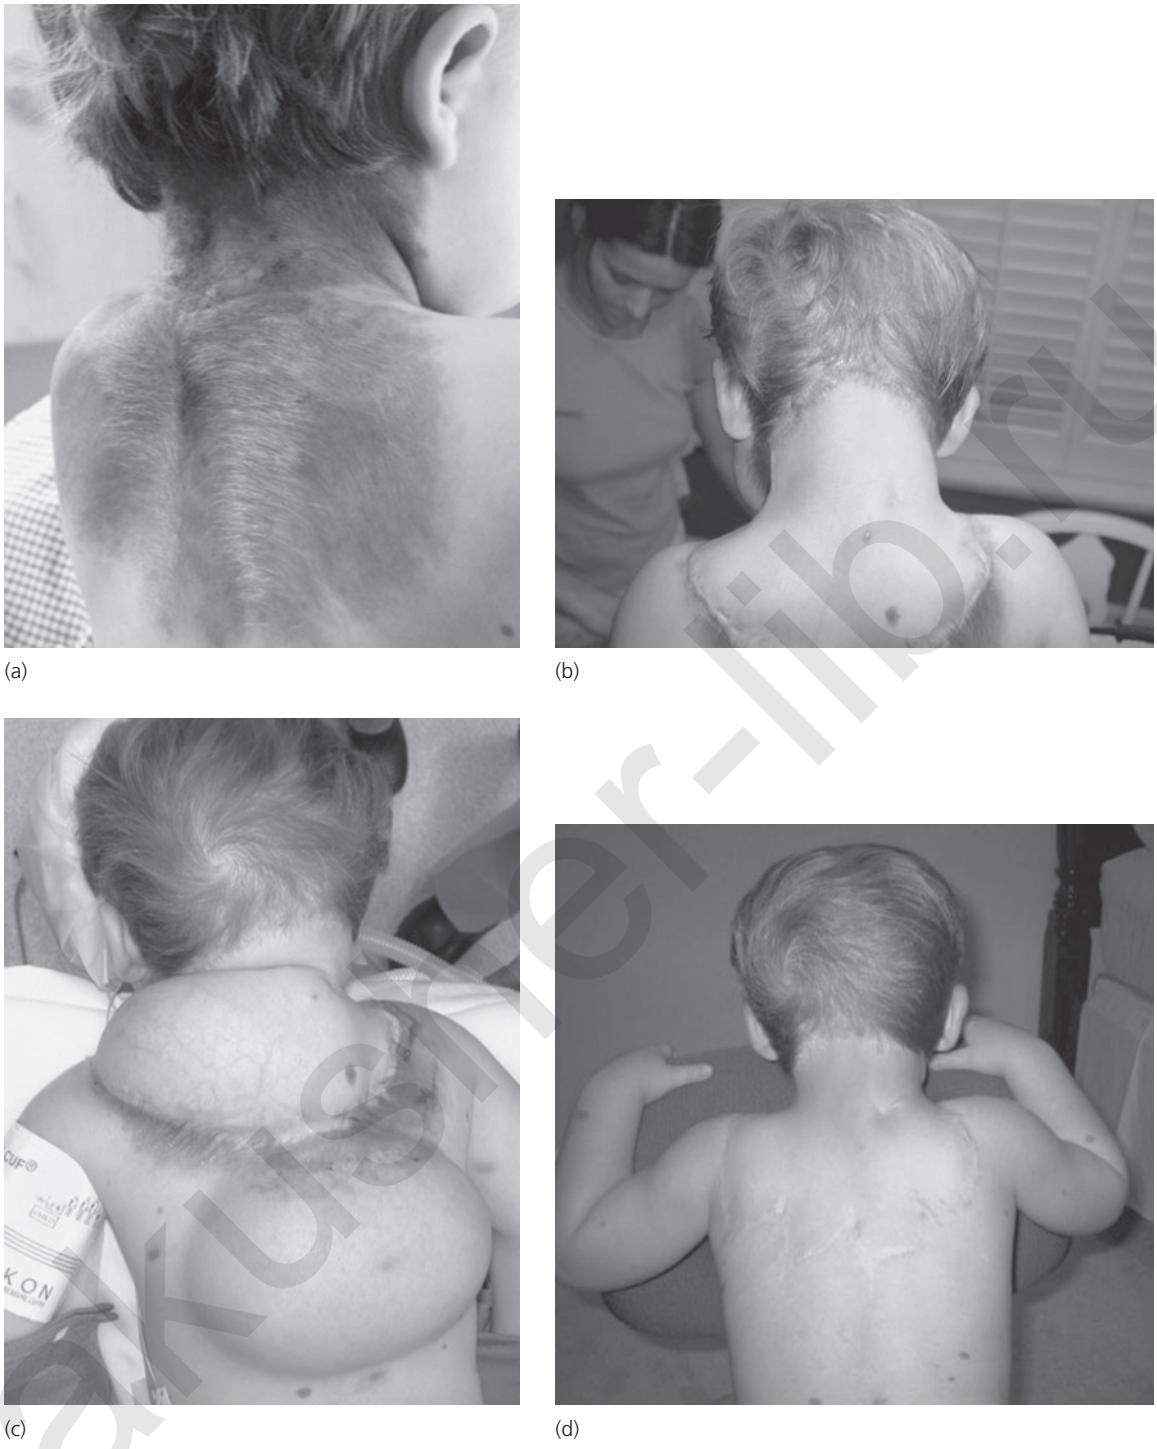


Figure 79.11 (a) Extensive large congential melanocytic nevus of the upper back and neck. (b) Reconstruction with expanded free transverse rectus abdominal muscle (TRAM) flap. (c) Re-expansion of free TRAM flap. (d) Final result with good contour and flexibility of the shoulders and neck.

pedicled approach has been successful in providing coverage for a lower leg lesion after ipsilateral thigh expansion in the young infant when lower extremity flexibility is at its peak with excellent results.[28] Finally, expanded free flaps offer another alternative for coverage of larger lesions of the extremities with improved functional and esthetic results.

COMPLICATIONS

Complications of surgical excision of LCMN with expanded flap reconstruction are uncommon despite the complex nature of these procedures and include expander infection/exposure, flap compromise, incisional dehiscence, and scarring. The

Figure 79.12 (a) Extensive nevus of the arm. (b) Expansion of abdominal donor site. (c) Attachment of pedicled abdominal flap for circumferential arm reconstruction. (d) Final result with good contour of arm and acceptable abdominal scarring.

incidence of expander infection has been reported at 5%, which can be due to inoculation during expander insertion or repeated expansions, after exposure of the expander or by hematogenous seeding from a distant infection.[29] These infections can usually be managed conservatively by antibiotic administration with completion of expansion and successful reconstruction. A low threshold for placement on oral antibiotics during healing problems or illness occurring during expansion may help minimize risk.

Expansion effectively increases the vascularity of a flap through the delay phenomenon making flap ischemia rare. Preservation of the capsule and avoidance of excessive

tension during closure can prevent this potentially devastating complication. Finally, meticulous closure and postoperative scar management help achieve optimal results.

CONCLUSIONS

The treatment of congenital large and giant nevi presents a continuing challenge to all individuals involved with these patients. The ability to present an organized discussion of current views on risk of malignant change to parents, patients (when old enough), referring physicians, and other allied health-care workers is critical. Treatment strategies should take into consideration the varied opinions regarding malignant risk, emphasize the benefits of early excision on lowering that risk, and most importantly, provide a means of dealing with these often devastating lesions in a manner that optimizes the functional and esthetic outcome and minimizes the need for major reconstruction in later life.

Lymphatic malformations (cystic hygroma)

EMILY CHRISTISON-LAGAY, VITO FORTE, AND JACOB C LANGER

INTRODUCTION

Lymphatic malformations (LMs) constitute one subset of a larger group of so-called vascular malformations which may affect any segment of the vascular tree including arterial, venous, capillary, and lymphatic vessels. All vascular malformations can be considered to be the result of errors of embryonic development and can be categorized according to the particular vascular component involved, as well as by physiologic flow properties. Thus, there exist slow-flow lesions (which include lymphatic, venous, and capillary malformations), fast-flow anomalies (which contain an arterial component) and complex, combined vascular malformations.

Commonly referred to as 'cystic hygroma' or 'lymphangioma', lymphatic malformations consist of a group of developmental anomalies of the lymphatic system. They are slow-flow anomalies which range in clinical presentation from small masses to large and sometimes debilitating, disfiguring, or invasive lesions. Structurally, they may be characterized as microcystic, macrocystic, or combined lesions, and these properties have significant clinical implications for treatment. The most common presentation of a LM is a ballottable mass beneath normal skin, although a large LM may transilluminate causing the overlying skin to attain a blue hue. Occasionally, dermal lymphatic involvement causes puckering, dimpling, or vesiculation.[1] Most commonly found in the neck and shoulder, LMs may also occur in the mediastinum, retroperitoneum, groin, and other areas. This chapter will provide an overview of the diagnosis and management of these often difficult lesions with emphasis on those involving the head and neck region.

EMBRYOLOGY AND ETIOLOGY

Most lymphatic malformations are sporadic, but some exhibit classic Mendelian inheritance. Although our understanding of lymphatic development (and, by extension, errors in lymphatic development) remains rudimentary, recent strides in the the field of vasculogenesis have opened the door for greater insight into observed aberrancies.

According to early work by Sabin,[2] development of the lymphatic system begins in the 6th to 7th week of embryonic life, approximately 4 weeks after the onset of vasculogenesis with the formation of five primitive 'lymph sacs': originating as a set of paired sacs lateral to the jugular vein, a retroperitoneal sac at the root of the small bowel mesentery, and paired sacs posterior to the sciatic veins. This process is thought to result from the migration of a specialized subset of endothelial cells from the anterior cardinal vein in response to mesenchymal expression of vascular endothelial growth factor C.[3] These sacs produce buds which arborize centrifugally to form the peripheral lymphatic system. Additional recent data suggest that there is a role of *in situ* differentiation of lymphangioblasts from mesenchymal cells into lymphatic endothelial cells with subsequent recruitment of these cells into developing lymphatic vessels.[4]

Lymphangiogenesis, like its counterparts – vasculogenesis and angiogenesis – is subject to an extraordinarily precise choreography of growth factors and signaling molecules. Important regulators include VEGF and the VEGF receptor families, angiopoietins and the Tie-2 receptor, TGF-β and its receptor, PDGF-B and its receptor, the Notch and Jagged families of membrane-associated molecules and the integrin family of cell surface receptors.[4–7] Overexpression of the isoforms VEGF-C and VEGF-D in transgenic mice induces the formation of hyperplastic lymphatic vessels.[8] Kinase-inactivating mutations in the human *VEGFR3* gene result in Milroy's disease.[9] Tie-2-deficient mouse embryos demonstrate normal initial vasculogenesis, but have a disorganized vascular network lacking appropriate hierarchical organization.[10] Tie-1-deficient models demonstrate decreased endothelial cell integration leading to embryonic edema, hemorrhage, and death, and the Tie-1 receptor has recently been shown to be required for normal embryonic lymphangiogenesis.[11,12] Ang1-4, members of the angiopoietin family, likely have roles in vessel stabilization and lymphatic development.[13] Mutations in the *Fox* family of transcription factors have been associated with congenital

lymphedema, and this family is thought to play a role in the formation of lymphatic valves.[14] Not surprisingly, the integrins, which mediate interactions within the extracellular matrix both as cellular adhesion molecules and as signal tranducers, appear to be important in formation of the vascular and lymphatic systems. Mutations or deletions in specific integrin subtypes can lead to abnormal lymphatic development.[15] Recently, integrin-α9 was found to be necessary for normal lymphatic valve morphogenesis and may be implicated as a candidate gene for primary lymphedema caused by valve defects.[16]

PRENATAL DIAGNOSIS

Lymphatic malformations are often diagnosed by prenatal ultrasound in the late first trimester.[17] The differential diagnosis of a cystic lesion in the fetus is extensive,[18] but in experienced hands the correct diagnosis can be made in most cases.[19] Although most lymphatic malformations presenting to the pediatric surgeon have an excellent prognosis, prenatal sonography has revealed a high 'hidden mortality' among fetuses with this condition.[20–23] The majority of fetuses with a lymphatic malformation develop hydrops fetalis or diffuse lymphangiomatosis prior to fetal demise (Fig. 80.1). There is often either an associated chromosomal abnormality (usually Turner syndrome,[24] although many others have been reported[25]), or a familial syndrome associated with other structural anomalies, such as multiple pterygium syndrome[26] or Robert syndrome.[27] Although most of these fetuses die *in utero*, spontaneous regression has occasionally been observed.[28–30]

Lymphatic malformations presenting in the fetus have a different natural history and prognosis from those presenting postnatally.[28,31] The natural history of cervical lesions detected prenatally varies according to the gestational age at which nuchal thickening appears and is further influenced by the presence or absence of hydrops or abnormal karyotyping. The cases diagnosed in the first trimester without any other abnormality usually have good prognosis with spontaneous resolution in the majority.[32–34] Conversely, those with hydrops and abnormal karyotype have a poorer outlook. The prognosis of patients detected in the second trimester is usually poor.[35] Lymphatic malformations diagnosed in late gestation appear to belong to a different spectrum of disease with a much more favorable prognosis. These cases are comparatively rare,[36–38] and likely to represent an etiologic mechanism occurring during the latter half of pregnancy. Prenatal diagnosis should be followed by delivery and aggressive surgical management at a perinatal center.

Occasionally, a fetus may be identified with a large anterior cervical lymphatic malformation which causes airway obstruction. These pose a challenge at the time of delivery, and are best managed using the *ex-utero* intrapartum (EXIT) procedure to gain access to the airway prior to dividing the umbilical cord (Fig. 80.2).[39,40] In severe cases, a tracheostomy can be performed or the child can be placed on

extracorporeal membrane oxygenation as part of the EXIT procedure.

Those LMs not diagnosed prenatally are generally evident at birth or before the age of two years; however, occasionally, they can manifest suddenly in older children and adults.

Clinical presentation and imaging

The majority of lymphatic malformations occur in the head and neck, axilla, or retroperitoneum; involvement of the mediastinum, groin, extremities, or face are less common (Table 80.1).[41,42] Approximately 80% are diagnosed before the age of five years, and over half present in the newborn period. Lymphatic malformations of the neck typically present as a soft, fluctuant swelling in the lateral or anterior neck. These lesions are frequently asymptomatic and age-related growth is variable (Fig. 80.3). LMs in the forehead and orbit cause localized overgrowth and proptosis. Cervicofacial LM can be associated with mandibular overgrowth causing an underbite.[43] LMs in the floor of the mouth and tongue are characterized by vesicles, intermittent swelling, and bleeding. Occasionally, huge malformations involving the floor of the mouth or the larynx will present at birth with airway obstruction (Fig. 80.4). Rapid increases in size or sudden pain may be due to hemorrhage into the tumor, or to infection. Cervical LMs involving the supraglottic airway may necessitate tracheostomy. Diffuse thoracic lymphatic anomalies or rare abnormalities of the thoracic duct or cisterna chyli can manifest as recurrent pleural and pericardial chylous effusion or chylous ascites. Anomalous lymphatics in the gastrointestinal (GI) tract can cause chylous ascites or present with a (typically asymptomatic) cystic abdominal mass (Fig. 80.5). Both congenital chylous ascites and chylothorax may be associated with the development of hypoalbuminemia as the result of chronic protein-losing enteropathy. Lymphatic malformations of the extremities may be small and localized, or may involve the entire extremity in an infiltrative and debilitating fashion associated with both soft tissue and skeletal overgrowth. Pelvic LMs can be accompanied by bladder outlet obstruction, constipation, or recurrent infection.

Table 80.1 LMs of the head and neck at the Hospital for Sick Children (1988–2000).[65]

Sites of involvement (130 patients)	No. cases
Neck[a]	97
Posterior	40
Anterior	38
Submandibular	37
Face and oropharynx[b]	46
Tongue	14
Floor of mouth	14
Cheek	17
Parotid	14
Larynx	5
Mediastinum and chest wall	14

Occasionally, LMs occur in the constellation of a well-described phenotype. The eponym 'Gorham-Stout syndrome' has been applied to a phenomenonon involving progressive osteolysis, caused by diffuse soft tissue and skeletal LM. Alternative names include 'disappearing bone disease' or 'phantom bone disease'.[44] Klippel–Trenaunay syndrome is a well-described combined capillary–lymphatic–venous

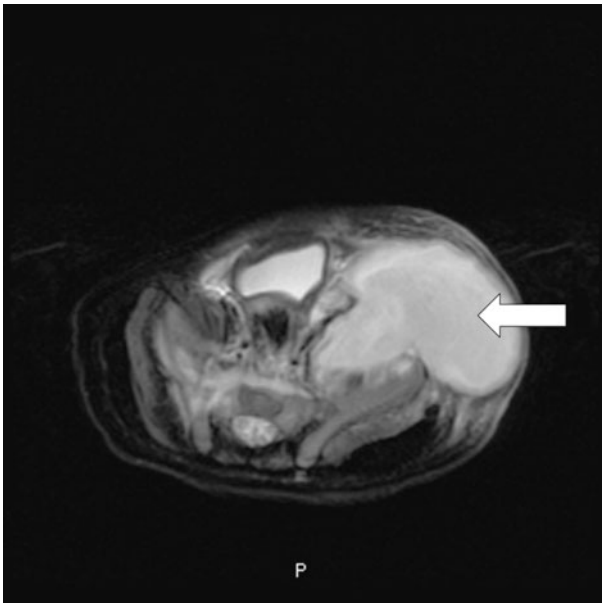

Figure 80.5 Magnetic resonance image of a retroperitoneal lymphatic malformation presenting as an asymptomatic abdominal mass in a newborn (arrow).

malformation associated with soft tissue and skeletal hypertrophy. The capillary malformations are multiple and typically arranged in a geographic pattern over the lateral side of the extremity, buttock, and/or thorax. Lymphatic hypoplasia is present in greater than 50% of patients with associated lymphedema or isolated lymphatic microcysts. The Parkes Weber syndrome shares many similarities with Klippel–Trenaunay syndrome, but should be distinguished by a component of an additional capillary–arteriovenous malformation. Lymphedema should also be included as a type of LM. Type I hereditary lymphedema (Milroy disease) is an autosomal dominant disorder presenting early in life with localized areas of edema. Affected areas are characterized by absent or hypoplastic superficial lymphatics. Linkage analysis demonstrated the locus of mutation on chromosome 5q35.3 corresponding to the gene encoding VEGFR-3.[45,46] Type II hereditary lymphedema (Meige disease) is a late-onset autosomal dominant disorder attributed to a mutation in the *FOXC2* gene with variable penetrance and phenotype. Associated features include distichiasis (a double row of eyelashes), ptosis, cleft palate, yellow nails, and congenital heart disease. The disorder is thought to arise from an impairment of lymphatic drainage, and lymphoscintigraphy demonstrates numerous dilated lymphatic vessels.[14]

INVESTIGATIONS

Magnetic resonance imaging (MRI) is the most useful imaging modality for lymphatic malformations, aiding in the classification of macrocystic and microcystic lesions, as well as defining anatomic relationships including important neurovascular structures (e.g. brachial plexus and carotid artery).[47–49] Lymphatic malformations demonstrate hyperintense signal intensity in T_2-weighted and turbo-STIR images, as well as rim enhancement after contrast application.[50] Microcystic lesions have an intermediate signal in T_1 sequences and an intermediate to high signal in T_2 sequences. Macrocystic lesions show low intensity in T_1 and high intensity in T_2. The new generation of ultrafast MRI scanners has permitted this technique to be used more frequently in small infants, and even in affected fetuses.[51]

Ultrasound may be a helpful adjunct in confirming the presence of macrocystic LM, and Doppler studies may be of additional assistance in looking at flow properties.[52–54] Computed tomography (CT) is extremely useful for assessing relationships to adjacent structures, especially within the mediastinum and retroperitoneum.[55,56] Coronal CT imaging may provide better visualization of neck and mediastinal masses in the newborn.[57]

Conventional contrast lymphangiography is rarely performed, but may be of help in establishing the location of a lymphatic or chylous leak in a patient with a diffuse thoracic lymphatic anomaly.[1,58] Boxen *et al.*[59] described the use of lymphoscintigraphy to define the lymphatic supply of a large lymphatic malformation.

Often a combination of techniques must be used to completely define the anatomic relationships of a large or complicated lesion.

DIFFERENTIAL DIAGNOSIS

The diagnosis of lymphatic malformation is usually straightforward and can be easily differentiated from lymphadenopathy, teratomas, and other solid tumors based on the clinical examination and imaging studies. Lipomas may also be confused with superficial lymphatic malformations, but will not have a cystic appearance on ultrasound examination. Hemangiomas may be present in the same location, but do not transilluminate and tend to collapse on compression. However, there are some patients who have features of both lymphatic and vascular malformation within the same lesion.

COMPLICATIONS

The two principal complications of LMs are intralesional bleeding and infection. Bleeding may occur spontaneously or as a consequence of trauma. It is associated with rapid, painful enlargement of the lesion with attendant ecchymosis. Analgesia and observation are generally sufficient. Prophylactic antibiotics are recommended in the setting of a large bleed. Hemorrhage and infection can transform a macrocystic lesion into a microcystic and scarred lesion.

It is not uncommon for LMs to increase in size in the event of a viral or bacterial infection. This is typically self-limited and thought to be related to changes in lymphatic flow. Nonetheless, bacterial superinfection of the malformation can be fatal and cause an ascending cellulitis and septicemia. Additionally, an infection in a cervicofacial LM can cause obstruction of the upper airway and dysphagia. Prolonged i.v. antibiotic therapy is frequently indicated, with choice of broad-spectrum antibiotic agents directed against

oral pathogens in the head and neck or enteric organisms in the trunk or perineum.

MANAGEMENT

The two strategies for treating lymphatic anomalies are sclerotherapy and surgical resection. Historically, irradiation,[60] incision and drainage, or injection of sclerosing agents,[61] or boiling water,[62] have all been used as non-surgical treatments of lymphatic malformations. With the exception of sclerotherapy, none has demonstrated reproducible success. Sclerotherapy uses a variety of agents to induce obliteration of the lymphatic lumen by chemical destruction of the endothelium with subsequent sclerosis/fibrosis. Success parallels the degree of damage inflicted upon the endothelial and deeper muscular and connective tissue layers. In general, macrocystic LMs are more amenable to sclerotherapy than microcystic as it is possible to drain the entirety of the cyst cavity and induce endothelial apposition prior to administration of a sclerosant. Of the available sclerosing agents, ethanol is often considered a first-line choice, although it has experienced greater success with venous than lymphatic malformations. Ethanol injection is quite painful, often requiring general anesthesia and subsequent pharmacologic pain relief. Local side effects include necrosis, blistering, and a self-limited neuropathy. Systemic side effects, although uncommon, result from the absorption of ethanol and include cardiac arrest, pulmonary vasoconstriction, and systemic hypotension. Ethibloc, a sclerosing solution of ethanol, amino acids, and contrast agent, available in Europe, has been used with reported success rates of 20–65%.[63,64] OK-432, a bacterial product derived from *Streptococcus pyogenes*, induces a significant local inflammatory response and has reported success rates of 60–100%.[65,66] The mechanism of action of OK-432 is not completely understood, but likely reflects a multi-tiered activation of the immunologic system, including neutrophils, macrophages, NK cells, and T cells.[67] No significant toxicity has been recorded. Antineoplastic agents, such as bleomycin[68] or cyclophosphamide,[69] and fibrin sealant[70] have also been attempted with limited success.

Resection is the only way to potentially 'cure' LM. Because of this, most authors advise early surgical excision of lymphatic malformations, to avoid the complications of infection, hemorrhage, and continued growth with further infiltration of surrounding tissues.[62] Spontaneous regression of these lesions after birth is thought to be rare.[71] Although safe surgical excision is now possible in most cases, some reports in the past decade have advocated injection sclerotherapy for cases which are located in regions where resection would be too hazardous, for cases which have been incompletely resected, and for recurrent tumors. Our own experience would suggest that the lesions that are reportedly responsive to agents such as OK-432, namely moderate- to large-sized cystic malformations, are those that can be safely excised with a single operative intervention. These 'easier' lesions also form the critical mass of cases required for gaining the surgical experience necessary for the successful surgical management of the more complex lymphatic malformations. In such lesions, staged excision is often necessary. In each resection a surgeon should focus on a defined anatomic region, attempt to limit blood loss, perform as thorough a dissection as possible, and be prepared to operate as long as necessary. Even with such an intensive approach to resection, subsequence 'recurrence' is as high as 40% after an incomplete excision and 17% after a macroscopically complete excision.[72]

SURGICAL MANAGEMENT

Most lymphatic malformations are easily resected without undue mortality or morbidity, as long as the following principles are adhered to:

- Adequate exposure must be obtained.
- Meticulous dissection must be used in order to preserve vital structures, including nerves, vessels, trachea, and esophagus. We have had success with the exclusive use of a microbipolar dissection technique.[73] This technique is of particular advantage when dissecting close to important neurovascular structures.
- Since this is a benign disease, it is not justifiable to sacrifice a vital structure in order to completely excise the lesion.
- Whenever possible, the lymphatic supply to the lesion should be ligated to prevent postoperative accumulation of lymph. In the head and neck region, the lymphatic supply to a lymphatic malformation is usually not visible, but it is possible that the microbipolar dissection technique may 'weld' these channels shut.

Lymphatic malformations of the neck can usually be approached through a transverse cervical incision under general intratracheal anesthesia. Perioperative antibiotics should be employed. After division of the platysma muscle, the mass is carefully dissected from all surrounding structures (Fig. 80.6). The large cystic malformations are usually well encapsulated, and every attempt should be made not to rupture the cysts. The fluid within the cyst aids the surgeon in defining the cyst wall, and therefore in finding the correct plane in which to dissect. Particular care must be taken to avoid injury to the carotid artery and its branches, or to the internal jugular vein. Preservation of other large venous channels, if possible, may also be beneficial in promoting regional drainage. A number of nerves are often closely associated with the lesion, including the facial nerve, the spinal accessory nerve, the vagus nerve, and the brachial plexus. Although pathological studies have shown that microscopic tumor is often left behind, recurrence is rare when all gross tumor is removed.[72] Once the malformation has been removed, and, if possible, the lymphatic supply to the malformation ligated, a closed-suction drain should be left in the tumor bed to prevent early accumulation of fluid. Dietary restriction of long chain triglycerides in the postoperative period may be of some benefit in reducing the amount of chylous lymph production.

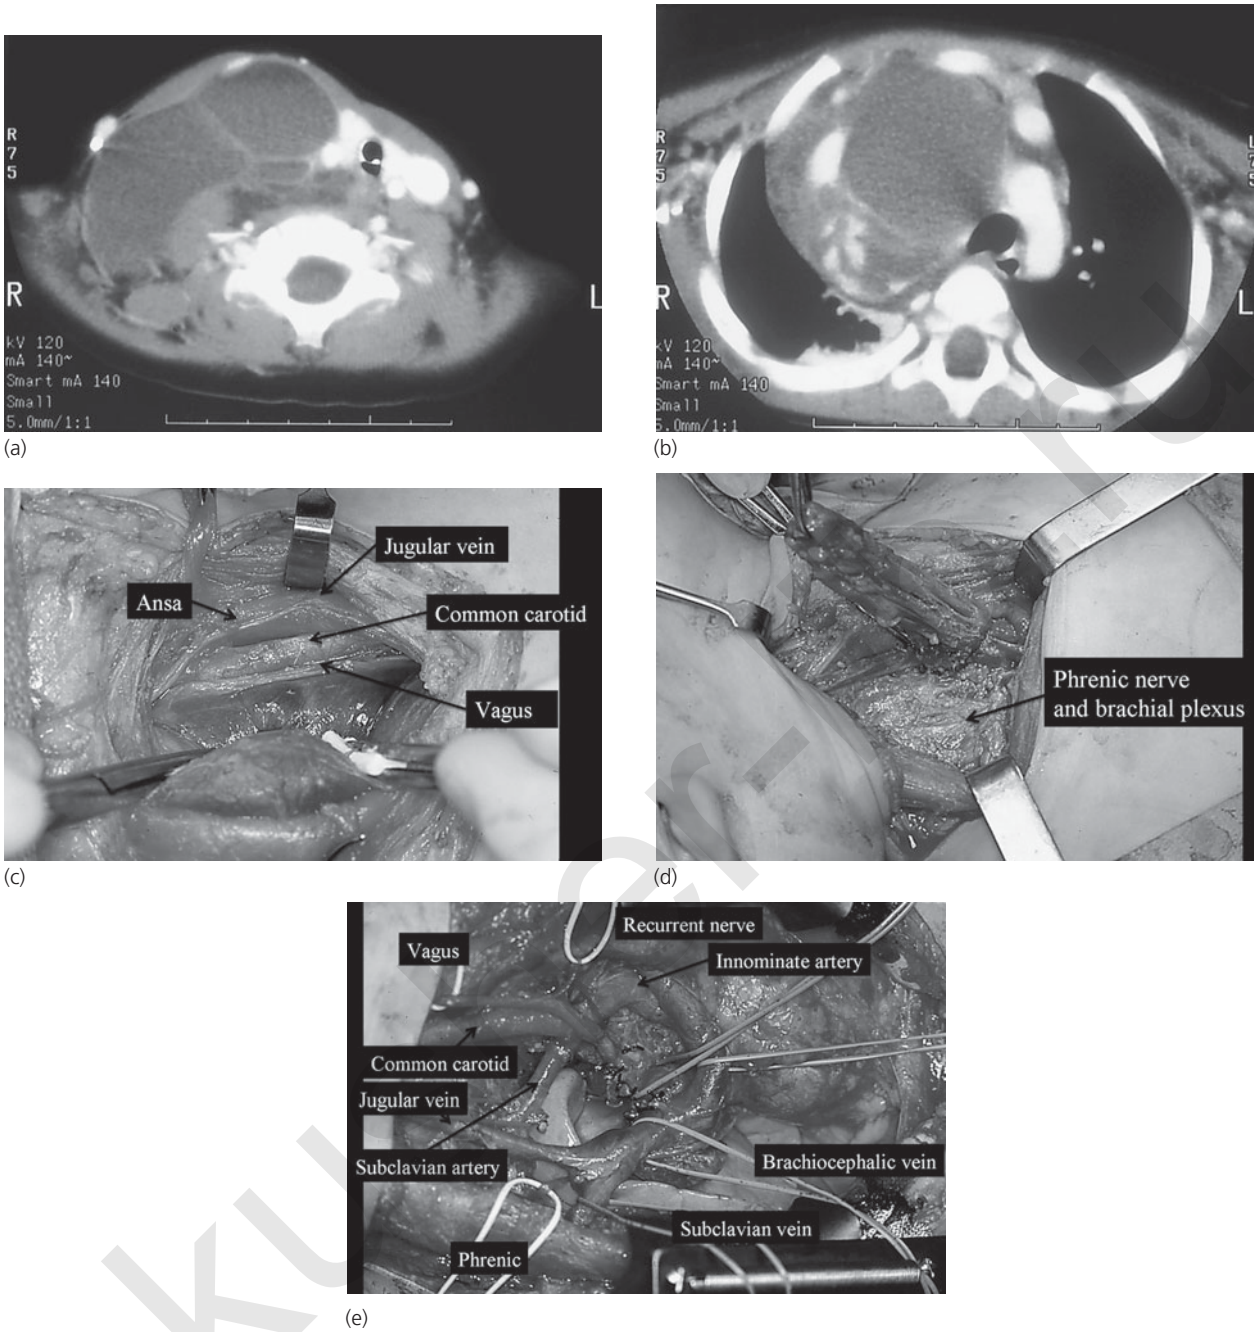

Figure 80.6 Surgical exposure of a cervico-mediastinal lymphatic malformation. Note location of vital neurovascular structures, which must not be damaged during the dissection. (a,b) Computed tomography scan demonstrating the lesion; (c,d) dissection of the cervical portion; (e) completed mediastinal dissection after extension of the incision and sternotomy.

A small number of cervical lesions extend into the axilla or the mediastinum. For axillary extension, the child should be elevated 15–20° on the involved side, with the arm draped free, and both cervical and axillary crease incisions should be used.[62] The cervical component is approached first, separating the lesion away from the brachial plexus until the cysts are seen to pass below the clavicle. The axillary portion is then dissected free. The most difficult aspect of the operation is removing the lesion from the brachial plexus behind the clavicle, where it is often densely adherent. Only careful, meticulous dissection will permit complete removal of the malformation without injury to the nerves.

Extension into the mediastinum also presents a difficult technical challenge. The best approach is one-stage resection through an 'inverted hockey-stick' incision, as described by Grosfeld *et al.*,[74] where a transverse neck incision is extended inferiorly into a midline sternotomy. Modifications of the Grosfeld approach, by either leaving a bridge of skin between the horizontal cervical and midline sternotomy incisions or by performing a partial upper sternotomy through the

cervical incision, may provide a cosmetically superior result without significantly compromising exposure. These approaches provide adequate exposure to safely dissect the lesion away from the jugular, carotid and subclavian vessels, and the aortic arch, esophagus, and pericardium, with preservation of the phrenic, vagus, and recurrent laryngeal nerves. The rare lymphatic malformation which is confined to the mediastinum can be approached through a lateral thoracotomy, a midline sternotomy,[75] or a thoracoscopic approach (Fig. 80.7).

Perhaps the most difficult lesions to approach surgically are the massive lesions which involve tongue, floor of the mouth, and larynx. These lesions are usually present at birth, and may result in early airway obstruction, either by sheer mass effect or as a result of hemorrhage into the tumor. In many cases, a tracheostomy is necessary as a life-saving procedure, followed by multiple extensive operative procedures.[76] For prenatally diagnosed cases, access to the airway can be achieved at the time of Cesarean section before clamping the umbilical cord (EXIT procedure).[39,77,78] The same surgical principles are employed as outlined above, but the strategy for each patient must be individualized. Recurrence rates in these patients are higher, but do not seem to correlate with the removal of all macroscopic tumor.[79] Historically, repeated or staged surgical approaches seemed to offer the best hope for palliation. Currently, if at all possible and feasible, our first choice is an aggressive, single-staged resection to avoid the need for tracheotomy or gastric tube feeding. The option of a more aggressive surgical approach has been made possible by advancements in anesthetic techniques, improved specialized neonatal and pediatric postoperative care units, and the use of the microbipolar dissection technique. Also, the use of laser technology for controlling airway obstruction from laryngeal or tracheal involvement has been highly successful in this group of patients.[79,80]

Lymphatic malformations involving the tongue pose a very difficult problem. As a general principle, direct surgical treatment of the tongue should be avoided if possible. Intermittent swelling of the tongue can be effectively controlled with systemic steroids. Capillary lymphatic malformations involving the mucosal surface of the tongue (also known as simplex), can cause blistering, bleeding, and pain, and are best handled with laser resurfacing techniques.[81,82] Persistent, symptomatic macroglossia involving the intrinsic muscles of the tongue may require reduction glossoplasty. Lymphatic malformations involving the floor of the mouth and tongue may also lead to bony malformations of the growing mandible, which may require subsequent surgical correction.[83]

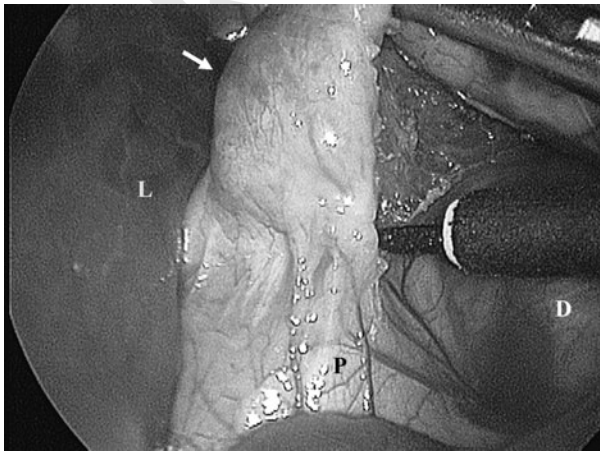

Figure 80.7 Thoracoscopic approach to a small mediastinal lymphatic malformation (arrow). D, diaphragm; L, lung.

Lymphatic malformations in the abdomen usually originate in the retroperitoneum or the intestinal mesentery. Either a laparotomy or a laparoscopic approach can be used. In either case, resection should be done using meticulous technique. Although a complete resection is sometimes possible, often some of the lesion must be left behind. The remaining cysts should be unroofed, since complications, such as postoperative ascites, are rarely seen. Image-guided laser coagulation has also been reported for unresectable lesions.[84] Primary intestinal lymphangiectasia presenting as a protein-losing enteropathy, has been reported in case studies to be successfully treated with segmental resection of involved small bowel.[85] Occasionally, a lymphatic malformation will present with scrotal swelling, and may be misdiagnosed and operated upon as a hydrocele. Once the diagnosis has become clear, these lesions should undergo complete resection if possible.

Lymphatic malformations of the extremities range from small, easily resected cysts to large, infiltrating lesions. The large malformations are often accompanied by poor lymphatic drainage, which predisposes the limb to edema, infection, and inhibition of function. Complete excision of these lesions may be impossible, and amputation may ultimately be necessary.

Surgical complications

In the modern era, the mortality associated with surgical resection of a lymphatic malformation should approach zero. Early intervention before infectious complications or airway obstruction, and strict adherence to the principles described above, permit safe removal with little morbidity in the majority of cases. The complications of surgery include seroma, infection, and neurological sequelae, such as Horner's syndrome, facial nerve palsy, or spinal accessory nerve injury. Although these problems are usually transient, surgical intervention may occasionally be required.[86] Table 80.2 outlines the perioperative complications seen in 130 consecutive surgical cases at our center.[87]

Recurrence can occur after surgical excision, especially if the first resection has been incomplete. These recurrences may represent fluid refilling cysts which had been decompressed, or may be due to filling of more distal cysts whose drainage has been interrupted by the surgical procedure. Ultrasound, computed tomography, and magnetic resonance imaging may all be useful for demonstrating these recurrent lesions.[87] Options for management include further resection or injection sclerotherapy, depending on the anatomic location and the likelihood of injury to neurovascular structures.

Cervical teratomas

MICHAEL WL GAUDERER

INTRODUCTION

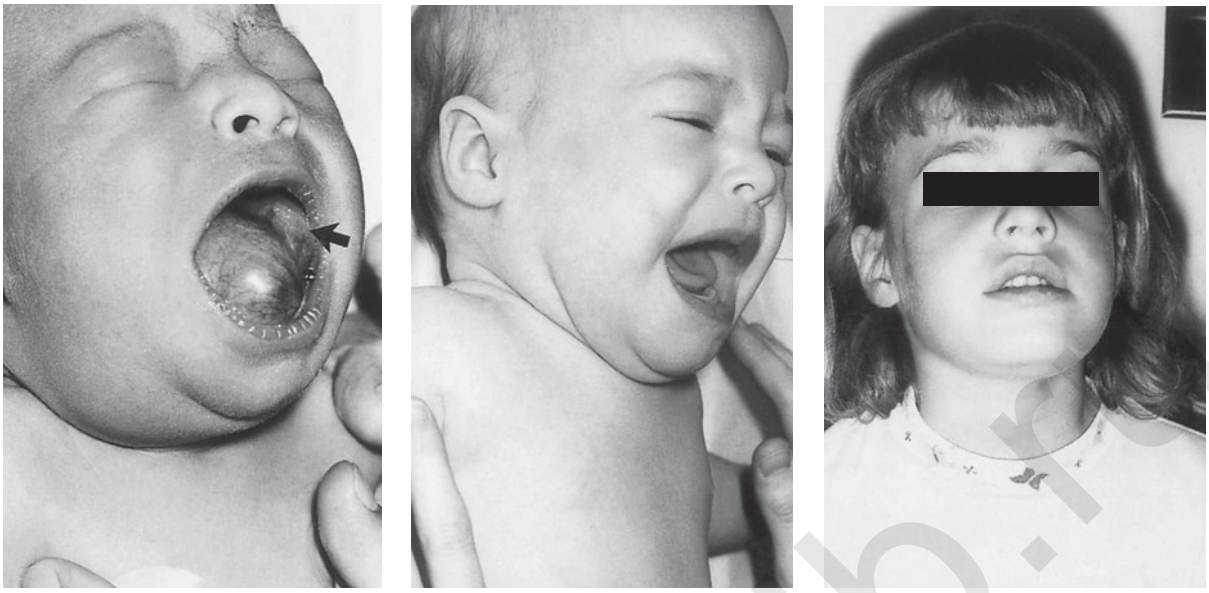
Cervical teratomas, although rare, are an important cause of neck masses in newborns and children. Because these lesions are often quite large, they can lead to precipitous airway obstruction necessitating prompt recognition and surgical intervention. Antenatal diagnosis and new techniques of multidisciplinary intrapartum management have contributed to an improved outlook for the survival of newborns at greatest risk of airway compromise.

PATHOLOGY

Teratomas are neoplastic lesions composed of tissues foreign to the anatomical site of origin, including all three germ layers. It is believed that most cervical teratomas arise from the embryonic thyroid anlage, although frequently clear association with the gland cannot be demonstrated.[1–4] In 1974, Roediger *et al.*[5] presented a comprehensive discussion of the histogenesis of this lesion. Although a wide variety of tissues from all three germinal layers have been found in cervical teratomas, there is a 68% incidence of neural tissue, which in many cases predominates in the solid portion of the tumor.[2–4,6] Thyroid tissue is present in 30% of specimens. The majority of cervical teratomas in the pediatric age group are benign (Fig. 81.1a–c); however, malignancy with and without distant metastases has been reported.[3,7–9] Conversely, the incidence of malignancy in adults with cervical teratomas is reported to be as high as 70%.[10] Although cervical teratomas are generally located anteriorly to the major neck structures (Fig. 81.2), significant distortions of normal anatomy are frequently encountered (Fig. 81.3).[3,4,9,11,12] Teratomas are usually single lesions, however they may occur in more than one site in the head and neck.[13] The presence of a teratoma arising in one fetus of a twin pregnancy has been described.[14] Associated anomalies are rare.[2–4]

INCIDENCE AND CLINICAL MANIFESTATIONS

In four large series of teratomas in infancy and childhood, the incidence of cervical location ranged from 2 to 9.3%.[15–20] Cervical teratomas are reported to occur in all races and there is a slight female preponderance.[2–4] There is a high incidence of prematurity, polyhydramnios, and birth dystocia. Polyhydramnios is probably secondary to inability of the fetus to swallow amniotic fluid.[2] Stillbirth is usually associated with giant cervical lesions and due to a combination of compression of vital structures and congestive heart failure.[21] The most common clinical presentation, in addition to the mass, is respiratory difficulty.[1,4,12,22] Respiratory symptoms may vary from total apnea to mild dyspnea or coughing with feedings. The dyspnea may also be positional. Although airway compression may not be noted at birth, it may progress rapidly over several hours to a life-threatening obstruction. These cervical teratomas clearly represent a spectrum. Some children are referred beyond the neonatal period,[23] while in others it only becomes manifest in adulthood.[3,10] A classification of cervical teratomas,[3] taking into consideration the age and clinical presentation (Table 81.1), clearly shows that almost half of the patients are newborns with respiratory distress (group II). Operative and non-operative management is accompanied by a 43% mortality in this subgroup.[3] The mortality rates in groups I and III will probably remain unchanged. However, establishment of an adequate airway followed by prompt excision of the tumor should lead to improved survival in group II, the most common presentation. Therefore, once such a lesion is diagnosed after birth,



(a) (b) (c)

Figure 81.1 (a) One-day-old, full-term female newborn born with right cervical teratoma that extended into the oral floor, displacing the tongue to the left (arrow). The lesion was firm, partially cystic and limited to the right anterior cervical triangle. She had mild respiratory distress, worsening when placed in the supine position. On the second day of life, the $6.5 \times 5.5 \times 4.5$-cm mass was excised through a transverse cervical incision, combined with intraoral dissection. The thyroid gland was not involved. Analysis of the specimen revealed a benign cystic teratoma containing neuroglia, choroids plexus, smooth muscle, respiratory and squamous epithelium, and pancreas. Transient difficulty with oral feedings occurred in the immediate postoperative period. (b) Same child at three months of age. Notice the well-healed scar following the natural skin crease and the normal position of the tongue. (c) Same child at six years. The scar is no longer discernible. Tongue motion and dentition are normal.

Figure 81.2 Very large cervical teratoma in a premature child.

prompt excision is mandatory. If diagnosed antenatally, recently developed intrapartum airway establishment techniques may be applied effectively;[12,24–27] this has changed the prognosis of select patients in group II (Table 81.1).

DIAGNOSIS

Cervical teratomas can accurately be diagnosed antenatally[3,4,28] using ultrasonography,[28] which is also the most useful immediate postnatal imaging study. Plain radiographs demonstrate calcification within the lesion in 16% of pediatric cases.[3,29] Tracheal deviation is common. Other imaging modalities, such as radioisotope scans, computed

Figure 81.3 Computed tomography scan of the neck of a five-month-old female patient. The lesion was initially thought to be a hemangiolymphangioma. Fortunately, this child had minimal or no airway compression, in spite of the location of the mass. The removed specimen was a benign teratoma containing neuroglia, choroid plexus, respiratory epithelium, pancreas, muscle, and cartilage.

Table 81.1 Classification of cervical teratomas by age and clinical presentation based on the review of 217 cases.[3]

Group		No. cases	Total cases (%)	Malignant (%)	Mortality (%)
I	Stillborn and moribund live newborn	27	12.4	2 (7.4)	100
II	Newborn with respiratory distress	99	45.6	2 (2)	43.4[a]
III	Newborn without respiratory distress	37	17.1	0	2.7
IV	Children age one month to 18 years	31	14.3	0	3.2
V	Adult	23	10.6	16 (69.6)	43.5[b]

[a]Includes operative and non-operative treatment.
[b]Incomplete follow up for six malignant cases.

axial tomography (Fig. 81.3), and magnetic resonance imaging (MRI) are helpful in more complex cases, but should be used with great caution because sedation for longer exposure times may be needed. MRI can be helpful in planning the operation, as it demonstrates planes of dissection and position of vital structures that have been displaced by tumor growth.[7] It is also useful in prenatal evaluation in preparation for operating on placental support.[30]

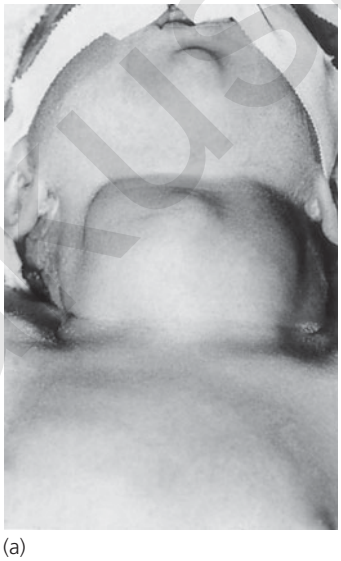
Differential diagnosis

Differential diagnoses should include cystic hygroma, lymphangioma, branchial cleft abnormalities, congenital goiter, thyroglossal duct cyst, dermoid cyst, neuroblastoma, and duplications.

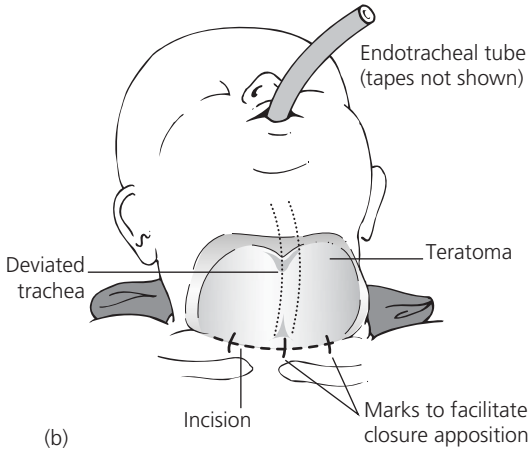
MANAGEMENT

The most difficult aspect of the management of orocervical teratomas is the establishment and maintenance of an adequate airway.[3,9,12,22] Orotracheal or nasotracheal intubation requires skill and patience in these infants due to tracheal deviation and/or compression. A useful adjunct is nasotracheal intubation with the aid of a flexible fiberoptic scope. The endotracheal tube is slipped over the scope and the endoscope is then inserted. Once the tip of the flexible scope reaches the carina, the endotracheal tube is advanced and positioned. The distance between the carina and the end of the tube can then easily be determined by direct visualization. Tracheostomy, as an emergency procedure, has obvious limitations, although it may be necessary in extreme situations.[22,26] Whenever possible, a tracheostomy should be avoided because it increases operative, as well as postoperative, morbidity.[3] If the teratoma is composed of one or more large cysts, emergency aspiration may be employed to reduce tumor size and alleviate pressure on the airway.

An exciting advance in the management of fetuses with a high probability of upper-airway compromise at or immediately after birth, is the development of the *ex utero* intrapartum treatment (EXIT).[12,24–27] This technique permits the establishment of a secure airway while the child is on placental support. The procedure requires a



(a)



(b)

Figure 81.4 Operative approach to the case in Fig. 81.3a. The intubated child's neck is elevated over a roll. Wide draping with adhesive plastic sheets allows for excellent exposure and helps prevent temperature loss. The incision is drawn with a marking pen on one of the skin creases, if possible. To facilitate proper apposition of the redundant skin following resection, multiple small cross-hatches are drawn with the pen. Following the skin incision, the marks are replaced by guy sutures that are helpful for traction on the flaps, as well as the final approximation. It must be remembered during the dissection that the trachea may not be in the center. Other vital structures may also be markedly displaced.

multidisciplinary approach of team members from the involved specialties: obstetrics, anesthesia, pediatric surgery, and neonatology.[24–27]

The incision for cervical and orocervical teratomas should be carefully planned to allow access not only to the neck, but also to the upper mediastinum or oral cavity, if needed. As opposed to lymphangiomas, teratomas can be usually be dissected without great difficulty (Fig. 81.4a,b). The lesion is often attached to one of the lobes of the thyroid. When dissection reaches this level, every attempt should be made to preserve the thyroid and parathyroids. Dissection around the trachea and the esophagus must be carried out with great care to avoid injury to the recurrent laryngeal nerves (Fig. 81.5). Tracheal, as well as esophageal, deviation should be constantly kept in mind. In the small neck of the newborn, deep dissection can lead to injury to the phrenic nerves. Once the tumor is removed, a soft, fine silicone rubber drain is placed and attached to a closed drainage system. The musculoaponeurotic layers are approximated with fine synthetic absorbable sutures and the skin is closed with subcuticular stitches. Postoperatively, vocal cord and diaphragmatic function should be assessed and recorded. Calcium levels are measured in the immediate postoperative period and thyroid function tests are obtained after a few weeks. Careful histological examination of the entire excised specimen is mandatory (Fig. 81.6). If the alphafetoprotein levels were initially elevated, follow-up determinations should be sought.

Figure 81.5 Complete excision of a large cervical teratoma. Notice the smooth surface of the removed specimen and retraction of the redundant skin flaps by the guy sutures.

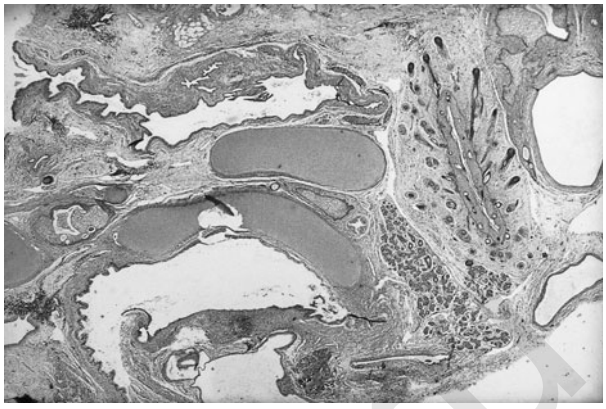


Figure 81.6 Histological section of a cervical teratoma demonstrating an array of various tissues.

CONCLUSION

The overall prognosis for cervical teratomas is good, particularly in the newborn, with little or no respiratory distress (Table 81.1).[3,4,9,17,23] If the lesion is diagnosed *in utero*, appropriate preparations can be made to assure prompt establishment of a good airway immediately at or following birth. Carefully planned excision is then possible. This should increase the survival in the newborn with significant respiratory compromise.

Sacrococcygeal teratoma

KEVIN C PRINGLE

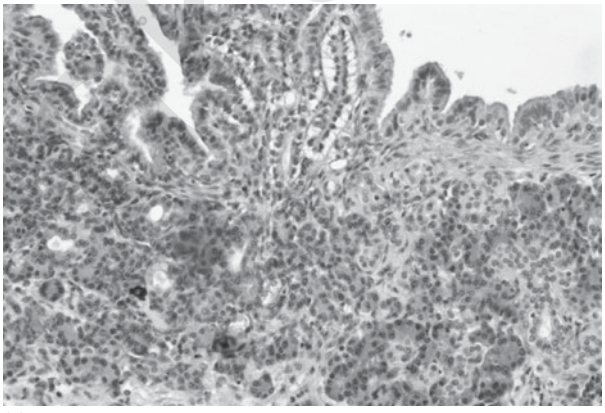
INTRODUCTION

A sacrococcygeal teratoma is a neoplasm arising from the caudal end of the spine, usually protruding from the inferior end of the infant's spinal column and displacing the anus forwards. These tumors have a female-to-male ratio of at least 3:1.[1–9] The incidence is approximately one in 40 000 live births.[10,11] There is general agreement that sacrococcygeal teratoma (SCT) is the result of continued multiplication of totipotent cells from Hensen's node which fail to apoptose at the end of embryonic life.[7,12,13] This concept has recently received support from the work of Busch *et al.*[14] who have identified histochemical markers in SCTs supporting an origin from caudal embryonic stem cells. This provides convincing evidence against the theory that these tumors arise from migrating germ cells traveling from the yolk sac to gonad. Most authorities reject the concept that these are suppressed twins or parasitic fetuses. Pantoja and Rodriguez-Ibanez[15] reviewed the conflicting theories as to the origin of these tumors. A familial distribution of sacrococcygeal teratoma has occasionally been reported.[16–18]

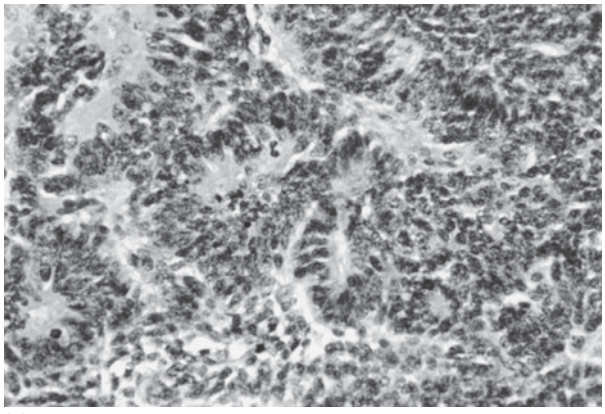
PATHOLOGY

Willis defined the term teratoma as follows: 'A teratoma is a true tumor or neoplasm composed of multiple tissues of kinds foreign to the part in which it arises'.[13] The sacrococcygeal teratoma was second on Willis' list of sites where teratomata are found, but in almost all pediatric surgical series, the sacrococcygeal site is the most common site.[1–4,19] By definition, then, sacrococcygeal teratomata are composed of several types of tissue, usually derived from two or three germ layers. Robbins[20] defines a teratoma as 'a tumor composed of cells representing more than one germ layer'. In fact, however, in any tumor consisting of an epithelial component and a supporting stroma, at least two germ layers are represented. Most carcinomata, therefore, would meet Robbins' definition of a teratoma.

Within any one tumor, the cells can vary from totally benign (even forming well-formed teeth, hair, or other organs) to cells that appear frankly malignant (Fig. 82.1). However, many sacrococcygeal teratomata contain malignant-looking cells (usually described as 'immature'), but if



(a)



(b)

Figure 82.1 Histology of two areas of the tumor from the patient shown in Fig. 82.3. (a) Apparently well-formed epithelium; (b) an area of primitive neuroglial tissue that could be diagnosed as being consistent with an aggressive neuroblastoma, were it not for the context in which it was found.

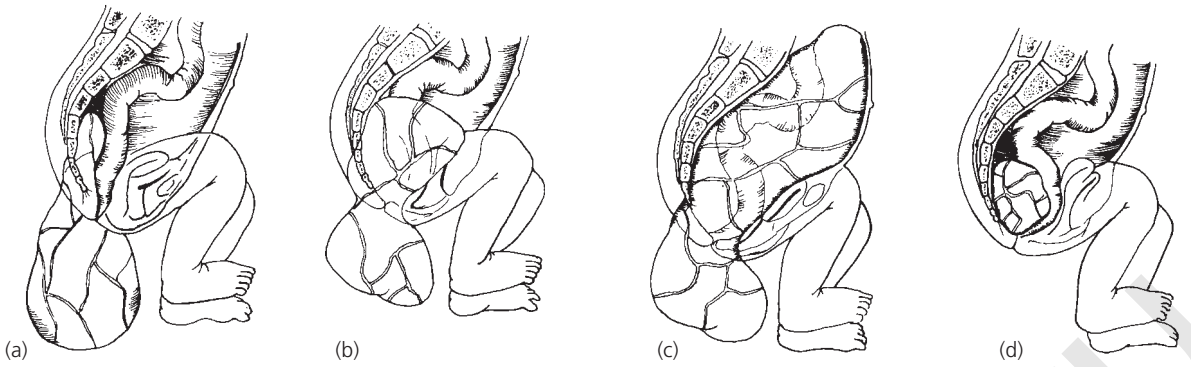


Figure 82.2 Sacrococcygeal tumors as classified by Altman *et al.*[19]

they are completely excised they do not recur. For this reason, the diagnosis of malignant sacrococcygeal teratoma can only be made if there are distant metastases.[19]

The risk of malignancy depends on two factors: (1) the site and the extent of the tumor and (2) the age at diagnosis. Tumors diagnosed after two months of age have a high risk of being malignant. An exception to this statement is the relatively rare presacral 'dermoid' tumors, which often present in adolescence or adult life with constipation or urinary obstruction, but if excised completely appear to be totally benign. Altman *et al.*[19] classified sacrococcygeal teratomata into four groups when they reported the results of the American Academy of Pediatrics (AAP) Surgical Section Survey. Type I tumors are almost exclusively exterior with a minimal pelvic component (Fig. 82.2a). They are rarely malignant (0% in the AAP survey). Type II tumors have a significant pelvic component. In the AAP survey, 6% of type II tumors were malignant (Fig. 82.2b). Type III tumors have an intrapelvic and intra-abdominal component greater than the external component (Fig. 82.2c). The intra-abdominal component can usually be palpated on abdominal examination. In the AAP survey, 20% of type III tumors were malignant. The type IV tumors are exclusively presacral; they had an 8% incidence of malignancy in the AAP survey (Fig. 82.2d).

PRESENTATION

Before routine antenatal ultrasound examinations became widely accepted, the most common presentation was as a large sacral mass that is immediately obvious at birth.[1–5,12,19,20] The malignant tumors tend to present as a swelling of the buttock at five to six months of age. However, with the advent of routine antenatal ultrasound, the most common presentation is now antenatal diagnosis by ultrasonography.[21–30] Series reporting the antenatal diagnosis of sacrococcygeal teratomata have revealed that many of those fetuses diagnosed as having a sacrococcygeal teratoma are likely to die before delivery.[21,23,31–33] Most of the fetuses reported to have died following antenatal diagnosis had tumors with a mass as great as or greater than the rest of the fetus. It is, therefore, entirely possible that these fetuses die of heart failure as the fetal heart is unable to pump sufficient blood to nourish both the tumor and the rest of the fetus. Certainly, in most of the antenatal series reported, fetal hydrops (non-immune hydrops) is very common, and is associated with an increased risk of fetal demise.[21,24,26,28–33] In 1990, Ikeda *et al.*[28] reported the characteristics of 20 cases of prenatally diagnosed sacrococcygeal teratomas. Six infants delivered at a gestational age of from 25 to 32 weeks died prenatally; 14 cases delivered after 32 weeks' gestation survived. Other articles, including three from the group in Chapel Hill (all reporting the same nine antenatally diagnosed sacrococcygeal teratomata[34–36]) also report a high mortality rate if fetal hydrops is noted or if the diagnosis is made early in gestation.[28–30,32,33] Wilson *et al.*,[37] from the Children's Hospital of Philadelphia, have recently emphasized the rate of growth of the tumor and the estimated fetal cardiac output as important prognostic indicators, with a growth rate of >150 mL/week and a combined cardiac output >650 mL/kg per min being associated with a worse prognosis. Benachi *et al.*[38] have similarly emphasized the prognostic importance of rapid fetal growth and high vascularity.

Recent improvements in magnetic resonance imaging (MRI) technology have enabled this modality to be used in the fetus without the need for fetal sedation or paralysis.[39–41] As more experience is gained with these techniques, it is becoming easier to define the anatomy of the tumor much more accurately, and it is sometimes possible to accurately determine the blood supply to the tumor *in utero*.

The improved diagnosis and the high mortality rate associated with fetal hydrops have provided a considerable impetus for some groups to consider fetal surgery for selected cases of antenatally diagnosed sacrococcygeal teratomata. The groups in San Francisco and at Children's Hospital of Philadelphia have had the greatest experience with this approach,[42–46] although other groups have also attempted fetal surgery[47] or percutaneous shunting or drainage to allow vaginal delivery[48,49] for these tumors. The results, so far, have been mixed.[42–49] A detailed discussion of this aspect of the management of sacrococcygeal teratomata is beyond the scope of this chapter, but it would be fair to say that the role of fetal intervention in the presence of this tumor has still not yet been defined.

One further presentation (not often reported) is when the tumor becomes impacted during delivery and either causes the death of the fetus by obstructing delivery, or the tumor

ruptures during delivery and the infant bleeds to death shortly after birth.[29,50–52]

CLINICAL FEATURES

Most cases presenting as neonates to pediatric surgeons will have a large skin-covered mass protruding from the coccygeal region, pushing the anus and vagina anteriorly (Fig. 82.3). There may be large veins visible on the surface and these usually drain into the surrounding structures. Large tumors may have ruptured (in which case they will bleed profusely) or may have an ulcerated area on the surface. Neonates with a tumor approaching the size of the rest of their body may be delivered prematurely and will often have some features of non-immune hydrops.[22,24–30,32,33]

Infants presenting with malignant tumors usually present with a rapidly growing buttock mass.[53,54] In such cases, distant metastases are usually present at diagnosis. With the increasing use of antenatal ultrasound in many countries in recent times, this should become an extremely rare presentation. The management of these tumors is beyond the scope of this chapter. Recent advances in multimodal therapy of these tumors has resulted in survival rates as high as 80%.[55] Children and adolescents with a benign presacral tumor usually present with constipation or urinary retention.[16,18,56–58] A retrorectal mass is easily recognizable on rectal examination. Again, management of these tumors is beyond the scope of this chapter.

In all cases, the tumor is firmly attached to, and may be said to arise from, the anterior surface of the coccyx. It may displace the coccyx posteriorly, but almost without exception, the sacrum is normal. The author has seen one infant who was delivered at 30 weeks' gestation with a large sacrococcygeal teratoma associated with agenesis of the coccyx and the last two sacral vertebrae.[26] Very rarely, however, the tumor can extend superiorly. In one reported case, the tumor extended within the spinal canal as high as T4.[59]

In most cases, the majority of the blood supply to the tumor is derived from the middle sacral artery[5,60] and during removal, once this vessel is controlled, blood loss is usually minimal. This is not always the case and a preliminary abdominal procedure to control the middle sacral artery in very large tumors, as suggested by some authors recently,[61–63] can occasionally yield very disappointing results, with only a very small vessel being identified.[64] In addition, on two occasions in the author's personal series, the bulk of the venous drainage from the tumor returned through the sacral hiatus and back to the azygous system via a large network of very friable epidural veins. This resulted in a frighteningly large loss of blood when the sacrum was divided. In both cases, the initial blood loss was controlled with pressure and the middle sacral artery was rapidly controlled, allowing the definitive control of the bleeding from the divided sacral canal with gelfoam on one occasion and bone wax on the other. With the improvement of the resolution of modern ultrasound machines and the introduction of color flow mapping using Doppler ultrasound, it may be possible to determine whether the venous return is via the sacral hiatus. The limited experience from the author's center suggests that this is possible. However, it should be stated that in the patients in whom preoperative color flow mapping has been used over the past five years, no sacral flow has been noted either on ultrasound or at operation. Clearly, more experience is needed. However, the simplicity of this examination with modern ultrasound machines makes this a useful addition to preoperative work-up.

Some authors have advocated laparoscopic procedures to divide the middle sacral artery.[63] This may be technically difficult if there is a large intra-abdominal component of the tumor.

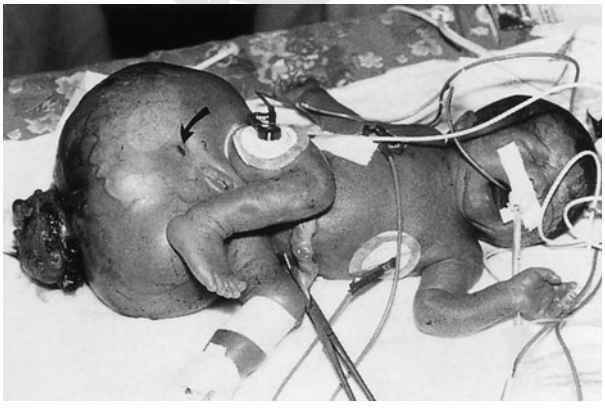

Figure 82.3 Premature infant with a large sacrococcygeal tumor that weighed almost as much as the rest of the infant. Note the displacement of the anus (arrow) and the vulva.

POSTNATAL DIAGNOSIS

The major differential diagnosis that should be considered is an anterior meningocele. This can usually be ruled out by physical examination, including rectal examination. In sacrococcygeal teratoma, the rectal examination will invariably reveal a solid presacral component. If an anterior meningocele is present, this will be cystic, and an anterior sacral defect will often be palpable. Dillard *et al.*[4] point out the need to observe the anterior fontanel during the rectal examination. In anterior meningocele, pressure on the sacral mass will result in a bulging fontanel. The diagnosis can be confirmed by radiography of the lumbosacral region, which will show a characteristic defect in the sacrum in a patient with a meningomyelocele. An MRI examination will confirm the diagnosis.

Another recently described addition to the list of differential diagnoses is a sacrococcygeal chordoma.[65] Lemire *et al.*[66] have produced a list of 20 different lesions that can possibly enter into the differential diagnosis. Most of these are extremely rare, but will usually be distinguishable from sacrococcygeal teratoma on careful physical examination. An abdominal ultrasound is useful to determine the size and consistency of any pelvic or abdominal component. It may be necessary to pass a catheter into the bladder and fill the bladder with water to allow it to be used as a sonic window.

With the rapid improvements in MRI technology, it is now possible to utilize MRI in neonates with minimal sedation, although in many cases a general anesthetic is still required for a detailed examination. Software packages allowing the use of MRI to delineate vascular anatomy are now available.[67–69] The use of gadolinium as a contrast medium has improved the delineation of the vascular anatomy. If oil is instilled into the rectum during the MRI examination while T_1-weighted images are gathered, then the oil can be used as a contrast medium during the scan,[70,71] although modern advances in MRI technology have now made this technique obsolete. MRI should clearly distinguish between sacrococcygeal teratoma and anterior meningocele, and may be able to detect the occasional extension of the tumor through the sacral hiatus into the spinal canal.[61]

PREOPERATIVE MANAGEMENT

If the lesion is intact and the infant is stable, then there is no need for immediate resection. However, a case can be made for resecting these lesions within the first 24 hours after birth, since the gut is not usually colonized in the first 24 hours after birth. Early resection, therefore, will reduce the risk of infection if the field is contaminated by stool during the resection. Perioperative antibiotics are advisable. They should be given immediately before surgery commences and be continued for 24–48 hours postoperatively. If the infant has been fed, or is several days old, then a case can be made for a formal bowel preparation prior to the operation.

Blood should be cross-matched, and adequate i.v. access is vital. An arterial line may also be useful during the operation. It is worthwhile to obtain blood for alpha-fetoprotein levels before surgery as a baseline, in order to confirm postoperatively that alpha-fetoprotein levels continue to fall at a normal rate.[26,72–74] It should be noted that in very rare cases, the alpha-fetoprotein level might not be elevated.[75]

If the tumor has ruptured, then a pressure bandage may stem the blood loss for a brief time. However, there is some concern that this may 'squeeze' immature cells into the venous drainage from the tumor. These cells will most likely lodge in the lungs. However, failure to slow the rate of blood loss in these infants may ensure that metastatic disease is not a problem for that infant. Obviously, emergency surgery is indicated in these circumstances.

In the past, there was often a reluctance to attempt the surgical removal of a tumor that might be as large as the rest of the baby. This is less common now, although there can be an understandable desire to let the baby grow before attempting the removal of the tumor, which will most likely be benign. This temptation should be resisted, however, as the risk of malignancy increases with age, suggesting that many of the tumors that were benign at birth become malignant after about two months.[3,5,7,8,12,16] If a surgeon in a peripheral hospital encounters one of these lesions, then transfer to a pediatric surgical unit is advisable, if this is possible.

OPERATION

The patient is anesthetized, intubated, and a catheter placed in the bladder to measure urine output throughout the procedure, before being positioned prone with a roll under the hips. The roll is positioned so that the infant's weight is taken on the anterior superior iliac spines. It is vital that the abdomen be left hanging free to ensure that respiration is not inhibited by the baby's weight. For this reason, the baby's shoulders should be supported either by a smaller roll lying transversely across the apex of the chest at the level of the medial ends of the clavicles, or by two rolls running parallel to the spine, each supporting the glenohumeral joints. The former option is illustrated in Figure 82.4. It is often useful to pack the rectum with Vaseline gauze to enable it to be readily recognized when the rectum is exposed later in the procedure. The packing also reduces the risk of stool contaminating the operative field. Many authorities state that the anus should be 'prepped' out of the field.[12,76] This author finds that approach both inconvenient and impractical, as access to the anus is often required during the procedure. The cautery pad can usually be placed across the shoulders. A clear plastic drape may conserve body heat and assist in prevention of hypothermia. The addition of a perforated blanket through which is pumped warmed, filtered air also helps to maintain body temperature.

A chevron incision is made in the skin over the dorsum of the mass (Fig. 82.5a,b) and is continued down to fascial layers. It is preferable not to dissect beyond the level of the deep fascia at this stage of the dissection. There are often several large veins in the subcutaneous tissue on either side of the midline; these should be cauterized, or if they are too large for that, they may be divided between ties. The incision should be placed so as to preserve as much normal skin as possible. Excess skin can always be trimmed later if necessary. The apex of the chevron should be over the lower sacrum. In the midline, the dissection should continue directly down to the sacrococcygeal junction, or even down to the fourth or fifth sacral vertebra. The edges of the sacrum are defined, and a clamp is passed across the sacrum at this level, keeping the tips of the forceps against the ventral surface of the bone (or cartilage) to ensure that the forceps pass between the sacrum and the underlying middle sacral vessels, which are usually substantial vessels, supplying the bulk of the blood supply to

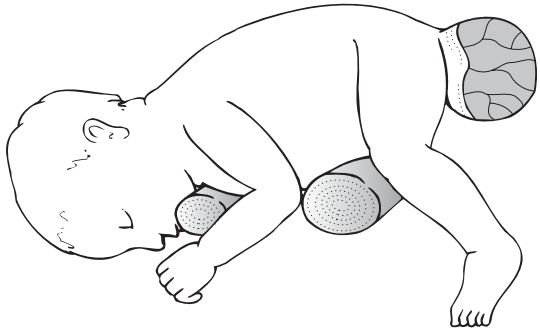

Figure 82.4 Infant with a sacrococcygeal teratoma positioned for surgical resection of the tumor. Note the large transverse roll under the pelvis and the smaller roll under the upper chest.

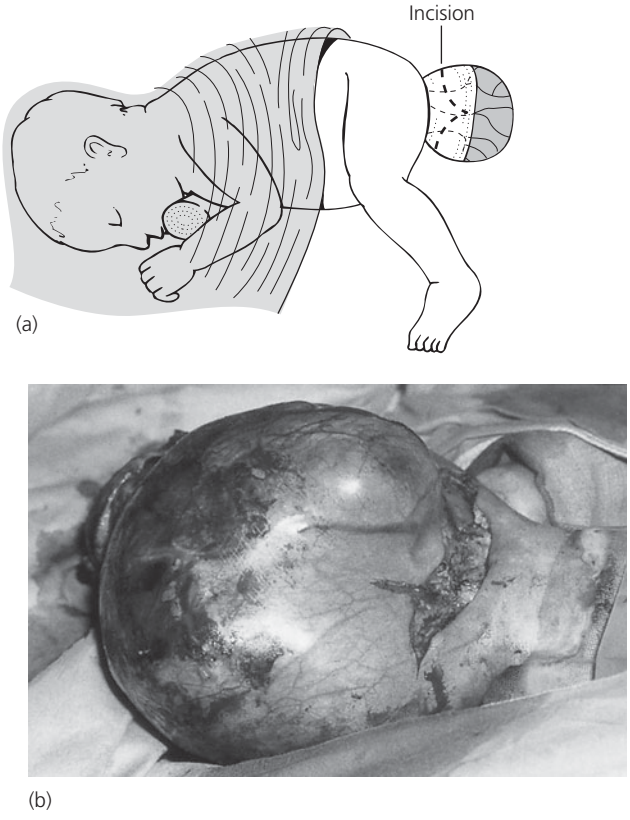

Figure 82.5 (a) Lateral view of the incision over the tumor. All normal skin that can possibly be preserved is retained, to be trimmed later if necessary. (b) Skin incision in the infant shown in Fig. 82.3. Her head is to the right.

the tumor. Once this maneuver is complete, the sacrum (which is usually completely, or at least largely, cartilaginous) can be divided with a scalpel and the severed section of the spine displaced slightly inferiorly to expose the middle sacral vessels (Fig. 82.6a,b). As mentioned earlier, this can very rarely result in catastrophic blood loss from the epidural veins, if the bulk of the venous return is passing back to the baby via the sacral hiatus. It may be necessary to divide some of the attachments of the thinned-out remnants of the levators to the edges of the lower end of the sacrum and coccyx to enable the distal portion of the sacrum and coccyx to be displaced caudally. The middle sacral vessels are then ligated in continuity and divided. This early division of the middle sacral vessels is essentially the same as the procedure advocated by Smith *et al.*[60]

This maneuver opens a plane of dissection that is outside the tumor capsule, but deep to the thinned-out remnants of the levators and gluteus maximus. The levators may be so thin as to be almost invisible (Fig. 82.7), but they will contract on stimulation, either with a muscle stimulator or the electrocautery. The dissection should continue laterally in this plane either side of the midline until the muscles are lost in the fascia of the tumor. At this point, they can be divided along a line parallel to the skin incision. This will allow the tumor to be further displaced in a caudal direction.

Attention is then directed to the pelvic extension of the tumor. Using blunt dissection with peanut swabs in the plane anterior to the middle sacral vessels, it is usually possible to displace the pelvic component of the tumor anteriorly until its upper extent is reached. This is normally an essentially avascular plane anterior to the sacrum, although some vessels feeding into the tumor from the internal iliac vessels may be encountered laterally. These can usually be controlled with cautery. In most cases, the tumor can be dissected out from the pelvis and rolled inferiorly over the patient's legs (Fig. 82.8).

This maneuver exposes the upper end of the rectum, which can be identified by a Vaseline gauze pack placed immediately before the operation is commenced or by passing a finger in through the anus. The tumor can be dissected off the rectum with a combination of sharp and blunt dissection, and rolled inferiorly until the plane of dissection moves away from the rectum and the anal canal. At all times during this dissection, it is best to try to maintain the plane of dissection on the capsule of the tumor and to preserve all normal structures no matter how distorted and thinned out they are. As the tumor is rolled inferiorly, it eventually becomes apparent that the plane of dissection has reached the subcutaneous tissue along the inferior surface of the tumor, posterior to the anus. Once the dissection has reached this point, the dissection can be terminated as long as the inferior skin flap that has been developed is of sufficient

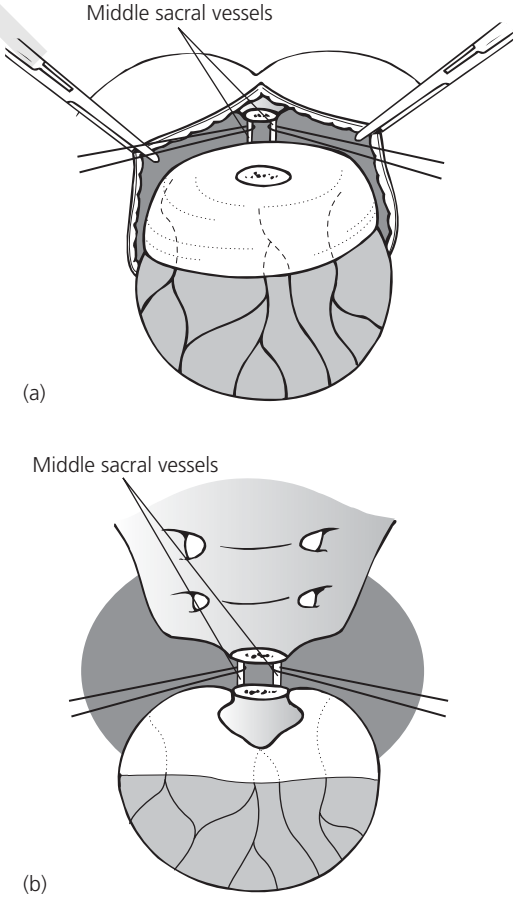

Figure 82.6 (a) Sacrum divided with the middle sacral vessels slung on ties. (b) The divided fifth sacral vertebral body, showing the tumor arising from the ventral surface of the coccyx.

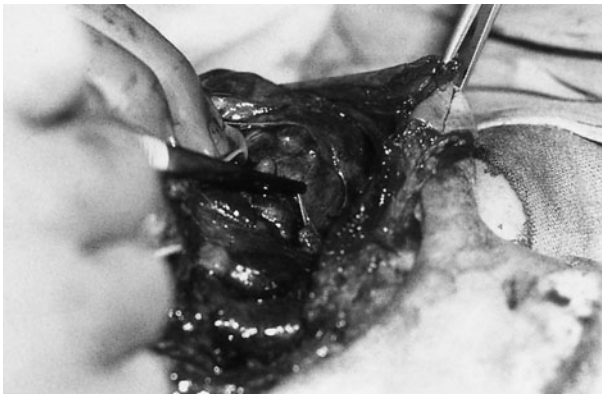

Figure 82.7 The sacrum has been divided and the forceps demonstrate the thinned-out levators (the head is to the right).

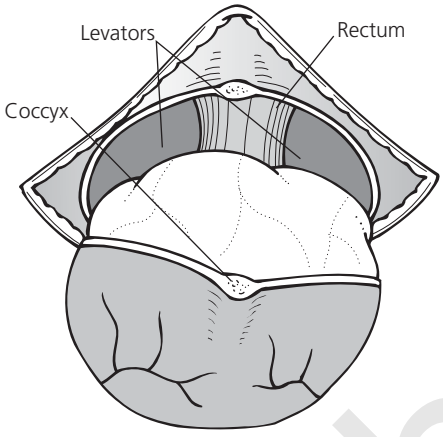

Figure 82.8 Completion of the pelvic dissection with the tumor rolled inferiorly, exposing the rectum.

length to allow easy closure of the wound (Fig. 82.9). The inferior skin flap can then be divided from the tumor and the tumor delivered from the field. A careful check of the tumor bed is carried out to ensure that meticulous hemostasis has been achieved. If the peritoneum has been opened during the pelvic dissection, then it is closed if possible.

Attention is then directed to reconstruction of the pelvic floor and closure of the wound. The remnants of the levator sling are identified and the central portion is sutured to the perichondrium of the anterior surface of the sacrum using 5-0 Maxon® (Cynamid Tyco Healthcare, Norwalk, CT, USA) (a monofilament absorbable suture) (Fig. 82.10a,b). This same suture is used for all subsequent muscle and fascial reconstruction. These initial fascial sutures, rather than the skin closure, should determine the siting of the anus. This aspect of the reconstruction, therefore, should be carried out with care to ensure both a functional and cosmetically pleasing result.

If a drain is to be placed, then it is placed at this stage, in the presacral space, led out through the gap in the levators and tunneled out through the subcutaneous tissue of the buttock. A closed-suction drain is preferred. If there are remnants of the levators recognizable lateral to the midline, these are repaired with interrupted 5-0 Maxon sutures. The medial edges of gluteus maximus are then closed in

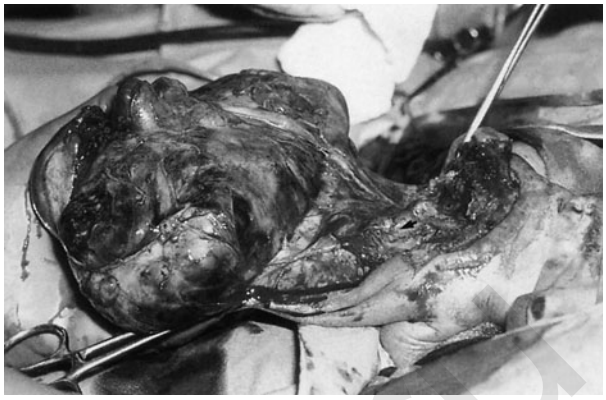

Figure 82.9 Completion of the pelvic dissection. The tumor has been dissected off the rectum (arrow) and the dissection has reached the stage where the division of the inferior skin flap can be contemplated. (Same patient as Fig. 82.3; the head is to the right.)

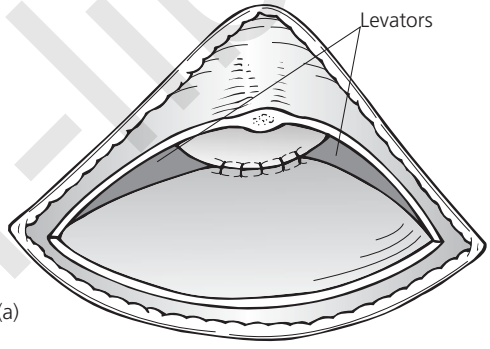

Figure 82.10 (a) Levators sutured to the perichondrium of the sacrum. These sutures set the anal position. the midline over the sacrum and the lower part of the levator sling (Fig. 82.11). The skin flaps are then trimmed to length. If possible, the subcutaneous tissues are closed with a running 5-0 Maxon suture and the skin is closed with a running 5-0 Maxon subcuticular suture. A steristrip and collodion dressing is then applied. If it is not possible to close the subcutaneous tissue, then a subcuticular suture may not be adequate for skin closure. In this case, 5-0 nylon skin

sutures are placed (Fig. 82.12a,b). The rectum is repacked with Vaseline ribbon gauze at the completion of the procedure in an attempt to obliterate dead space. It is useful to suture a 2-0 silk suture to the end of this pack to aid its retrieval, should the pack become displaced higher up the rectum in the immediate postoperative period.

Preliminary abdominal exploration is indicated in three circumstances: (1) if there is a large abdominal component,[76,77] (2) if the tumor has been ruptured and is actively bleeding,[64] and (3) in the rare case when a premature baby is delivered in a hyperdynamic state and preliminary devascularization is needed to stabilize the patient before proceeding to definitive resection.[30] In these cases, the abdomen is opened via a transverse infra-umbilical incision placed just below the upper limit of any intra-abdominal mass or just below the umbilicus if there is no abdominal component. In either case, the aim is to find and ligate and then divide the middle sacral vessels if at all possible. If this is not possible, then either an arterial occlusive sling[64] or a small vascular clamp is placed across the aorta below the origin of the inferior mesenteric artery. The abdomen is closed temporarily with a running 3-0 nylon mass closure and dressed with a clear plastic adhesive dressing. The patient is repositioned and the tumor is then resected from behind as outlined previously. When the pelvic portion of the dissection is completed, the patient is repositioned in the supine position and the clamp or aortic occlusive sling is removed before the abdomen is closed in layers with 4-0 Maxon sutures to the fascia and 5-0 Maxon subcuticular sutures to the skin.

Some authors[62] have advocated an abdominoperineal approach in all cases with routine devascularization of the tumor through an abdominal approach, followed by resection of the tumor (under the same anesthetic) with the patient in the supine position. Some surgeons in Melbourne (B Bowkett, personal communication) also advocate resection of the tumor in the supine position, with the initial incision being in the midline, extending from the sacrum down to the tumor. These authors cite the ability to devascularize the tumor from the abdominal approach and the ease with which external cardiac massage can be applied as the main advantages of this approach. The current author retains significant reservations about this approach. There is a need to control the blood supply to the tumor from above in a minority of cases and it is felt that if there is significant venous drainage through the epidural veins, then blood loss from this source would be extremely difficult to control with the patient in the supine position.

POSTOPERATIVE MANAGEMENT

The infant is nursed in a prone position for several days postoperatively. The urinary catheter can be removed as soon as the baby's condition is stable and the infant can be extubated as soon as its respiratory condition allows. The infant can usually be fed as soon as it is extubated. The Vaseline pack is usually removed in the first postoperative day by pulling on the 2-0 silk suture left attached to the distal end. Any drain can usually be removed within the first few days of the procedure.

Alpha-fetoprotein levels should be determined immediately postoperatively and on discharge. In spite of the fact that alpha-fetoprotein is stated to have a half-life of only 3 days, the levels usually take several months to return to normal. The infant should then be followed at monthly intervals for three months and then at three-monthly intervals for one year. At each visit, a rectal examination will detect any local recurrence and an alpha-fetoprotein level will detect any distant spread. The alpha-fetoprotein level is often very high (of the order of 100 000 IU or more[26,72])

and even in normal babies it may be over 100 000 IU.[72–74] These high levels usually take over a year to fall to normal adult levels. As long as the alpha-fetoprotein level continues to fall steadily, recurrence is thought to be unlikely. However, it is important to not rely solely on the alpha-fetoprotein levels, as in one patient in the author's series, a very large pelvic recurrence (sufficiently large to produce urinary obstruction) occurred in the presence of a continuously falling alpha-fetoprotein level. None of the other patients who developed recurrent tumors (including the patient who developed metastases in the inguinal lymph nodes) showed a rise in the alpha-fetoprotein levels.

Follow up should continue for at least five years, and preferably through puberty, if at all possible. It is important to obtain renal ultrasounds on an annual basis for the first few years, and vital to obtain one on an urgent basis if there are any new urinary symptoms. One patient in the author's series had a normal renal ultrasound close to her second birthday in April. In September of that year, she presented for routine follow up with a history of having had three urinary tract infections in the previous two months. A renal ultrasound obtained shortly after that visit revealed severe hydronephrosis bilaterally, and her serum creatinine level was significantly elevated, having been normal only a few months before. Urodynamic studies revealed that she had a hostile, high-pressure neurogenic bladder. The hydronephrosis resolved considerably with the introduction of clean intermittent catheterization, although this has placed a considerable strain on the family.

PROGNOSIS

In the absence of distant metastases at presentation, and if the excision is complete, then the life expectancy should be normal, although the appearance of the buttocks usually leaves something to be desired (Fig. 82.12b).

There are very few papers in the literature that focus on long-term outcome. One recent paper[55] reported the results in a series of 23 patients followed for up to 22 years. Four patients with malignant tumors had recurrence-free intervals ranging from nine to 14 years. There were two patients with nocturnal enuresis, one of whom had perineal anesthesia. There was one child with a patulous anus and one patient with a neurogenic bladder. The authors emphasized the need for long-term follow up and the need to be alert for the late appearance of urinary or fecal incontinence.

Another paper, from Liverpool, reports the results in 33 patients over 25 years treated in a single center.[78] Surprisingly, only one patient was described as having an immature teratoma and six patients were described as having malignant tumors, two of whom died of metastatic disease. Some of the other patients in this report appear to have been diagnosed as having malignant tumors on the basis of histology and were then treated with chemotherapy on the basis of that diagnosis. In the author's series, there have been local recurrences treated only by repeat resection, without any adjuvant therapy. The only patient treated with chemotherapy was the patient who presented two months after resection with evidence of spread to the inguinal lymph nodes. She is a long-term survivor 16 years after a course of intensive chemotherapy.

The prognosis for patients presenting with a malignant sacrococcygeal teratoma must still be guarded. Modern chemotherapy has produced a considerable improvement in survival.[52,79] The chemotherapy regimens are relatively toxic and these patients require close monitoring during their treatment. Survival rates as high as 80% have been recorded.[52]

Continence, surprisingly, is usually normal, although the cautionary tale mentioned earlier should be noted. However, other recent papers[78,80] have suggested that the incidence of problems with urinary and/or fecal incontinence may be as high as 30%.

Nasal tumors

PETER LAMESCH

INTRODUCTION

Congenital masses of the nasal midline are very rare, occurring in one in every 20 000–40 000 newborns. Although benign, these masses may cause large facial deformities, such as hypertelorism, cerebrospinal fluid (CSF) fistulae, cerebral herniation, visual alterations, meningitis, and cerebral abscess.[1,2]

Nasal gliomas are typically diagnosed in newborn patients. However, the first report on a surgically treated nasal glioma published by Guthrie in 1924 concerned a 48-year-old patient.[3] In a second paper published in 1927, Guthrie wrote in the introduction, 'The cranial and nasal cavities lie in such close proximity to each other that one might naturally suppose that both are liable to be involved in the same disease process'.[4]

There are various types of congenital nasal tumors, which may be classified in accordance with their embryonic origin. The most common are dermoid cyst, glioma, and encephalocele (Box 83.1).[1,5,6]

Box 83.1 Differential diagnosis

Ectodermal
- Dermoid cyst

Neurogenic
- Meningocele
- Encephalocele
- Glioma
- Neurofibroma

Mesodermal
- Hemangioma
- Vascular malformation

Mixed origin
- Teratoma

EMBRYOLOGY

At an early stage of development during the third and fourth week, there is a protrusion of the forebrain and dura through the foramen cecum into the prenasal space, which is limited by frontal and nasal bones on the anterior aspect and posteriorly by a cartilaginous capsule. During further development, the dural process is sealed and the foramen becomes obliterated. Any failure of this obliterating procedure leaves a canal, a pathway favoring the extension of the glial tissue, hence the development of encephaloceles and gliomas.[5,7]

An encephalocele is a herniation of brain tissue into the prenasal space; a glioma is derived from an encephalocele sequestered from the brain. For some authors, glioma are hidden encephaloceles or sequestered encephalocele.[8]

The frontal and nasal bones are formed by intramembranous ossification. At this stage of development, there is a gap between these bones, the fonticulous nasofrontalis, filled by a membrane; the dura and the skin are in contact without interposition of bony tissue. Part of the ectoderm may fail to separate from the dura and so remain in the depths of the nasal space. This displaced ectopic ectodermal tissue is the origin of a dermoid cyst. If a connection does exist with the skin, a dermoid sinus will result.

All these tumors or heterotopias are located in the midline (nasofrontal) or asymmetric unilateral (naso-ethmoidal) position. They are present at birth. They often produce hypertelorism, telecanthus, and nasal deformity.

CONGENITAL TUMORS OF NEUROGENIC ORIGIN

Nasal glioma

Gliomas of the nose are rare, always benign heterotopias, and they should not be considered as tumors. Approximately 250 cases of nasal gliomas have been described in the literature.[9] Their incidence is one in 250 000 births with a

male-to-female ration of 3:1.[10,11] Nasal gliomas account for approximately 20% of all congenital nasal masses;[12] 60% of the tumors are extranasal, while 30% are intranasal and 10% both.[1,13,14] Although most gliomas are located around the midline region of the nose, there are reports with gliomas located in the scalp, cheek, soft palate, tonsils, tongue, leptomeninges, middle ear, orbit, and in limbal dermoids.

A nasal glioma is firm, gray-pink to purple, rounded or dome-shaped polypoid, non-compressible and non-pulsatile mass of glial tissue of congenital origin that may appear in an extra- or intranasal location at or near the root of the nose (Fig. 83.1). They show no impulse when the patient cries. The covering skin may look like a hemangioma. Gliomas are unilateral or in the midline, but are usually located at the side of the nasal bridge. The root of the nose is often enlarged; there may be an orbital hypertelorism. The diameter of the tumor varies from 1 to 3 cm. Their growth rate is usually the same as that of the surrounding tissue according to the infant's growth.

The intranasal type is located high in the nasal fossa. The septum may be displaced and the nasal passage may be obstructed. Increased lacrimation may result from compression of the lacrimal duct. These tumors may present as early neonatal respiratory distress.[15]

In intra-extranasal gliomas, there is a communication between the two components of the mass, usually through a defect in the nasal bone or at the lateral margin of the nasal bone.

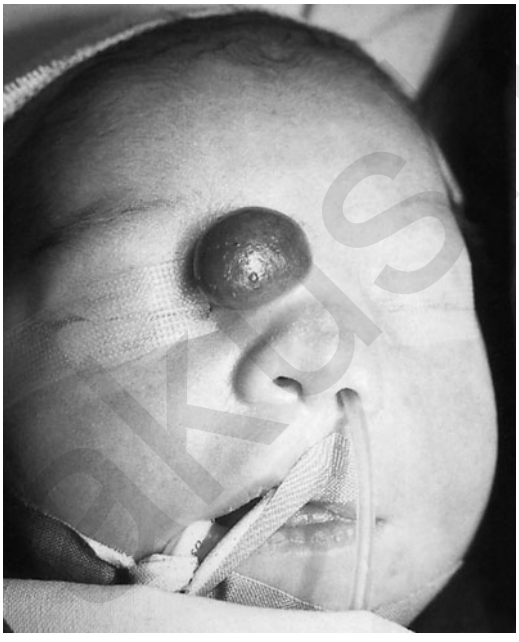

Figure 83.1 Nasal glioma in a newborn.

HISTOLOGY

A glioma consists of glial and fibrous tissue with an overlying flattened epidermis.[13] The specimens consist of fibrillary astrocytes and fibrous connective tissue. True neurons are seen rarely.[16] It does not contain a cerebrospinal fluid-filled space communicating with the ventricular system of the brain or the subarachnoid space. In two heterotopias, cellularity in places approached that of low-grade neoplastic glioma.[17]

DIAGNOSIS: IMAGING

Preoperative imaging is essential for an appropriate surgical approach by delineating the exact site and extension of the tumor.[13,18] It is important to distinguish nasal tumors or masses from basofrontal encephaloceles to avoid inadvertent exposure of the brain during the surgical removal of mass lesions.

Computed tomography (CT) scanning is useful to visualize bony defects, but is not reliable for soft-tissue contrast. Magnetic resonance imaging (MRI) is superior for imaging brain tissue; it should therefore be used preferentially for definition of the tumor mass and to disclose intracranial extension.[18]

De Biasio *et al.*[19] reported a case of fetal nasal glioma diagnosed at 21 weeks' gestation. The glioma appeared as a moderately hypoechoic mass near the junction of the medial aspect of the left orbit and the lateral aspect of the nose. It showed no internal vascularization on color and power Doppler ultrasonography. The glioma was resected after an uneventful pregnancy at the age of four months.

TREATMENT

Though benign and relatively slow growing, these heterotopias can cause disturbances of growth and subsequent deformity by encroachment upon the bony frameworks of the nose. Furthermore, they are unsightly and some of them, located at the root of the nose, such as encephaloceles and gliomas, may interfere with vision. Hence, early surgical excision is advisable.

Complete surgical excision of nasal gliomas (with repair of any hypertelorism) is the treatment of choice. The most conservative cosmetic surgical technique should be chosen after intracranial connection has been ruled out.

TECHNIQUE

An elliptical incision is made around the base of the tumor and the mass is removed *in toto*. In order to avoid recurrences, it is important to excise or coagulate the small deep stalk, which may pass upwards for a short distance under the nasal bone. This tract is exposed by splaying open the nasal bones through a midline nasal incision. In the case of a high-situated intranasal glioma, an extracranial extranasal approach may be necessary to provide wide access to the nasal cavity. A lateral rhinotomy is most often used. Burckhardt and Tobon[20] described an endoscopic approach in a case of intranasal glioma. In cases with intracranial lesion, craniotomy is mandatory.

COMPLICATIONS

Incomplete excision

Recurrences due to incomplete excision are rare (11%). In 13% of the cases, there is a connection with the intracranial

nervous system by a pedicle of fibrous tissue, passing through the cribriforme plate. Nasal gliomas with a cystic component seem to have a greater tendency for recurrence, however the reason for this remains unclear.[21] Levine *et al.*[16] reported a case in which a nasal glioma masqueraded as a capillary hemangioma with a subsequent inadequate treatment, which indicates the need for a preoperative histologic examination in some cases.

A recurrence can be avoided by a detailed evaluation of the preoperative imaging and a meticulous dissection in order to expose a stalk or a possible intracranial connection. Only a complete excision prevents recurrence.[21–23]

Dural defect

As normally there is no permeable communication with the subdural space, an accidental dural defect is theoretical. Should it occur, it must be promptly closed to prevent a CSF fistula. If such a defect is large, an epicranium graft may be needed for a safe and tight closure.

Hematoma

This can be avoided by careful hemostasis with bipolar coagulation.

Skin defect

In some cases, the skin defect is closed directly. Large defects can be covered by free skin grafting, by glabellar skin flaps, or by tissue expansion:

1. **Free skin graft**. This is an ideal method for covering skin defects, when there is a suitable recipient ground. Reconstruction is obtained without additional scars. The technique is easy and the cosmetic result is excellent. The graft takes in almost all cases. The best skin graft is a retroauricular full thickness skin graft.
2. **Flaps**. The skin in the glabellar donor area provides a good color and texture match for the resurfacing of the upper nasal defect. The glabellar flap can be transferred in three ways: as a classic glabellar flap, as a midline transposition flap, and as an island flap:
    a. Classic glabellar flap: the time-honored reconstructive technique in the upper nasal area. The drawback is that eyebrow hair may be moved down into the medial canthral area by rotation of the skin (Fig. 83.2a–c).
    b. Midline transposition or finger flap, which is a good method for reconstructing the glabellar region. The finger flap is reliable and suitable. The finger has a simple design and allows transfer of the thin non-hair-bearing skin. The harvesting area is closed directly. If the flap has any skin excess it will be exhibited by a standing cone in the inferior rotation area. This excess can be trimmed without any problem involving the blood supply. The result of this method is usually excellent (Fig. 83.3a–c).
    c. The glabellar island flap is an interesting, although more time-consuming procedure. The use of magnification is recommended. The main advantage of this technique is the lack of skin distortion, i.e. a standing cone. The harvesting defect is closed directly with excision of triangles of skin superiorly and inferiorly. There is no deformation of local morphology. The initial swelling due to the subcutaneous pedicle will subside with time (Fig. 83.4a–d).
3. **Tissue expansion** as described by Radovan[24] is a new method. This is a two-stage procedure based on the principle to develop donor tissue by expansion adjacent to the defect. Reconstruction can be performed with contiguous tissue of similar texture, color, thickness, and sensation.

Meningocele and encephalocele

The encephalocele is a protrusion of brain inside a dural sac through a skull defect. The tumor contains an ependyma-lined space filled with the CSF; it communicates with the ventricular system. Encephaloceles are located at the root of the nose, midline (nasofrontal) or asymmetric lateral (naso-ethmoidal); they are most frequently intranasal.[1,25] The bridge of the nose is broadened and often hypertelorism and nasal deformity are produced. Depending on the contents, meningoceles and encephaloceles are taut or soft, compressible and pulsatile tumors, enlarging when the patient cries (Fürstenberg sign).

PREOPERATIVE EXAMINATION

Evaluation should include a complete rhinologic and neurologic examination.[26] The dominant clinical sign of encephaloceles is an intermittent rhinoliquorrhea that can be distinguished from normal nasal secretion by the typically high glucose concentration in the liquor. The defect at the base of the skull is demontrated by radiological examination; an intracranial lesion is best disclosed with MRI and/or CT scanning.[18,27] Three-dimensional CT provides additional useful information in cases with significant bony abnormalities at little additional cost or time.[28]

TREATMENT

The treatment of choice is excision of the tumor with the herniated brain and closure of the dural defect. Usually there are no problems for closure of the wound the covering skin being normal. According to Macfarlane *et al.*,[29] primary and secondary hypertelorism regressed in most instances where patients were treated before the age of two years. In their series of 114 patients treated over a 15-year period, in 59% of the children the developmental outcome was normal, 18% had mild mental or physical disability, and in 23% severe impairment occurred.

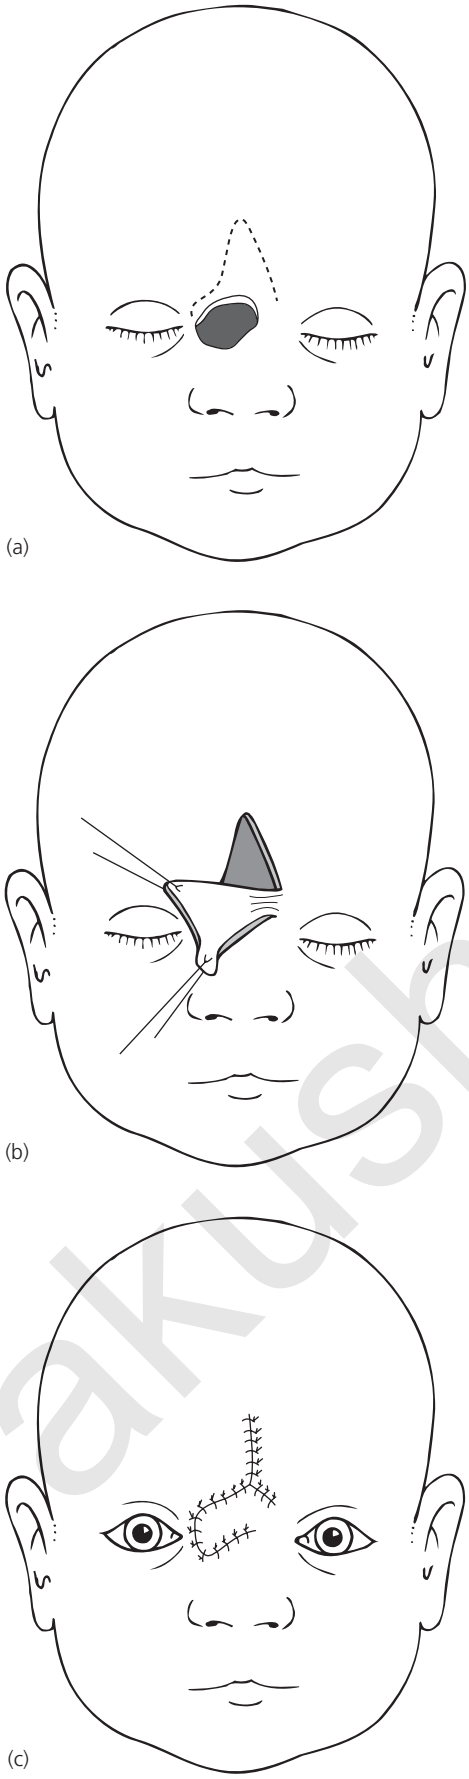

Figure 83.2 (a–c) Classic glabellar flap.

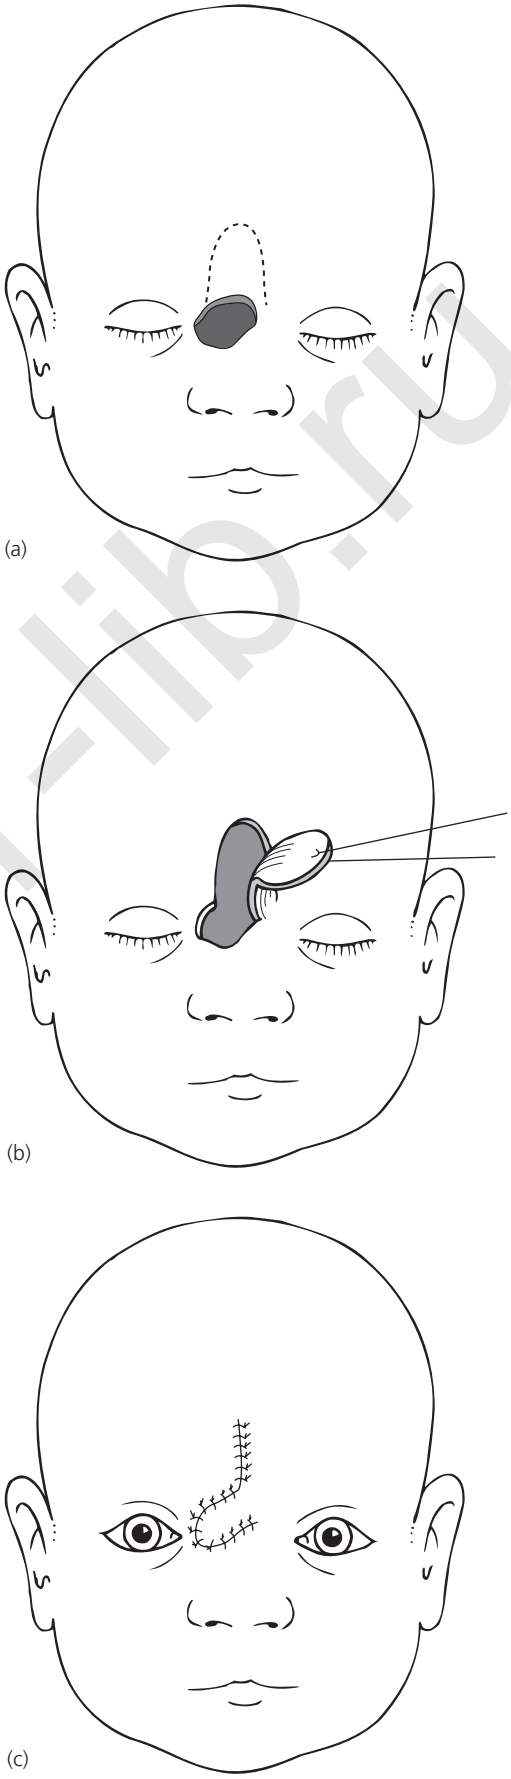

Figure 83.3 (a–c) Finger flap – midline transposition flap.

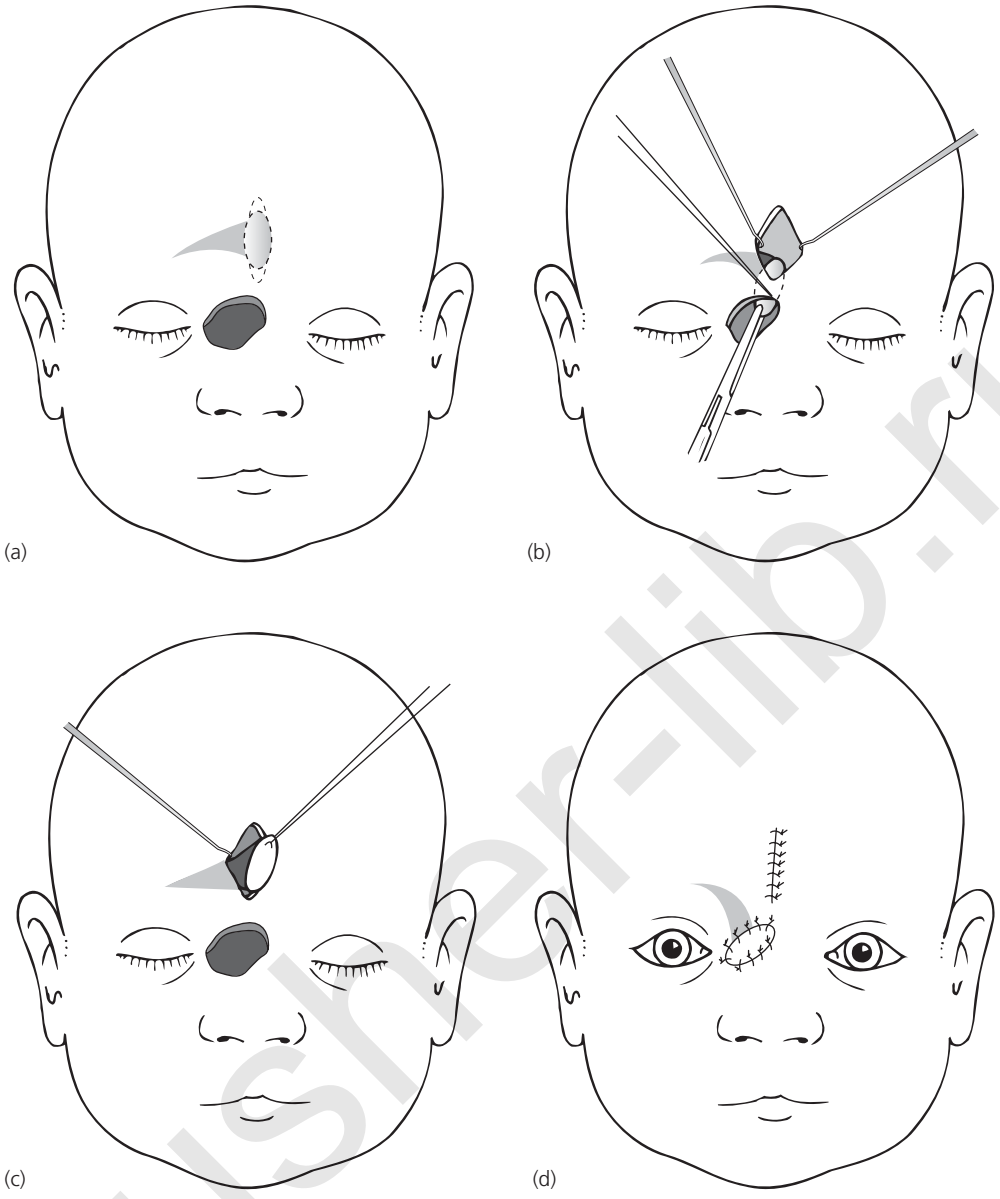

Figure 83.4 (a–d) Glabellar island flap.

COMPLICATIONS

The main postoperative complication is leakage of CSF because of a large dural defect.[26,29] In Macfarlane's series,[29] it occurred in one out of 114 patients. The dural defect must be closed tightly to prevent such a fistula. If the defect is too large for direct closure, an epicranial or a fascia lata graft may be a valid alternative.

CONGENITAL DERMOID CYSTS AND DERMOID SINUS

Congenital dermoid cysts are the most frequently found congenital nasal tumors. During early embryonic development, a portion of the dura begins to grow in close association with nasal skin. Eighty-four percent are found in the head and neck, 37% of these are located in the orbit and periorbit, and 10% are found in the midline of the nasofrontal region. External dermoid cysts present clinically as firm, non-fluctuating, and non-pulsatile mass. The Fürstenberg sign is negative.[1] The dermoid sinus appears externally, sometimes as a dimple with protruding hair; in these cases only a thorough examination will reveal the diagnosis. The dimple usually leads to a sinus tract which extends along the nasal septum, underneath the nasal bones, towards the base of the anterior cranial fossa; it may enter the skull (dumb-bell cyst).[5]

HISTOLOGY

Dermoid cyst and sinuses are both lined by squamous epithelium with various dermal appendages, such as glands and hair follicles.

COMPLICATIONS

Repeated infections may form multiple sinus tracts, making complete excision difficult. Sometimes, the mass of the cyst may erode nasal bones and associated sinuses, although rarely a liquorrhea may occur.

TREATMENT

The treatment of choice is operative removal, preferably before potentially chronic infections occur.

TECHNIQUE

A midline nasal incision and excision of the mass is the best technique. The tract passing into the nasal septum must be exposed after opening the nasal bones. All epithelial elements must be removed. The stalk is carefully dissected cephalad; if it enters the skull, a craniotomy is mandatory in order to remove the intracranial part of the lesion.

Neuroblastoma

ANDREW M DAVIDOFF

INTRODUCTION

Tumors in the newborn are relatively rare, comprising only about 2.5% of all childhood malignancies.[1] The majority of these tumors are benign lesions, but malignancies can occur. Overall, neuroblastoma is the fourth most common cancer of childhood, comprising 7–10% of all malignancies diagnosed in children younger than 15 years of age. However, neuroblastoma is second only to teratoma as the most commonly diagnosed tumor in the neonate and is, overall, the most common malignancy in the newborn, accounting for 30% of all tumors in this age group, with an estimated prevalence of 2–6 per 100000 live births in the United States.[2,3] With the increasing use of perinatal imaging, this number is likely to increase.

Neuroblastoma is a heterogeneous disease; tumors can spontaneously regress or mature without treatment, or display a very aggressive, malignant phenotype. Although the specific reasons for these differences in biologic behavior are yet to be completely elucidated, certain clinical and biologic factors have been identified that predict, to a significant degree, the tumor phenotype. Among these, patient age at diagnosis is one of the most powerful, with age less than 1–1.5 years conferring a favorable prognosis.[4,5] It follows, then, that neuroblastoma diagnosed in the newborn period is associated with a very favorable outcome. The challenge in managing these patients is to maintain an excellent survival rate, while minimizing the toxicity of any therapy.

ETIOLOGY

Neuroblastoma is derived from cells of the neural crest. During normal development and renewal, neural crest cells migrate and evolve to perform highly specialized functions to meet the physiologic needs of the body. This involves tightly regulated processes that include continued cell proliferation, differentiation, and programmed death (apoptosis). An intricate system of checks and balances ensures proper control over these physiologic processes. For example, small nodules of primitive neuroblasts are routinely found in the developing adrenal gland and even during the early postnatal period. Beckwith and Perrin[6] first described these microscopic nodules that they termed 'neuroblastoma *in situ*' in the adrenals of infants undergoing autopsy following death from non-malignancy-related causes. The incidence of this finding was more than 200-fold greater than the clinical incidence of neuroblastoma, suggesting that perhaps many neuroblastomas spontaneously regress or mature into lesions that never become clinically apparent. Even clinically apparent neuroblastoma can regress or spontaneously mature. Although initially thought to be mediated by the immune system, this may be the result of the withdrawal of neurotrophic maintenance factors, such as nerve growth factor (NGF). Neuroblastoma probably represents failure of this process of regression. Although the precise etiology of neuroblastoma is currently unknown, as with all cancer, genetic, epigenetic, and environmental factors appear to contribute.

Inherited genetic factors

Neuroblastoma generally occurs sporadically, but familial neuroblastoma does occur in about 2% of the cases. Interestingly, however, substantial biologic and clinical heterogeneity is often observed in familial cases. Recently, the germline mutation associated with hereditary neuroblastoma has been identified – activating mutations in the tyrosine kinase domain of the anaplastic lymphoma kinase (*ALK*) oncogene on the short arm of chromosome 2 (2p23).[7] These mutations can also be somatically acquired although the prevalence of ALK activation in sporadic neuroblastoma remains to be determined.

Environmental factors

In addition to genetic factors, environmental factors may have a direct impact on cell phenotype and fate by causing DNA

damage that permanently alters the host genome, although few environmental factors have been convincingly linked to the development of neuroblastoma. Several case-control studies have examined the relationship between maternal and paternal occupation and exposure, and the risk of neuroblastoma in offspring.[8] Several other studies have also suggested a relationship between the use of certain medications just prior to and during pregnancy and neuroblastoma, specifically hormone use and fertility drugs, and phenylhydantoin for seizure disorders.[9,10] Similarly, the results for smoking, alcohol, illicit drug use, and the use of hair dye in some studies are suggestive but not conclusive.[11,12]

PATHOLOGY

Neuroblastoma is an embryonal tumor of the sympathetic nervous system. These tumors arise during fetal or early postnatal life from sympathetic cells (sympathogonia) derived from the neural crest. Therefore, tumors can originate anywhere along the path which neural crest cells migrate, including the adrenal medulla, paraspinal sympathetic ganglia, and sympathetic paraganglia, such as the organ of Zuckerkandl.

Neuroblastoma can be distinguished histologically by the presence of neuritic processes (neuropil) and Homer Wright rosettes (neuroblasts surrounding eosinophilic neuropil). Scattered ganglion cells or immature chromaffin cells may also be seen. The appearance of the tumor cells may vary from undifferentiated cells to fully mature ganglion cells. In addition, neuroblastomas have variable degrees of Schwannian cell stroma, reactive non-neoplastic tissue recruited by the tumor cells.

Shimada classification

In 1984, Shimada and colleagues first developed an age-linked classification system of neuroblastic tumors based on tumor morphology in which neuroblastomas were divided into two prognostic subgroups, favorable histology and unfavorable histology. In 1999, the International Neuroblastoma Pathology Classification (INPC) was devised and then modified in 2003,[13] and is an adaptation of the original Shimada system (Table 84.1). The INPC is an age-linked classification that depends on the differentiation grade of the neuroblasts, the cellular turnover index (mitosis–karyorrhexis index (MKI)), and the presence or absence of Schwannian stroma; and classifies neuroblastic tumors into three morphologic categories: neuroblastoma, ganglioneuroblastoma, and ganglioneuroma.

Neuroblastomas are, by definition, Schwannian stroma-poor (<50% of the tumor tissue) and can be subtyped as undifferentiated, poorly differentiated (<5% of tumor cells have features of differentiation), or differentiating (>5% of tumor cells show differentiation towards ganglion cells). Additional factors that contribute to the prognostic distinction of stroma-poor, neuroblastic tumors (neuroblastoma) as favorable or unfavorable subtypes include the MKI, which is defined as the number of tumor cells in mitosis or karyorrhexis per 5000 neuroblastic cells (i.e. low MKI, <100 cells; intermediate, 100–200 cells; high, >200 cells) and the patient's age (<1.5 years, 1.5–5 years, >5 years). It has been hypothesized that neuroblastic cells with maturational potential require an *in vivo* latent period before demonstrating histologic evidence of differentiation; therefore, there is a certain allowance for mitotic and karyorrhectic activities of neuroblastic cells in tumors in infants and younger children.[14] Thus, newborns with neuroblastoma are very likely to have favorable histology disease.

Table 84.1 Prognostic evaluation of neuroblastic tumors according to the International Neuroblastoma Pathology Classification.[14]

	Neuroblastoma pathology	Classification
Neuroblastoma	Schwannian stroma-poor	
< 1.5 years	Poorly differentiated or differentiating and low or intermediate MKI tumor	Favorable
1.5–5 years	Differentiating and low MKI tumor	
< 1.5 years	(a) undifferentiated tumor, or (b) high MKI tumor	Unfavorable
1.5–5 years	(a) undifferentiated or poorly differentiated tumor, or (b) intermediate or high MKI tumor	
≥ 5 years	All tumors	
Ganglioneuroblastoma, intermixed	Schwannian stroma-rich	Favorable
Ganglioneuroblastoma, nodular	Composite Schwannian stroma-rich/ stroma-dominant and stroma-poor	Unfavorable or favorable (based on nodule histology)
Ganglioneuroma	Schwannian stroma-dominant	
Maturing		Favorable
Mature		

MKI, mitosis–karyorrhexis index.

Molecular pathology

Although there is no single genetic abnormality or initiating event common to all neuroblastomas, a number of different genetic alterations have been identified that provide powerful

prognostic information and play crucial roles in risk assessment and treatment planning.

DNA CONTENT

Normal human cells contain two copies of each of 23 chromosomes; thus, a normal diploid cell has 46 chromosomes. The majority (55%) of primary neuroblastomas are triploid or 'near-triploid/hyperdiploid' and contain between 58 and 80 chromosomes; the remainder (45%) are either 'near-diploid' (35–57 chromosomes) or 'near-tetraploid' (81–103 chromosomes).[15] The 'DNA index' of a tumor is the ratio of the number of chromosomes present to a diploid number of chromosome (i.e. 46). Therefore, diploid cells have a DNA index of 1.0, whereas near-triploid cells have a DNA index ranging from 1.26 to 1.76. Importantly, patients with near-triploid tumors typically have favorable clinical and biologic prognostic factors and excellent survival rates, as compared with those patients who have near-diploid or near-tetraploid tumors.[16] This association is most important for infants with advanced disease;[17] the prognostic significance of tumor ploidy appears to be lost in patients older than two years.

AMPLIFICATION OF *MYCN*

Early studies of neuroblastoma cell lines showed the frequent presence of extrachromosomal double-minute (DM) chromatin bodies and chromosomally integrated homogeneously staining regions (HSRs) characteristic of gene amplification.[18] Since that time, it has been shown that the amplified region was derived from the distal short arm of chromosome 2 (2p24) and contained the *MYCN* proto-oncogene.

Overall, approximately 25% of primary neuroblastomas have MYCN amplification, being present in 40% with advanced disease, but only 5–10% with low-stage disease.[19] The copy number, which can range from 5- to 500-fold amplification, is usually consistent among primary and metastatic sites and at different times during tumor evolution and treatment.[20] This finding suggests that *MYCN* amplification is an early event in the pathogenesis of neuroblastoma. Amplification of *MYCN* is associated with advanced stages of disease, rapid tumor progression, and poor outcome; therefore, it is a powerful prognostic indicator of biologically aggressive tumor behavior.[19,21]

CHROMOSOMAL CHANGES

Approximately 20 to 35% of primary neuroblastomas exhibit 1p deletion, as determined by fluorescent *in situ* hybridization (FISH), with the smallest common region of loss located within region 1p36.[22] About 70% of advanced-stage neuroblastomas have 1p deletions.[23] Molecular studies have shown that there is a strong correlation between 1p deletion and *MYCN* amplification and other high-risk features such as age older than one year and advanced-stage disease.[22] A recent study has demonstrated that 1p deletions are independently associated with a worse outcome in patients with neuroblastoma.[24]

OTHER MOLECULAR ABNORMALITIES

Neurotrophins and their tyrosine kinase receptors are important in the development of the sympathetic nervous system and have been implicated in the pathogenesis of neuroblastoma. Three receptor–ligand pairs have been identified: TrkA, the primary receptor for nerve growth factor (NGF); TrkB, the primary receptor of brain-derived neurotrophic factor (BDNF); and TrkC, the receptor for neurotrophin-3 (NT-3). TrkA appears to mediate differentiation of developing neurons or neuroblastoma in the presence of NGF ligand, and apoptosis in the absence of NGF.[25] High TrkA expression is associated with favorable tumor biology and good outcome[26] and is inversely correlated with *MYCN* amplification.[27] Conversely, the TrkB/BDNF pathway appears to promote neuroblastoma survival through autocrine or paracrine signaling, especially in *MYCN*-amplified tumors.[28] TrkB is expressed in about 40% of neuroblastomas, usually advanced-stage disease. TrkC is expressed in approximately 25% of neuroblastomas and is strongly associated with TrkA expression.[29]

PRESENTATION

When symptomatic, children with neuroblastoma usually present with signs and symptoms that reflect the primary site and extent of disease. An abdominal mass may be detected on physical examination when the primary is adrenal or retroperitoneal. Respiratory distress may be a reflection of a thoracic tumor. Altered defecation or urination may be caused by mechanical compression by a pelvic tumor, or by spinal cord compression by a paraspinal tumor. A tumor in the neck or upper thorax can produce Horner syndrome (ptosis, miosis, and anhydrosis), enophthalmos, and heterochromia of the iris. Acute cerebellar ataxia has also been observed, characterized by the dancing-eye syndrome, which includes opsoclonus, myoclonus, and chaotic nystagmus. Two-thirds of these cases occur in infants with mediastinal primary tumors.[30] Additional signs and symptoms that reflect excessive catecholamine or vasoactive intestinal polypeptide secretion include diarrhea, failure to gain weight, and hypertension.

There are differences in the distribution of the primary site and extent of disease between newborns and all children with neuroblastoma. Newborns have a higher incidence of adrenal primaries (90 versus 50%) and a lower incidence of disseminated disease at presentation (20 versus 60%) with bone metastases, in particular, rarely occurring in newborns. Newborns with localized disease, especially those whose lesion was detected on routine perinatal imaging are almost always asymptomatic. Infants with metastatic neuroblastoma may have stage 4S disease, which, by definition, is a localized primary tumor in patients younger than one year, with dissemination limited to skin, liver, or bone marrow (<10% of nucleated cells). These patients may present with 'blueberry muffin' cutaneous lesions, respiratory distress secondary to massive hepatomegaly, and anemia secondary to bone marrow disease (see below under Stage 4S neuroblastoma).

Laboratory findings

LACTATE DEHYDROGENASE

Despite its lack of specificity, serum lactate dehydrogenase (LDH) can have great prognostic significance. High serum levels of LDH reflect high proliferative activity or large tumor burden, and an LDH level higher than 1500 IU/L appears to be associated with a poor prognosis.[31] Thus, LDH can be used to monitor disease activity or the response to therapy.

FERRITIN

High levels of serum ferritin (>150 ng/mL) may also reflect a large tumor burden or rapid tumor progression. Elevated serum ferritin is often seen in advanced-stage neuroblastomas and indicates a poor prognosis;[32] levels often return to normal during clinical remission.

URINARY CATECHOLAMINES

Measurement of homovanillic acid (HVA) and/or vanillylmandelic acid (VMA) in the urine is a critical component of the preoperative assessment. Together with a positive bone marrow, elevated levels can be used to make the diagnosis of neuroblastoma and, if elevated at diagnosis, can be used as a marker of disease status (e.g. progression or recurrence).

Diagnostic imaging

STANDARD RADIOGRAPHS

Chest radiography can be a useful tool for demonstrating the presence of a posterior mediastinal mass, which in an infant is usually a thoracic neuroblastoma. A Pediatric Oncology Group (POG) study demonstrated that a mediastinal mass was discovered on incidental chest radiographs in almost half of patients with thoracic neuroblastoma who had symptoms seemingly unrelated to their tumors.[33] Abdominal radiography is less often the modality by which a neuroblastoma is discovered; however, as many as half of abdominal neuroblastomas are detectable as a mass with fine calcification.

ULTRASONOGRAPHY

The vast majority of abdominal neuroblastomas in the newborn are diagnosed by ultrasonography, either in the prenatal period, as part of routine surveillance of the fetus, or in the postnatal period, to evaluate an abdominal mass. Although ultrasonography is the modality most often used during the initial assessment of a suspected abdominal mass, its sensitivity and accuracy are less than that of computed tomography (CT) or magnetic resonance imaging (MRI) for diagnosing neuroblastoma.

Computed tomography

CT remains a useful, commonly used modality for the evaluation of neuroblastoma. It can demonstrate calcification in almost 85% of neuroblastomas, and intraspinal extension of the tumor can be determined on contrast-enhanced CT. Overall, contrast-enhanced CT has been reported to be 82% accurate in defining neuroblastoma extent, with the accuracy increasing to nearly 97% when performed with a bone scan.[34]

Magnetic resonance imaging

MRI is becoming the most useful and most sensitive imaging modality for the diagnosis and staging of neuroblastoma. MRI appears to be more accurate than CT for detection of stage 4 disease: the sensitivity of MRI is 83%, and that of CT is 43%; and the specificity of MRI is 97%, and that of CT is 88%.[35] Metastases to the bone and bone marrow, in particular, are better detected by MRI, as is intraspinal tumor extension.[35]

METAIODOBENZYLGUANIDINE IMAGING

Metaiodobenzylguanidine (MIBG) is transported to and stored in the distal storage granules of chromaffin cells in the same way as norepinephrine. MIBG has been used for scintigraphic imaging of neuroblastoma. The MIBG scintiscan is the imaging study of choice in evaluating the involvement of bone and bone marrow by neuroblastoma, having largely replaced technetium-99m methylene diphosphonate (^{99m}Tc-MDP) bone scans.

MANAGEMENT

Diagnosis

In most instances where an adrenal or posterior mediastinal mass has been detected in a newborn, performing a biopsy before resection is unnecessary; most of these lesions will be localized, resectable neuroblastoma and will not receive adjuvant therapy. In the rare case of disseminated disease in the newborn, a biopsy is appropriate, rather than upfront resection, as all of these patients will receive chemotherapy, which, given in the neoadjuvant setting, may make resection of the primary tumor easier.

Staging

Current staging of neuroblastoma is based on the International Neuroblastoma Staging System (INSS) (Table 84.2).[36] Evaluation of the primary tumor and involvement of metastatic sites in the INSS system depend largely on the imaging studies described above (CT or MRI, and MIBG). In addition, children with localized neuroblastoma who are currently enrolled on a Children's Oncology Group (COG) protocol will also have 'image-defined risk factors' assessed by central review of diagnostic imaging studies. This will be performed to determine whether these factors are more prognostically relevant than INSS staging for patients with localized neuroblastoma. These image-defined risk factors (Table 84.3) were proposed by the European International Society of Pediatric Oncology Neuroblastoma Group and

Table 84.2 International Neuroblastoma Staging System.

Stage	
1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with primary tumor may be positive)
2A	Localized tumor with incomplete gross excision; representative ipsilateral non-adherent lymph nodes negative for tumor microscopically
2B	Localized tumor with or without complete gross excision, with ipsilateral non-adherent lymph nodes positive for tumor. Enlarged contralateral lymph nodes must be negative microscopically
3	Unresectable unilateral tumor infiltrating across the midline,[a] with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement
4	Any primary tumor with dissemination to distant lymph nodes, bone marrow, bone, liver, skin, and/or other organs (except as defined for stage 4S)
4S	Localized primary tumor (as defined for stage 1, 2A, or 2B), with dissemination limited to skin, liver, and/or bone marrow[b] (limited to infants <1 year of age)

[a]The midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.
[b]Marrow involvement in stage 4S should be minimal, that is, $<10\%$ of total nucleated cells identified as malignant on bone marrow biopsy or on marrow aspirate. More extensive marrow involvement would be considered to be stage 4. The metaiodobenzylguanidine scan (if performed) should be negative in the marrow.

generally reflect the presence of encasement of major vessels or nerves, or the infiltration of adjacent organs/structures by locoregional tumor. Cecchetto *et al.*[37] reported in 2005, that the presence of one or more of these image-defined surgical risk factors was associated with a lower complete resection rate and a greater risk of surgery-related complications when attempting an initial resection of a localized neuroblastoma.

Risk stratification

As previously mentioned, one of the notable characteristics of neuroblastoma is the substantial heterogeneity of the disease. Increasing evidence indicates that the biologic and molecular features of neuroblastoma are highly predictive of clinical behavior. Current treatment is based on risk stratification that takes into account both clinical and biologic variables predictive of disease relapse. The most important clinical variables appear to be age[5] and stage[38] at diagnosis. The most powerful biologic factors at this time appear to be *MYCN* status,[19,21] ploidy[16] (for infants), and histopathologic classification.[39] However, additional biologic and molecular variables continue to be evaluated, and the allelic status at chromosomes 1p36 and 11q23 are currently being used to

Table 84.3 Objective surgical risk factors for primary resection of localized neuroblastoma.[37]

Site	
Neck	1. Tumor encasing major vessel(s) (e.g. carotid artery, vertebral artery, internal jugular vein) 2. Tumor extending to base of skull 3. Tumor compressing the trachea 4. Tumor encasing the brachial plexus
Thorax	1. Tumor encasing major vessel(s) (e.g. subclavian vessels, aorta, superior vena cava) 2. Tumor compressing the trachea or principal bronchi 3. Lower mediastinal tumor, infiltrating the costovertebral junction between T9 and T12 (may involve the artery of Adamkiewicz supplying the lower spinal cord)
Abdomen	1. Tumor infiltrating the porta hepatis and/or the hepatoduodenal ligament 2. Tumor encasing the origin of the celiac axis, and/or the superior mesenteric artery 3. Tumor invading one or both renal pedicles 4. Tumor encasing the aorta and/or vena cava 5. Tumor encasing the iliac vessels 6. Pelvic tumor crossing the sciatic notch
Dumb-bell tumors with symptoms of spinal cord compression: any location	
Infiltration of adjacent organs/structures: diaphragm, kidney, liver, duodeno-pancreatic block, and mesentery	

define the duration of therapy for certain patients. Taken together, these variables currently define the COG risk stratification (Table 84.4) for therapeutic approach, with children being categorized into three risk groups predictive of relapse: low, intermediate, and high risk. The probability of prolonged disease-free survival for patients in each group is $>95\%$, $>90\%$, and $<30\%$, respectively. The vast majority of newborns with neuroblastoma will have low-risk disease; rarely do they have high-risk disease. In particular, only 3% of all patients with stage 1 or 2 neuroblastoma have *MYCN*-amplification with the incidence in newborns being even lower.[40]

Treatment

LOW-RISK DISEASE

The treatment for patients with low-risk disease is generally surgical resection alone, even in the presence of microscopic residual disease (stage 1), gross residual disease (stage 2A), or gross residual disease with ipsilateral lymph node involvement (stage 2B), if the tumor has favorable biologic characteristics (i.e. is without *MYCN* amplification). Infants with stage 4S disease who are not experiencing substantial symptoms may undergo an initial biopsy and observation only, if the tumor has favorable biologic factors. Infants with an adrenal mass who meet certain imaging and biochemical

Table 84.4 Children's Oncology Group risk stratification for children with neuroblastoma.

Risk stratification	INSS stage	Age	Biology
Low			
Group 1	1	Any	Any
	2A/2B (>50% resected)	Any	*MYCN*-NA, any histology/ploidy
	4S	<365 days	*MYCN*-NA, FH, DI > 1
Intermediate			
Group 2	2A/2B (<50% resected or Bx only)	0–12 years	*MYCN*-NA, any histology/ploidy[a]
	3	<365 days	*MYCN*-NA, FH, DI > 1[a]
	3	≥365 days–12 years	*MYCN*-NA, FH[a]
	4S (symptomatic)	<365 days	*MYCN*-NA, FH, DI > 1[a]
Group 3	3	<365 days	*MYCN*-NA, either UH or DI = 1[a]
	4	<365 days	*MYCN*-NA, FH, DI > 1[a]
	4S	<365 days	*MYCN*-NA, either UH or DI = 1[a] or unknown biology
Group 4	4	<365 days	*MYCN*-NA, either DI = 1 or UH
	3	365–<547 days	*MYCN*-NA, UH, any ploidy
	4	365–<547 days	*MYCN*-NA, FH, DI > 1
High			
	2A/2B, 3, 4, 4S	Any	*MYCN*-amplified, any histology/ploidy
	3	≥547 days	*MYCN*-NA, UH, any ploidy
	4	365–>547 days	*MYCN*-NA, UH or DI = 1
	4	>547 days	Any

[a]If tumor contains chromosomal 1p LOH or unb11qLOH, or if data are missing, treatment assignment is upgraded to next group.
DI, DNA index; FH, favorable histology; *MYCN*-NA, *MYCN* not amplified; UH, unfavorable histology.

criteria may also be observed on a protocol (see discussion of ANBLP2, p. 777).

INTERMEDIATE-RISK DISEASE

Patients receive cycles of cyclophosphamide, doxorubicin, carboplatin, and etoposide given every 3 weeks on the current COG protocol, ANBL0531. The duration of therapy (i.e. the number of cycles), will depend upon which of three intermediate risk groups a patient is placed in, with group stratification again being based on clinical and biologic risk factors (Table 84.4). One of these biologic factors will include loss of heterozygosity (LOH – loss of one of two normally paired chromosomal regions) at chromosome 1p or 11q (unbalanced), as these events have been shown to be independently associated with decreased progression-free survival in patients with low- and intermediate-risk disease.[24]

The overall surgical goal in intermediate-risk patients is to perform the most complete tumor resection possible, consistent with preservation of full organ and neurologic function. This may necessitate leaving residual disease adherent to critical anatomic structures. It is no longer required that infants with 4S disease undergo resection of their primary tumor. In addition, if these infants are too unstable at presentation, it is no longer required that they even undergo an initial biopsy.

HIGH-RISK NEUROBLASTOMA

The general approach to treating patients with high-risk neuroblastoma includes intensive induction chemotherapy, myeloablative consolidation therapy with stem cell rescue, radiation therapy, and immunotherapy for minimal residual disease. Other approaches, such as targeted therapy and anti-angiogenic therapy, are also being evaluated. The role of surgery for control of locoregional disease is controversial. Several reports have suggested that patients with INSS stage 3 or 4 disease who undergo gross total resection of their primary tumor and locoregional disease experience improved local tumor control and increased overall survival;[41–43] however, other reports have not confirmed these observations.[44,45] Despite the uncertainty of the role of surgery, the COG high-risk protocol currently recommends attempting gross total resection of the primary tumor and locoregional disease in patients with high-risk neuroblastoma.

Surgical management

PREOPERATIVE PREPARATION

All patients, prior to surgery, should have a complete blood count, chemistry panel (to include liver function tests if the liver is involved), and a coagulation screen. Urinary catecholamines, and serum ferritin and LDH, should already have been obtained as part of the initial work-up (see above Laboratory findings). Blood pressure should be normalized with pharmacologic means if hypertension was present at presentation. Operations on neuroblastoma are often hazardous and hemorrhage is a frequent problem, hence packed red blood cells should be available for transfusion during or immediately after the operation.

OPERATIVE APPROACH (OPEN)

Tumor size, the extent of vascular encasement, and exact tumor location should be considered in selecting the approach for a retroperitoneal neuroblastoma. Options available for the abdominal incision include a transverse incision, bilateral subcostal (Chevron) incisions, or a midline incision (Fig. 84.1). A transthoracic (intercostal), transdiaphragmatic extension can be added for resection of neuroblastomas with either thoracoabdominal extension or extensive periaortic or celiac axis encasement. The tumor should be carefully exposed to determine the relation between the tumor and normal organs and vessels. If encasement of major vessels, such as the aorta, vena cava, or their branches, is found, tumor dissection must be performed to free the vessels completely. With deliberate dissection of the tumor from the mesenteric and renal vessels, injury to the liver, bowel, spleen, and kidneys can be avoided (Fig. 84.2), although this frequently results in piecemeal division and excision of the tumor.[45] For a more detailed description of extensive surgical resection of neuroblastoma, see Ref. 45.

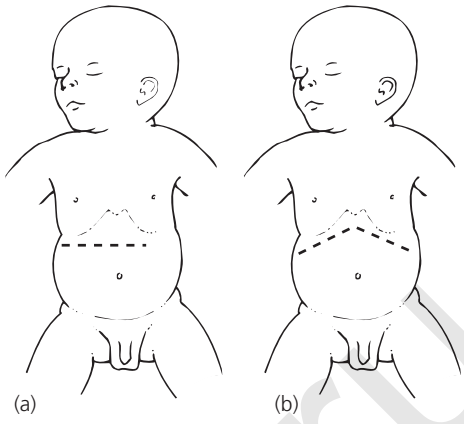

Figure 84.1 Incisions for retroperitoneal neuroblastoma resection. (a) Transverse abdominal incision (right-sided tumor); (b) bilateral subcostal incision.

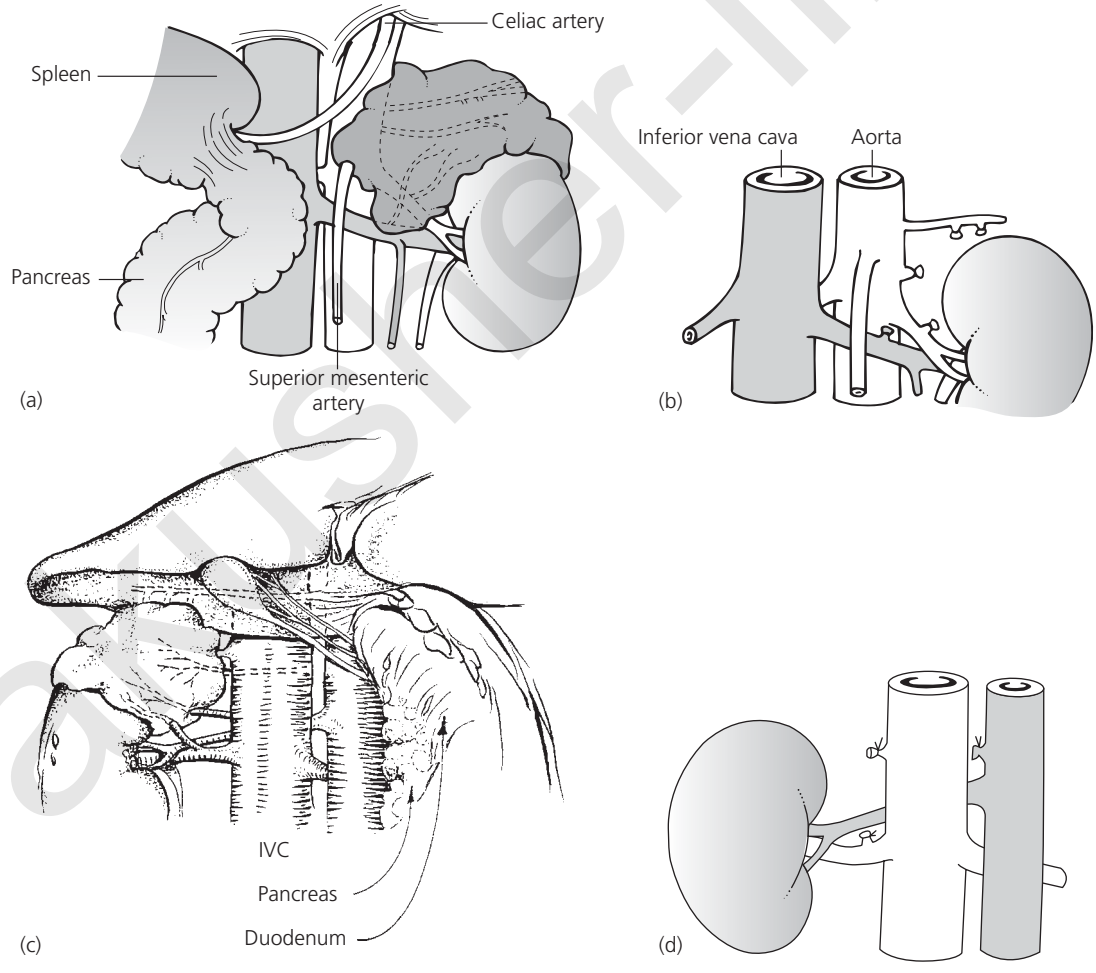

Figure 84.2 Right adrenal tumor. (a) The lienorenal ligament has been divided allowing mobilization of the spleen and pancreas to the right. The renal vessels are visible and dissected out – branches to the tumor are divided. Next, the tumor is dissected from the aorta dividing any vessels. (b) Tumor has been removed and the vascular supply divided. (c) The duodenum and head of pancreas with important structures in the lesser omentum mobilized to the left. The renal vessels are dissected out and branches to the tumor are divided. Medially, the tumor is juxtaposed to the inferior vena cava and sharp dissection may be needed to separate it. At least one vein will need to be secured and divided. (d) The tumor has been removed. Left adrenal tumor.

OPERATIVE APPROACH (LAPAROSCOPIC)

Laparoscopic adrenalectomy is feasible in children and may have some benefits (less pain, shorter hospitalization, improved cosmesis) compared to open adrenalectomy. Laparoscopy may be a reasonable approach in neuroblastoma, in particular, where negative margins, piecemeal removal of the specimen, and leaving residual tumor are not usually of concern. In addition, vascular encasement, characteristic of high-risk neuroblastoma in older children does not usually occur in newborns, making a minimally invasive approach feasible. However, an appropriate oncologic procedure, that currently still includes bilateral lymph node sampling for staging, is required. The surgeon also should consider that, as discussed previously, small adrenal masses discovered in the perinatal period and 4S neuroblastomas may not need to be removed.

Transperitoneal laparoscopic adrenalectomy is generally performed with the operative side up, but in such a fashion that allows rapid transition to an open procedure, if that becomes necessary. The table is tilted into the reverse Trendelenburg position and can be flexed to increase the distance between the costal margin and the iliac crest. Generally, four ports are used (Fig. 84.3). Dissection is performed in much the same manner as the open procedure with care being taken to secure the adrenal vein and to avoid the renal vessels. Bilateral retroperitoneal lymph node sampling is currently still required for appropriate neuroblastoma staging.

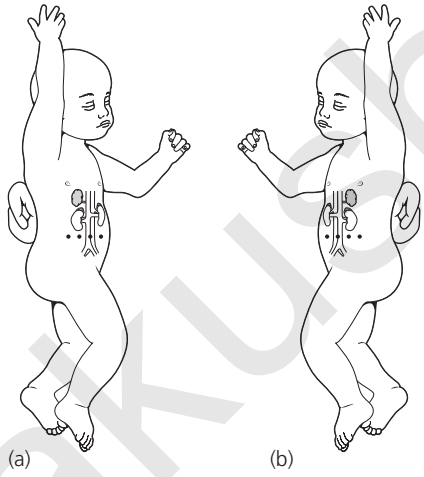

Figure 84.3 Trocar placement for laparoscopic adrenalectomy for (a) right- and (b) left-sided tumors.

Special management situations

SCREENING FOR NEUROBLASTOMA

Because the two most important clinical variables for predicting outcome in patients with neuroblastoma are tumor stage and patient age at the time of diagnosis, it was hypothesized that earlier detection of neuroblastoma through mass population screening might significantly impact neuroblastoma-associated mortality. In Japan in the 1980s, mass screening of neuroblastoma was performed in infants by quantitating urinary VMA and HVA; initially, the mass screening showed very encouraging results.[46] However, subsequent population-based studies with concurrent control groups performed in Germany and North America found that although the incidence of neuroblastoma increased, the additional cases were largely early-stage, favorable biology, low-risk tumors.[47] Because the overall mortality of patients with neuroblastoma was not affected, the implication of these studies was that mass screening most likely detected tumors that would have undergone spontaneous regression and not been detected clinically. Thus, there currently appears to be no role for screening infants for neuroblastoma.

EXPECTANT OBSERVATION OF PERINATAL ADRENAL MASSES

Small, localized neuroblastomas in young infants tend to regress spontaneously, particularly if the lesion is cystic. Based on this observation, the COG protocol, ANBLOOP2, evaluates the safety of expectant observation of patients with these lesions to further define their natural history. This study is designed to prove the hypothesis that close biochemical and sonographic observation can be used for safe clinical management of infants with small adrenal masses; surgical resection is reserved for those rare cases in which there is evidence of continued growth (or parent preference for surgical resection). To be eligible, infants with an adrenal mass must be less than six months of age when the mass is first identified; the mass must be <16 mL in volume, if solid, or <65 mL if at least 25% cystic; and disease must be limited to the adrenal gland. Eligible patients will then be placed on study and either be observed according to the schema detailed in Table 84.5 or have immediate surgery if that is the parents' preference. For those patients being observed, any increase in tumor volume or urine catecholamines will trigger more frequent surveillance, followed by surgical resection if the increase continues.

Table 84.5 Follow-up evaluations on ANBLOOP2.

Observation	Week of study								
Follow-up investigation	0	3	6	12	18	30	42	66	90

CT, computed tomography; HVA, homovanillic acid; MRI, magnetic resonance imaging; VMA, vanillylmandelic acid.

STAGE 4S NEUROBLASTOMA

In 1971, D'Angio *et al.*[48] reported a number of patients with a 'special' variant of metastatic neuroblastoma, termed IV-S (now referred to as 4S). These patients were infants who

typically had a single, small primary tumor; however, these infants often had extensive metastatic disease in the liver, resulting in significant hepatomegaly, skin nodules ('blueberry muffin' lesions), and small amounts of disease in the bone marrow (<10% of the mononuclear cells). Patients with 4S neuroblastoma were quite remarkable, because the large amount of disease generally underwent spontaneous regression, even without treatment, and the infants ultimately had no evidence of disease.

Only supportive therapy has been recommended for this stage of neuroblastoma because of the high incidence of spontaneous regression and the resultant good prognosis.[49] Most of these patients have tumor with favorable biology (single-copy *MYCN*, favorable Shimada histology, and DNA index >1); therefore, they are assigned to the low-risk classification and receive no therapy. However, despite the generally benign course of their malignancy, these infants can die of complications caused by the initial bulk of their disease. Limited chemotherapy, local irradiation, or minimal resection can be used to treat infants with life-threatening symptoms of hepatomegaly. Operative placement of a Silastic pouch as a temporary abdominal wall may be a choice for those with significant liver enlargement that causes either respiratory compromise secondary to diaphragmatic elevation or obstruction of the inferior vena cava. This procedure may help to avoid life-threatening events until shrinkage of the liver is achieved by either spontaneous regression or therapy. The rare infant with 4S disease and either unfavorable Shimada histology or a DNA index of 1 (or if the biology is not known) will be treated for intermediate-risk disease (group 3), and those with 4S disease that is *MYCN* amplified will be treated for high-risk disease.

INTRASPINAL EXTENSION OF NEUROBLASTOMA

In a subset of patients with paraspinal neuroblastoma, tumor growth may extend into the spinal canal ('dumb-bell' tumors). If neurologic symptoms result, urgent treatment is required to prevent permanent injury caused by compression of the cord. Each of the three main therapeutic modalities (surgery, radiation therapy, and chemotherapy) has been used in the past; the POG report by Katzenstein *et al.*[50] showed similar rates of neurologic recovery in patients treated with surgery or chemotherapy, but significant orthopedic sequelae were seen more commonly in patients treated with surgery. Although chemotherapy is probably considered most appropriate for the initial management of these patients, improvements in neurosurgical techniques, including the use of laminotomy instead of laminectomy to access the intraspinal tumor, may necessitate reconsideration of this approach, especially in those patients with acutely progressive symptoms.

The appropriate approach for patients with asymptomatic intraspinal tumor extension is also uncertain. For patients with low- or intermediate-risk disease, the risks of attempting to remove the intraspinal component of a paraspinal tumor probably outweigh the benefits. This situation most commonly arises in patients with thoracic primary tumors. The intrathoracic component is resected and gross residual disease remains in the spinal canal. Because residual foraminal disease rarely grows to a symptom-developing size, the importance of conservative therapy in this circumstance should be emphasized. For patients with high-risk disease, the importance of resecting gross intraspinal disease is uncertain.

OPSOCLONUS–MYOCLONUS SYNDROME

The opsoclonus–myoclonus syndrome (OMS) consists of myoclonic jerks and random eye movements or progressive cerebellar ataxia. OMS occurs in as many as 4% of patients, usually infants with thoracic primary tumors. Although the exact etiology of this syndrome is not known, the presence of crossreactive autoantibodies to neural antigens in some of these patients suggests that it is it mediated by the immune system.[51] Although patients generally have a good prognosis with regard to their tumor, neurologic symptoms often persist after successful removal of the tumor and can be quite debilitating.[30] Some symptomatic relief may be attained by high doses of corticosteroids or adrenocorticotropic hormones and some studies have suggested that chemotherapy, i.v. IgG therapy, or both may improve the long-term neurologic outcome for these patients.[52] The COG is currently testing this approach in a prospective clinical trial.

COMPLICATIONS

Because extensive surgery is often required, intraoperative and postoperative complications are not uncommon.[53,54] As many as 80% of patients will experience significant blood loss during surgery that requires transfusion of blood and blood products either in the operating room or in the early postoperative period. Up to 10% will suffer an injury to a major vascular structure (aorta, vena cava, or renal vessels), and injury to other viscera (stomach, bowel, liver, spleen, or kidney) also occurs in approximately 5% of cases. On occasion, this necessitates removal of injured organs, with the kidney being the most common. As with all surgical procedures, there is also a risk for anesthetic complications, with infants being at higher risk. The overall mortality for young infants undergoing adrenal surgery for tumor resection appears to be about 2%.[55] Postoperative complications have a wide range. Wound complications occur in 1–5% of cases, as does postoperative bowel obstruction. In addition, hypertension, chyle leak, pleural effusion, infection and sepsis, diarrhea, and prolonged total parenteral nutrition (TPN) requirement can occur. Rarely, a patient will have to be urgently re-explored for postoperative hemorrhage or for bowel obstruction.

LONG-TERM RESULTS

Most newborns with neuroblastoma will have low-risk disease and be treated either with surgery alone or expectant observation. The treatment plan of surgery alone for patients with low-risk disease was established on the basis of the prior

experiences of each of the legacy children's oncology groups in the United States, the Pediatric Oncology Group, and the Children's Cancer Group (CCG). The POG 8104 study found that two-year survival was 89% for patients with POG stage A (INSS stage 1) disease despite microscopic residual disease, when patients were treated with surgery alone.[56,57] In a similar cohort of patients, the CCG 3881 study found three-year event-free survival (EFS) and overall survival to be 94 and 99%, respectively, for patients with Evans stage I disease.[58] That study also found that although patients with Evans stage II disease (similar to INSS 2A/2B) had a three-year EFS of 81% irrespective of the extent of surgical resection and subsequent treatment, the overall survival for these patients was 99%.[58] This finding suggests that even if these patients experience disease relapse, most can be salvaged with additional therapy. Therefore, neither adjuvant chemotherapy nor radiation therapy appears to be necessary for the initial management of most patients with low-risk disease.

On the basis of these data, a group-wide study (COG P9641: Primary surgical therapy for biologically defined low-risk neuroblastoma), was conducted from 1998 to 2006 to evaluate primary surgical therapy for biologically defined low-risk neuroblastoma. The overall strategy of this study was to treat patients with low-risk neuroblastoma with surgery and supportive care only; adjuvant therapy was given only when less than 50% of the tumor was resected or when symptoms that were life- or organ-threatening developed. A probability of three-year survival more than 95% was predicted for these patients with low-risk disease. Although the final published results from this study are still pending, the current recommendation continues to be that patients with low-risk neuroblastoma be treated with surgery alone.

The safety of expectant observation of adrenal masses in appropriate neonates is the primary study question of an ongoing clinical trial and so has yet to be answered definitively. However, there are significant published clinical data supporting this approach, emanating primarily from Japan.[13–15]

Soft-tissue sarcoma

MARTIN T CORBALLY

INTRODUCTION

Solid tumors presenting in the neonatal or perinatal period are rare and usually benign. Malignant tumors at this extreme of life are rare and account for less that 2% of all malignant tumors in childhood with an approximate incidence of one in 30 000 live births. Their rarity and the complexity of surgery, chemotherapy, and radiotherapy in this age group make management complicated and challenging. Immature neonatal metabolism and physiology affect drug absorption and distribution and makes chemotherapy difficult to administer, complex, and challenging. Increasing awareness of the long-term effects of chemotherapy in both older children and neonates and the age-dependent sensitivity of their evolving physiological systems and evolving neural development underscore the need to modify treatment protocols to the particular needs of the neonate. In addition, some tumors such as sacroccygeal teratoma have certain malignant potential in the absence of radical surgery, whereas others such as fibrosarcoma, despite alarming histopathological features behave in a benign way and yet aggressive surgery is clearly not appropriate. In a biological sense, neoplasms such as neuroblastoma may undergo spontaneous resolution, while others may behave as typical neuroblastoma. Benign tumors by virtue of their location may pose a serious threat to survival, e.g. cervical fibrosarcoma may pose a threat to the child's airway and aggressive, urgent surgery is indicated.

GENETICS

The majority of malignant tumors in the neonatal period have significant genetic elements, either inherited or acquired, and multifactorial factors contribute to their development. Single gene mutations and more complex constitutional chromosome anomalies favor the development of neonatal neoplasms. Some are well known, e.g. the association of Down syndrome and leukemia and hepatoblastoma and rhabdomyosarcoma in familial Li–Fraumeni syndrome. Other well-described associations include 11p mutation and nephroblastoma, Wilm's tumor and the Denys–Drash syndrome (11p13 and WT1 mutations) and the T-chromosomal translocation involving the *ETV6* and *NTRK3* genes, which are more common in fibrosarcomas that occur in the neonatal period or earlier infancy and the allelic loss of the 11p15 region in embryonal rhabdomyosarcoma.

Soft-tissue sarcomas are a heterogenous group of tumors that are derived from mesenchymal cells and can therefore differentiate into muscle, fibrous structures, fat, etc. Although by its nature soft-tissue sarcoma is a rare disease in neonates and young infants, it is nevertheless an important differential diagnosis of any infant that presents with an unusual mass or obstruction. Other presentations that are or can be a cause of concern are unusual visceral bleeding or prolapse of the neoplastic mass from vaginal, urethral, or other orifice.

Soft-tissue sarcomas account for approximately 10% of all neonatal tumors and only 2% of all childhood sarcomas. In general, they fall into three different groups:

1. Congenital fibrosarcoma
2. Rhabdomyosarcoma
3. Non-rhabdosarcoma soft-tissue sarcomas.

OVERVIEW AND PRINCIPLES OF MANAGEMENT

It is important to stress that the management of soft-tissue sarcomas in the neonatal period involves significant early input at a multidisciplinary level, including histopathology, oncology, surgical oncology, radiotherapy, radiology, and nursing. Treatment is generally tailored to the needs of the individual patient with the aim of controlling the tumor, while limiting toxicity of therapy. While chemosensitivity and response to radiotherapy varies from patient to patient, it is modified to minimize the severity of myelosuppression and serious infection. In addition, the aggravated late effects of radiotherapy in this population make radiotherapy suitable only as a treatment of last

resort and proportionately greater emphasis is therefore placed on surgical removal. Clearly, histological diagnosis is generally surgical, although in some situations the diagnosis may be made on fine needle aspiration cytology (FNAC). Generally, localized soft-tissue sarcomas are best treated by wide local excision. This treatment option, however, should not be mutilating or interfere with growth and or function. Limited surgical resection (debulking) may be the only appropriate surgical procedure if surgical clearance was considered to be mutilating since chemotherapy may result in more manageable complete surgery after tumor shrinkage.

At presentation, it is important not simply to provide tissue for histological diagnosis, but also accurate tumor staging must be performed. This will include a variety of imaging, such as ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI). These may or may not require sedation or anesthesia. In addition, bone marrow samples are taken to assess metastatic involvement. Pleural effusions may need aspiration or chest drain insertion if symptomatic. Accurate histology and clinical and radiological staging facilitates appropriate chemotherapy.

Histological diagnosis is made from either an open or through cut biopsy or in some cases by FNAC. It is most important that the biopsy is taken by (or following consultation with) the surgical oncologist, who should be ultimately responsible for the surgical care of the patient. An inappropriately sited biopsy site may compromise the subsequent surgical approach and make complete tumor clearance impossible. Essentially, the needle tract or open biopsy tract must be in the line of the ultimate incision for surgical clearance. The essence of biopsy is to secure enough tissue for accurate diagnosis and appropriate biological studies, if necessary. The biopsy, where possible, should minimize tumor spillage and this may be facilitated by the generous use of Hibitane sponges. The use of an argon diathermy may be useful in controlling any local spillage which occurs as a result of the biopsy. If it is possible to resect the tumor primarily, then this is always a superior option provided this does not cause any mutilating effect. Clearly, wide local excision is not considered if there is evidence of metastatic disease. Drains are best avoided if possible. All tissue should be sent fresh to the laboratory.

If complete excision is considered possible, then representative nodal sampling should be included to facilitate accurate staging. Primary excision demands clear margins both clinically and histologically and residual positive margins may indicate the need for a re-excision including the original skin incision and all tissue layers to the site of origin. A reasonable margin of 2 cm or so all around the tumor with en bloc resection should be adequate to ensure that capsular invasion does not compromise the completeness of the margin. It may, at times, be necessary to have frozen section confirmation that margins are negative and if not, then an additional excision should be performed.

SPECIFIC TUMORS

Congenital fibrosarcoma

There are two kinds of fibrosarcoma seen in childhood that share similar histological appearances (but different outcomes). The congenital infantile fibrosarcoma is a well-recognized tumor with a very low tendency to metastasize and an overall excellent cure rate of more than 90%. While more common on the extremities it may also occur on the back, retroperitoneum, head and neck. Spontaneous resolution has been described. The so-called adult-type fibrosarcoma is indistinguishable from the congenital type, but is differentiated on its clinical behavior and age at presentation (occurring more typically in children aged 10–15 years). Histologically, the tumor is composed of spindle-shaped fibroblasts, exhibits variable collagen production and no other differentiation (Fig. 85.1). A recurring translocation (t(12;15)) involving the *ETV6* and *NTRK3* genes has been documented in congenital infantile fibrosarcoma, but not in the 'adult type'. The presence of this translocation may confer a better prognosis. Relapse is common in both types and treatment is aimed at complete excision where possible or staged excision following cytoreduction with vincristine, cyclophosphamide, and actinomycin D. Local recurrence is possible and could be as high as 40%, but does not have an impact on survival as aggressive behavior and metastasis is rare.

Rhabdomyosarcoma

Rhabdomyosarcoma (RMS) is an extremely rare tumor in the neonatal period. The Intergroup Rhabdomyosarcoma Study in 1994 reported on 14 patients with RMS out of a total of 3217 patients. The tumor can develop in any location where mesenchymal tissue other than bone is present and it typically can spread to nodes, lung, and marrow. It arises

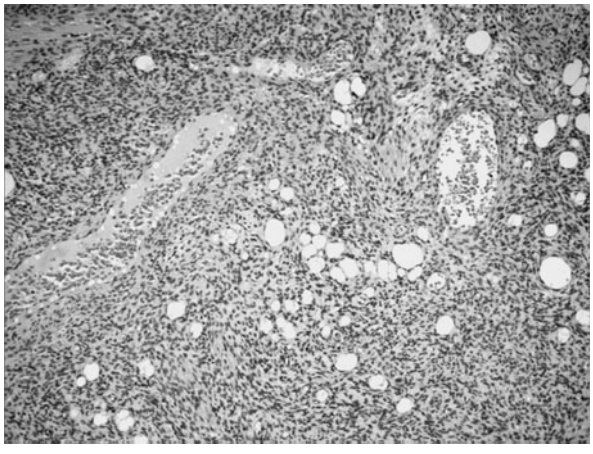

Figure 85.1 Congenital fibrosarcoma. Spindle cell proliferation infiltrating fat (adipocytes are the white blob-like cells) showing 'blood lakes' characteristic of this entity.

from mesenchymal tissue and has a strong tendency towards myogenesis. There is an association with RMS and the Li–Fraumeni syndrome and neurofibromatosis type 1.

There are two different histological subtypes, embryonal and alveolar, which exhibit different clinical outcomes and distinct chromosomal translocations (Fig. 85.2). Embryonal subtype is associated with the allelic loss of the 11p15 region. Histologically, the lesion is marked by degrees of myogenic differentiation that express desmin and muscle-specific actin. However, MyoD and myogenin are the most significant diagnostic markers.

While RMS can occur at any anatomic site, they are most common in the head and neck and genitourinary areas. Approximately 50% of RMS arises in the bladder, vagina, testicular and sacrococcygeal sites, and over 50% of RMS have metastatic disease at presentation, making it an aggressive tumor. Fortunately, the majority of these tumors are of the embryonal type (as distinct from alveolar RMS) and survival with this histology and complete resection is better than 90%. However, with metastatic disease, survival is less than 30%. While prognosis depends on histological characteristics and stage at presentation, it is also dependent on site of the primary lesion, with head and neck RMS (not parameningeal) and genitourinary having better than 90% survival.

Treatment is aimed at complete surgical resection if possible, but adjuvant chemotherapy is necessary in all, even where it appears that surgery has been complete. Chemotherapy includes cyclophosphamide, vincristine, and actinomycin D.

Aggressive surgical resection is not indicated in the presence of non-sterilized metastases or if such surgery would be associated with significant morbidity. Radiotherapy is reserved for loss of local control.

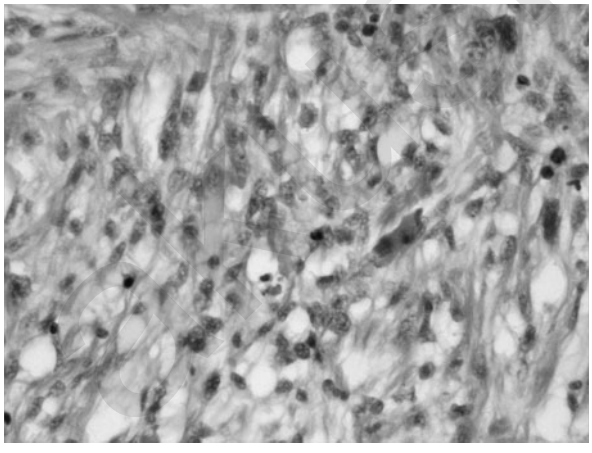

Figure 85.2 Embryonal rhabdomyosarcoma. Spindle cell sarcoma with elongated strap-like cytoplasmic processes and hyperchromatic nuclei showing considerable pleomorphism. The intensely eosinophilic cytoplasm is characteristic of skeletal muscular differentiation.

Non-rhabdomyosarcoma soft tissue sarcomas

These comprise an extremely rare group of neonatal sarcomas and include such entities as malignant mesenchymal sarcoma, primitive sarcoma, angiosarcoma, and rhabdoid sarcoma (Fig. 85.3), tending to arise on the trunk, extremities, and head and neck area. They clearly exhibit marked clinical histologic and biologic heterogenicity and usually present as painless growing mass. Only about 10% will have regional and or distant metastases at presentation. In general, the management of these rare neoplasms reflects that used in the treatment of RMS, with complete wide excision where possible being the mainstay of treatment. Chemosensitivity is less predictable than in RMS and radiotherapy more often needed.

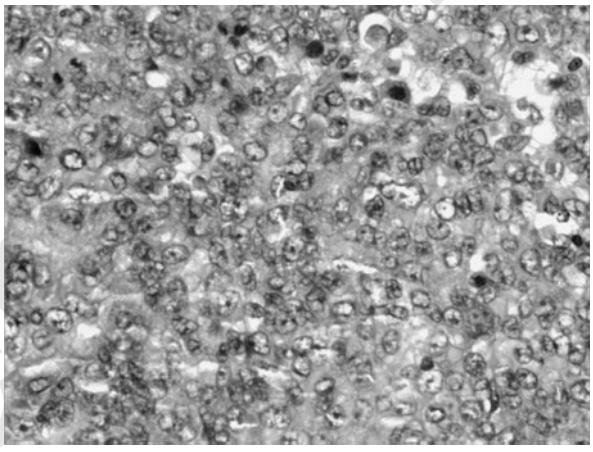

Figure 85.3 Rhabdoid sarcoma. The tumor cells are round with abundant eosinophilic cytoplasm and contain large, vesicular nuclei with prominent micronucleoli. Multiple mitotic figures are evident in the field imaged. The cytoplasm classically shows condensation of intermediate filaments, as seen here, which produces the 'rhabdoid' phenotype.

Hepatic tumors

JAI PRASAD AND MICHAEL P LA QUAGLIA

INTRODUCTION

Benign and malignant liver tumors in infants are being detected perinatally with increasing frequency using ultrasound. The spectrum of such pathologic masses in newborns and infants is different from that in older children (see Fig. 86.1). With advances in the understanding of the biology of these tumors over the last decade, the approach to their treatment has also evolved. This chapter aims to describe the current and evolving approaches to the management of the most common benign and malignant liver tumors occurring in newborns (see Table 86.1).

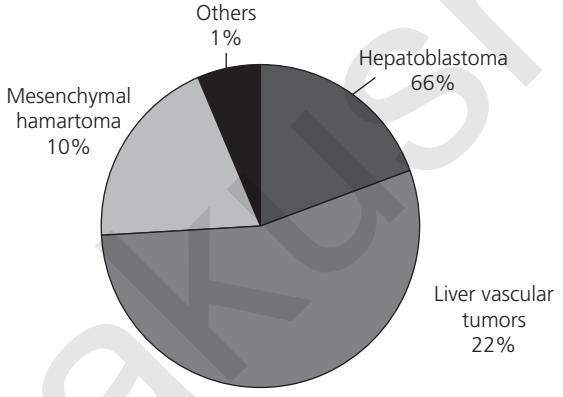

Figure 86.1 Distribution of neonatal liver tumors. Data from von Schweinitz D. Neonatal liver tumours. *Semin Neonatol* 2003; **8**: 403–10.

BENIGN LIVER TUMORS

Hemangiomas

Liver vascular tumors are the most common pediatric tumor, affecting 4–5% of white infants.[1] The exact incidence is difficult to calculate, as a large proportion of these lesions are asymptomatic and detected incidentally. This section describes the current classification, management, and outcomes for hemangiomas.

Table 86.1 Primary pediatric liver tumors.

Age group	Malignant (%)	Benign (%)
Infants, toddlers	Hepatoblastoma (43)	Hemangioma (14)
	Rhabdoid tumors (< 1)	Mesenchymal Hamartoma (6)
	Malignant germ cell tumors (< 1)	Teratoma (< 1)
School age/ adolescents	Hepatocellular carcinoma and transitional cell tumors (23)	Hepatic adenomas (2)
	Sarcomas (7)	Focal nodular hyperplasia (2)

Hemangiomas are benign endothelial cell neoplasms characterized by proliferation of normal or abnormal blood vessels. While most infantile and congenital hemangiomas are cutaneous, liver lesions are fairly common.[2] Both visceral and cutaneous hemangiomas exhibit similar biologic behavior. Despite a landmark paper by Mulliken and Glowacki[3] that grouped vascular birthmarks into two major categories, hemangiomas and malformations, clinicians and pathologists do not agree about the descriptions of vascular lesions in the liver, using the term 'infantile hemangioma' interchangeably and inclusively for true hemangiomas, arteriovenous malformations, and hemangioendotheliomas.

TUMOR BIOLOGY

Infantile hemangiomas (also referred to in the literature as 'infantile hepatic hemangioendotheliomas') typically present

shortly after birth and are characterized by a rapid proliferation of capillaries in the first year of life (proliferative phase), followed by a gradual, inevitable regression of the tumor over one to five years (involuting phase), and continual improvement until resolution and replacement of the tumor with fibrofatty tissue (involuted phase). Histologically, in the proliferative phase, they are observed to have endothelial hyperplasia with incorporation of H-thymidine and large numbers of mast cells.[4] This phase is defined by high expression of proliferating cell nuclear antigen, type IV collagenase, and vascular endothelial growth factor. High expression of tissue inhibitor of metalloproteinase, TIMP-1, an inhibitor of new blood vessel formation, is found exclusively in the involuting phase.[5] In contrast, vascular malformations do not express any of these biologic markers or show signs of spontaneous regression, instead continuing to grow with the child.

Glucose transporter 1 (GLUT1) immunoreactivity is found in virtually all hemangiomas, except for a subgroup of solitary liver hemangiomas that shares characteristics with a recently described group of cutaneous hemangiomas called the 'rapidly involuting cutaneous hemangioma' (RICH). Vascular malformations do not express GLUT1.[6,7] Mutations in the *VHL* tumor suppressor gene in a family with pheochromocytomas and hepatic hemangiomas have recently been described.[8]

CLASSIFICATION

Hepatic hemangiomas in infancy and childhood have been widely referred to as 'hemangioendotheliomas' and divided into types 1 and 2. However, this term is misleading, as their behavior is different from epitheloid hemangioendotheliomas (with metastatic potential) and Kaposiform hemangioendotheliomas (associated with the Kasabach–Merritt phenomenon[9]), both of which are true neoplasms showing no signs of spontaneous regression.

The International Society for the Study of Vascular Anomalies (ISSVA) settled that cutaneous vascular tumors should be classified into two categories: hemangiomas (GLUT1-positive) and a heterogenous group of anomalies represented by vascular malformations (GLUT1-negative).[3,9] Drawing parallels from this, Mo *et al.* have suggested two groups for hepatic vascular tumors: hepatic infantile hemangiomas (GLUT1-positive and typically multiple, but may be focal) and hepatic vascular malformations with capillary proliferation (GLUT1-negative, solitary masses).[7]

Christison-Lagay *et al.*[1] and Dickie *et al.*[10] have proposed classifying hemangiomas based on imaging characteristics. Three types of lesions have been described: focal, multifocal, and diffuse (see Fig. 86.2a–c). Focal lesions are solitary and are usually GLUT1-negative. Multifocal lesions are discrete hypodense lesions with intervening normal hepatic parenchyma. Diffuse hepatic hemangiomas present with extensive hepatic involvement and near-total replacement of the hepatic parenchyma with innumerable lesions. Both multifocal and diffuse lesions are GLUT1-positive. Some authors have proposed that a subgroup of GLUT1-indeterminate or negative solitary hepatic vascular tumors may exhibit behavior and immunohistochemical characteristics similar to those of the RICH.[1,11,12] Table 86.2 presents the currently accepted ISSVA classification for vascular anomalies.

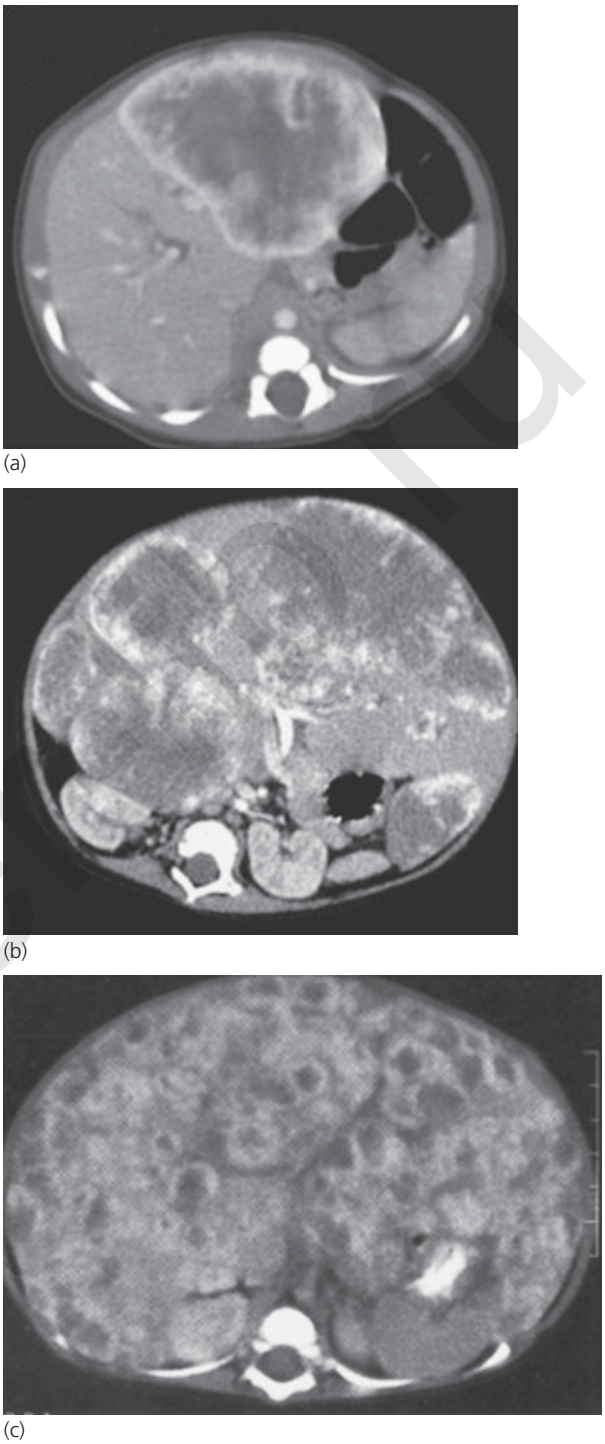

Figure 86.2 (a) Solitary infantile hepatic hemangioma; (b) multifocal hepatic infantile hemangioma; (c) diffuse infantile hepatic hemangioma. Reprinted from Meyers RL. Tumors of the liver in children. *Surg Oncol* 2007; **16**: 195–203. Copyright Elsevier.

Table 86.2 Vascular anomalies: International Society for the Study of Vascular Anomalies classification.

Vascular tumors	Vascular malformations
Infantile hemangioma	Slow flow vascular malformations:
Congenital hemangioma (RICH and NICH)	Capillary malformation
Tufted angioma	Port-wine stain
Kaposiform hemangioendothelioma	Telangiectasia
Spindle-cell hemangioendothelioma	Angiokeratoma
Other, rare hemangioendotheliomas (epitheloid, composite, retiform, etc.)	Venous malformation
Dermatologic acquired vascular tumors (pyogenic granuloma, targetoid hemangioma, etc.)	Lymphatic malformation
	Fast flow vascular malformations:
	Arterial malformation
	Arteriovenous fistula
	Arteriovenous malformation
	Complex combined malformations:
	CVM, CLM, LVM, CLVM, AVM-LM, CM-AVM

AV, arteriovenous; C, capillary; L, lymphatic; M, malformation; NICH, non-involuting congenital hemangioma; RICH, rapidly involuting congenital hemangioma; V, venous.

CLINICAL PRESENTATION

Clinical presentations of the various lesions described above overlap considerably. Infantile hepatic hemangiomas are frequently associated with cutaneous hemangiomas, the incidence of liver lesions being higher with multiple or large skin lesions.[2] Most liver hemangiomas may be clinically silent and escape detection. Some, however, remain asymptomatic and are discovered on routine prenatal or postnatal imaging performed for unrelated reasons. The most common presenting features are an abdominal mass, hepatomegaly, and anemia. Patients with large tumors can be critically ill at presentation with congestive heart failure (CHF), inferior vena cava compression, respiratory distress, and even abdominal compartment syndrome and multiorgan failure. Hypothyroidism may be present due to type III iodothyronine deiodinase activity in the liver hemangioma and may contribute to CHF. It is more common in the diffuse type, but has been noted in multifocal and large solitary hemangiomas. Screening with thyroid function tests at presentation is, therefore, advisable. Rarely, hemorrhagic shock with or without disseminated intravascular coagulation may follow a rupture of the lesion. Rupture can be precipitated by percutaneous needle biopsy.

INVESTIGATIONS

No serum marker is clinically useful for diagnosis, although elevations in alpha-fetoprotein (AFP) concentration have been reported.[13–15] These elevations are usually mild and call into question the importance of differentiating larger lesions from hepatoblastoma.

Liver hemangiomas are generally diagnosed using multi-detector-row computed tomography (CT) and magnetic resonance imaging (MRI) with contrast enhancement. These lesions are hypodense on CT scanning with centripetal (outside-in) enhancement. On MRI, they are hypointense on T_1- and hyperintense on T_2-weighted sequences. Imaging criteria used in the diagnosis include nodular peripheral enhancement followed by centripetal fill-in, change to isodensity on CT, or isointensity on MRI with the blood vessels and a complete fill-in in the late phase on contrast-enhanced images.

Contrast-enhanced ultrasonography (CEUS) is being increasingly used as the first-line imaging modality in the characterization of liver lesions.[16,17] The nodular peripheral enhancement expanding centrally is also seen with CEUS. This may offer a diagnostic advantage over CT and MRI in view of the low rate of adverse reactions from the microbubble contrast, allowing for multiple injections and assessments and its use in patients with decreased renal function.[17–19]

Angiography has been declining as a diagnostic modality in vascular anomalies of the liver. Endovascular modalities are now used to outline the vasculature of tumors in a subgroup of infants who present with high-output cardiac failure for whom a high-flow shunt amenable to embolization is suspected.

Infantile hemangiomas must be distinguished from epithelioid hemangioendothelioma, an intermediate-grade neoplasm that has the potential to metastasize. This is a tumor seen mostly in adults and rarely in older children.[20–22] It has not been reported in newborns. It consists of multifocal and confluent masses of homogenous liver nodules with peripheral enhancement. Treatment usually involves liver resection or transplantation.

MANAGEMENT

Asymptomatic focal lesions do not need treatment and may be followed with serial ultrasound examinations until resolution. This can be every one to two months until the lesion is stable, after which scans can be performed two to three times a year until involution is demonstrated. If there are signs of asymptomatic shunts, a closer follow-up schedule can be implemented. Multifocal lesions have a similar natural history to that of focal lesions and can be similarly observed. Patients with focal lesions or multifocal lesions large enough to cause shunts leading to CHF should undergo a careful assessment and work-up in an intensive care unit with electrocardiography, echocardiogram, and thyroid function tests. Congestive heart failure should be managed in consultation with a pediatric cardiologist. Diffuse liver lesions are the most difficult subgroup to manage. In addition to the

above, an early consultation with the transplant team should be considered for patients whose disease progresses despite medical management.

CORTICOSTEROIDS

Glucocorticoids at varying doses have been used for many decades as the first line of treatment for cutaneous and hepatic hemangiomas. A possible mechanism is the negative effect of steroids on angiogenesis. Administration of 2–5 mg/kg of oral prednisolone or an i.v. equivalent is commenced for patients with hemodynamically significant shunts or signs of CHF. Response rates in the literature vary, with good responses ranging from 30 to 75% for multifocal and diffuse disease.[1,23] Steroids may also be indicated for co-existing cutaneous lesions that may-threaten vision (e.g. eyelids) or be life-threatening (e.g. paratracheal or pharyngeal lesions). Lesions have been reported to stabilize between two and four months. The duration of therapy is guided by serial imaging and generally ranges from five to eight months.[1,10,23]

CHEMOTHERAPEUTIC AGENTS

Interferon-alpha has been used in corticosteroid-unresponsive cases with promising results. In a report by Ezekowitz *et al.*,[24] liver hemangiomas regressed by 50% or more in 18 of 20 patients receiving interferon alpha-2a (up to 3 million units/m^2 body surface area) after an average of 7.8 months with no long-term adverse effects. However, its use has been guarded since 6.1% of children younger than one year experienced spastic diplegia and motor developmental disturbances after receiving interferon.[24,25]

Vincristine is a mitotic inhibitor that inhibits the formation of tubulin microfibrils and arrests mitosis in the metaphase. It has been used in steroid-resistant, life-threatening hemangiomas at a dose of 1–2 mg/m^2. The high content of tubulin in the endothelial cells of hemangiomas makes this tumor particularly sensitive to vincristine.[26,27]

ENDOVASCULAR INTERVENTIONS

Use of angiography and embolization of arteriovenous shunts, although not curative, can provide major symptomatic relief from the hemodynamic effects of high-flow shunts in hemangiomas. Hemangiomas can derive collaterals from any of the hepatic, phrenic, intercostal, superior mesenteric, or adrenal arteries. It has been indicated primarily for CHF refractory to medical management, steroids, or additional chemotherapy. It has also been employed to shrink large hemangiomas, symptomatic by the mass effect causing caval compression or abdominal compartment syndrome. An angiographic classification has been proposed based on the number of lesions: flow characteristics (high versus low); presence; type of shunt (arteriovenous, arterioportal, or portovenous); and major anomalies of hepatic vessels (particularly venous varices).[28] The best response to embolization is found in patients with macroscopically visible shunts on angiography associated with single or multifocal lesions. Hemangiomas with extensive portal venous supply are more difficult to treat and may require multiple embolizations.[28] There is a risk of fatal hepatic necrosis after hepatic arterial embolization. The expertise required to perform and interpret angiography in this group of infants is generally found only in highly specialized referral centers.

SURGERY

Liver resections for hemangiomas have declined with better understanding of the biologic behavior of these tumors, improvements in pharmacotherapy, advances in endovascular techniques, and better pediatric intensive care. Recent reports have argued for surgery to be a last recourse after pharmacotherapy for the tumor, medical management of CHF, and endovascular interventions have all failed to achieve symptomatic control and tumor regression.[10,28,29] Kassarjian *et al.*[28] reported a series of 15 patients managed with endovascular interventions with one death in a patient who had diffuse liver hemangioma, severe CHF, and hypothyroidism. Dickie *et al.*[10] reported a series of 16 patients with no mortality and only two patients who required surgery (a left lobectomy and an orthoptic liver transplant). In contrast, Moon *et al.*[23] employed hepatic resection as a primary treatment modality for solitary, resectable, and symptomatic lesions. They used hepatic artery embolization as a second line of treatment, with one death from postoperative hemorrhage among nine patients who underwent surgery. Surgery and open biopsy are also indicated when a distinction cannot be made between a hepatoblastoma and a hemangioma.

LIVER TRANSPLANTATION

A small number of patients with diffuse hepatic lesions replacing most of the hepatic parenchyma develop life-threatening complications, including CHF, consumptive coagulopathy, abdominal compartment syndrome, and multiorgan failure. Because these patients may be those most likely to benefit from liver transplantation, early involvement of the transplant team has been advocated if there is a poor response to initial pharmacotherapy.[1] Embolization, even in the context of diffuse lesions, has been shown to prevent transplant.[29] The outcome following transplantation is varied, although some authors report good outcomes.[30–32]

FUTURE DIRECTIONS

The classification and treatment of hepatic hemangiomas will continue to evolve. Prospective characterization of patients will further the understanding of these uncommon tumors. While there is reasonable concordance about classification of GLUT1-positive multifocal or diffuse liver lesions, there remains a lacuna in the biologic, clinical, and radiologic characterization of certain solitary liver vascular tumors. The Children's Hospital Boston has proposed and created a worldwide web-based registry for longitudinal accrual of patients with liver hemangiomas.[1]

Anti-angiogenic drugs show potential in the treatment of liver hemangiomas. Bevacizumab, a recombinant monoclonal

antibody against vascular endothelial growth factor, was incidentally found to reduce the size of liver lesions significantly in a patient with colorectal adenocarcinoma initially suspected to be metastases, but later found on biopsy to be hemangiomas.[33] A similarly dramatic response was seen in a 41-year-old patient with pulmonary epitheloid hemangioendothelioma.[34] No trials of bevacizumab have yet been conducted in children or infants with hemangiomas, although a recent phase I trial in children 1–21 years with various solid tumors indicates that it is tolerated well in children.[35]

Recent reports have documented propranolol to be effective at reducing the size of hemangiomas. These reports show that fairly modest doses (3 mg/kg per day) of propranolol reduce the size of infantile hepatic hemangiomas. Indeed, propranolol has been suggested as a first-line therapy for high-risk hemangiomas.[36,37] A two-month-old infant with diffuse hepatic hemangioma with near-total replacement of the liver parenchyma had a dramatic response to propranolol at 2 mg/kg per day, after corticosteroids and vincristine had failed.[38] Possible mechanisms postulated are vasoconstriction, decreased expression of vascular endothelial growth factor, and apoptosis of capillary endothelial cells.

Mesenchymal hamartoma of the liver

Mesenchymal hamartomas (MHL) usually present as solitary hepatic lesions and are the second most common benign liver tumor after hemangiomas in newborns. They accounted for 6% of pediatric liver tumors in a series of patients compiled by Weinberg and Finegold in 1983.[39] The understanding of the biology of this tumor has evolved greatly since it was definitively described in 1956 by Edmondson.[40] More than two-thirds are diagnosed in children less than one year of age, although rarely can they be detected in adults.[41] A systematic review of the literature found that 85% of children presented before the age of three and that the tumor was slightly more common in boys.[42] Mesenchymal hamartomas must be distinguished from other congenital and infective cystic diseases, hemangiomas, and other liver tumors.

PATHOLOGY AND PATHOGENESIS

Right lobe tumors are three times more common than left, and 10–20% can be pedunculated. A small proportion of cases may involve both lobes.[42,43] Mesenchymal hamartomas usually contain both cystic and solid components, the proportion of which varies. Tumors can be very large, up to 20–30 cm in diameter and weighing up to 3 kg. The majority (about 50%) are multicystic, with the intervening myxoid stroma containing fibroblasts, blood vessels and lymphatics, collagen, bile ductules, and islands of hepatocytes. Less commonly, the cysts can be very small and sometimes absent, resulting in a predominantly solid tumor.[44,45] The cystic spaces are filled with a clear or mucoid liquid and may or may not be lined by epithelium, the latter seen more often in larger cysts. Mesenchymal hamartomas are usually well circumscribed and are surrounded by a rim of compressed hepatic parenchyma, but are devoid of a true capsule.[42] There have been a few reports of multifocal MHL. Small satellite lesions at the margins of the tumor have been described and may explain recurrent disease after excision of the main tumor.[46]

The pathogenesis of this tumor is not clearly defined. The prevailing opinion is that these tumors are developmental aberrations that arise from ductal plate malformations from the primitive mesenchyme late in the course of embryogenesis, trapping islands of hepatocytes and dysplastic bile ducts within their structure.[44] Some investigators have argued that they may be true neoplasms. The histopathologic and immunohistochemical similarities between undifferentiated embryonal sarcoma (UES) of the liver and MHL can be striking. It has been postulated that UES – with its onset in older children, benign bile ductular elements within a malignant mesenchyme, its predisposition to the right lobe, and occasional pedunculation – may be preceded by an MHL.[47,48] Several reports describe cases of UES arising within a previous MHL, two of which occurred after incomplete excision. Aneuploidy has been detected by flow cytometry in two out of eight MHLs in one study.[48] Cytogenetic abnormalities involving the same breakpoint on chromosome 19 (band 19q13.4) have now been reported in nine cases; three of which involved a UES originating within an MHL.[49–52] These karyotypic and cytogenetic abnormalities in at least some MHLs may indicate a clonal defect.

CLINICAL PRESENTATION

Mesenchymal hamartomas present most commonly as abdominal distention or an upper abdominal mass. Large tumors can cause respiratory distress or compression of the inferior vena cava with distended superficial abdominal veins or lower limb edema. Abdominal pain is unusual in children, but more common in adults. Examination reveals a large, smooth, non-tender mass in the upper abdomen. The tumor can be detected on prenatal ultrasound and may cause fetal hydrops, polyhydramnios, and fetal demise.[53,54] Case reports of MHL describe presentation with obstructive jaundice, vascular steal phenomenon, high-output cardiac failure, and perinatal tumor rupture in the newborn.

INVESTIGATIONS

Liver function tests are usually normal. Alpha-fetoprotein concentrations may be moderately elevated. Levels return to normal after tumor removal, but may take up to a year due to liver regeneration. Thus, MHL should be distinguished from hepatoblastoma and may require biopsy.

A CT or ultrasound examination is diagnostic in most patients. The typical finding of a multiseptate cystic tumor with distinct margins is rarely seen in other pediatric tumors and is diagnostic of an MHL. The cystic areas appear hypodense and hypovascular on imaging. Solid areas (within mixed solid-cystic or predominantly solid tumors), septae, and peripheral areas may show heterogenous enhancement

after i.v. contrast on CT.[45,55] The differential diagnosis in totally solid tumors in newborns and infants should include various hepatic tumors, such as hepatoblastoma, hepatocellular carcinoma, and hemangiomas.

On MRI, lesions typically have a low intensity on T_1-weighted sequences, but have variable signal intensity on T_2-weighted sequences. When diagnosis is in doubt, the pathology is usually confirmed after resection of the tumor or by an open or percutaneous tumor biopsy (see Fig. 86.3a,b).

TREATMENT

Mesenchymal hamartoma of the liver is best treated by anatomic resection of the involved liver segments. While the tumors themselves are not very vascular, the surrounding compressed hepatic parenchyma can be very vascular. However, in the rare case that a tumor is too large for an anatomic resection, enucleation can be performed. The tumor mesenchyme sharply demarcates the surrounding compressed hepatic parenchyma, allowing for this approach. However, incomplete excision and marsupialization result in a high rate of recurrent disease and are best avoided.[56]

Variable degrees of spontaneous regression have been noted. A systematic review of the literature by Stringer and Alizai[42] found nine such cases, four of which had a prominent vascular component. None, however, regressed completely, and the follow-up time in all was under three years. In view of the association between UES and MHL, the safety of this approach cannot be determined without long-term follow up.[42]

In the very rare case, a liver transplantation may be an option for recurrent or unresectable MHL. The United Network for Organ Sharing group reported two cases of transplants performed in children who had progressive liver failure after resection of MHL, one of whom died from postoperative bleeding. A third case was reported of a newborn girl who developed a diffuse hemangioma of the liver remnant four months after a resection for MHL.[22,57,58]

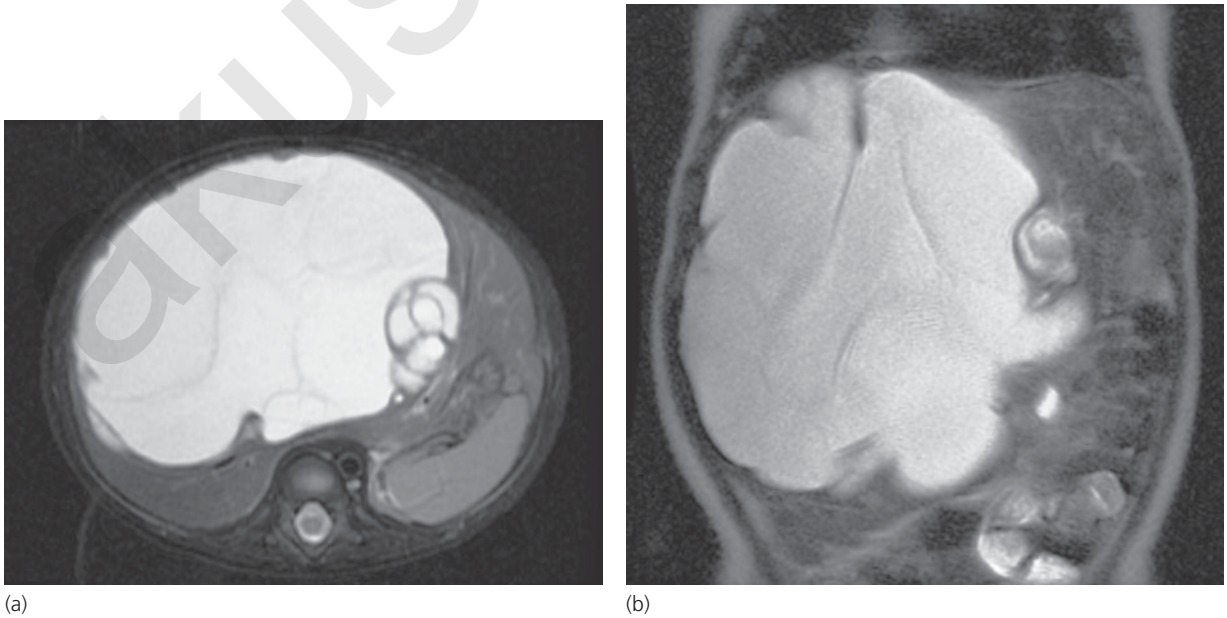
MALIGNANT LIVER TUMORS

Hepatoblastoma

The incidence rates for primary liver cancer, as published by the Surveillance, Epidemiology and End Results (SEER) program of the National Cancer Institute in Bethesda, MD, USA, are 5 per million in the 0–4 age group and 1 per million in the 5–9, 10–14, and 14–19 age groups. The incidence of hepatoblastomas in infants less than one year of age was 11.9 per million.[59] Five percent of all cancers and more than 95% of all hepatic cancers in this age group are hepatoblastomas. In the Pediatric Oncology Group series, 11% of hepatoblastomas occurred in the first six months of life. Of these, 50% were congenital, as evinced by their size at the time of diagnosis, usually at two to three months.[60] Hepatoblastomas accounted for 1% of all liver and bile duct tumors diagnosed in the United States between 2002 and 2006.

The Children's Tumor Registry in Manchester, UK, reported that the incidence of hepatoblastomas increased from 0.4 to 1.0 per million between 1971 and 1983. SEER reports an average annual increase of 5.2% from 1973 to 1992.[61] This may be due to the increase in survival of premature low- and very-low-birth-weight infants, a factor that has been associated with hepatoblastomas.[62–64]

Evidence for genetic or epigenetic origins of hepatoblastoma comes from its strong association with familial adenomatous polyposis (FAP), Gardner's syndrome, and Beckwith–Wiedemann Syndrome.[65] The risk of hepatoblastoma rises 1000–2000-fold in children with this family



(a) (b)

Figure 86.3 T_2-weighted magnetic resonance image of a large mesenchymal hamartoma showing a multiseptate cystic tumor. The patient underwent enucleation of the tumor. (a) Axial view, (b) coronal view.

history.[66–69] The risk of hepatoblastoma in patients with FAP is around 1%.

HISTOLOGY

Hepatoblastomas usually occur as a solitary mass in the liver, but are occasionally multicentric. Rarely is the tumor composed solely of one cell type. In a review of cases for the Pediatric Oncology Group, 5% were small cell undifferentiated and 7% were of the pure well-differentiated fetal type. The rest of the tumors were a mixture of diverse epithelial cell types in varying proportions. For this reason, both fine needle aspiration and needle biopsies may sample a non-representative section of the tumor. Among all cases, 85–90% contain both fetal and embryonal cells and 20% may have stromal components.[60]

The small cell type is particularly aggressive, especially when present in a significant portion of the hepatoblastoma (75% or so) as the sole cell type. This histology is more common in neonates and infants. AFP levels may not be raised.[70] It has a poor prognosis due to lack of response to current therapy. The significance of smaller proportions of small cells is not yet known. Occasionally, rhabdoid cell types are found intermixed with small cells. The rhabdoid tumor cells as an exclusive cell type are rare and probably represent a biologically different tumor (see below under Malignant rhabdoid tumors). The presence of mixed histologic features has no prognostic significance. In current Children's Oncology Group (COG) hepatoblastoma treatment protocols (see Table 86.3), tumors with pure fetal histology are designated as favorable histology; all other tumors are classified as unfavorable (see Fig. 86.4a–c).

Table 86.3 Classification of hepatoblastomas.

Major categories	Small cell, undifferentiated
Epithelial	Rhabdoid
Fetal, well-differentiated (mitotically inactive with minimal mitotic rate of $\leq$2 mitoses per 10, $\times$40 objective fields)	Mixed stroma having osteoid features; rarely striated muscle, cartilage, or minor components as follows:
Fetal, mitotically active ($>$2 mitoses per 10, $\times$40 objective fields)	Cholangioblastic (ductal)
Embryonal	Intestinal glandular epithelium (teratoid)
Macrotrabecular	Neuroid-melanocytic (teratoid)
	Rhabdomyoblastic
	Chondroid
	Blastemal

GENETIC CHANGES

Hepatoblastoma is tightly linked to excessive Wnt/beta-catenin signaling. There is a high rate (50–90%) of mutations found in *CTNNB1,* which encodes β-catenin, placing hepatoblastoma among the most common human tumors with constitutive activation of β-catenin/Tcf signaling.[71–73] *APC* gene (involved in degradation of β-catenin) mutations have been characterized regularly in kindred of FAP and in a variable number of sporadic hepatoblastomas.

Cairo *et al.*[74] reported two major molecular subclasses of hepatoblastomas that evoke early and late phases of prenatal liver development. Using a 16-gene signature that correlated with the phase of liver development, they established a tight correlation between the stage of hepatic differentiation and clinical behavior – notably vascular invasion, metastatic spread, and patient survival. This demonstrated strong prognostic relevance compared to clinical criteria (tumor stage and predominant histotype) on multivariate analysis. Also, *Myc* repression in hepatoblastoma cell lines with constitutively activated β-catenin impaired tumorigenesis, suggesting that *Myc* genes may be the main effectors of the oncogenic Wnt/β-catenin pathway in aggressive hepatoblastomas.[74]

Other molecular mechanisms implicated in the growth of hepatoblastomas include the overexpression of insulin-like growth factor-I[75,76] and downregulation of a novel tumor suppressor gene, *RASSF1A*, by promoter methylation.[77,78] Methylation of the *RASSF1A*, gene was an independent risk factor on multivariate analysis. Upregulation of the *MAPK* pathway has also been noted in aggressive hepatoblastomas with a small cell component.[79]

Cytogenetic studies in HB have shown recurring patterns of chromosomal abnormalities. The most common involve trisomies, particularly of chromosomes 2, 8, and 20. Translocations involving chromosomes 1, more specifically bands 1q12–21, have been described as a recurring translocation in hepatoblastoma and were found in 20 of 55 patients in a series of hepatoblastomas.[80]

CLINICAL FINDINGS

The majority of infants with hepatoblastoma present with an asymptomatic abdominal mass noticed incidentally by a family member or a pediatrician. An array of non-specific symptoms, such as abdominal pain, fever, irritability, weight loss, or gastrointestinal disturbances, may occur in a small percentage of patients, especially those with advanced disease. Clinical examination usually shows an expansile solitary mass in the liver. Thrombocytosis, with the platelet count ranging in the millions, is a well- known, albeit uncommon, feature of hepatoblastoma. Thrombopoietin production by the tumor has been proposed as possible cause of the thrombocytosis.[81,82] Hormone elevations that lead rarely to symptoms are due to human beta-chorionic gonadotropin, testosterone, adrenocorticotrophic hormone, or parathormone-related peptide.[83,84]

The AFP level is markedly elevated in more than 90% of patients with hepatoblastoma, in whom it is used as diagnostic tool and as a tumor marker to monitor therapeutic response. The half-life of AFP in the first month of life is 5–6 days, increasing to approximately 42 days by six

months of age. Levels in preterm babies (earlier than 37 weeks' gestation) are significantly higher with a negative correlation between gestational age and AFP levels.[85] AFP levels are usually less than 10 ng/mL by one year of age, although persistent elevations, especially in preterm babies without any known associated factors, have been observed (see Table 86.4).

Table 86.4 Physiologic alpha-fetoprotein level.

Age	Mean ± SD (ng/mL)
Premature	134 734 ± 41 444
Newborn	48 406 ± 34 718
Newborn to 2 weeks	33 113 ± 32 503
Newborn to 1 month	9452 ± 12 610
2 months	323 ± 278
3 months	88 ± 87
4 months	74 ± 56
5 months	46.5 ± 19
6 months	12.5 ± 9.8
7 months	9.7 ± 7.1
8 months	8.5 ± 5.5

IMAGING

An abdominal CT (with and without contrast) or MRI and magnetic resonance angiogram (MRA) can be performed at presentation, according to the local practice. A Doppler ultrasound (if an MRA has not been performed) will define any involvement of the portal or hepatic veins and inferior vena cava. It can be difficult to distinguish direct involvement of the veins from external compression.

A CT scan of the chest (without contrast) and a posteriolateral chest x-ray should be performed on all patients with a primary liver tumor. Technetium-99m methylene-diphosphonate nuclear bone scintigraphy is not routinely recommended due to the rarity of bone metastasis in hepatoblastomas and is performed only if there is clinical suspicion.[86] The role of positron emission tomography has not been evaluated in hepatoblastomas. A small series showed fluorodeoxyglucose uptake in the primary tumor; however, larger studies need to confirm such findings and outline a

role for this modality.[87] As resection of the primary tumor is essential for survival, liver imaging must define the segmental involvement of the liver and associated vasculature, both of which are indicators of resectability (see Fig. 86.5a,b).

(b)

Figure 86.5 Focal and multifocal hepatoblastoma. (a) Focal hepatoblastoma involving the left lobe of the liver; (b) multifocal hepatoblastoma with largest lesion involving the left lobe with multiple satellite tumors in segments IV, V, and VIII. This patient underwent an extended left hepatectomy.

STAGING

The COG employs a staging scheme after applying the results of surgery (resection or biopsy) (see Table 86.5). Risk stratification in the current COG hepatoblastoma protocol is based on the predominant tumor histology, presence of gross residual disease, distant metastasis, and the presence or absence of a low AFP level (< 100 ng/mL) at diagnosis (see Fig. 86.7).

The Liver Tumor Strategy Group (SIOPEL 1) of the International Society of Pediatric Oncology (SIOP) introduced the PRETEXT (*Pre*treatment *Ext*ent of disease) system of staging liver tumors.[88,89] PRETEXT designates the following sections in the liver: (1) left lateral (Couinaud 2 and 3); (2) left medial (Couinaud 4); (3) right anterior (Couinaud 5 and 8); and (4) right posterior (Couinaud 6 and 7) (see Fig. 86.6). Risk stratification in PRETEXT is based on the number of contiguous tumor-free regions of the liver and

Table 86.5 The Children's Oncology Group staging system.

Stage	
I	Complete gross resection at diagnosis with clear margins, pure fetal histology (PFH) and unfavorable histology (all histology, except PFH)
II	Complete gross resection at diagnosis with microscopic residual disease
III	Biopsy only at diagnosis; or gross total resection with nodal involvement; or preoperative tumor spill/rupture
IV	Distant metastatic disease at diagnosis

the involvement of the caudate lobe; invasion of the vena cava or all three major hepatic veins; portal vein involvement; contiguous extrahepatic growth; tumor rupture or hemorrhage; and distant metastasis denoted by the letters 'C', 'V', 'P', 'E', 'H', and 'M', respectively (see Table 86.6). PRETEXT stage has been shown to be an independent predictor of five-year overall survival.[89]

In addition to small cell undifferentiated histology, the presence of a low AFP level (< 100 ng/mL) at diagnosis has been shown to be an independent predictor of a poor outcome. This fact likely indicates a more undifferentiated tumor and is more common in infants and newborns.[90,91]

The PRETEXT system has recently been validated by the COG, and future trials within the COG will use the PRETEXT staging system as an objective tool to monitor the effect of neoadjuvant chemotherapy and to determine the timing and extent of surgical resection.[92] It is hoped that this tool will allow better intergroup collaboration in the development of new therapeutic strategies for the highest-risk groups that continue to have a poor response to current treatment approaches.

TREATMENT

The treatment of hepatoblastomas is a success story in pediatric oncology. Overall survival has increased from 30 to 70% in the last 30 years.[93] Overall survival by COG stage I (with pure fetal histology), stage I (with unfavorable fetal histology), stage II, stage III, and stage IV is 100, 97.5, 100,

Table 86.6 PRETEXT number and its meaning.

PRETEXT No.	Definition
I	One section is involved and three adjoining sections are free
II	One or two sections are involved, but two adjoining sections are free
III	Two or three sections are involved, and no two adjoining sections are free
IV	All four sections are involved
Standard risk (SR-HB)	PRETEXT I–III, V-, E-, P-, M-, H-
High risk (HR-HB)	PRETEXT IV, V+, E+, P+, H+, M+, or AFP <100 ng/mL

E, extrahepatic disease; H, tumor rupture or intraperitoneal hemorrhage; M, distant metastases; P, portal vein involvement; V, involvement of the IVC and/or major hepatic veins.

70.2, and 39.3%, respectively.[92] The advent of 'platinum'-based chemotherapy protocols, along with advancements in surgical techniques, have spurred this progress. Various collaborative groups have researched and developed successful treatment strategies for hepatoblastomas.

Active agents against hepatoblastoma are cisplatin, 5-fluorouracil, vincristine, doxorubicin, ifosfamide, and irinotecan. The standard chemotherapy regimen in SIOPEL is cisplatin and doxorubicin. This is being evaluated against cisplatin monotherapy in standard-risk hepatoblastoma in the SIOPEL-3 trial (see Table 86.6). High-risk hepatoblastoma (HR-HB) patients are randomized to receive a more dose-intensified therapy with cisplatin, carboplatin, and doxorubicin than the HR-HB arm of SIOPEL-3 in the new SIOPEL-4 protocol.[94]

The COG uses C5FV as the standard chemotherapy regimen for low- and intermediate-risk tumors. The addition of doxorubicin to cisplatin offered no survival advantage for low-risk (COG stage I or II) tumors and was associated with increased incidence of adverse events. However, an improved event-free survival was noted in patients receiving cisplatin-doxorubicin compared with C5FV for stage III and IV patients.[93,95] The current COG study (AHEP-0731) randomizes intermediate-risk hepatoblastoma to cisplatin, 5-fluorouracil, vincristine, and doxorubicin against standard therapy. The use of irinotecan as window therapy for high-risk hepatoblastoma is also being evaluated for stage IV hepatoblastoma, for which outcome on current therapy continues to be dismal (see Fig. 86.7).

The key difference in approach between the COG and SIOPEL is the timing of surgery and the use of neoadjuvant chemotherapy. The COG's approach has been to primarily resect tumors when possible, then to administer adjuvant chemotherapy for tumors with histologies other than pure fetal histology. Neoadjuvant chemotherapy after open or percutaneous needle biopsy is given to infants who present with an unresectable tumor. The SIOPEL approach has been to treat all patients diagnosed with hepatoblastoma (based on imaging and image-guided percutaneous needle biopsy) with neoadjuvant chemotherapy. They have argued towards less extensive surgical resections and shown operations to be easier and safer in pretreated tumors. Biopsy of the tumor, as is a prerequisite for such an approach, has also been found to be technically safe with a very low risk of tumor spread.[96]

The timing of surgery after induction therapy is another consideration. The current COG and SIOPEL protocols recommend an assessment for resection after two cycles of chemotherapy followed by two further cycles if the tumor is unresectable. A recent study found no statistically significant decline in tumor volume after the second cycle of chemotherapy.[97] These findings were similar to those of a previous study from our institution on pediatric solid tumors that included three hepatoblastomas.[98] This may have implications for reduced toxicities with shorter regimens and early referral for transplant in the absence of a chemotherapeutic response.

For multifocal, PRETEXT IV tumors, liver transplant has emerged as a viable option. Six-year tumor-free survival of

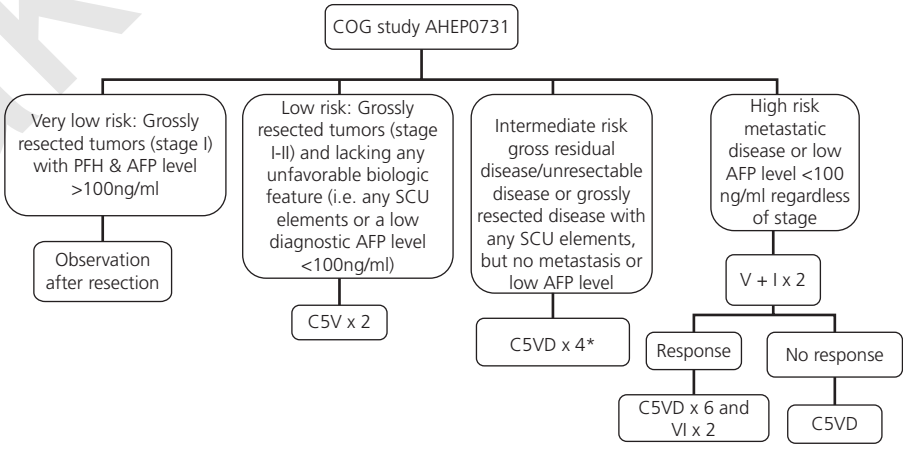

Figure 86.7 Children's Oncology Group hepatoblastoma current study: COG AHEP0731. Adapted from Otte JB. Progress in the surgical treatment of malignant liver tumors in children. *Cancer Treat Rev* 2010; **36**: 260–71. Copyright Wolters Kluwer Health.

82% was achieved with primary liver transplant, compared to 30% for rescue transplants due to either tumor recurrence or technical failures. Live-related donor and cadaveric liver transplantation had disease-free survivals of 82 and 71%, respectively. Macroscopic venous invasion, albeit a significant factor in overall survival, is not a contraindication to transplant, as long as the transplant can be performed without leaving gross tumor behind.[99]

The significance of pulmonary metastasis at presentation and later is currently being evaluated. The incidence of pulmonary metastatic disease can be as high as 40%. The outcome of this group of patients is markedly poorer.[100,101] The Children's Cancer Group reported long-term survival with resection of pulmonary metastasis and systemic chemotherapy where the lungs were the only site of metastatic disease and where the primary tumor had been successfully treated.[102,103] A recent study from the COG reports excellent outcome following pulmonary metastasectomy of lung metastasis detected at presentation (eight of nine patients were long-term survivors), but a poorer outcome for pulmonary recurrence after chemotherapy, where four of 13 were long-term survivors.[101]

EMERGING THERAPIES

Transcatheter arterial chemoembolization (TACE), which uses a percutaneously placed intra-arterial catheter, has recently emerged as an option for advanced, unresectable hepatoblastomas (see Table 86.7). It has the potential for making inoperable hepatoblastomas resectable or transplantable. Four series of hepatoblastomas, which included 36 patients ranging from 50 days to five years of age, have reported a resectability rate of 88.8%.[104–107] One of the 32 patients had a transplant, while all others underwent left/right hepatic resection or trisegmentectomy. The role of TACE is being evaluated prospectively in the second Japanese Study Group for Pediatric Liver Tumors (JPLT-2) trial.

Novel chemotherapeutic strategies are also being evaluated for the treatment of high-risk, especially small cell undifferentiated, hepatoblastomas, which respond poorly to current chemotherapy protocols. The COG and JPLT-2 are currently prospectively evaluating the use of irinotecan (a topoisomerase-1 inhibitor) in this subgroup of patients.

Gene-directed therapeutic strategies currently being investigated include Bcl-2 silencing and the targeting of *Myc* and *β-catenin* genes. The use of gene therapy to activate 5-fluorocytosine (an inactive prodrug) to 5-fluorouracil has been described in preclinical trials (see Table 86.7).

Malignant rhabdoid tumor

Malignant rhabdoid tumors of the liver are poorly understood extremely rare tumors, with a grave prognosis. Fewer than 50 cases have been reported in the literature.[108] They have sometimes presented with an abdominal mass, distention, or fever. Four of 19 patients in a series were three months old or younger.[109] More commonly, they present as central nervous system or renal tumors. Differentiating the tumor from a small cell undifferentiated-type hepatoblastoma can be difficult, as they share clinical and histologic features.[110] The tumor is very friable, can present with rupture, and can bleed uncontrollably following biopsy. There appears to be a strong correlation between the loss of *INI1* immunostaining and the presence of an INI1 mutation, suggesting that the former may be a reliable marker of rhabdoid tumors in children.[110,111] Confirmatory immunohistochemical stains for these tumors usually include expression of vimentin, cytokeratin, and epithelial membrane antigen and the absence of INI1 protein.

Malignant rhabdoid tumors are usually resistant to chemotherapy, with a median survival of only 15 weeks.[109] There are two reported cases of long-term survival: a 13-month-old girl following right hepatectomy and multiagent

Table 86.7 Reports of transcatheter arterial chemoembolization (TACE) in unresectable hepatoblastoma.

Reference	No. of patients	Age range	No. of treatments	Resectability	Overall survival	Complications of TACE
Han *et al.*[104] (1999)	4	8–22 months	2	4/4 underwent hepatic resections	100%, 16–52 months follow up	None
Li *et al.*[105] (2008)	16	50 days–60 months	1–3 (cisplatin/ adriamycin)	13/16 – complete resections (including one OLT); 3/16 – partial resection	1-yr OS: 87.5%; 3-yr OS: 68.7%; 5-yr OS: 50%	None
Xuewu *et al.*[106] (2006)	8	2–12 months	1–3 (adriamycin/ vincristine/ cisplatin)	6/8 – complete resection; 1/8 – no surgery as tumor completely regressed; 1/8 – died of pneumonia before surgery	15-49 months follow up	One case of pneumonia
Oue *et al.*[107] (1998)	8	4–26 months	1 (heterogenous group, 3, patients received pre- or post-TACE chemotherapy)	8/8 resected (one patient had pulmonary metastasis)	6/8 disease free at 46 months; 2/8 died of metastatic disease	Fever

chemotherapy with ifosfamide, vincristine, and actinomycin D;[112] and a three-year-old boy after combination chemotherapy with ifosfamide, carboplatin, and etoposide alternated with vincristine, adriamycin, and cyclophosphamide and liver transplantation.[113]

Germ cell tumors

While germ cell tumors in children are fairly common, their occurrence in the neonatal liver is quite rare. Large series of fetal and neonatal tumors spanning decades have documented only isolated cases in the liver. As a group, they account for around 2% of tumors in this age group.[43,114,115]

CHORIOCARCINOMA

Choriocarcinoma in the neonatal period is a rare, life-threatening malignancy, but one that is highly responsive to the appropriate early treatment instituted. However, it is generally recognized late in the neonate. Choriocarcinoma is a rapidly growing, hemorrhagic tumor of the trophoblastic tissues. It has been documented and treated successfully, both in the presence and absence of maternal or placental disease.[116–118] An obvious explanation would be that it could be metastatic disease from a placental primary, although a *de novo* origin cannot completely be ruled out in certain cases.[119] The absence of placental disease can be explained by the presence of even a microscopic focus of primary disease in the placenta missed on histopathology. A placental focus of choriocarcinoma is not always present in maternal disease.

Choriocarcinoma is detected easily in the newborn by the presence of an elevated serum β-HCG (human chorionic gonadotropin) level. The neonate usually presents with an abdominal mass, hepatomegaly, and anemia. This 'infantile choriocarcinoma syndrome' was first described by Witzleben and Bruninga[120] in 1968 in infants aged five weeks to seven months, although this can easily be applied to the newborn. The presence of choriocarcinoma in the mother who has delivered a live baby is rare and should prompt a screen for a neonatal tumor in the first month of life. Also, suspicion of choriocarcinoma in the neonate should prompt a search for the same in the mother. The tumor can metastasize rapidly to the lungs, brain, and skin, and usually is fatal within weeks owing to uncontrolled hemorrhage.[119]

If detected early, the choriocarcinoma is highly chemosensitive to methotrexate and agents used for other germ cell tumors, such as etoposide, bleomycin, and cisplatin. Paclitaxel can be used as second-line chemotherapy for cisplatin-unresponsive disease. Residual disease in the liver, lungs, or brain can be resected or observed as per the response monitored radiologically (CT/MRI) and biochemically (serum β-HCG). Not surprisingly, there has been an increasing number of reports of successful treatment since the 1990s.[117,121–126]

OTHER GERM CELL TUMORS

The few reported cases of teratomas of the liver in the newborn have been mature teratomas, although more examples of all kinds have been reported in infancy.[127–129] Interestingly, a large series of teratomas in children included two liver tumors, both of which occurred in newborns.[130] The AFP is usually elevated regardless of the presence or absence of malignancy. Treatment usually consists of resection and chemotherapy guided by the malignant cell type.

PRINCIPLES OF LIVER RESECTIONS

The details of individual major hepatic resections are beyond the scope of this chapter, and the reader is referred to a text on hepatobiliary surgery.[131] However, the general principles of liver resections in neonates and infants are similar to those in adults. The main hazards are of blood loss and bile leak. Eighty-five percent of the liver can be safely removed in small infants. Liver regeneration is rapid and almost complete within three months.[132] Central hepatectomy has also been shown to be a feasible, although technically challenging, operation in children with hepatoblastomas.[133] Values on liver function tests usually return to normal within a few weeks.

Bloodless hepatic dissection is crucial in newborns in whom the blood volume is no more than a few hundred milliliters. The surgical approach is based on a thorough understanding of the hepatic anatomy as described by Couinaud.[134] Skilled anesthetic management and maintenance of a low central venous pressure in the patient minimizes blood loss. Hepatic resections in children can be carried out through a transverse or subcostal incision, and vertical extension is unnecessary. After division of the ligamentum teres and the falciform ligament, a thorough examination of the liver is undertaken to identify the site or sites of tumor involvement. Further mobilization of the left or right lobe is undertaken with division of the respective peritoneal reflections on the diaphragm. The mobilization of the right lobe is completed once the fibrous tissue over the inferior vena cava is divided with scissors or the endoscopic gastrointestinal anastomosis vascular stapling device (Endo-GIA; United States Surgical, Norwalk, CT, USA). The use of intraoperative ultrasound at this stage is useful in identifying the location of hepatic vessels, particularly the hepatic veins.

The next stage is establishing inflow control and identifying and preserving the components of the biliary tree. Control of the branches of the hepatic artery and the portal vein supplying the part of the liver to be resected can be achieved individually by extrahepatic dissection or by transecting the relevant pedicle within the substance of the liver. During left hepatectomy, the left branch of the portal vein and left hepatic artery are divided within the umbilical fissure. Dissection of the extrahepatic biliary structures is not necessary and carries the risk of inadvertent bile duct injuries, especially in the presence of variant anatomy. Division of the biliary radicals can be achieved at the time of parenchymal transection by dividing them laterally within the pedicles.

Establishing control of the venous outflow is the aspect of the operation most fraught with the risk of blood loss and air embolism. This dissection is performed with the patient in the 15° Trendelenburg position and with the anesthesiologist

maintaining a central venous pressure of less than 5 mmHg. The individual hepatic veins are carefully dissected, divided within vascular clamps, and oversewn with 3-0 polypropylene sutures. Alternatively, they can be divided using the Endo-GIA vascular stapling device.

Division of the liver parenchyma should be considered to be more akin to fine dissection than a fracture and division. This may be accomplished by a simple crushing technique. The authors apply intermittent inflow occlusion (Pringle maneuver) for periods of up to 7 minutes with 1-minute windows when hemostasis is achieved on the cut surface. The Glisson's capsule is scored with cautery and a Kelly clamp used to fracture the liver substance. A combination of titanium hemoclips and the Endo-GIA vascular stapler is used to transect the liver substance. The authors employ a saline-linked radiofrequency ablation device called Tissue-Link (TissueLink Medical, Diver, NH, USA) and the argon beam coagulator to achieve hemostasis. Routine drainage of the abdominal cavity is not employed.[135]

CONCLUSION

The understanding of hepatic tumors in newborns and infants has evolved rapidly in the treatment of both benign and malignant disorders. Newborns and infants with these disorders present with a unique set of problems without parallel in other age groups. It is hoped that the increasing international intergroup collaboration will produce continued success and help develop novel therapeutic approaches in managing these rare disorders.

Congenital mesoblastic nephroma and Wilms' tumor

ROBERT CARACHI

INTRODUCTION

Congenital mesoblastic nephroma (CMN) first described by Kastner in 1921,[1] is the most common renal tumor in the neonate, although rare cases present in later childhood. It is also known as a fetal renal hamartoma, mesenchymal hamartoma of infancy, or lipomyomatous hamartoma. It has an incidence of 2.8% of all renal tumors of childhood, with a mean age of presentation of 3.4 months in contrast to an average age of three years in Wilms' tumors.[2] It has been documented as being 22.8% of all primary tumors in children one year old or less.[3] A neoplasm in the kidney of a child less than three months old is usually a CMN. The majority of renal neoplasms originating in the fetus and found during the first weeks of life, differ in structure and in biological behavior from a nephroblastoma. In contrast to cystic lesions of the kidney, solid renal neoplasms are rare in the newborn and account for only 8% of neonatal tumors. In the Children's Cancer Group (CCG) Neonatal Study, there were 25 neonatal renal neoplasms, of which 17 were CMN and the rest were Wilms' tumors.[4] A review of neonatal Wilms' tumors in the national Wilms' tumor register identified 15 cases out of 6832 patients with an incidence of 0.16% demonstrating how rare malignant renal neoplasms are in neonates. Although prenatal ultrasound is capable of detecting renal neoplasms *in utero*, there are no specific sonographic characteristics that can differentiate a CMN from a Wilms' tumor. Both tumors present as a palpable abdominal mass in the neonate. Males outnumber females by 2 to 1 with CMN and both sexes are equally affected by Wilms' tumors.

PATHOLOGY AND CYTOGENETICS

In 1967, Bolande and colleagues[5] recognized CMN as a unique lesion that could be distinguished clinically and pathologically from true congenital Wilms' tumor by its benign clinical behavior, a preponderance of mesenchymal derivatives and lack of the malignant epithelial components typical of Wilms' tumor. A definite infiltrative tendency distinguishes CMN from hamartomas with more limited growth potential. CMN is usually solid, unilateral, and can attain a very large size like a uterine fibroid.

Histological differentiation is that of a spindle cell neoplasm with interlacing bundles of fibroblasts and myofibroblasts. Tumor types have irregular interdigitating margins in the perirenal fat and wide margins of excision are desirable for complete removal. Incomplete removal results in tumor recurrence which happens within a year of resection in most instances. No chemotherapy or radiotherapy is indicated here and a wide surgical resection is the treatment of choice.[6]

Atypical and more aggressive mesoblastic nephromas tend to be soft, fleshy tumors with areas of gross hemorrhage and necrosis and are more cellular without recognizable normal glomeruli or tubules.

Another variant is a congenital cystic mesoblastic nephroma (cellular variant) which can present as a unilocular hemorrhagic cyst. This can be detected antenatally and misdiagnosed as a hemorrhage into the kidney. The lining of the wall of this cyst shows a typical cellular rim comprising mitotically active small round and spindle-shaped cells giving the diagnosis of CMN (Murthi, Carachi, Howatson, personal communication). The treatment for this tumor is surgical.

Gaillard and colleagues[7] recently reported pathological and molecular characteristics of CMN in 35 cases. Based on cellular criteria, 14 were classified as classical, four as partly cellular, and 17 as cellular CMN. The mean ages were 24, 11, and 70 days, respectively. There were 13 intrarenal tumors (stage I), but nine classical, three partly cellular, and five cellular CMNs extended to the perirenal fat (stage II), and five cellular tumors ruptured (stage III). In order to assess cellular proliferative activity, silver staining of nucleolar organizer region (Ag-NOR) proteins was performed on 19 CMNs. The number of Ag-NOR dots per cell was significantly lower in

classical and partly cellular CMN than in cellular CMN, whatever the stage. Within the cellular CMNs, the mean number of Ag-NOR dots was statistically higher in the single case that recurred with fatal outcome. The number of Ag-NOR dots, DNA content measurements, the histological subclassification, and the presence or absence of tumor at the surgical margins, may be useful features in selecting those patients who will benefit from further treatment after nephrectomy.

A characteristic chromosomal translocation, t(12;15)-(p13;q25) has been described which results in fusion of the ETV6 (TEL) gene from 12p13 with the NRTK3 neurotrophin-3 receptor gene (TRKC) from 15q25. This results in a chimeric RNA which is characteristic of both infantile fibrosarcoma and the cellular variant of congenital mesoblastic nephroma. This suggests a close relation between these two conditions.[8]

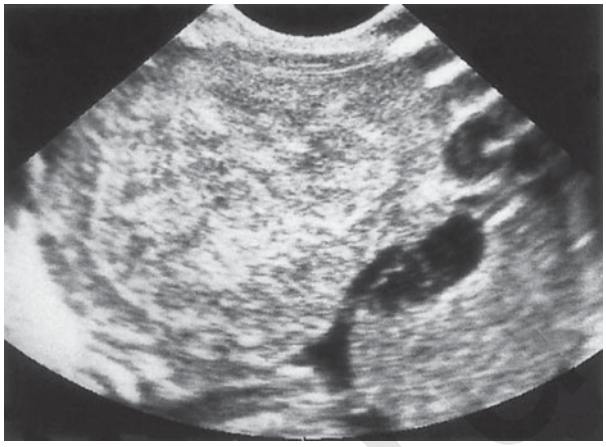
Human epidermal growth factor receptors (HER) play a critical role in the branching morphogenesis of renal tubules. In addition, HER2 expression in Wilms' tumor had been assessed and its role in tumorigenesis has been established. Amplification and overexpression increases the metastatic potential of a tumor and promotes chemoresistance.[9]

It has been reported that abnormal renin production and hypertension are common features of CMN. Several investigators have reported distinctive patterns of immunoreactive renin staining, suggesting that mesoblastic nephromas are a source of increased renin production producing hypertension.[10,11] The most intense staining for renin was observed within areas of recognizable cortex trapped within the tumor. Renin was localized in cells in the walls of vessels running up to the glomeruli.

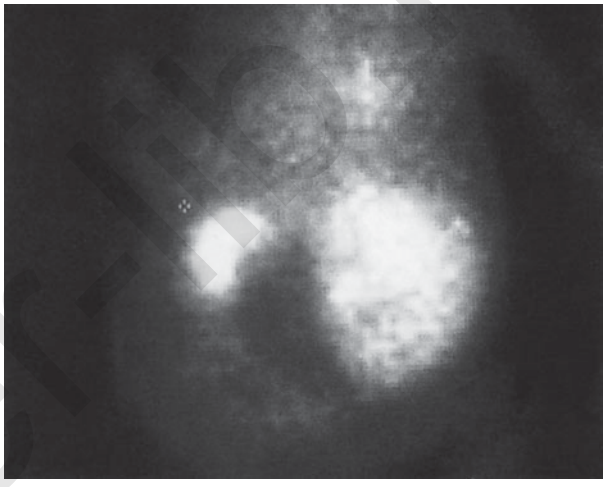
CLINICAL FEATURES

The newborn usually presents with a large, non-tender abdominal mass. Maternal polyhydramnios and prematurity are frequently seen, although the reason for this is unclear. Male to female ratio ranges from 1.8:1 to 3:1.[6,11] Hypertension has been recognized as a presenting feature, and there is an association between preoperative hypertension and cardiac arrest during surgery.[6] Some patients present with hematuria. In the congenital cystic mesoblastic nephroma variant, the patient may present with a hemorrhagic problem. Recently, mind maps have been introduced to explain in a didactic fashion the clinical features, investigations, differential diagnosis and management of CMN and Wilms' tumor.

Detailed antenatal ultrasound scans may pick up a solid tumor of the kidney. Plain films of the abdomen show a large, soft-tissue abdominal mass that is rarely calcified. Sonography demonstrates the solid nature and renal origin of the mass and most commonly shows a mixed echogenic intrarenal mass (Fig. 87.1a,b). CMN should easily be distinguished from more common renal masses in the newborn[12] – hydronephrosis or multicystic kidney – which are sonolucent. Magnetic resonance imaging (MRI) gives detailed imaging of the renal tumor and its surrounding structures.



(a)



(b)

Figure 87.1 (a) Sonography demonstrates a mixed echogenic mass. (b) ^{99m}Tc-DTPA renal scintigraphy shows function within the mass in the kidney.

TREATMENT

Nephrectomy of this benign tumor is curative without the need for supplementary radiation or adjuvant chemotherapy. Even when there has been intraoperative rupture, excisional surgery is curative, and local recurrence is rare. Distant metastasis has been reported, but is extremely uncommon[13] A review of 38 patients with the cellular variant of mesoblastic nephroma showed that seven children had recurrence and three died. According to the review, pathologically positive surgical margins were the only statistically significant predictor of recurrent disease. Frozen section may help in obtaining tumor-free margins during surgery. Recent studies on molecular biology may shed further light on tumor behavior and add criteria for further therapy after surgery.

PREOPERATIVE PREPARATION

Blood samples are obtained for a full blood count, group, and crossmatch. Tumor markers renin, active renin, and inactive renin should also be assayed because these tumors have been

documented as producing high levels of these hormones.[11] Erythropoietin levels should also be assayed. Careful monitoring and control of blood pressure is required to prevent dangerous perioperative fluctuations. A central venous cannula for i.v. infusion is inserted into the neck vein or subclavian vein, as well as an arterial cannula to monitor blood pressure.

OPERATIVE TECHNIQUE

Position

The patient is placed supine with a roll under the lumbar spine to create a lordosis.

Incision

An upper transverse muscle-cutting incision from the flank across the midline provides adequate exposure (Fig. 87.2a).

Laparotomy and exposure of the renal pedicle

The abdomen is entered, taking care not to cut into the tumor while incising the abdominal wall muscles. The small intestine is displaced towards the opposite side and covered with moist packs. The liver and the opposite kidney are inspected for the presence of any other disease. This is very rare in this condition. Free fluid is sampled and sent for cytology.

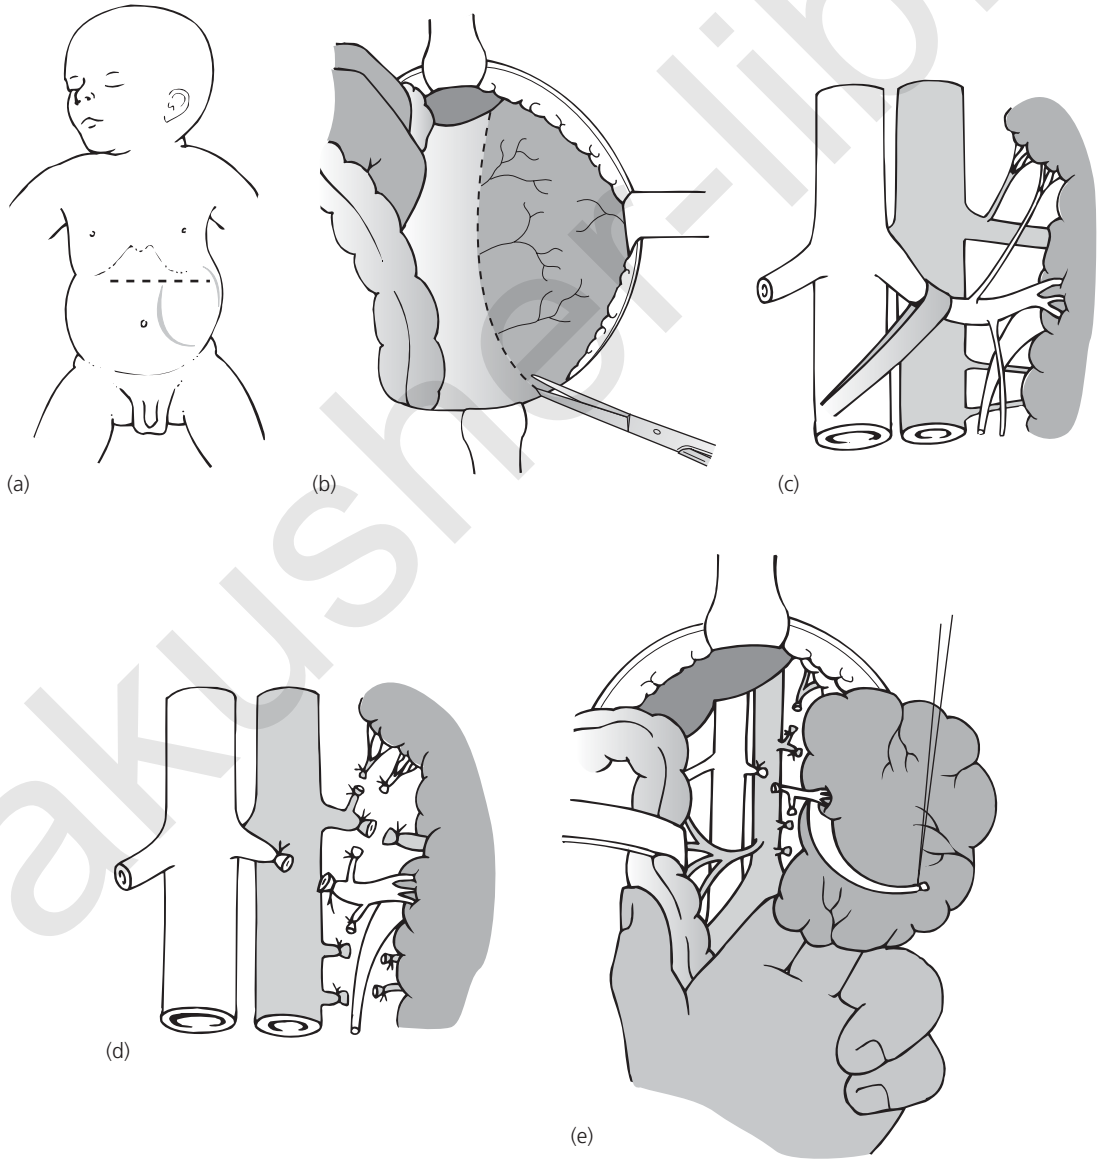


Figure 87.2 Resection of left mesoblastic nephroma: (a) incision; (b) colon retracted medially and posterior peritoneum incised; (c) ureter, gonadal vessels, and renal vessels identified; (d) ureter and gonadal vessels ligated and divided – this is followed by ligation and division of renal vein and artery; (e) tumor is removed from the posterior abdominal wall using sharp and blunt dissection.

The colon overlying the tumor is retracted medially and the posterior peritoneum lateral to the colon is incised and reflected forward to the midline (Fig. 87.2b). Tumor handling should be minimized in hypertensive patients to prevent excessive release of renin. The inferior vena cava and renal veins are both palpated for the presence of tumor. The ureter is identified (Fig. 87.2c) and a tape is passed around it. It is traced as far down as possible into the pelvis, ligated with 3-0 chromic catgut and divided. Next, the gonadal vessels are ligated and divided. Before mobilization of the tumor, abdominal packs are used to isolate the operative site from the rest of the abdominal cavity. This is to prevent any dissemination of tumor if there is spillage during the time of surgery. The renal vein is doubly ligated and divided (Fig. 87.2d). The renal artery is exposed and transfixed with non-absorbable sutures. The para-aortic lymph glands, together with surrounding tissue, are dissected off the aorta and inferior vena cava and labeled carefully. The tumor is removed from the posterior abdominal wall using finger dissection (Fig. 87.2e). The excised specimen should contain kidney, Gerota's fascia, fat from the lumbar fossa and para-aortic lymph glands.

After removal of the tumor, hemostasis is obtained with diathermy coagulation or suture ligatures. No drain is usually required.

POSTOPERATIVE CARE

Postoperative recovery following resection of mesoblastic nephroma is rapid. Nephrectomy of this benign tumor is curative. If on histology the tumor is found to be Wilms', it should be treated in accordance with the degree of involvement as outlined in the National Wilms' Tumor Study Programs.

COMPLICATIONS

The main complication of CMN is rupture of the tumor during surgery. Howell and colleagues[6] reported intraoperative rupture in 20% of their cases. In practice, this is extremely rare despite intraoperative rupture, excellent subsequent relapse-free survival has been reported.

Neonatal ovarian tumors

CHAD WIESENAUER AND MARY E FALLAT

INTRODUCTION

For decades, ultrasound examination, both pre- and postnatal, has made it possible for clinicians to recognize ovarian cysts and other masses. True neoplasms are rare, simple ovarian cysts are common, and large or complex cysts often demand surgical attention. A variety of approaches including aspiration (both pre- and postnatal), surgical removal, or observation have been proposed and are acceptable depending on the radiographic and clinical circumstances.

ETIOLOGY

Although not fully understood, it is widely believed that ovarian cysts derive from ovarian follicles. Mature follicles can be found in up to 60% of newborn ovaries. It is widely cited that fetal follicle-stimulating hormone (FSH), fetal luteinizing hormone (LH), estrogens (maternal, placental, and fetal), and placental human chorionic gonadotropin (HCG) all stimulate the ovarian follicle.[1–3] At birth, HCG and estrogen levels fall precipitously, leaving only the fetal pituitary gonadotropins LH and FSH to stimulate or maintain the ovarian follicle. The newborn hypothalamus and pituitary become sensitive to negative feedback by about four to six months of age, decreasing secretion of LH and FSH. By this time, most if not all stimulation of the ovarian follicle halts, and fetal cysts should involute. Simple ovarian cysts are known to resolve spontaneously in most cases by one to six months.[1,4–6]

An alternative theory has been recently proposed by Enriquez *et al.*,[7] in which abnormal development of the primitive gonad, and not just hormonal stimulation, is the root cause of fetal cyst formation. Cyst formation becomes a consequence of germinal epithelial secretion in a dysgenetic gonad.

Incidence

The normal newborn ovary will demonstrate several scattered anechoic cysts from 4 to 5 mm in diameter. More than 80% of newborn ovaries will have ovarian cysts <9 mm in diameter, whereas cysts >9 mm occur in from 20 to 34% of ovaries.[8] There is general consensus that newborn cysts, less than 2 cm in maximal diameter, are considered normal and unlikely to cause problems.

Torsion

Torsion is believed to occur when a relatively large, mobile mass twists on a long, thin pedicle. Many authors consider cysts of diameter greater than 4 or 5 cm at high risk for complications, most commonly torsion.[1,4–6,8–10] Other authors use a more conservative diameter of 2.0 cm to direct management.[11] Three series report that between 27 and 53% of antenatally diagnosed ovarian cysts (both simple and complex) were found to be torsed at operation.[1,11,12]

PATHOLOGY

Pathologic examination, possible only if surgical removal is performed, will often confirm the diagnosis of an ovarian cyst. The vast majority of cysts are of follicular origin. Torsed ovaries will have suffered a variable period of ischemia, so examination may not reveal any identifiable ovarian follicles or parenchyma. Tumors, as stated above, are rare in the newborn, but careful examination of the literature reveals examples. In what appears to be the most extensive review in the English language, of 257 antenatally diagnosed ovarian cysts, Brandt and co-workers reported three cystadenomas and two teratomas out of 170 surgically removed ovaries.[1] Three other authors have reported antenatally diagnosed tumors including two germ cell tumors, one teratoma, and one serous cystadenoma.[11,13,14] There exist two reports of ovarian carcinomas found at fetal autopsy. These were bilateral ovarian cancer in a 30-week fetus, and a granulosa cell carcinoma in a stillborn fetus.[15,16] Juvenile granulosa cell tumor, a tumor that may be considered malignant due to its aggressive potential, is reported in children less than seven

months of age in three reports.[17–19] Finally, there exist reports of one endodermal sinus tumor and one teratoma in children under one year of age.[20]

HISTORY AND PHYSICAL EXAMINATION

Most newborns with ovarian cysts will have a normal physical examination at birth. Since the ovary is an intra-abdominal organ in an infant, large cysts will displace the intestinal tract and present as palpable, but generally non-tender, masses. These infants rarely have signs of intestinal obstruction if the mass reaches substantial size.

PRESENTATION

Most neonatal ovarian cysts are first diagnosed at prenatal ultrasound. Their appearance is almost exclusively in the third trimester, at around 28 weeks' gestational age.

DIAGNOSIS

Ultrasound is the modality of choice for both the child and mother, being quick, relatively inexpensive, and safe, compared to other imaging modalities. Magnetic resonance imaging (MRI) has been proposed as more reliable by some authors,[21] but discounted by others.[22] The basic criteria for ultrasound diagnosis are: (1) cystic structure in the lower or lateral abdomen and (2) normal urinary and gastrointestinal tracts.[22] Differential diagnoses include urachal cyst, enteric duplication, hydrometrocolpos, choledochal cyst, renal cyst, hydronephrosis, distended bladder, perforated meconium cyst, duodenal atresia, anterior myelomeningocele, mesenteric cyst, lymphangioma, and omental cyst; with the latter three entities being the most easily confused with ovarian cyst.[1,6,23,24] Nussbaum *et al.*[25] proposed useful criteria for simple and complex ovarian cysts in 1988. Simple cysts are completely anechoic with an imperceptible cyst wall (Fig. 88.1), whereas complex cysts demonstrate a fluid/debris level, have a retracting clot, are septated, or are solid (Fig. 88.2). Of all 'complex' cysts, Monnery-Noché *et al.*[11] found 89% to be torsed, with the remainder being hemorrhagic.

Evolution

Prenatal and postpartum sonographic observation has allowed investigators to determine how ovarian cysts are likely to behave. Anywhere from 44 to 70% of antenatally diagnosed simple cysts will convert to complex, presumably by torsion, by the first postpartum ultrasound.[6,11,12,26,27] These five studies considered simple cysts of all diameters. Some authors have correlated antenatal cyst size with risk of ovarian loss,[1,4,9] but more recent investigations have demonstrated no correlation between size and risk of ovarian loss.[11,12,26,28] The latter studies call into question the usefulness of cyst diameter in surgical decision-making.

Simple cysts (all diameters) are known to regress spontaneously postpartum in at least 82% of cases.[6,27] Sakala *et al.*[29] cite 50% resolution by one month, 75% by two months, and 90% resolution by three months. The remainder of these simple cysts are generally aspirated or operated upon for failure to regress in size after a period of observation.

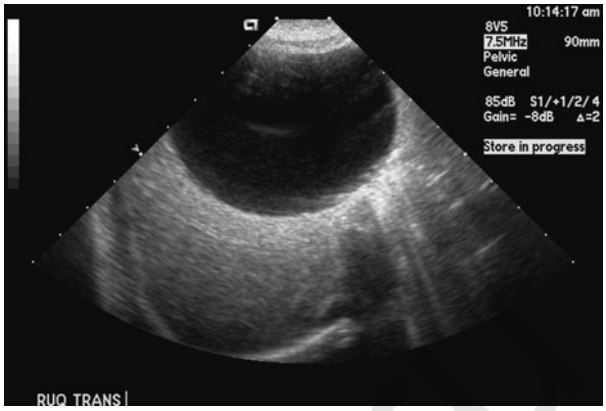

Figure 88.1 Transabdominal ultrasound of a simple ovarian cyst, 5.5 × 6 cm. Note the lack of internal echoes and no perceptible cyst wall.

Figure 88.2 Transabdominal ultrasound of a complex ovarian cyst, 2.5 × 3.5 cm. Features include a relatively thick cyst wall, fluid/debris level, and multiple septations. This ovary was found to be torsed and non-viable.

Concerning complex cysts, three studies have observed them postpartum, with an involution rate of between 58 and 77% by one year.[6,26,27] Most ovaries that did not involute as witnessed by ultrasound were operatively treated with removal, if torsed and necrotic. Viable, follicular ovaries were detected by ultrasound in 16 to 25% of formerly complex cysts that were observed. In those cases where the complex cyst involuted and a viable ovary was not subsequently seen, it may be speculated that the gonad was torsed and necrotic, and eventually resorbed spontaneously. More reports are needed to know if observation in these cases is a legitimate therapeutic option.

MANAGEMENT

The treatment of newborn ovarian cysts remains controversial. Considering only simple cysts, the majority of authors still

selectively operate or aspirate (including *in utero* aspiration) based on a maximal diameter of 4 or 5 cm.[1,6,8,10,30,31] although other authors support close ultrasound observation for larger simple cysts with good results.[12,23,27] As for complex cysts, a growing number of authors support ultrasound observation, with surgical treatment only if they fail to demonstrate continuous regression over time.[6,7,12,23,26,27] Other surgeons prefer to definitively exclude malignancy by removal of the complex ovarian cyst.[1,3,10,31]

In utero aspiration

To avoid the 44–70% risk of *in utero* torsion of the simple cyst discussed above, some investigators have attempted *in utero* decompression of simple cysts. Bagolan *et al.*[31] appear to have published the largest series of 14 patients without complication. After two of these ovaries torsed despite aspiration, their ovarian preservation rate was 86% – clearly better than historical controls of waiting until birth (44–70% torsion). They, along with others, recommend *in utero* decompression for anechoic cysts $\geq$4 cm, cysts that are rapidly enlarging, or cysts that wander in the abdomen.[30] Of note, Bagolan *et al.*[31] did report two errant prenatal diagnoses among their *in utero* aspirations. These cases were two hydronephroses, and both fetuses suffered no untoward effects from these aspirations. This therapy deserves further study.

Postnatal aspiration

Proponents of postnatal aspiration point to maximal preservation of ovarian tissue coupled with cyst decompression to potentially prevent torsion. Also, many authors mention that the majority of operatively managed ovarian cysts involve oophorectomy, not cystectomy or fenestration, thereby removing any chance of viable ovarian tissue on the affected side. Opponents point out lack of a definitive diagnosis, i.e. risk of cancer. Kessler *et al.*[8] reported 17 aspirated ovarian cysts, both simple and complex (not widely supported), with a 67% ovarian preservation rate. No complications were reported, although three cysts recurred and responded to repeat aspiration. Other investigators have had similar success,[10] yet Puligandla *et al.*[32] report a case whereby an enteric cyst was mistaken for ovarian pathology, and aspiration led to a devastating complication.

Operative removal

The majority of large simple cysts and complex cysts are removed via laparotomy or laparoscopy. A large cyst is defined as greater than either 4 or 5 cm in maximal diameter, although at least one group operatively removed simple cysts greater than 2 cm in diameter.[11] Although the goal is always ovarian tissue preservation, more often than not the entire ovary is removed for lack of identifiable ovarian parenchyma.[2,7,8,12,13,23,29] Fenestration of the cyst wall is an option if the cyst wall cannot safely be entirely separated from ovarian tissue. Of course, operative removal is the only method to exclude neoplasia, and also the only method that results in no chance of viable ovarian tissue on the affected side. Proponents of operative removal also cite risk of adhesive bowel obstruction as potential complications of the unremoved ovarian cysts.[2,3,11] Surgeons have come up with many creative alternatives to suprapubic laparotomy (Fig. 88.3), including exteriorization-aspiration, transumbilical removal (Fig. 88.4), and modifications using the laparoscopic approach.[33–37] An ovarian-sparing cystectomy can be facilitated by injecting saline in the interface between the cyst and ovary, using a scalpel or electrocautery to begin the dissection, and then the cyst can often be peeled off the surface of the ovary using a moist cotton-tipped dissector or swab to facilitate the dissection (Fig. 88.5). Subsequent bleeding at the ovarian

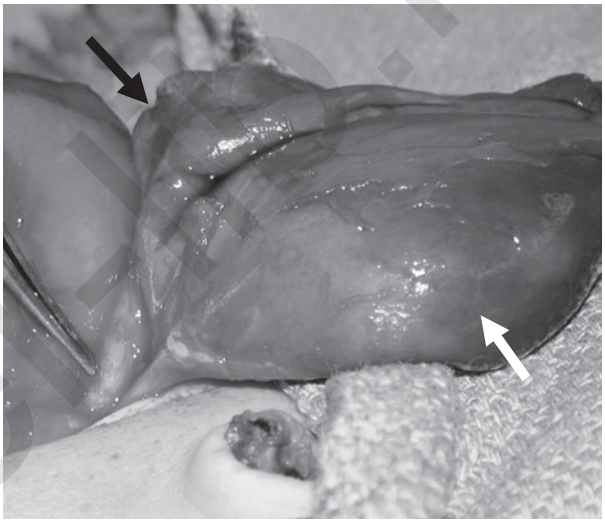

Figure 88.3 Torsed ovary with large attached cyst, exteriorized via a suprapubic transverse incision. White arrow points to cyst, black arrow to torsed and non-viable right ovary, forceps points to healthy uterus. Viable left ovary and tube are to left of uterus.

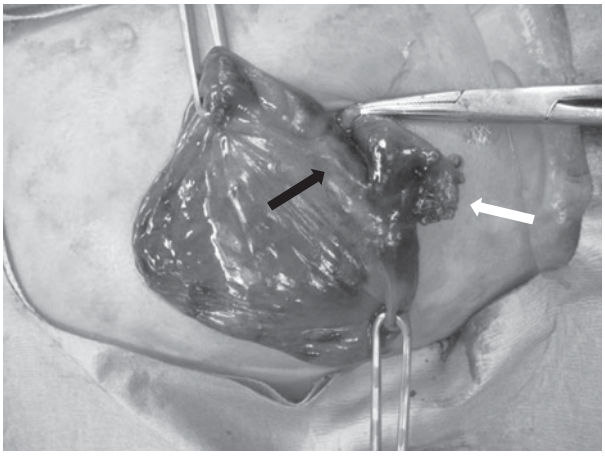

Figure 88.4 Simple ovarian cyst drained and exteriorized via umbilical incision. This is the cyst from Fig. 88.1. White arrow points to Fallopian tube, black arrow to thin rim of ovarian parenchyma.

surface can be controlled using electrocautery. It is not necessary to reapproximate ovarian tissue, but an absorbable small gauge absorbable suture, such as polyglactin 910 (Vicryl; Ethicon Inc.) should be used if this is felt necessary.

COMPLICATIONS

Complications of cyst observation include a missed malignancy, although this is very rare. As stated above, some authors believe that torsed, necrotic ovaries have the potential to cause adhesive bowel obstruction. Complications of cyst aspiration include misdiagnosis and any consequences of unintentional needle injury of another organ. Complications of operative removal include injury to viable ovarian tissue that might have been functional without intervention, and also the risk of adhesive bowel obstruction inherent to any transabdominal operation.

LONG-TERM RESULTS

No long-term studies to date have examined future fertility in the population of newborns and infants who had ovarian cysts or tumors subjected to a variety of therapeutic options.

SPINA BIFIDA AND HYDROCEPHALUS

This page intentionally left blank

89

Spina bifida and encephalocele

MICHAEL D JENKINSON, MAGGIE K LEE, AND CONOR L MALLUCCI

INTRODUCTION

Neural tube defects (NTD) encompass a variety of congenital anomalies ranging from anencephaly to spina bifida occulta and arise due to defects in the morphogenesis of the neural tube. While spina bifida remains the most common congenital central nervous defect encountered in neurosurgical practice, the overall incidence of NTDs is in decline.[1–4] Multiple factors account for this change, including increased antenatal diagnosis, declining birth rates, changing social attitudes, and improved standard of living and diet. Nevertheless, a diagnosis of spina bifida can have devastating consequences and the 'correct' management of these patients is a continued source of medical, ethical, and legal controversy. A multidisciplinary team is required including neurosurgeons, pediatricians, neurologists, urologists, orthopedic surgeons, physiotherapists, social workers, psychologists, and nursing staff. At the center are the patient and family with the common goal being social integration and a meaningful life.

HISTORY

Caspar Baulinin is credited with the first accurate description of spina bifida in the early seventeenth century.[5] The term 'spina dorsi bifida' was coined by Nicholas Talpius (Tulp) in 1641[6,7] and Virchow introduced the term 'spina bifida occulta' in 1875.[8] The association of hydrocephalus and spina bifida was recognized by Morgagni in 1761, and he also described anencephaly and spina bifida as expressions of the same pathological process and attributed bladder, rectal, and limb abnormalities to the neuronal damage in the defective spinal cord.[5]

Aspiration of the lesion was the time-honored method of management, but had catastrophic consequences. Forestus ligated the sac,[9] and sac excision was attempted by Tulp with fatal results.[7] The Clinical Society of London[9] recommended the use of a local sclerosing technique as the preferred method of treatment, which was initially advocated by Morton.[10] Excision of the sac was again popularized by Bayer[11] and Frazier[12] in the early twentieth century, however, the mortality rate remained high. With the advent of antibiotics and the introduction of cerebrospinal fluid (CSF) shunts in the 1950s, the operative results encouraged more surgeons to introduce comprehensive, aggressive management. In 1963, Sharrard *et al.*[13] proposed emergency operative closure of the back lesion to decrease mortality and improve muscle function. This provided new hope for these patients. However, in the latter part of the decade, it became evident that the mortality remained high and those who survived had major handicaps. Lorber,[14] who was one of the supporters of the aggressive policy of the Sheffield group, reviewed 524 cases of myelomeningocele treated actively and concluded that there were four main criteria associated with a poor prognosis: gross hydrocephalus, severe paraplegia, kyphosis, associated gross congenital anomalies or major birth injury. He advocated that patients with one or a combination of these criteria should be managed conservatively as very few patients survived, and those who did would suffer severe mental and physical handicap. In recent years, the reliability and 'predictive value' of these four criteria have been questioned. It has been suggested that the management of these infants should be individualized and changed whenever necessary in the best interest of the patient and family.[15–17]

INCIDENCE AND EPIDEMIOLOGY

There are geographic variations in the incidence of spina bifida and neural tube defects worldwide, for example, the incidence of spina bifida cystica varies between 0.3 per 1000 live births in Finland, to 4.5 per 1000 live births in Ireland.[18] There is greater reported variation in the incidence of spina bifida occulta which ranges between 1 and 50% depending upon the age group.[19] Caucasians are at higher risk than black people of developing spina bifida[20] and lower socioeconomic groups also seem to have a higher incidence of the defect.[21]

EMBRYOLOGY

Neural tube defects are the results of an abnormality in the process of neurulation. The primitive streak and Hensen's nodes are present in the embryo at 2 weeks' gestation. The notochord starts extending rostrally from Hensen's node and this induces the process of neural tube formation. Thickening of the ectoderm cephalic to Hensen's node occurs and forms the neural plate. Folding and later fusion of these folds form the neural tube. This process continues caudally up to the somites, which have started to appear from the 3rd week. Other ectodermal tissue closes over this and buries the tube. The unfused rostral and caudal neural folds are called the anterior and posterior neuropores. These are closed at about 25 and 30 days, respectively. The process of neurulation is then completed. At this stage, there are about 21–29 somites. Four somites are incorporated into the occipital bone and 20 for the cervical and thoracic vertebrae. Caudal to this, the remainder of the tube forms the caudal cell mass. During the next 4–5 weeks, canalization of this cell mass occurs; this is followed by the regression of the most caudal part of the neural tube, which forms the filum terminale. The notochord separates from the neural tube dorsally and the gut ventrally forming sub- and epichordal spaces.

PATHOGENESIS

All developmental defects of the central nervous system are NTDs, while neurulation defects in a strict sense make up a subgroup of NTDs. These defects can involve:

- Brain
  - Anencephaly: a result of persistence of the anterior neuropore. This allows some part of the developing brain to remain in contact with the amniotic cavity. The types are holocrine, if the defect extends to involve foramen magnum, and mesoacrania, if the foramen is not involved.[22]
  - Encephalocele: the result of defective cephalic neurulation.
- Spinal cord
  - Meningocele: a post-neurulation defect.
  - Myelomeningocele: defective caudal neurulation results in myelomeningocele, which can occur anywhere from cervical to lumbar sites. There are various theories put forward to explain the precise mechanism of the defective neurulation. These are either due to failure of neural folds to fuse or a reopening of the normally fused neural tube. Defective neuroepithelium itself may be responsible for the failure of neural folds to fuse[23] or the defect may lie in the mesoderm, which deters the closure of neural folds. The normally fused neural tube may reopen because of increased intraluminal pressure[24] or a primary defect in the neuroepithelium.
  - Associated Arnold Chiari malformation may be secondary to failure of ascent of the cord within the spinal column because of tethering or as a result of descent secondary to increased pressure of hydrocephalus.
- Brain and spinal cord: craniorachischisis is the defect involving brain and spinal cord.
- Other defects occur secondary to various post-neurulation abnormalities involving the neural tube or mesoderm, or because of persistence of totipotent cells. These lesions are diastematomyelia, complete anterior and posterior spina bifida, butterfly vertebrae, lipoma, hemangioma, dermoid cyst, and sacrococcygeal teratoma. A partial duplication and separation of the notochord can result in herniation of the endoderm of the yolk sac, called 'split notochord syndrome'. If the hernia ruptures, it may result in ectopic bowel, sinus, or fistula.[25]

TERMINOLOGY AND CLASSIFICATION

The types of NTDs vary from anencephaly to spina bifida occulta. These lesions can be classified as shown in Table 89.1. Myelomeningocele is one of the most common congenital malformations.

Spina bifida occulta

The term 'spina bifida occulta' refers to the form of spinal dysraphism not accompanied by the extrusions of the contents of the vertebral column. Spina bifida occulta,

Table 89.1 Classification of neural tube defects.

Site	Lesion	Pathology
Craniospinal	Craniorachischisis	Involves brain and spine
Cranial	Anencephaly	Brain and skull poorly developed
	Exencephaly	Exposed brain without skin or bone cover
	Encephalocele	Brain herniation through congenital opening of skull and covered by meninges and skin
Spinal	Spina bifida cystica	
	Myelomeningocele	Open cord defect at any point from cervical to sacral
	Meningocele	Skin covered sac formed of meninges – defect in posterior arch
	Spina bifida occulta	Absent spinous process and varying amounts of lamina (may be associated with lipomyelomeningocele, tethered cord, dermal sinus tract, diastematomyelia, hemangioma)

without any external evidence, is rarely diagnosed in the newborn. Occasionally, it may cause neurological deficit because of a tethering of the cord, or some patients may have external evidence of spina bifida occulta. These lesions include a small dimple, sinus, tuft of hair (Fig. 89.1), or hamartomatous lesions, such as hemangioma, lipoma, and nevi. Neural involvement may manifest as urinary problems, e.g. recurrent urinary infection or enuresis, motor deficit with pedal deformity, pelvic tilt and muscle weakness, and sensory involvement in the form of trophic ulceration. All these patients warrant careful examination and investigation. Spinal x-ray will show evidence of spina bifida and other spinal abnormalities. Ultrasonography can be useful in the newborn period to diagnose diastematomyelia.[26] The common clinically relevant lesions are lipomyelomeningocele, tethered cord, dermal sinus tract, and diastematomyelia. All of these lesions need referral to a neurosurgical specialist and therefore when these lesions are noted, a craniospinal magnetic resonance image (MRI) is indicated. Many of these lesions require follow up and surgery at some point in the future. The increased incidence and treatment of these lesions over the last 10–20 years probably reflects increased diagnosis due to the more widespread availability of MRI.

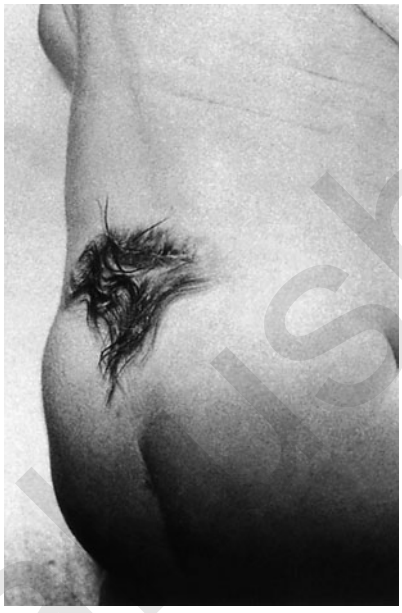

Figure 89.1 Spina bifida occulta. A large tuft of hair over the lumbosacral region in this baby was associated with spina bifida occulta and a tethered cord.

Spina bifida cystica: meningocele

A meningocele is an epithelial lined sac filled with CSF, which communicates with the spinal subarachnoid space. Meningocele, which comprises about 5% of all spina bifida cystica cases, is usually not associated with neurological deficit and hydrocephalus, and is most frequently observed in the lumbar region.

Spina bifida cystica: myelomeningocele

Myelomeningocele is the most common form of NTD (Fig. 89.2). A neural plaque is centrally placed, around which there is a cystic lesion with attenuated meninges and skin (Fig. 89.3). Although the pathological changes are obvious at the site of the lesion, additional changes involve the whole of the nervous system and other systems, especially genitourinary and skeletal.

Figure 89.2 Dorsolumbar myelomeningocele. This infant had normal movement in both lower limbs.

Figure 89.3 Myelomeningocele. Lesion showing neural plaque in the center covered by a thin membrane.

ETIOLOGY

The precise etiology of NTDs is not known, however genetic and environmental factors have been implicated.

Genetics

The exact mode of inheritance is not known, although ethnic variation, gender (females are more commonly affected than males), increased incidence with parental consanguinity and familial tendency, suggest a multifactorial hereditary predisposition. An individual's risk of having other children with spina bifida increases to one in 20–25 if there is one child with spina bifida in the family.[27,28] This risk is one in eight to ten if there are two children with NTDs.[28] The risk of having an affected child is of lesser magnitude (one in 200) if one of the parents had spina bifida than if a sibling had spina bifida.[27]

Dietary factors

Substantial data have been accumulated to suggest that myelomeningocele and other neural defects may be reduced by improved maternal nutritional status. Mothers of spina bifida patients were found to have an increased incidence of folate metabolism abnormalities[29] and it has since been suggested that folic acid might be involved. Several studies have reported a beneficial role of folic acid and other vitamins.[30–33] The Medical Research Council conducted a randomized double-blind prevention trial with factorial design at 33 centers in seven countries to determine whether supplementation with folic acid or a mixture of seven other vitamins (A, D, B_1, B_2, B_6, C, and nicotinamide) around the time of conception could prevent NTDs.[34] The women at risk were randomly allocated to various groups including a control group to avoid bias. This study found a significant reduction in the number of children born with NTDs to high-risk mothers who had taken folic acid in the periconceptional period. Periconceptional use of folic acid has been recommended to all women with or without risk. A concern that large doses of folic acid may delay the diagnosis of pernicious anemia has led to the fortification recommendations being limited to a level that may add, on average, only about 0.1 mg folic acid/day. However, others feel that a daily dose of 0.4 mg/day should be continued.[35] Indeed, recent studies published from Canada, the United States, and Australia have shown a decline in neural tube defects, especially in high-risk groups not only with folic supplementation, but also with food fortification.[3,36,37]

Teratogens

Many agents have been blamed as possible teratogens responsible for the occurrence of NTDs. Exposure to the antiepileptic drugs valproate[38,39] and carbamazepine[40] *in utero* carries a 1.2% risk of fetal NTDs, which have been reported to be more severe open defects with a high incidence of hydrocephalus.[41] Certain viruses[42] and hyperthermia have also been hypothesized to cause NTDs, and exposure to heat in the form of a hot tub, sauna, or fever in the first trimester of pregnancy has also been associated with an increased risk of NTDs.[43–45]

PRENATAL DIAGNOSIS

Prenatal diagnosis of myelomeningocele allows both improved obstetric care and, conversely, termination of an affected fetus if desired.[46]

Alpha-fetoprotein in maternal serum

Alpha-fetoprotein (AFP) can be detected in maternal serum in open NTDs. It is an effective method for mass screening to identify pregnancies requiring further evaluation. Elevated levels after 16 weeks' pregnancy are suspicious; the test is repeated a week later to confirm the presence or absence of NTDs. The sensitivity of this test is about 97% for anencephaly and 72% for spina bifida.[47] This second test requires further confirmation by amniocentesis and prenatal ultrasonography after appropriate counseling.

Ultrasonography

Prenatal ultrasonography may be used as a primary screening procedure. It is a safe and effective method of antenatal screening if the ultrasonographer is experienced,[48] and levels of up to 98% specificity and 94% sensitivity have been reported.[49] Within Europe, there are formal national ultrasound screening policies for structural anomalies.[50] However, detection rates are influenced by gestational age and type of NTD. Spina bifida has a higher detection rate of 92–95% in the second trimester compared to a lower rate of 44% in the first trimester.[51] Three-dimensional sonography has an advantage over conventional two-dimensional ultrasound in predicting the level of lesion and this may offer a predictive morbidity.[51] Prenatal MRI screening is not currently readily available due to limited resources and there is no evidence showing superiority over ultrasound.

Amniocentesis

While many now question the use of amniocentesis in the era of modern high quality ultrasonography, there remains a role in some cases for amniotic fluid biochemical markers for assessment of risk of neural tube defect and other anomalies.[52] Using ultrasound guidance, amniotic fluid is obtained transabdominally at about 16 weeks' gestation. Alpha-fetoprotein and acetylcholinesterase (ACE) levels are estimated to confirm the presence of NTD. The risk of an open NTD is 60% if the levels are $\geq +3$ standard deviations (s.d.) above normal, and rises to 86% if the levels are $\geq +5$ s.d. The combined analysis of AFP and ACE in amniotic fluid increase the accuracy of diagnosis.[53] Specimens contaminated

with fetal or maternal blood can cause potential problems with interpretation of results and repeat amniocentesis may be required.

CLINICAL MANAGEMENT

This section relates primarily to the management of myelomeningocele as this is the most common NTD that presents to pediatric neurosurgical practice.

Prenatal assessment and antenatal counseling

Once a prenatal diagnosis of myelomeningocele has been made, an MRI of the fetus is obtained to determine the level and extent of defect. This allows the neurosurgeon to predict the likely degree of neurological deficit and facilitates prenatal counseling. Antenatal counseling is undertaken in specialist clinics and involves fetal medicine specialists, obstetricians, neurosurgeons, and radiologists. Parents need to be given realistic expectations regarding the prognosis for intellectual development, ambulation and survival, as well as information on hydrocephalus and neurogenic bowel and bladder. In the UK, a review process is underway with a view to setting up a national standard.

It still remains controversial whether Cesarean section should be carried out if the prenatal diagnosis of myelomeningocele has been made. Some authors[54] report that Cesarean section offers advantages to those born by this route as compared to those born by vaginal delivery, although other authors do not support this.[55] Luthy *et al.*[54] reported that delivery by Cesarean section for the fetus with uncomplicated myelomeningocele before onset of labor may result in better subsequent motor function than vaginal delivery or Cesarean section after labor has commenced. While there is no clear evidence, either way, Cesarean section facilitates a timed delivery to allow planning for surgical closure of the myelomeningocele.[56]

In utero surgery

There is a potential role for fetal surgery as neural tube defects are diagnosed prenatally. It is estimated that just over 400 fetal operations have been performed for myelomeningocele worldwide. The techniques using endoscopy, percutaneous fetoscopic patch coverage, and recently via hysterotomy have been described. However, there is little evidence as to the benefit of fetal surgery itself.[57] Currently, the Management of Myelomeningocele Study (MOMS) is being conducted in the United States. This study is a three-center randomized prospective trial comparing prenatal (18–25 weeks' gestation) and postnatal repair of myelomeningocele. Outcomes assessed include death, the need for ventricular decompressive shunting by one year of life, and neurological function at 30 months of age. The results are expected in December 2011.[58]

Postnatal assessment

LOCAL EXAMINATION

The sites affected are the lower thoracic, lumbar, sacral, cervical, and upper thoracic regions. In about 80% of infants with myelomeningocele, the defect includes the lumbar region because this is the last region of the neural tube to close. Occasionally, more than one lesion can be found[56] and there is often marked kyphosis or scoliosis present. Most myelomeningoceles contain an enlarged subarachnoid space ventrally, with the neural tissue displaced dorsally; in combination, this creates a herniated sac on the infant's back.

MOTOR FUNCTION

Motor function is assessed when the infant is at rest. Sharp stimulation above the level of the meningocele is administered with careful observation of voluntary movement below the affected level. Varying degrees of paralysis below the level of the lesion are common, except in rarer cervical and upper thoracic lesions, which are usually spared. The paralysis is usually flaccid, indicating a complete neural lesion. It must be borne in mind that there are some abnormal reflex activities in the lower extremities that have no bearing on volitional motor function.

SENSORY LOSS

Sensory loss is determined by pinprick test from distal to proximal, looking for an upper limb or facial response characteristic of those experiencing a pain sensation. The level at which anesthesia starts indicates the myotome level of the lesion and predicts the degree of disability.[57] Proper care is necessary to avoid trophic changes in anesthetic areas.

BLADDER AND BOWEL INVOLVEMENT

Over 90% of patients with myelomeningocele have a form of neurogenic bladder. The vast majority of these patients have disturbances of detrusor and sphincter balance resulting in a large, trabeculated bladder with urinary stasis. The anal external sphincter and puborectalis are often involved, resulting in patulous anus and sometimes rectal prolapse. It is difficult to ascertain bladder involvement in the newborn, but steps should be taken to ensure the bladder is kept empty. The upper urinary tract is usually normal, but some affected patients will experience changes in the upper urinary tract at birth.[59] These patients need careful urological and renal follow up.

HYDROCEPHALUS

Approximately 85–95% of patients with myelomeningocele have some degree of hydrocephalus. Assessment of the anterior fontanelle, and occipito-frontal circumference are important to determine the timing of any CSF diversion procedures. In those infants with clear evidence of hydrocephalus, early CSF diversion is indicated. Delayed placement

of a ventriculoperitoneal shunt is not associated with a lower infection rate compared to placement at the time of myelomeningocele closure.[60,61] Almost half of meningocele patients shunted at birth require shunt revision in the first year of life, mostly due to mechanical failure.[62] Endoscopic third ventriculosomy (ETV) has also been used in some patients, although the failure rate is high when performed as a primary procedure.[63,64] In patients presenting with shunt malfunction, secondary ETV has a better success rate and is therefore best reserved for later management.[63]

CHIARI II MALFORMATION

Chiari II malformation is invariably associated with spina bifida. MRI demonstrates caudal displacement of the posterior fossa contents, the elongated brainstem, small fourth ventricle, aqueduct stenosis, and tectal 'beaking'. Between 25 and 33% of patients are symptomatic from the Chiari II malformation and in the infant this manifests as brainstem dysfunction associated with sleep apnea and lower cranial nerve palsies. Stevenson *et al.*[65] reported that apnea, stridor (vocal cord paresis), and swallowing difficulties in infancy were associated with a 15% mortality rate in those affected. Whether early decompression improves symptoms remains controversial as surgery-related morbidity and mortality is high in infants (up to 15–20%).[66,67] From a practical point of view, symptomatic Chiari II are rare in infants as long as the hydrocephalus is correctly managed. Chiari II can become a secondary problem in adult life with delayed deterioration.

SKELETAL ABNORMALITIES

Club foot is the most commonly occurring abnormality with spina bifida. Other deformities include dislocation of the hip, genu recurvatum, and kyphoscoliosis. Orthopedic assessment and specialist physiotherapy services are required to manage these problems and minimize the extent of deformity.

Investigations

A full blood count is obtained and blood is crossmatched with maternal serum. A plain x-ray of the spine will reveal the extent of the bony lesion and associated kyphoscoliosis. An ultrasound scan of the head and renal tract are carried out as baseline investigations. MRI of the entire craniospinal axis will determine the presence of associated congenital abnormalities.

Parental discussion

Babies born with NTDs deserve an ethical, humane program of management based on accurate background data involving the parents fully in the decision-making process.[15,68] The management of each child should be individualized and reviewed regularly. It has been observed that in spite of early closure and application of all measures available, there is still a significant rate of disability and mortality.[69–71] Historically, Lorber[14] outlined some adverse criteria for conservative management of these patients, including gross paraplegia, hydrocephalus exceeding the 90th centile by 2 cm or more, severe kyphosis, thoracolumbar lesions, and other associated congenital anomalies (Fig. 89.4). These criteria are based on the belief that these patients will die early in infancy; this type of management will also give some time for discussion with the parents, enabling them to make rational decisions. These severely affected babies were often managed conservatively with demand feeding and sedation. In the past decade with improved antenatal diagnosis and prenatal counseling, many of the severe defects are avoided with early termination and therefore the trend in the Western world is for active management as outcomes are improving. Parents are usually aware of the expected prognosis for intellectual development, ambulation, and survival after antenatal counseling.

Figure 89.4 Large dorsolumbar myelomeningocele. This baby had bilateral lower limb paralysis, hydrocephalus, and bilateral dysplastic kidneys. The baby was managed conservatively.

Operative treatment and technique

All actively treated spina bifida patients should undergo closure of the defect within 24–48 hours of delivery. It was previously thought that early closure resulted in improved neurological outcome,[12] but this has not been supported by more recent studies.[72,73] Early defect closure prevents infection and further damage to exposed neural tissue – the aim being to preserve existing function. The principle of surgery is to reconstruct the spinal cord by five-layer closure of the pia and arachnoid, lumbar fascia, subcutaneous tissue, and skin. The vascular supply to the neuroplaque is maintained and unnecessary neural injury is avoided. The patient is placed in the prone position with a soft roll under the hips and shoulder, and with the head turned to the right through 90° (Fig. 89.5a). Swabs are taken from the lesion for microbial examination and culture. An antiseptic soak is placed over the anus. The lesion is covered with a warm swab

and the surrounding skin is cleaned and draped. The skin is incised at the junction of the arachnoid membrane and skin (Fig. 89.5b). The membrane between the edge of the skin defect and neural plaque is removed carefully to avoid inclusion cysts (Fig. 89.5c). The dura is freed laterally and then superiorly and inferiorly to normal intact dura (Fig. 89.5d). Dura is then sutured in the midline with continuous monofilament absorbable sutures (Fig. 89.5e). A suction drain may be placed extradurally, although this is not mandatory. The lumbodorsal fascia is incised laterally and dissected free from the posterior lilac crest. These are folded medially and sutured over the dorsal dural layer. The subcutaneous tissue is closed with absorbable interrupted sutures and then the skin is closed with interrupted nylon stitches (Fig. 89.5e). The infant is nursed in a prone position. Feeding is commenced once the bowel starts working. The wound is periodically inspected. The suction drain is removed 24–48 hours after operation.

Postoperative management and complications

Infection is common[74] and treatment is with appropriate antibiotics and local drainage. Wound dehiscence may occur and is usually secondary to undue tension on the skin edges or skin necrosis. If the involvement is deep to the lumbodorsal fascia, it may cause meningitis or ventriculitis. These are vigorously treated with local dressings, systemic antibiotics, and external ventricular drainage if hydrocephalus is present and CSF leak occurs. With meticulous closure of the dura, CSF fistula should be rare, however if it does occur, immediate repair is preferred rather than conservative treatment. Hydrocephalus may be present in about 15% of patients with myelomeningocele at birth, while it eventually develops in 85% of these patients. The exact reason for this is not clear; it may be aggravated by a shift in the brainstem after repair, which produces changes in the aqueduct or the Chiari malformation, leading to a further alteration in the

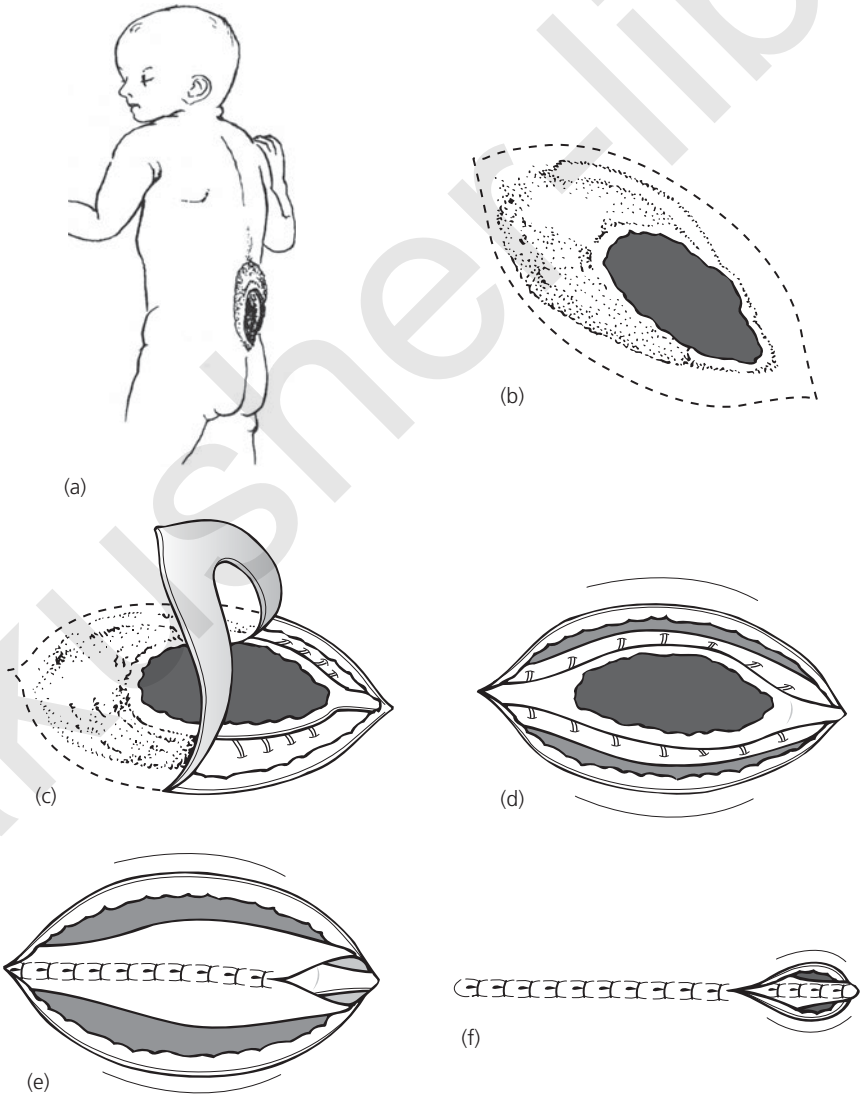

Figure 89.5 Closure of myelomeningocele. (a) Position of the patient on the operating table; (b) an elliptical incision at the junction of the arachnoid membrane and the skin; (c) membrane is excised and neural plaque freed; (d) the dura is dissected laterally from the underlying muscle; (e) dura is closed with an interrupted or continuous 5-0 monofilament absorbable sutures; (f) skin is closed with interrupted 5-0 nylon sutures.

CSF dynamics. From a practical point of view, after neurosurgical closure and shunt placement if indicated, referral and management is continued by pediatric orthopedic surgeons, urologists, and physiotherapists, thus encompassing a multidisciplinary team approach.

CLINICAL OUTCOME AND LONG-TERM MANAGEMENT

The results of myelomeningocele operations vary considerably because of differences in approach to management. Historically, in the units where a highly selective approach was taken, all 100% conservatively managed patients died, while only 14.3% of actively managed patients died.[75] In centers where patients were managed unselectively, a 41% mortality rate has been reported.[69] In the modern era, we await the results of cohort studies of patients treated from the 1990s onwards, as these will likely reflect reduced early mortality and less severe disability.

Medical problems

URINARY INCONTINENCE

Only 10% of myelomeningocele patients have a normal bladder, the remainder have a neurogenic bladder. The introduction of clean intermittent self-catheterization, pharmacological agents (e.g. anticholinergics), external devices, biofeedback, and innovative surgical procedures for the neurogenic bladder have enabled patients to develop social relationships while preserving renal function – up to 75% of these patients can be socially continent of urine.[76] Urodynamic studies in the newborn period are useful in identifying 'at-risk' children with high bladder pressure and detrusor instability.[77,78]

CHIARI II MALFORMATION AND HINDBRAIN DYSFUNCTION

Older children and young adults with Chiari II malformation may complain of symptoms related to foramen magnum impaction, such as headache, neck pain, and upper limb sensory disturbance. Brainstem dysfunction and lower cranial nerve palsies may also be present. Surgical treatment may be indicated in symptomatic patients, once adequate CSF diversion by either shunting or endoscopic third ventriculostomy has been established.[79] In our own series of 21 patients with myelomeningocele surviving into adulthood, eight patients underwent foramen magnum decompression for late deterioration, which stabilized symptom progression.[80]

HYDROCEPHALUS

Shunt placement has a significant impact for the future life of the child and parents. Shunt malfunction and complications (e.g. infection, hemorrhage) in myelomeningocele patients has a cognitive impact,[81] as well as being related to long-term survival.[70,82,83] If shunt malfunction occurs in later childhood, then ETV has a 89% success rate and should be considered before shunt revision.[79]

Lifestyle issues

Whether patients are managed conservatively or actively, the quality of life is an important factor in those who survive. In the long-term follow-up study by Oakshott and Hunt[69,70] of 117 patients treated unselectively, who were followed up for 16–20 years, it was found that 41% of patients had died before 16 years of age. Of the survivors, almost 31% were educationally subnormal and 48% were unable to live without help or supervision, while only about one-quarter of the survivors were capable of competitive employment.[69,70]

INTELLIGENCE

Patients who have associated hydrocephalus and episodes of shunt malfunction (blockage and infection) have lower intelligence than those who only have myelomeningocele.[81] Two recent studies have demonstrated significant cognitive impairment in myelomeningocele patients in the pediatric population that have been attributed to the structural defects associated with the Chiari II malformation, rather than repeated episodes of hydrocephalus.[84,85] Fiber tract anomalies in the limbic system were correlated with memory deficits.[84] In a small adult cohort undergoing in-depth neuropsychological testing at our own center, visuospatial construction and memory were impaired in all myelomeningocele patients.[80] Nevertheless, patients, although severely physically disabled, but who have relatively mild cognitive impairment, can be self-supporting and in competitive employment.

AMBULATION

Ambulatory potential and capacity are related to intelligence, orthopedic deformity, level of lesion, obesity, and motivation. Most of the patients with lesions below L5 are ambulators, those with lesions at L4 are functional ambulators, and those with lesions above L3 are wheelchair-bound.[86,87] The proportion of those patients who retain ambulant status into adulthood gradually decreases due to combinatorial factors including increasing weight, spinal and foot deformity, and respiratory compromise. Long-term follow-up studies have reported that only 30% of patients remain ambulated at 30 years of age.[88] A wheelchair is certainly a more energy efficient means of mobility.[89]

PSYCHOSOCIAL PROBLEMS

Educational mainstreaming, special counseling, improved understanding of the patient's potential and increased public awareness of spina bifida contribute to a reduction in stress through psychosocial problems originating within themselves, their families, and society.

ENCEPHALOCELE

Encephalocele constitutes 10–20% of all NTDs and has a prevalence of between 1 in 2000 and 1 in 5000 live births.[1,90] Encephaloceles have a higher incidence in Asia than in Western countries.

Pathology

With this anomaly, there is a defect in the cranial vault which is either oval or circular in shape, with variable degrees of abnormality, ranging from skin-covered meningocele to gross herniation of abnormal brain. These abnormalities are classified according to location as occipital, parietal, frontal, nasopharyngeal, nasal, frontoethmoid, and basal encephalocele. Occipital encephalocele is the most common type in the Western world, while the frontal lesion predominates in Asia.[56] The contents of the encephalocele vary according to its location and size. Brain tissue has been described in 25–80% of cases, usually in occipital encephalocele. In addition to the brain tissue in the sac, the rest of the brain, especially the optic pathway, is distorted and may be associated with microgyria, holoprosencephaly, heterotopia, agenesis, hydrocephalus, cerebellar aplasia, pyramidal tract aplasia (causing spasticity), and spinal cord distortion. Encephaloceles are also commonly associated with other congenital anomalies, including spina bifida, Klippel–Feil syndrome, facial cleft, and renal, cardiac, and pulmonary anomalies.

Clinical features

Most encephaloceles are obvious at birth and some may have been diagnosed prenatally. The size, content, and location are variable, occipital encephalocele being the most common (Fig. 89.6), and there may be an overlying hamartomatous lesion. Anterior lesions may cause airway obstruction. Occasionally, the diagnosis may be delayed and only becomes evident when a CSF leak occurs and the child presents with episodes of recurrent meningitis. A full neurological examination is necessary to determine any spasticity, focal motor weakness, or visual impairment. Physical examination will reveal any associated anomalies.

Figure 89.6 Occipital encephalocele.

Differential diagnosis

The anterior lesion can be difficult to diagnose and may need to be differentiated from the nasal polyp, glioma, dermoid cyst, teratoma, neurofibroma, meningioma, and hamartoma. A pulsatile mass that increases in size with crying is the classical sign of an encephalocele.

Investigations

Craniospinal MRI should be performed on all patients with encephalocele to determine the severity and extent of the abnormality, as well as screening for associated congenital malformations (Fig. 89.7). Visual evoked response will establish the presence of the occipital cortex within the sac, which may be helpful in surgical planning.

Figure 89.7 Encephalocele. Sagittal T_1-weighted MRI shows a large mass arising from the occipital region.

Treatment

Conservative treatment may be justified for patients with microcephaly and large amounts of brain within the encephalocele, where death is inevitable. Most of the patients are treated by surgical repair of the encephalocele. The aims of the surgery are excision of the extracranial non-functioning brain tissue, closure of the dura at the level of the cranium, and restoration of cranial contour with good skin coverage. Taking these steps to treatment also helps to prevent infection and preserve function.

OPERATIVE TREATMENT AND TECHNIQUE

Under general anesthesia, the patient is positioned with the encephalocele uppermost (e.g. prone for an occipital lesion). The lesion is prepped and draped, while ensuring adequate support for the encephalocele. Large lesions may be aspirated to facilitate handling and dissection. A sample of CSF is sent for microbiological examination and cultures. Usually a transverse ellipse incision is made near the base of the lesion, planned so as to enable closing it without causing undue tension (Fig. 89.8). The incision is then deepened until the dura is seen, which is traced up to the bony defect. The sac is opened where the cerebral tissue is not adhered. If the cerebral tissue is too large, necrotic, and if no visual evoked potentials are demonstrated, it is excised. Every effort should be made to preserve brain tissue without causing an acute rise in intracranial pressure. Bony defects may sometimes need to be enlarged. While dissecting the dura and brain tissue, care must be taken to avoid abnormal venous sinuses and venous connections. The distal sac is then excised. The dura is closed with continuous monofilament absorbable sutures and a dural graft may be required (pericranium is ideal). Meticulous hemostasis is achieved with the closure of all layers. A small suction drain is occasionally used. Subcutaneous tissue is approximated with fine, absorbable interrupted sutures, and the skin is closed with interrupted nylon or continuous absorbable subcuticular stitches (Fig. 89.3). A dressing and bandage is applied.

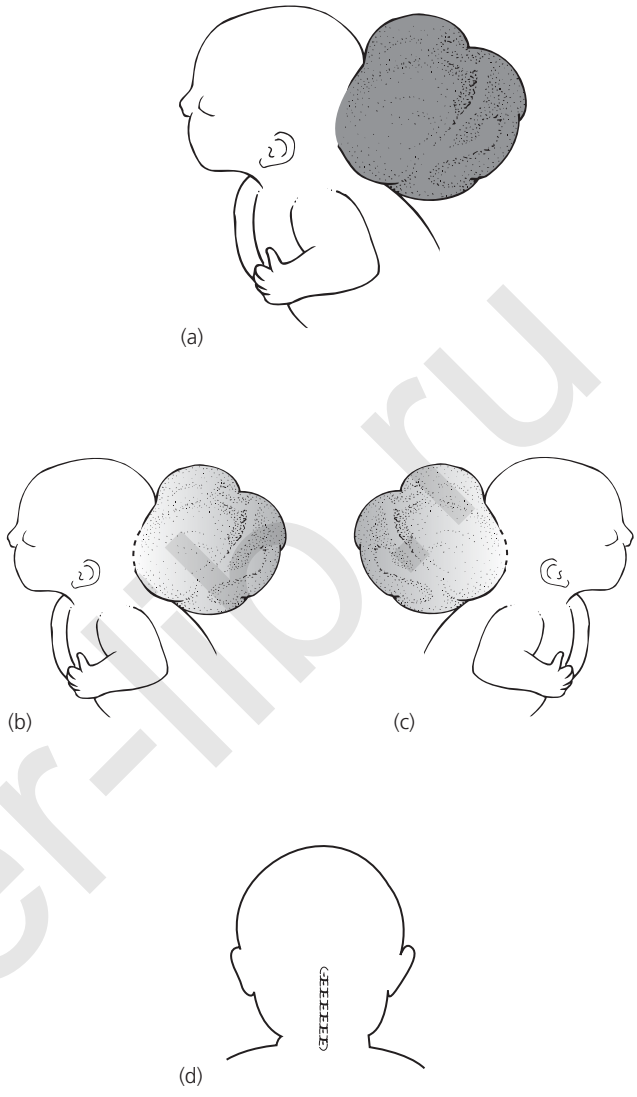

Figure 89.8 Closure of encephalocele. (a) Diagrammatic representation of occipital encephalocele; (b,c) incision around the base of the encephalocele; (d) skin closure.

POSTOPERATIVE CARE AND COMPLICATION

The infant is nursed opposite to the site to minimize pressure in the wound and closely observed for signs of increasing intracranial pressure or development of hydrocephalus. Meningitis is common with anterior encephalocele repair, where contamination is more likely because of the proximity to the nose, mouth, and air sinuses. An intracranial approach may help to avoid this. A CSF leak can occur despite meticulous dural closure. Once hydrocephalus has been excluded with a CT scan, CSF leaks are managed with additional skin sutures and a lumbar drain. If a CSF leak persists, then wound revision may be indicated. Most infants with encephalocele repair develop hydrocephalus which should be treated with a CSF shunt.

RESULTS

Encephalocele carries a high rate of mortality (up to 50%).[35] These deaths may be due to cerebral anomalies, associated congenital abnormalities, an acute rise in intracranial pressure and shunt malfunction and complications.

PROGNOSIS

Simple isolated encephalocele, without associated abnormalities, has a good prognosis. However, the prognosis is worse with larger lesions, those associated with microcephaly and hydrocephalus, and those forming part of other syndromes (e.g. trisomy 18, Meckel syndrome).[91,92] Anterior encephalocele has a poorer prognosis than posterior lesions.

Hydrocephalus

JOTHY KANDASAMY, MAGGIE K LEE, AND CONOR L MALLUCCI

INTRODUCTION

The term 'hydrocephalus' relates to the presence of an excessive amount of cerebrospinal fluid (CSF), which may cause an increase in intracranial pressure (ICP) with or without associated abnormal enlargement of the cerebral ventricles. Rather than being a single pathological disease, hydrocephalus can result from a variety of pathological processes or insults that end with an imbalance between the production and absorption of CSF. Numerous classifications and categories exist with two widely used functional subdivisions being obstructive (where there is an anatomical obstruction to flow of CSF within the ventricles) and communicating hydrocephalus (where there is either presumed blockage with the circulation of CSF in the subarachnoid space or failure to absorb CSF).

The estimated prevalence of congenital and infantile hydrocephalus is between 0.5 and 0.8 per 1000 births (live and still).[1–3] Until the advent of shunts (over 55 years ago), hydrocephalus was usually fatal. The mainstay of treatment of hydrocephalus in the infant remains CSF diversion procedures with shunting; however, the evolving role for neuroendoscopy has proven successful for specific pathological entities. Technological advances in neuro-imaging, neuro-navigation and shunt hardware, and with a better understanding of CSF dynamics and hydrocephalus pathophysiology, are leading to a more 'tailored' patient-specific approach to this complex and multifactorial pathological entity. Hydrocephalus may cause pathological changes to brain morphology, microstructure, circulation, biochemistry, metabolism and maturation. Although treatment does not always reverse the damage, the timing of therapy is crucial in determining the reversibility of the lesions and the subsequent outcome for the patient. In essence, once the diagnosis is confirmed a definitive treatment should not be unduly delayed.

CSF CIRCULATION

The three components influencing CSF dynamics are production, circulation and drainage. CSF is derived by adenosine triphosphate (ATP)-dependent active secretion from cerebral arterial blood across epithelial walls. The global average rate of CSF production is constant under normal and stable conditions at 0.35 mL/min.[4,5] The current widely accepted view is that CSF circulation is via bulk flow.[6] It is produced mainly in the choroid plexus of the lateral and third ventricles and flows along the aqueduct of Sylvius to reach the fourth ventricle. CSF flows out of the fourth ventricle through the midline foramen of Magendie and the lateral foramina of Luschka into the subarachnoid space comprised of an interconnecting network of basal CSF cisterns. CSF flows around the tentorium upwards to the superior sagittal sinus. Some CSF flows downwards towards the lumbar subarachnoid space. Drainage of CSF into the venous compartment is predominantly a pressure-dependent one-way pathway through the arachnoid villi granulations that penetrate the walls of the superior sagittal sinus.[4,6]

Although our understanding of CSF dynamics is still incomplete, the distinction between communicating and obstructive hydrocephalus remains important (albeit sometimes knowingly inaccurate) as it affects treatment options. Obstruction of CSF flow between the third and fourth ventricles results in accumulation of CSF in the lateral and third ventricles. This is described as obstructive (non-communicating) hydrocephalus and may be the result of a congenital or acquired stenosis of the aqueduct. Endoscopic fenestration of the floor of the third ventricle (ventriculostomy) has been shown to be effective in this category of hydrocephalus. Impaired CSF flow and absorption in the subarachnoid space and arachnoid granulations, respectively, may arise as part of a post-meningitic or post-hemorrhagic complication and result in communicating hydrocephalus. Third ventriculostomy is less likely to be effective in this category and shunting may be the treatment of choice.

CAUSES OF HYDROCEPHALUS

The numerous causes of hydrocephalus are outside the scope of this chapter. Only those most relevant to the newborn

are outlined and divided into the following causative categories: (1) obstructive hydrocephalus (radiologically visible obstructive lesion), (2) communicating hydrocephalus (non-obstructive/no radiologically visible obstructive lesion), (3) external hydrocephalus, and rarely, (4) overproduction of CSF.

Obstructive hydrocephalus

AQUEDUCT STENOSIS

This accounts for about 6–66% of cases of hydrocephalus in children. In the vast majority of cases, aqueduct stenosis cases are sporadic, however rare X-linked syndromic cases have been described.[7] Aqueductal obstruction may be caused by gliosis secondary to infection or hemorrhage or acquired stenosis due to compression from neoplastic (e.g. tectal tumors), vascular (e.g. vein of Galen aneurysms), or congenital central nervous system (CNS) malformations (Dandy–Walker, Chiari, spina bifida). Magnetic resonance imaging (MRI) is mandatory to confirm the status of the aqueduct which cannot be visualized on computed tomography (CT).

SPINA BIFIDA AND CHIARI MALFORMATION

Approximately 95% of patients with spinal myelomeningocele involvement have some degree of hydrocephalus, which is almost invariably associated with the Chiari II malformation.[8] The major craniocervical features of a Chiari II lesion include: caudal displacement of the fourth ventricle into the upper cervical canal, elongation and thinning of the upper medulla and lower pons, caudal displacement of the medulla and lower cerebellum through the foramen magnum, and various bony defects of the upper cervical vertebrae and occiput (see Chapter 089, Spina bifida and encephalocele).[9]

DANDY–WALKER COMPLEX AND POSTERIOR FOSSA CYSTS

The 'Dandy–Walker complex' is a term encompassing a rare group of varying malformations in which abnormal posterior fossa CSF collections show clear communication with the fourth ventricle. Dandy–Walker malformation is included in this category and typically involves cystic dilatation of the fourth ventricle, partial or complete agenesis of the cerebellar vermis, and hydrocephalus in up to 90% of cases.[10] It can be associated with other nervous or systemic abnormalities. Posterior fossa arachnoid cysts do not communicate directly with the fourth ventricle. Both third ventriculostomy and shunting are valid surgical options and overall morbidity appears to be related to early and adequate treatment of the associated hydrocephalus.[11,12]

NEOPLASTIC LESIONS

Fortunately, brain tumors in newborns are very rare. The most common types in newborns are often of neuroectodermal origin and are more commonly supratentorial. Hydrocephalus can result from obstruction at various points of the CSF pathway by any neoplastic lesion.

Communicating (non-obstructive) hydrocephalus

POST-HEMORRHAGIC HYDROCEPHALUS

Hemorrhage in the neonatal period is a common cause of hydrocephalus.[13,14] The premature infant born before 32 weeks' gestation is especially vulnerable and the hemorrhage most commonly originates in the highly vascularized germinal matrix. Most studies agree that the incidence is highest in infants weighing less than 1.5 kg at birth and up to 50% of hemorrhages occur within 8 hours of birth.[13,14] In the term neonate, the most common site of hemorrhage is from the choroid plexus, but this accounts for only a small percentage of neonatal hemorrhages. Post-hemorrhagic hydrocephalus (PHH) can be defined as progressive dilatation of the ventricular system that develops as a complication of neonatal intraventricular hemorrhage (IVH). The hemorrhage is postulated to provoke an inflammatory response leading to thickening of arachnoid in the basal cisterns and temporary or permanent occlusion of the arachnoid villi.[15] Although historically classified under communicating/non-obstructive hydrocephalus – the obstruction at the level of the basal cisterns demonstrates the flaw in the simple classifications of hydrocephalus. PHH may contain elements of both communicating and obstructive hydrocephalus at varying stages. The incidence of PHH after IVH of prematurity ranges from 25 to 74% and is proportionately linked to the degree of blood load within the ventricular system.[14] The continuous improvement in perinatal care has led to an increased survival rate in preterm infants, and thus the greater risk of these infants developing IVH. Fernall *et al.*[16] reported that an infant born very preterm has a 60 times higher risk of developing infantile hydrocephalus than an infant born at term. Ultrasonography has been shown to be sensitive and specific in diagnosing IVH and some advocate routine ultrasonography in any infant born before 34 weeks' gestation and/or for those infants weighing less than 1.5 kg at birth.[17–19] Most IVHs are small and resolve spontaneously, but the more severe hemorrhages are associated with an increased risk of developing PHH, and higher risk of mortality and neurodevelopmental outcome.

The risk of IVH in the preterm infant has been significantly reduced by measures that may indirectly ameliorate fluctuations in cerebral blood flow, such as surfactant to reduce pulmonary hypertension and antenatal steroid administration.[16,20] Some also advocate that premature infants should be maintained on paralytics and sedation for the first 72 hours following birth to reduce the risk of IVH.[20] Once PHH has been diagnosed radiologically, temporizing interventional methods may be employed, as some patients may either be too unstable for surgery or their hydrocephalus resolves with degradation of the IVH without obvious lasting imbalance to the CSF dynamics. Most cases of PHH occur 3–4 weeks after IVH, but it is important to note that many of these cases are clinically silent and early detection requires a high index of suspicion and serial radiological monitoring. Of those who develop PHH, over 50% become shunt-dependent with a high rate of neurodevelopmental disabilities. Medical

and surgical management options will be discussed in the following sections of this chapter.

Post-infective hydrocephalus

Intrauterine infection by cytomegalic inclusion disease, mumps, toxoplasmosis, and syphilis may cause congenital hydrocephalus. Also, in the postnatal period following meningitis and/or ventriculitis, hydrocephalus may form from either adhesions in the subarachnoid space or internal obstruction affecting the basal cisterns. Meningitis in the newborn may result from amniotic infection where the membranes have been ruptured for a prolonged period. In the first 2 weeks of life, the organism is usually that of *Escherichia coli* and other Gram-negative enteric bacilli. In the second 2-week period, the pathogens are more likely to be Gram-positive cocci, *Listeria* and *Pseudomonas*.[21–23] Post-infective hydrocephalus (PIH) typically occurs 2–3 weeks following diagnosis of bacterial meningitis and studies have shown that associated complications include abscess formation, ventriculitis, and subsequent CSF loculations and intraventricular septations.[23,24] The management is difficult and frequently requires multiple shunt placements and revisions with associated poor developmental outcome and high morbidity and mortality rates.

External hydrocephalus

This controversial pathological entity is also linked to or referred to as 'pseudohydrocephalus', 'benign subdural effusion', 'benign enlargement of the subarachnoid spaces', and 'benign pericerbral effusion'. Its etiology and pathophysiology in relation to CSF dynamics is uncertain, but include abnormal collections of fluid in the subarachnoid or subdural space overlying the cerebral convexity. The condition occurs while the cranial sutures are open. Although most cases do not require intervention and maintain a benign course, some patients present with features related to mass effect and raised intracranial pressure and in rare cases may require management with a subdural peritoneal shunt.

Overproduction of CSF

Choroid plexus papillomas are intraventricular tumors that may cause overproduction of CSF resulting in massive ventricular enlargement. They are most often found in the lateral ventricle and appear as homogenously enhancing lesions on MRI. They are vascular lesions and resection of the tumor may be curative if the tumor is benign.

CLINICAL FEATURES OF HYDROCEPHALUS IN THE NEWBORN

Despite the vast variation in etiology, the clinical presentation of hydrocephalus is remarkably similar in all pathological processes and is mainly related to signs and symptoms of localized or generalized raised intracranial pressure.

An increase in head size is the major feature of hydrocephalus in the neonate, with an increasing deviation of head circumference from the normal centiles for age. Incremental plotting of head circumference is essential in this regard, using a centile chart, such as that produced by Gairdner and Pearson, allowing for gestational age at birth.[25] It should be noted that there are causes for head enlargement other than hydrocephalus (e.g. a familial tendency for a large head, osteofibromatosis, macrocephaly, or intracranial cysts). The head shape may also be abnormal.

Bulging of the anterior fontanelle with a variably open posterior fontanelle, separation of the suture lines and dilatation of superficial scalp veins (due to venous reflux from cerebral sinuses) are classical features of raised intracranial pressure in hydrocephalus. 'Setting sun sign', an upward gaze palsy may be seen with the superior sclera visible. The component parts of this phenomenon consist of downward rotation of the eyeballs and retraction of the upper eyelids and may be accompanied by brow raising. It may be intermittent, disappearing when ICP is reduced. However, this sign can also be seen and elicited, although rarely in normal infants. Sixth nerve palsy can be seen as this nerve is most sensitive to pressure due to its long intracranial course. Papilledema, decreased level of consciousness, and other focal neurological deficits can also be presenting signs. Opisthotonic posturing, bradycardic and apneic episodes are critical signs of raised intracranial pressure suggesting brainstem compromise and require emergent neurosurgical assessment and treatment.

Other important presenting symptoms of hydrocephalus in the infant are related to raised intracranial pressure, such as irritability, lethargy, poor feeding, vomiting, failure to thrive, and delayed motor development. The clinical presentation may also include features specifically related to the associated causative pathology.

CURRENT IMAGING AND INVESTIGATIVE TECHNIQUES FOR HYDROCEPHALUS IN THE NEWBORN

Skull x-rays are largely obsolete in the management of hydrocephalus in the newborn. Historically, widening of the sutures beyond 3 mm can be seen with associated lacunar skull defects. Ultrasonography is exceptionally useful as a non-invasive technique (Fig. 90.1).[17–19] Antenatal sonography can detect hydrocephalus *in utero* and is the screening procedure of choice in patients under the age of 18 months. In the newborn, the anterior fontanelle provides a window. Measurements of both the ventricle size and the cortical mantle are possible. Serial ultrasonography has not only improved the ability to detect hydrocephalus, but has also resulted in more prompt treatment of this condition and has proved extremely useful in detecting IVH and hydrocephalus in premature infants. It is considered the initial investigation of choice for neonates with hydrocephalus (Fig. 90.1) and can be performed at the bedside.[17–19] It is worth noting that

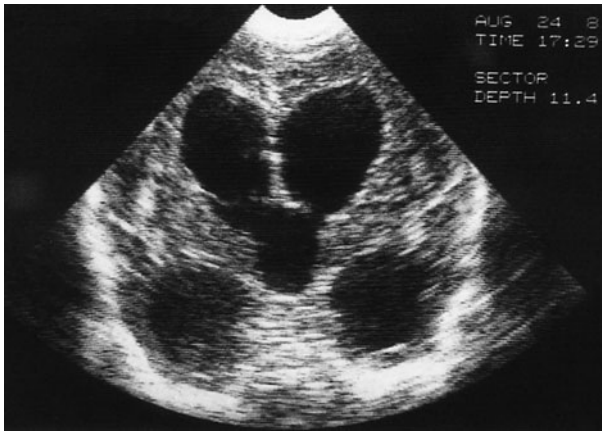

Figure 90.1 Aqueduct stenosis. Coronal section on sonography showing dilated lateral ventricles and foramina of Monro passing into a dilated third ventricle.

although sensitive and specific for the diagnosis of hydrocephalus, clarification of its pathology usually necessitates subsequent CT or MRI.

CT is used where greater detail is required (Fig. 90.2). A complete high resolution CT can be obtained within 2 minutes of the patient being on the CT table. MRI is the gold standard for diagnosing hydrocephalus-related causative pathology and demonstrates the ventricular and CSF anatomy in exquisite detail. Pathological entities, such as aqueductal stenosis, Chiari malformation, and neoplastic lesions, are readily identifiable. MRI also allows for detailed surgical planning when considering the options of endoscopic third ventriculostomy, shunting, posterior fossa surgery, etc. MRI T_1- and T_2-weighted dynamic flow sequences can highlight the relevant ventricular, periventricular, and CSF flow with remarkable clarity.[26] This is particularly useful when assessing the anatomy of the third ventricle and aqueduct in relation to determining the surgical procedure of choice. Volume datasets for both CT and MRI

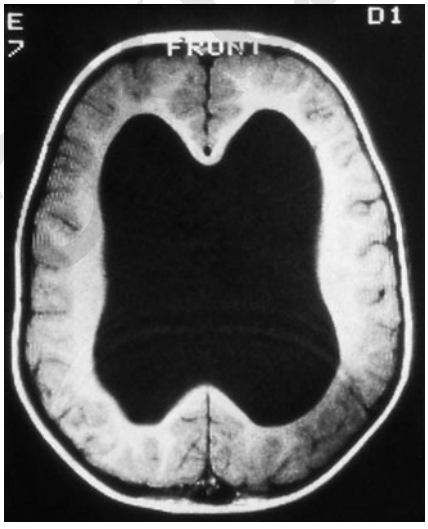

Figure 90.2 Computed tomographic scan of head showing dilated lateral ventricles.

are now readily obtainable which are compatible to bespoke three-dimensional neuronavigation workstations for shunting and neuroendoscopic procedures. MRI is increasingly used for antenatal investigation and is valuable in both outlining congenital malformations and hemorrhage.[27]

Postoperative imaging to assess ventricular size after shunting or neuroendoscopy can be performed with both CT and MRI. However, after a third ventriculostomy, phase contrast dynamic MRI sequences are required to identify CSF flow through the ventriculostomy and is best visualized on sagittal images.[26,28] Invasive pressure measurements, such as fontonometry, are less often justified as they are unreliable when compared with modern methods of imaging.

An antibody screen should be carried out if an intrauterine infection is considered. CSF analysis is indicated where infection or hemorrhage is suspected, as these factors may influence the subsequent clinical management. A raised protein level, or indeed blood-stained CSF, is not necessarily a contraindication to shunting, but is taken into consideration when determining the timing of shunt placement. It may be appropriate to delay surgery until the protein count and/or the blood in the CSF clears to an acceptable degree. If active infection is suspected then a temporizing external ventricular drain would be preferred before a permanent shunt can be implanted once the infection has been treated and confirmed with sterile CSF samples.

TREATMENT OPTIONS FOR HYDROCEPHALUS IN THE NEWBORN

Non-surgical/medical management

The complications associated with surgery in the low birth weight neonate or neonates with coexisting unstable medical conditions raises the need to explore non-surgical means of managing hydrocephalus. The additional possibility of occasionally self-limiting conditions such as PHH may only require temporizing management options. However, pharmacotherapeutic agents, such as acetozolomide, frusemide, and steroids, have not been shown to be effective in reducing the rate of shunting and cannot be recommended.[29,30] Although historically a common practice, serial lumbar punctures should probably no longer be used. A published meta-analysis concluded that no evidence of benefit was demonstrated with a significant risk of secondary infection.[31] Similarly, serial multiple percutaneous ventricular taps have been abandoned by most large tertiary neurosurgical centers due to the numerous associated complications such as 'puncture porencephaly', infection, and encephalomalacia.[32,33]

Surgical management

Surgery remains the overwhelming mainstay of treatment for hydrocephalus in the newborn, shunting converted hydrocephalus from what was an almost exclusively terminal disease to a frequently curable condition. The first permanent CSF diversion for hydrocephalus was performed in Mikulicz

in 1893 in the form of a ventriculo-subarachnoid-subgaleal shunt.[34] This procedure was also simultaneously the first intrathecal ventriculostomy. Since then, virtually every anatomical cavity has been utilized as a potential reservoir or conduit for CSF drainage with varying degrees of success, which included subcutaneous tissues of the scalp, atria, pleura, ureters, gallbladder, and thoracic duct. Most of these are no longer considered in standard first-line practice in newborn hydrocephalus. This section outlines the most common surgical techniques in newborn hydrocephalus surgery.

EXTERNAL VENTRICULAR DRAINAGE

External ventricular drainage (EVD) has been in wide use in the temporary treatment of hydrocephalus for several decades. The frontal and occipital horns of the lateral ventricles are the site of choice via a single burr-hole and the CSF is drained into a sterile closed circuit system which can be continuously controlled by a simple gravity-based outflow valve. It is of particular use in the presence of active infection whereby a permanent shunt system cannot be placed until the infection has been successfully treated and also until a high related CSF protein level (as seen in some peri- and post-infectious settings) normalizes to allow shunt placement. It also allows for the direct administration of intrathecal antibiotics into the infected CSF space. EVD is also potentially useful in IVH or PHH as a temporizing measure before either persistent hydrocephalus has been confirmed or the blood load has reduced. In the emergent setting arising from tumor-related obstructive hydrocephalus, EVD may provide necessary control until such time as to allow definitive tumor resection or reduction of related high CSF protein levels that may cause occlusion of a permanent shunt system. Despite the introduction of antibiotic impregnated EVD systems, they are still prone to significant infection rates and catheter dislodgement. Several studies have assessed the efficacy of intraventricular fibrinolytic therapies and CSF irrigation; however, these have not translated to proven clinical practice and remain experimental.[33,35]

SUBCUTANEOUS RESERVOIR VENTRICULAR CATHETER SYSTEM

This device may be indicated in the newborn infant whose low birth weight and/or the potential for spontaneous arrest of the hydrocephalus preclude the immediate need for a permanent shunt. It is a viable option in PHH. The reservoir allows easy CSF tapping, lower infection rates compared to EVD, and access for intraventricular antibiotic. Complications and limitations include skin erosion and only intermittent pressure control.

VENTRICULO-PERITONEAL SHUNT

The majority of hydrocephalic newborns undergoing CSF diversion surgery will have a ventriculo-peritoneal shunt (VPS). The principle of VPS remains unchanged since first described in 1908 and was initially less favored than the ventricle-atrial (VA) or ventriculopleural shunt.[34] The peritoneum has since become the choice of drainage site when complications with VA shunts, such as sudden death from pulmonary embolism, endocarditis, and nephritis, were noted. Another recognized problem in many VA shunts in the neonate is the need to lengthen the lower end as the child grows and the catheter pulls up out of the atrium. This can be obviated with VPS in the neonate with a longer intraperitoneal catheter. The hardware required for a VPS includes a ventricular catheter, CSF reservoir, shunt valve, and distal peritoneal catheter. Recently introduced antibiotic-impregnated shunt tubing with *in vivo* antibacterial activity is gaining popularity and may confer a protective benefit against infection, particularly in the neonatal setting.[36] Further randomized studies are required to confirm this and the effect of other potential antimicrobial shunt tubing materials on the market, such as those with silver coating.

The choice of valve type remains a regular source of debate within the neurosurgical community. Valve types include differential-pressure, flow-regulating, gravity-actuated, and programmable valves. All the valve types only allow unidirectional flow of the CSF. An anti-siphon device may be included in the system to prevent overdrainage. There are no studies that conclusively prove one valve type to be superior.[37,38] In practice, some factors that may influence decision-making include valve size and profile in relation to newborn/premature neonate scalp skin, cortical mantle thickness, cost, and individual surgeon experience. Some authors advocate a flow control valve for shunts in the newborn to avoid the later complication of slit ventricle syndrome. This is related to chronic overdrainage and is seen most commonly in patients who have a shunt implanted in the first two years of life.[39] Overdrainage and development of subdural hematomas in newborns with large ventricles and thin cortical mantle may be avoided with high-resistance valves.[40]

Both frameless and frame-based neuronavigation systems have been utilized to reduce the incidence of poorly sited ventricular catheters and recent studies have shown benefit in catheter placement accuracy, but it remains to be seen if this relates to a significant reduction in shunt revision rates in the long term.[41] With the bespoke electromagnetic (EM), frameless neuronavigation system, no rigid head fixation, pins, or screws are required and this confers a significant advantage for neonatal shunt surgery. Previous studies on endoscopic versus non-endoscopic catheter placement did not demonstrate any difference in shunt revision rates.[42]

Complications of VPS most commonly includes infection, malposition of the ventricular catheter, mechanical failure leading to suboptimal drainage or blockage, overdrainage, shunt migration/disconnection, and less commonly intra-abdominal sequelae, such as bowel perforation, hernias, hydroceles, appendicitis, and peritonitis. Shunt complication rates are significantly higher in the newborn, and studies have shown low birth weight to be linked to a higher incidence of shunt infection and revision rates.[43] If the CSF is sterile on insertion, the usual organisms causing postoperative shunt infection are skin commensals, such as

Staphylococcus epidermidis (*albus*). Where infection has been proven, the removal of the entire system and temporary CSF diversion via an EVD and concomitant intrathecal antibiotic administration is usually necessary. The treatment of shunt infections has been reviewed extensively by Bayston.[44]

Unfortunately, despite advances in neuronavigation and shunt tubing material, shunt failure remains a considerable source of morbidity for hydrocephalus patients with up to 40% of shunts failing in the first year.[45] Indeed, shunt failure remains an almost inevitable consequence during a patient's life, up to 80% of shunts requiring revision after 12 years.[46]

NEURO-ENDOSCOPY AND ENDOSCOPIC THIRD VENTRICULOSTOMY

Advances in fiberoptic camera technology combined with high-resolution MRI have seen renewed widespread enthusiasm for neuroendoscopy as a therapeutic option in hydrocephalus. Endoscopic third ventriculostomy (ETV) was first performed as an open procedure in 1922 by Dandy, and subsequently as an endoscopic procedure by Mixter in 1923.[33]

Endoscopic third ventriculostomy is a minimally invasive procedure most commonly performed via a single paramedian coronal burr hole to gain access into the lateral ventricle. The ventricle is cannulated with a 10- or 12-Fr cannula which then serves as a conduit for the rigid or flexible endoscope. The endoscope is then introduced and advanced towards and into the enlarged foramen of Munro and then into the third ventricle. A midline fenestration and dilatation is performed in the thinned third ventricle floor avoiding critical structures, such as the mammillary bodies and the basilar artery. The endoscope is then advanced through the fenestration to ensure that effective communication into the interpeduncular and pre-pontine subarachnoid space has been achieved by further opening any thickened membranes that may be present deep to the fenestration. At completion, the endoscope and cannula is removed and no hardware is left *in situ*.

The obvious advantages of shunt independence have made this an attractive surgical option; however, current evidence suggests that patient selection is crucial to outcome success rates. ETV in obstructive hydrocephalus with maintained CSF absorption, such as in congenital aqueduct stenosis, is associated with the highest success rates. While in older children, the indications for endoscopic treatment have been relatively well defined, much debate continues on the value of this treatment in the first few months of life.[47–49] While various studies have reported differing success rates, there remains a lack of consensus on the value of third ventriculostomy in infants and neonates.

The ongoing International Infant Hydrocephalus Study (IIHS) is an international multicenter prospective randomized, controlled trial of endoscopic third ventriculostomy versus shunting in children presenting under the age of two years with pure aqueduct stenosis and aims to provide more evidence in this area.[50,51] The role of ETV as a secondary treatment option after initial or multiple shunt failures is gaining popularity with encouraging success rates.[52] This is relevant to the newborn with PHH or PIH who may benefit from a primary shunt (where primary ETV is ineffective) and then be considered for a secondary ETV when presenting with a future shunt failure.

ETV may also have an important role in the treatment of hydrocephalus in developing countries.[53] The lack of a follow-up service for children in developing countries having permanent shunt implants reinforces the obvious advantage of a shunt-free therapeutic option – ETV. PIH accounts for up to 60% of hydrocephalus cases in certain developing countries.[53] In keeping with published results for infants in developed countries, success rates in a relatively large series of patients treated in a developing country in the under one year group was lower than in the older child. Nevertheless, up to a 60% shunt avoidance rate has been reported in infants in developing countries presenting with PIH aqeuduct stenosis undergoing ETV.[53] The challenge posed by the lack of a shunt follow-up service in developing countries and the consequent impetus for ETV as a treatment modality had also potentially led to a clinical situation in which ETV may be performed on a patient whose CSF absorption capability has not recovered sufficiently, whereas these patients would probably have been treated with a shunt in a developed country. The combination of ETV and choroid plexus cauterization (CPC) may be a viable option in temporarily reducing the rate of CSF production until the absorptive function potentially returns. Results from a study employing this management technique on patients in the developing world reported a success rate of over 70% in infants under one year with PIH and an open aqueduct.[54]

Other applications of neuroendoscopy include aqueductal stenting for isolated fourth ventricle enlargement, multiloculated hydrocephalus requiring communication of CSF spaces via septum pellucidotomies, cyst fenestrations, and as an adjunct to shunt surgery by aiding shunt placement under direct endoscopic vision.

Although a safe procedure in well-trained and experienced hands, the complications of neuroendoscopy can be devastating. Severe hemorrhage, cardiac arrest, cerebral infarction, diabetes insipidus, and damage to the fornices resulting in memory deficit have all been reported.[55] Also of importance is the rare but potential risk of sudden post-ETV death due to closure of the ventriculostomy.[55] Nevertheless, neuroendoscopy alone or in combination with permanent shunting, and the development of computerized neuronavigation for both, has an increasingly important role in the management of hydrocephalus.

FETAL SURGICAL THERAPY

Hydrocephalus is detectable *in utero* and the question of prenatal intervention arises. In spite of extensive experimental work and indeed some human intervention in countries where abortions are legally banned, the results in general, so far, have been poor and this method of management is not currently recommended.[56] The majority of patients who had undergone fetal surgery for hydrocephalus required VPS insertion after birth.

SHUNT OPERATION TECHNIQUE

Ventriculo-peritoneal shunts

Routine preoperative preparations, such as blood parameters, are a necessity.

The patient is positioned while under general endotracheal anesthesia. Antibiotic prophylaxis is recommended such as a cephalosporin, e.g. cefotaxime, at the time of induction. The head is rotated to the opposite side to the shunt with the neck extended to create a straight line between the scalp and abdominal incision. The site of the burr hole and abdominal incision should be marked prior to skin preparation and draping (Fig. 90.3). Occipital burr holes are usually 3–4 cm from the midline along the lambdoid suture. Frontal burr holes are 2–3 cm along the coronal suture from midline. It is vital to tailor the burr hole to the ventricular morphology on imaging so as to ensure optimal ventricular catheter placement. In infants with splayed sutures, access can be achieved via an opening of the sutures. The site of the burr hole is according to the surgeon's preference as there is little evidence showing advantages of one over the other. Occipital burr holes are traditionally used as they are more cosmetically acceptable (Fig. 90.4a). Durotomy is made and the brain pia is cauterized. Dural opening should be kept minimal to reduce the risk of CSF escape around the ventricular catheter, hence promoting CSF leak (Fig. 90.4b).

Figure 90.3 The dotted line represents the course of the ventricular catheter. The patient is positioned with a roll of gamgee under the shoulders to straighten out the neck and allow easier passage of the cannula. The skin is marked, predisinfection, with a pen, showing the curved incision site behind the posterior parietal eminence. The transverse abdominal incision site is also marked with a dark line.

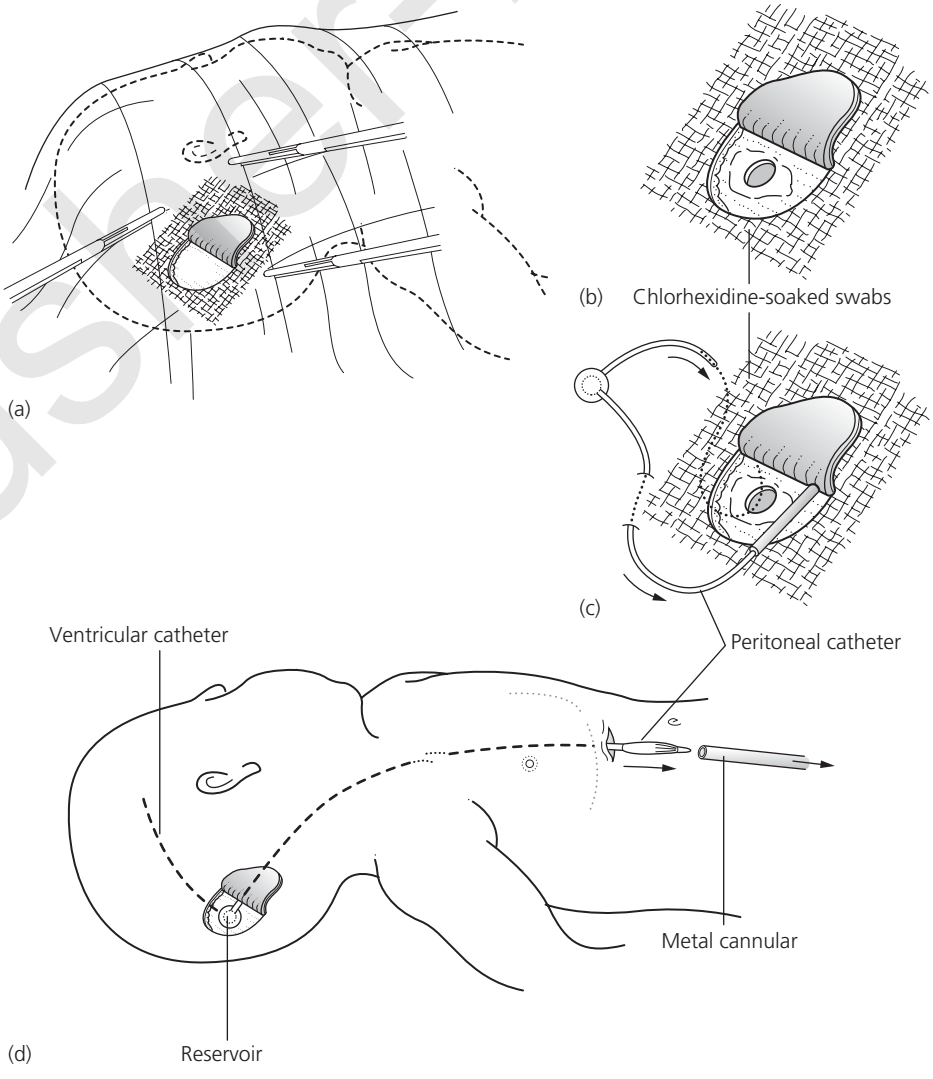

Figure 90.4 (a) Wound drapes surrounding the scalp incision. An upper incision to the pericranium is made. (b) The pericranium is diathermied and rasped peripherally and a burr hole made. (c) Following incision in the abdomen, a long trocar and cannula are passed percutaneously to exit at the lower incision. The long trocar is removed, allowing passage of the peritoneal catheter along the metal cannula. The trocars in some prepared shunt sets have a device for attaching the distal catheter and allowing it to be pulled through distally. (d) Having lightly diathermied the dura, a small hole is made in it and the ventricular catheter introduced and connected to a reservoir. With free flow from the distal end, the catheter is placed in the peritoneal cavity and the peritoneum closed snugly around it.

The abdominal incision is usually performed on the same side, either upper midline or paraumbilical site, however the site is unimportant. The most crucial part is to be sure that the peritoneum space is opened. An open technique, use of trocar,[57] and more recently laparoscopic assistance have been described.[58] The distal catheter is tunneled subcutaneously from the burr hole site to the abdominal opening, or vice versa. If a frontal burr hole is used, an intervening incision is made at the occiput.

The ventricular catheter is introduced mounted on a stylet. The trajectory is determined according to external landmarks. From the occipital burr hole, the target is at the midpoint of the forehead at the hairline so that the lateral frontal horn will be entered. From a frontal burr hole, aim for a target at the intersecting planes' midpupillary line and the external auditory meatus. Intraoperative ultrasonography or image-guided stereotaxy (for example, EM guidance)[41] can be used for more accurate positioning of the catheter. CSF pressure may be measured at this point and a sample of CSF taken for biochemical and microbiological examination. The proximal catheter is connected to the distal catheter via a reservoir and a valve system, depending on the type being used.

The distal end is examined to ensure that there is free-flowing CSF. The distal catheter is placed within the peritoneum. The peritoneum is closed using absorbable sutures, the muscle layers and skin are then closed (Fig. 90.4d).

Ventriculo-atrial shunts

These may be performed in a similar fashion to ventriculoperitoneal shunts, except for the lower incision which is over the right side of the neck. The objective is for the shunt tip to lie in the superior vena cava just rostral to the tricuspid valve. The two most common methods are open versus percutaneous insertion. Access to the jugular vein can be achieved by exposing the common facial vein, which is tied proximally and held with a stay suture at the venotomy site; the distal catheter is fed into the superior vena cava. Intraoperative fluoroscopy or x-rays are helpful in achieving the ideal position. Throughout the procedure, the anesthiologist should inform you of any cardiac alterations or rhythm changes. A purse-string suture is closed around the catheter sufficiently to prevent hemorrhage, but not so tight as to cause obstruction to the catheter. Percutaneous methods into the jugular or subclavian veins can be achieved with the aid of ultrasound guidance and fluoroscopy.[59–61] Complications include cor pulmonale and catheter emboli.

Ventriculopleural shunts

The proximal approach is identical to the ventriculoperitoneal shunt placement. The pleural space can be entered at a variety of sites, however along the anterior axillary line in the fifth intercostal space is both convenient and safe. Intercostal muscle layers are split on the upper border of the rib to avoid the neurovascular bundle to reveal the pleura. It is then opened, the distal catheter is gently introduced into the space to avoid entering the lung parenchyma. The muscle is closed to avoid further air entry into the pleural space. Distal catheter placement may be aided by thoracoscopy.[58] Contraindications for this technique include previous thoracic surgery, acute or chronic pulmonary disease, and poor pulmonary function. CSF will usually accumulate as benign pleural effusion, however if this is progressive it may lead to respiratory distress and therefore vigilance for this complication is important. This technique, however, is rarely applicable in newborns or indeed infants as the pleural cavity cannot cope with the CSF load at this age. The technique is thus usually reserved for very rare cases where few options for the distal catheter remain in older children.

Other sites for the distal catheter include the cerebral venous system, gallbladder, ureter, and bladder. These sites are used rarely in neonates because of their complexity and complications leading to increased morbidity and mortality.

POSTOPERATIVE CARE

Postoperative scans are obtained and act as a reference to future surgery and shunt positioning. Continual monitoring of head circumference is required.

OUTCOMES

The outcome of hydrocephalus will ultimately be determined by the underlying pathological entity that caused it, the treatment selected and complications thereof, the socioeconomic status of the child, and numerous other factors beyond the scope of this chapter. The important message to remember is that hydrocephalus is not a single disease entity, that the treatment must be tailored to the etiology and age of the patient. Avoidance of complications is of paramount importance as complications, such as infection, may dramatically alter the natural history and outcome of the disease.

Urinary tract infections

MARTIN A KOYLE

INTRODUCTION

A urinary tract infection (UTI) is not an uncommon event early in life. This condition should be given strong consideration in the differential list when evaluating the febrile, ill neonate. The diagnosis of a UTI can lead to significant morbidity for the child, not only from the disease process itself, but also from the formidable diagnostic evaluation subsequent to their initial presentation. Given the premature immune system, infants and particularly neonates, are at risk for disseminated bacteremia which can lead to a more dangerous scenario than in older children and adults. Due to this associated danger, a thorough evaluation and prompt treatment when necessary are mandatory. In addition, the pediatric specialist needs to recognize that UTI may be a marker of a more serious, underlying urologic congenital and/or functional anomaly, which may be amenable to operative correction and cure.

Potential urological sequelae from a UTI include renal scarring and compromised renal function, although such severe morbidity may be less likely than formerly perceived. Indeed, with the popularity of maternal fetal ultrasound and antenatal detection of congenital anomalies it is now well documented that such scarring is more often due to dysplasia. This is most obvious in the neonate with congenital vesicoureteral reflux (VUR). Regardless, it is still known that acquired renal scarring can occur in the vulnerable child, even when febrile UTI occurs and VUR is absent on radiological imaging. Current investigations are attempting to identify those specific groups at risk for renal damage. However, serious compromise of function is uncommon nowadays, especially when prompt treatment is instituted. An accurate evaluation is paramount given the implications of delayed or incorrect diagnosis which negatively impacts the start of timely therapy. Diagnostic tests recommended after a urinary tract infection vary, and the usefulness of invasive testing is being questioned. Treatment, although benign and effective, has potential risks, in particular the generation of resistant bacterial strains. Needless to say, a urinary tract infection carries with it a significant emotional and economic burden for the family of the sick child.

INCIDENCE

Urinary tract infections account for 0.7% of all pediatric office encounters and 5–14% of pediatric emergency department visits in the United States.[1,2] In addition, UTI has consistently been the most commonly diagnosed serious bacterial infection in the first months of life with a prevalence varying from 1.8 to 7.5%. It is also the most consistently missed serious bacterial infection in studies attempting to define low risk criteria for the evaluation of fever in the neonatal age group.[3] This unquestionably translates into a significant number of physician visits annually and/or extended hospitalizations of neonates, which add significantly to already escalating healthcare costs. It must be acknowledged that estimated costs do not include charges for subsequent evaluations, including clinic visits, follow-up studies, and time missed from work by parents.

Neonates represent a special subgroup in regards to UTI with a male predominance of 2.5- to 6-fold, which is in striking opposition to the high prevalence rate of UTI among females in the over-six months age group.[2] Overall, the reported incidence of neonatal UTI varies between 0.1 and 1% in the general population of healthy newborns.[4] In preterm neonates, the incidence is much higher. Furthermore, this incidence is estimated at 10% in low-birth weight infants.[5]

Reported prevalence in the preterm neonate ranges between 4 and 25%.[6] A meta-analysis of studies looking at the prevalence of UTI in febrile children less than three months of age found that febrile female infants had a relatively high prevalence rate of UTI (5% in the first three months). Uncircumcised males under three months had the highest rate at 20.1%, whereas circumcised males had the lowest rate (2.4%).[7]

ETIOLOGY

Numerous factors seem to predispose the child's urinary tract to infection. Most pathogenic bacteria that cause UTIs arise from a reservoir in the intestinal tract (Fig. 91.1). *Escherichia coli* is by far the predominant bacteria to cause UTI because of the unique ability of certain serotypes to adhere to the urothelium. One way of differentiating strains of *E. coli* is based upon differences in the antigens they elaborate on their polysaccharide capsule, which surrounds the bacteria. These antigens are known as K antigens and it has been demonstrated that certain K antigenic *E. coli* have a much higher propensity for causing UTI than other strains.

Perhaps the most significant predictor of a bacteria's uropathic potential is its ability to adhere to the epithelial membrane where they cause infection – in the urinary tract, the urothelium. Pili or fimbrae are long filamentous appendages, composed of protein, that project from the bacterial surface and allow for this adhesion to take place. In *E. coli*, type 1 pili is highly associated with bacteria that cause UTI. Type 1 pili act to bind uroplakin, a protein cap that is elaborated by the umbrella cell or urothelial cell. Another form of pili, P pili, named for its ability to bind the P antigen of blood group antigens, is highly associated with strains of *E. coli* that cause pyelonephritis. Bacterial adherence, colonization, and subsequent UTI is a complex process that involves a balance between bacterial virulence factors and a host's immune response to invasive bacterial infection and colonization. Clearly, there are specific strains of enteric bacteria that cause UTI with a much higher virulence than many of the bacteria harbored in the gut. In addition, there are also individuals that are much more prone to UTI due to the complexity of the relationship between host and bacterial factors that allow adherence to first occur. Other uncommon organisms leading to newborn urinary tract infections include *Klebsiella*, *Proteus*, *Pseudomonas*, and *Enterobacter* (Table 91.1).

P fimbriae *E. coli* adhere to the urothelial cells and lead to a decrease in ureteral peristalsis. Bacterium secretes endotoxins that cross the ureteral mucosa and leads to paralysis of ureteral smooth muscle along with risk of ascent and reflux of bacteria. Consequently, this slows flow in the peripheral ureters, and adherent bacteria are not washed away.

Practice parameter: The diagnosis, treatment, and evaluation of the initial urinary tract infection in febrile infants and young children. *Pediatrics* 1999; **103**: 843–52.

Table 91.1 Common uropathogens.

Bacteria	Incidence (%)
Escherichia coli	77–93
Klebsiella	0–11
Enterococcus	2–9
Serratia	~1
Staphylococcus aureus	~1
Psuedomonus aeruginosa	~1
Enterobacter cloacae	~1
Streptococcus	~1
Proteus	~1

Compromise of host natural immune defenses that protect the urinary tract from infection, in particular immunologic immaturity, also predispose pediatric patients to the development of UTI. In addition, some children will have colonization of their feces by virulent bacteria.[8] This is especially true in those patients with slow stool transit times and severe constipation, a cofactor that is more common in older children in the potty training age group.

PRESENTATION

In neonates, the most common clinical presentation varies and is less classical than in older children and adults. Symptoms such as fever, irritability, food intolerance, respiratory distress, and jaundice are common; in premature infants, symptoms encountered may be even more nondescript or 'urinary tract specific', including feeding intolerance, apnea, bradycardia, lethargy, and abdominal distention.[9] Rarely will symptoms referable to the urinary tract, such as hematuria and foul smelling urine, be observed in the neonate. Given this diagnostic dilemma, many UTIs are either not diagnosed or are diagnosed late, some are undoubtedly missed or treated as another entity. Primary care providers must have a high index of suspicion for UTI in the neonatal period to achieve an accurate diagnosis and, of course, obtain a properly collected urine specimen.[10]

Additional concerns of the practitioner lie in the knowledge that not only is the risk of serious bacterial illness higher in young infants and neonates, but also the clinical clues that are often used to detect serious illness are not reliable. Clinical illness indicators, such as state variation and reaction to parental stimulation, are not reliable predictors of serious illness. As many as 65% of neonates with a febrile illness involving a serious bacterial infections appear well on initial examination.[11]

Clinical manifestations of neonatal UTI can be similar to clinical signs of neonatal sepsis, although digestive symptoms have been reported to be more frequent in newborn infants. Elevation of body temperature and poor feeding were the most frequent clinical symptoms, in particular in infants with community-acquired infections. Children younger than three months with a UTI are more likely than older children to have bacteremia, sepsis, and congenital genitourinary abnormalities.[1] Bacteremia associated with UTIs is mostly observed in patients less than six months of age, particularly those less than two months of age, whose risk of bacteremia is estimated to be between 4.0 and 22%.[12]

IMPACT OF CIRCUMCISION

As we debate the medical indications for circumcision in this country, it is well documented that newborn uncircumcised males are at higher risk for urinary tract infections. Uncircumcised boys have an overall 12-fold increased risk of UTI compared with circumcised boys during the first six months of life.[13] The benefit of circumcision in terms of UTI prevention is known to extend for six months after birth, and possibly for as long as one year. After one year of age, there is no evidence that circumcision affects the rate of UTI in males.

Uncircumcised boys less than six months have a greater quantity of both *E. coli* and Gram-negative uropathogens in their urethras as compared with circumcised cohorts. Voiding pressures in newborn males are higher on urodynamic evaluation. Higher voiding pressures, along with a higher risk for cystitis and colonization, amount to an increased propensity for illness in these children. Total costs for treating UTI are reported to be ten-fold higher in uncircumcised than in circumcised male infants, which reflect the greater number of UTI diagnosed in this patient group and possibly a higher number of hospital admissions.[14] Findings confirm the strong body of evidence of attesting to the protective effect of newborn circumcision against UTI in the first year of life, an age when infections are most severe and likely lead to hospital admission.[14] Still, there is morbidity to this procedure and it is estimated that the number needed to treat is approximately 111, that is, 111 boys need to undergo circumcision in order to prevent one UTI.[15]

BREASTFEEDING

Breastfeeding may have a protective role in preventing UTI in premature infants and should be encouraged.[9] Breastfeeding has been significantly associated with a lower risk of UTI. It has been reported to have a protective effect against many infections in the first year of life, including gastroenteritis, acute otitis media, pneumonia, bacteremia, and meningitis. The protective effect is attributed to its action on the intestinal flora, including its high concentration of IgA, which inhibits adherence of bacteria. In addition, lactoferrin prevents the growth of intestinal *E. coli*. Furthermore, the low pH of stool in breastfed babies allows for the growth and colonization with less virulent organisms such as bifidobacteria and lactobacilli.[9]

DIAGNOSIS

Unlike older children, neonates lack diurnal temperature variation and have less normal temperature variability

Table 91.2 Prominent symptoms in neonatal nonobstructive urinary tract infection.

Symptom	Prevalence (%)
Failure to thrive/weight loss	51
Fever	41
Jaundice	12
Cyanosis	30
Vomiting	35
Diarrhea	20

Modified from Phol *et al.*[21]

(Table 91.2). During an acute infection fever is commonly absent in neonates.[16] The general appearance and physical examination of the febrile neonate cannot be relied on to exclude a serious bacterial infection. Multicenter prospective studies of febrile infants who were 60 days of age or younger and evaluated in an emergency room for fever, circumcision status, and height of fever were associated with an increased likelihood of UTI.[3] Hyperbilirubinemia with prolonged jaundice (lasting more than 14 days) is commonly the main clinical feature at presentation that may be the only manifestation of UTI.[4] Jaundice can be an early sign in afebrile infants and was more common in those neonates with nosocomial UTI. Positive urinalysis findings have been reported in approximately 56% of cases.[6]

The most common current emergency department (ED) practice management of even a well appearing febrile neonate is a full sepsis evaluation, including a complete blood count (CBC), blood cultures, urinalysis and urine culture, evaluation of cerebrospinal fluid (CSF), and administration of antibiotics (ampicillin, cefotaxime, or gentamicin), with hospitalization pending culture results.[17] The initial evaluation must include a detailed history along with a thorough physical examination. Care must be taken when evaluating the newborn for abdominal masses. The back must be carefully examined for the presence of dimples or abnormalities suggestive of a spinal dysraphism. The degree of phimosis should be noted if the child is uncircumcised, and although rare, labial adhesions must be ruled out in female newborns. The presence of adhesions and recurrent UTI is an indication for intervention. In neonates, adhesions are treated surgically in order to avoid the utilization of estrogen or betamethasone ointments which are commonly recommended in older children (older than six months of age).

The definitive diagnostic test of a UTI is a positive urine culture. This can be obtained through suprapubic aspiration or urethral catheterization. A false-positive culture obtained via a bag specimen may lead to inappropriate treatment, misdiagnosis, and unnecessary testing. The urinalysis which is immediately available is suggestive but not diagnostic. Although the presence of leukocyte esterase has a high sensitivity it lacks specificity; the nitrate test behaves conversely. When combined with microscopic findings, the sensitivity approaches 100% when all three are positive, and the specificity is 100% when all three are negative.[18] The presence of any bacteria on Gram stain has a sensitivity of 93% and specificity of 95%, better than dipstick evaluation for leukocyte esterase and nitrates.[10] There are four ways that urine can be obtained: (1) a bagged specimen, where a bag is taped to the perineum and urine obtained after the child voids (useful in infants, but there is a high risk of obtaining a contaminated specimen); a midstream collection (unreliable in children, especially in young girls and uncircumcised boys in whom contamination is likely) is useful if negative, but if positive, it is hard to tell if the collection was contaminated; (3) a catheterized specimen (obviously traumatic in children and further, in the uncooperative girl it can easily be contaminated); and (4) suprapubic aspiration, clearly the least likely to be contaminated, but again traumatic in children and rarely practiced in the current litigious environment.[10]

In neonates less than three months old, a catheterized urinalysis or suprapubic bladder aspiration is part of the standard work up for fever. Suprapubic aspiration, although not usually necessary, is considered the gold standard method for obtaining urine. It is performed after cleaning the suprapubic area with antiseptic solution. A 21- to 25-gauge needle is inserted one finger breadth above the symphysis pubis perpendicularly, while aspirating until urine is obtained. Although suprapubic aspiration is popular in some emergency departments, it is both invasive and has variable success rates for obtaining urine because of the lack of urine in the bladder. Physical examination to palpate for a full bladder is sometimes limited if the child is very upset. Ultrasound, if available, may be useful to check bladder fullness before aspiration. For males with phimosis, tight foreskin, or stricture, and for girls with severe labial adhesions, suprapubic aspiration may be the only method for obtaining clean urine.[19] Although the probability of a true infection with a positive culture obtained via suprapubic aspiration is approximately 99%, this method is the most technically challenging and is associated with the lowest rate of success (23–99%).[20]

Recovery of any organism from a suprapubic specimen, at least 50 000 colony-forming units per milliliter (CFUs/mL) from a catheterized specimen, or at least 100 000 CFUs/mL from a clean-catch specimen is considered significant bacteriuria.[1] We should re-emphasize the importance of accurate diagnosis and the appropriate collection of specimen. Results affect the child's care, and can potentially subject them to invasive procedures, and parents to undue stress. The American Academy of Pediatrics (AAP) has published recommendation for the diagnosis, treatment, and evaluation of initial UTI in febrile infants and young children, however, no recommendations for neonates less than two months of age have been suggested.[6] Investigators have commented on the value of urine smell in the diagnosis of UTI. Struthers *et al.*'s study[21] demonstrated no association between reported abnormal or different urine smell and UTI.

CRP >20 mg/L, ESR >30 mm/hour, and WBC >15000/μL are key findings in various studies on febrile infants. The diagnostic value of these for predicting serious bacterial infection in febrile infants, however, is conflicting. Lin *et al.*[22] showed that febrile infants with CRP >20 mg/L and ESR >30 mm/hour were at risk for UTI, but that a WBC count >15000 was not significantly associated with UTI. Although the specificity of ESR and CRP was high, their sensitivity was relatively low, demonstrating that elevated CRP and ESR are poor predictors for identifying UTI in febrile illness.

VESICO-URETERAL REFLUX

Prenatal hydronephrosis is noted in 1–5% of pregnancies. The rate of prevalence of vesico-ureteral reflux in neonates varies from 11 to 12.5%. Considering fetal and postnatal dilation as a combined test and a value of less than 10 mm as a negative indication for voiding cystourethrogram (VCUG) results in increased sensitivity and diagnostic odds ratio for detecting clinically significant VUR.[23] The likelihood of significant renal abnormalities postnatally correlates with the severity of anterior posterior diameter (APD) dilation. A meta-analysis of 17 studies reported the risk of renal abnormalities for three classifications of antenatal hydronephrosis. The probability of ureteropelvic junction obstruction increased, but there was no association of VUR with APD measurement (Tables 91.3 and 91.4).[24]

Table 91.3 Degree of prenatal hydronephrosis and postnatal risk of renal abnormalities.

Degree of hydronephrosis	Postnatal risk (%)
Mild	
<7 mm in the second trimester <9 mm in the third	11
Moderate	
7–10 mm in the second 9–15 mm in the third	45
Severe	
>10 mm in the second >15 mm in the third	88.3

Table 91.4 Prenatal hydronephrosis and risk of postnatal VUR.[Hothi et al.]

Degree of hydronephrosis	Postnatal risk (%)
>12 mm at 20 weeks and >14 mm at 34 weeks	15
6–8 mm during second or third trimester	5

The incidence of VUR in children presenting with symptoms of a UTI is in the order of 30–50%. The incidence, however, is believed to be lower in neonates. Standard of care calls for antibiotic prophylaxis in a child presenting with a febrile UTI, or recurrent non-febrile UTIs, until VUR can be ruled out. Traditionally, recommended work-up has consisted of a renal and bladder ultrasound, as well as a voiding cystourethrogram, or a nuclear medicine cystogram, both of which are invasive studies. The false-negative rate of VCUG is estimated at 20%. A nuclear medicine cystogram involves a fraction (1%) of the radiation exposure experienced with a VCUG. Although its sensitivity is excellent, one major disadvantage is the lack of anatomic detail. It is difficult to identify Hutch diverticula, bladder trabeculation, or a dilated posterior urethra with a nuclear medicine study.

A DMSA scan at the time of presentation is the hallmark of the 'top-down' approach. Some authors advocate that 50% of children will have a positive DMSA during the acute phase. Of those children with a positive DMSA scan, 30–40% will demonstrate reflux. Conversely, 90% of children with VUR will have had a positive DMSA scan. If VCUG is deferred for those children with febrile UTI and a positive acute DMSA scan, presence of hydronephrosis, or a dilated ureter, one would miss 10% of children with VUR, most of these being children with low-grade and low risk for UTI and late renal scarring.[25] Small studies looking into early DMSA scanning in neonates, mainly females and uncircumcised males, agree that DMSA is helpful in ruling out later development of permanent renal damage, but was not predictive of the absence of dilating VUR. Therefore, if dilating VUR is to be ruled out a VCUG needs to be performed even in the presence of a normal DMSA scan.[26] Neonatal reflux, even high grade, is more likely to resolve than VUR detected after UTI at a later age. Prospective data on the follow up of infants with prenatal hydronephrosis diagnosed with grade III, IV, or V showed resolution rates of 53, 28, and 40%, respectively, at four years.

The goal of radiologic studies is to identify genitourinary malformations and defects that can predispose the newborn to recurrent urinary tract infection. Anatomic obstruction (posterior urethral valves, ureteropelvic junction obstruction, ureterovesical obstruction, and ureterocele) as an etiology for UTI is seen in 2–10%.[27] Urethral obstruction during fetal development secondary to anatomic reconfiguration of the bladder neck is suggested as the cause of high-grade bilateral reflux in male neonates.[28] Hoberman *et al.*[29] evaluated the value of renal ultrasound after first febrile UTI in children as young as one month. Their conclusion was that in less than 1% of their study, renal US after first febrile UTI will show findings significant enough to impact management, including additional imaging studies. In their conclusion, the authors did not recommend ultrasonography after a first febrile UTI in children with unremarkable prenatal ultrasound after 30–32 weeks of gestation. In a study of early DMSA scanning in neonates with febrile UTIs, Siomou *et al.*[26] found that the ability of DMSA to predict dilating VUR was low, since the majority of children with greater than grade III VUR had normal DMSA results. Moreover, they noted that none of these patients were noted to have normal renal US.

MANAGEMENT

Developmental considerations exist that must be taken into account when treating neonates with a UTI. Glomerular filtration rate is low at birth and develops with age. This must be taken into consideration when prescribing medication and calculating fluid requirements.[5] Treatment depends on the diagnosis of either cystitis or pyelonephritis, and whether the diagnosis is either simple or complicated. Simple cystitis requires a short course of oral antibiotics based on suseptibilities (3-day course). A complicated UTI will require a longer course and even parenteral antibiotic administration based on initial presentation. Pyelonephritis

requires a 10- to 14-day course of parenteral medication followed by oral administration based on initial presentation. It has been established that oral and i.v. antibiotics have been equally effective in treating young children with acute pyelonephritis. It was shown that time to defervescence and return to sterile urine within 24 hours was identical; also that the cost of a 10-day oral course was significantly lower, without clinical compromise, i.e. reinfection or renal scarring.[30] Studies evaluating the treatment of febrile UTIs in young children with oral versus i.v. antibiotics have demonstrated similar efficacy with the use of third-generation cephalosporins.[31]

The antibiotic repertoire available to the physician in the newborn period is significantly more limited than that available to older children. Aminoglycosides, penicillins and cephalosporins can be utilized in the newborn period, however, their use is not without risk. Potential complications associated with their use include diarrhea, intolerance, and allergic reactions including anaphylaxis, as well as nephrotoxicity if not carefully dosed and monitored. Nitrofurantoin has been linked to hemolytic anemia in the neonatal period, and should not be utilized in children with glucose-6-phosphate dehydrogenase deficiency because of the risk of hemolysis. Given low tissue levels attained during administration, nitrofurantoin is a poor choice for the treatment of pyelonephritis. Trimethoprim use should be avoided in patients with megaloblastic anemia with folate deficiency, or in children with sodium-wasting disease (i.e. posterior urethral valves or renal insufficiency) because of potential hyperkalemia by blocking the sodium channels present in the principal cells of cortical collecting ducts. It can also increase serum creatinine levels by blocking the proximal tubular secretion of creatinine. Trimethoprim/sulfamethoxazole should not be used in the newborn period because of concerns for hyperbilirubinemia and kernicterus. The metabolic acidosis seen in patients taking trimethoprim/sulfamethoxazole is attributed to bicarbonate loss induced by the sulfamethoxazole component through an acetazolamide-like effect on the proximal tubules.[28]

PROPHYLAXIS

The benefits from prophylactic antibiotic use have been debated (Table 91.5), including their use in those children with VUR and those without it. Some have published short follow-up studies demonstrating their inefficacy in the management of low and moderate VUR.[32] Recently, results from the PRIVENT trial were published demonstrating a modest reduction in the rate (7%) of recurrent symptomatic urinary tract infection in predisposed children, including those with VUR and those with a previous UTI with the use of prophylactic antibiotics.[33]

SURGERY

Surgical intervention in the newborn for recurrent UTI is rarely necessary. Indications for surgery include recurrent episodes of urinary tract infection, and/or deteriorating renal function noted on nuclear medicine studies (Table 91.6). Infection in the face of hydronephrosis from a ureteropelvic junction obstruction mandates consideration for surgical reconstruction. Surgery can also be considered for ectopic ureteral insertion, and distal ureteral obstruction with recurrent infection, with or without antibiotic prophylaxis. The size of the newborn bladder has to be taken into consideration during reconstruction, given that a ureteral reimplantation into a small newborn bladder can be a difficult task. Some authors advocate the utilization of proximal, or distal diversion in order to allow the bladder time to grow, and attain a larger capacity. Staged repairs can be considered, especially if there is the potential need for tapering of the distal ureter during reimplantation. The presence of a ureterocele and infection calls for prompt incision followed by antibiotic prophylaxis given the high likelihood of vesico-ureteral reflux. Ureterocele puncture or incision is usually followed by reconstruction of the bladder.

Since its approval by the Federal Drug Administration, dextranomer/hyaluronic acid (Dx/HA) copolymer has revolutionized the management of vesico-ureteral reflux. Its applicability to newborns has not been well documented. However, given the low morbidity associated with this procedure, injection therapy is a viable option in the face of recurrent UTIs and low-grade vesico-ureteral reflux. It should be noted, however, that injection into a newborn bladder can be challenging and long-term follow-up studies after injection in younger children are lacking.

Urinary tract infections in the myelodysplastic newborn warrant earlier urodynamic evaluation, the implementation

Table 91.5 Prophylactic antibiotic regimens for prevention of urinary tract infection.

Antibiotic	Dose
Trimethoprim	2 mg/kg daily
Trimethoprim-sulfamethoxazole (TMP-SMX)	2 mg/kg TMP, 10 mg/kg SMX daily
Nitrofurantoin	1–2 mg/kg daily
Amoxicillin	20 mg/kg daily
Cefexime	4 mg/kg daily

Table 91.6 Surgical conditions leading to febrile urinary tract infection.

	Condition
Anatomic	Vesico-ureteral reflux
	Ureterocele
	Ureteropelvic junction obstruction
	Posterior urethral valves
	Ureteral or renal calculi
	Obstructed megaureter/megacalicosis
Functional	Neurogenic bladder – myelomenigocele
	Dysfunctional voiding – Hinman's syndrome

of anticholinergic therapy, and clean intermittent catheterization, along with the use of prophylactic antibiotic therapy. Recurrent infections may require surgical intervention in the form of vesicostomy, and rarely more proximal diversions, such as ureterostomy/pyelostomy. Recurrent infections following ablation of posterior urethral valves (PUV), and persistent hydronephrosis can also lead to diversion, including the use of ureterostomy or pyelostomy to prevent recurrent infections. Prior to diversion in the PUV, patient imaging studies (VCUG) should be obtained confirming that the valves have been adequately ablated. A thorough urodynamic evaluation is also recommended. However, in the author's opinion, the use of diversion rarely affects the clinical course of the patient, and rarely seems to affect the recurrence rate.

CONCLUSION

Neonates are particularly susceptible to develop urinary tract infection which may be explained by the compound effect of immaturity of the local defense mechanisms (decreased uroepithelial bactericidal activity, low levels of local immunoglobulin A, decreased urinary acidification) and heavy periurethral colonization occurring in healthy neonates and gradually resolving after six months of age.[2] The benefit of circumcision in the prevention of early urinary tract infection is not questionable in the neonate. In the general population, the recurrence rate for UTI is very high. Within one year of a first infection, approximately 30% of boys and 40% of girls will develop a repeat infection. The rate will double for each subsequent episode.[27] Unfortunately, recurrence is not uncommon in the neonatal period. With the widespread use of prophylactic antibiotics, recurrence with multiresistant organisms is also a possibility. The need and extent of radiologic imaging required following a neonatal UTI is still under investigation. The usefulness of invasive, expensive studies continues to be questioned.

Pediatric UTIs constitute a significant health burden. Although the actual costs are not known, it is estimated to be in the order of US$180 million for inpatient costs in the United States. This fails to include the costs to society of parental productivity from lost wages, treatment, and follow up after the infection.[10] There are a number of complex host and bacterial virulence factors that play into the susceptibility of children to UTI. It is important that the clinician be familiar with the spectrum of UTI, and children at risk of UTI, so infants and children that need to be evaluated for anatomic or functional abnormalities of the urinary tract are correctly identified and managed.

Imaging of the renal tract in the neonate

LORENZO BIASSONI AND MELANIE HIORNS

INTRODUCTION

The widespread use of antenatal ultrasound in the last 25–30 years has allowed the early identification of a number of congenital nephro-urological abnormalities, which are now assessed with imaging soon after birth. In addition, a congenital nephro-urological abnormality may declare itself postnatally, for example with a urinary tract infection, anomalies in urine stream, septicemia, metabolic upset due to renal failure, or simply vomiting. Occasionally, the neonate may have hematuria due to renal vein thrombosis, especially in the case of a prolonged labor with hypoxic events. A well neonate may present with an abdominal mass found on routine examination or with an apparently unrelated congenital abnormality, e.g. esophageal atresia.

Once the attention of the clinical team has been focused on the genitourinary tract, the role of the radiologist is to establish whether the child has been born with a normal urinary tract and whether he is therefore suffering from an acquired condition, or whether he suffers from a congenital anomaly.

Usually, the questions asked by the clinical team are the following: (1) how many kidneys are present and where are they within the abdomen; (2) is there dilatation of the renal collecting system and is the renal parenchyma normal or abnormal; (3) are the bladder and the urethra normal or is there a thick-walled bladder and/or an obstructed urethra; and (4) what is the renal function, both in absolute terms and in terms of the split function of each kidney.

The radiologist has three key imaging examinations available, which can provide an answer in the vast majority of cases: the abdominal ultrasound (US), the micturating cystogram (MCU), and the radioisotope examinations. Nowadays, there is no indication for i.v. urography (IVU) in the neonatal period (and almost no role in the older child). Computed tomography (CT) in the neonatal period would be confined exclusively to the assessment of a renal mass if the US had not been able to provide satisfactory information, and if magnetic resonance imaging (MRI) was not available. MRI has an important role to play in the work-up of renal tumors and in the assessment of the morphology of the urinary tract, again, if insufficient information has been obtained by US. In this instance, most babies can undergo a 'feed and wrap' technique and will not necessarily require sedation or a general anesthetic.

COMMONLY AVAILABLE IMAGING MODALITIES

Abdominal ultrasound

The first imaging examination of the urinary tract should always be an abdominal US. With modern US equipment and well-trained personnel, it is possible to obtain anatomical detail of the entire urinary tract. The equipment is mobile, and a comprehensive US examination can be undertaken even in the ill neonate in an incubator on intensive care. The results of the US examination set the framework of the anatomical state and frequently permit the nephro-urological team to begin therapy with either a shortlist of differential diagnoses or a presumed single diagnosis. In the majority of cases, the US examination will identify how many kidneys are present, the renal size, whether the kidneys are simplex or duplex, if the parenchyma is sonographically normal, and if there is dilation of the renal collecting systems. The bladder should be examined at the beginning of the US examination, as micturition may occur at any moment and a full bladder is useful when searching for dilated ureters behind the bladder (Fig. 92.1). Bladder wall thickness is easy to identify and measure; the proximal posterior urethra may be dilated in the male with posterior urethral valves, and this can be identified during micturition if looked for. The patient needs no preparation for an US examination. The examination should be performed with both the standard curvilinear probe and also with a high frequency (and thus high resolution) linear probe. Ideally, the infant should be scanned both supine and prone, although if a neonate is being ventilated it will not be possible to obtain prone images.

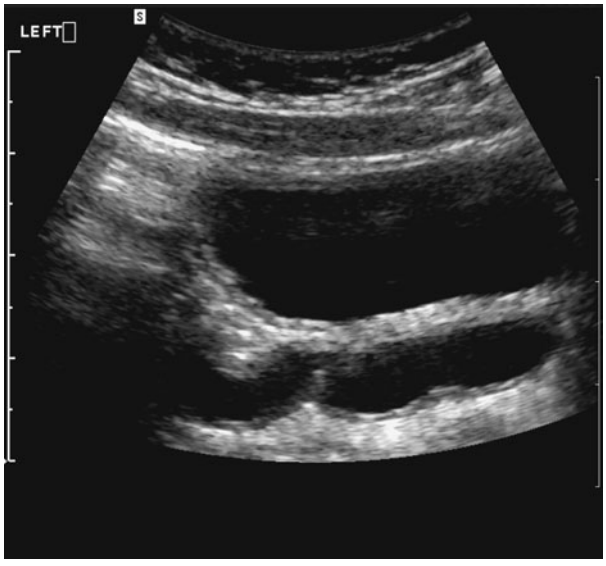

Figure 92.1 Ultrasound showing a dilated left ureter behind the bladder, in this patient this was secondary to a vesico-ureteric junction obstruction.

The normal US appearance of the kidney in a neonate is of a slightly echo bright cortex, when compared to the adjacent liver or spleen, with a slightly echo poor medulla (pyramids). The difference between the cortex and the medulla is termed corticomedullary differentiation. A small kidney with loss of corticomedullary differentiation indicates an abnormal parenchyma (Figs 92.2 and 92.3). This may be due to an acute insult, such as acute renal failure or renal vein thrombosis, or may represent an underlying intrinsic abnormality, such as renal dysplasia, which may be associated with cysts to varying degrees. The presence of dilatation of the collecting system must raise the possibility of obstruction, but does not necessarily infer this. If the dilatation is bilateral, then bladder outlet pathology must be excluded. However, vesico-ureteric reflux (VUR) may give a very similar appearance.

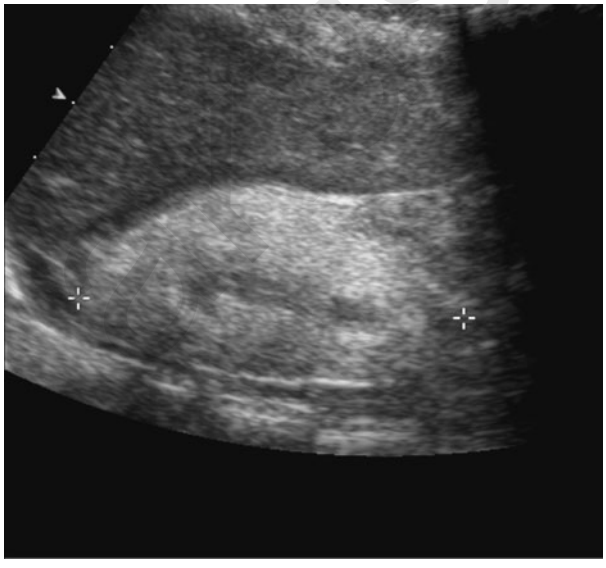

Figure 92.2 Ultrasound in a newborn male patient with primary hyperoxaluria. The kidney is echo bright compared to the adjacent liver and has lost its corticomedullary differentiation. In this condition, the brightness represents global nephrocalcinosis.

Figure 92.3 Ultrasound in a 4-week-old male patient with congenital nephritic syndrome. The kidney is bright and enlarged, but some of the normal architecture can still be recognized.

In the neonate, features on US of echogenic areas within the kidneys may suggest nephrocalcinosis (Fig. 92.2), and this is the most common cause of focally echo bright kidneys following furosemide diuretic therapy. Tamm Horsfall proteins may give a similar appearance, but are transitory.

There are two important pitfalls in the use of US that should be stressed. The first is in the presence of a sick neonate who is either anuric or oliguric, when US may not reveal any dilation, but an obstructive uropathy may still be present. In this clinical situation, a repeat US must be carried out once the infant starts to produce urine. The second pitfall is in the case of antenatally diagnosed unilateral hydronephrosis: here, the US may fail to show significant dilation during the first 48 hours of life due to physiological dehydration and the US should be done on the 3rd postnatal day or later.

Micturating cystourethrogram

An MCU gives invaluable anatomical information about the bladder, and the bladder outflow tract in the male, and if VUR is detected, then details of the ureters, pelvis, and calyces are well outlined (Fig. 92.4). Contrast showing calyceal detail may suggest renal dysplasia. The combination of US and MCU allows adequate evaluation of all kidneys and collecting systems shortly after birth and permits appropriate management to be instituted immediately in all cases, especially if an obstructive uropathy is present, e.g. posterior urethral valves (Fig. 92.5). The timing of the MCU will depend on clinical presentation and clinical state of the baby.

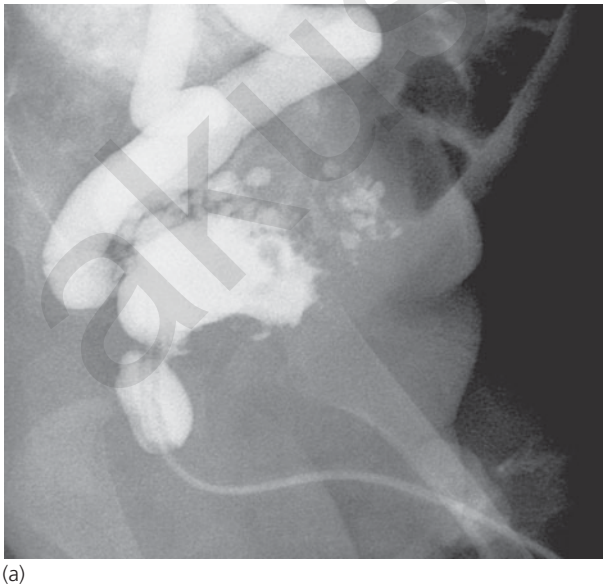
The baby will need to be catheterized and in most patients a 6-F feeding tube can be used. It is not necessary to use a catheter with a balloon as there is no indication to inflate the balloon for this study. The voiding views of the urethra in the male child should be obtained with both the tube still in and

with it removed to ensure that a tiny valve leaflet is not missed. Antibiotic cover should be given before and after the procedure, which should be done under sterile conditions.

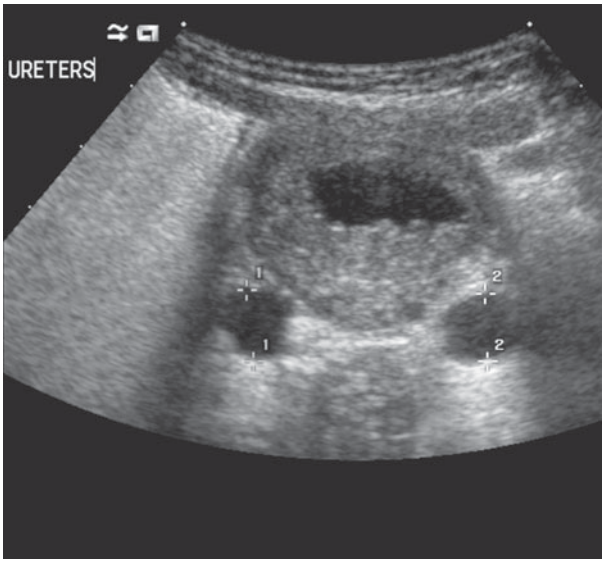
An MCU is only rarely indicated in the immediate neonatal period, although there may be extended indications when the infant is slightly older. In the neonatal period it is most commonly indicated with the US finding of bilateral hydronephrosis. This raises the possibility of an obstructive uropathy either in the urethra (posterior urethral valve in the male infant), at the bladder base (ureterocele), at the vesicoureteric junction (VUJ) bilaterally, or a bilateral pelviureteric junction (PUJ) obstruction. Bilateral VUR may give identical images (Fig. 92.4). In this context, an MCU should be carried out as soon as the baby is in a good clinical state.

Figure 92.4 Micturating cystogram in a patient with gross reflux outlining the hydro-ureteronephrosis and the configuration of the collecting system. There was no outflow tract obstruction in this patient (no posterior urethral valve).

(b)



(a)



(c)

Figure 92.5 (a) Micturating cystourethrogram in a newborn male demonstrating a tight posterior urethral valve and a very trabeculated and thickened bladder wall; (b) a later view in the same patient showing gross reflux in both ureters to the level of the collecting systems; the bladder has preferentially refluxed contrast into the upper tracts as this presents less obstruction than overcoming the tight posterior urethral valve; (c) ultrasound in the same patient showing a very thick-walled bladder and bilateral dilated ureters behind the bladder.

If an MCU is being performed for possible posterior urethral valves and these are confirmed, then the catheter should not be removed; the diagnosis has been established and there is no additional information to be gained by a tube-out view, and there is a risk of a difficult recatheterization to re-establish continued bladder drainage.

The neonates with an antenatal diagnosis of hydronephrosis requiring an MCU include all those with postnatal US confirmation of either a dilated ureter, bilateral hydronephrosis, or an abnormal bladder. Unilateral hydronephrosis with a normal opposite kidney and bladder on US in a well neonate does not require an MCU.

If the clinical question is only about the presence of VUR, and the anatomy of the urethra in a male infant has already been assessed with a previous MCU, a radioisotope cystogram (direct isotope cystography, DIC) will answer the question, with a negligible radiation burden (less than a chest x-ray) to the infant. This test is obtained by positioning the child on the gamma camera head and catheterizing the bladder. A minimal amount of Tc-99m pertechnetate (20 MBq is sufficient) is then instilled in the bladder via the catheter. The catheter is connected to a bag with saline; the saline is run and the bladder is filled until the child feels the urge to void. The acquisition begins after instilling the tracer in the bladder and continues until the end of the emptying phase (or when VUR has been demonstrated). If there is VUR during the bladder-emptying phase, this will be detected with high sensitivity (Fig. 92.6).

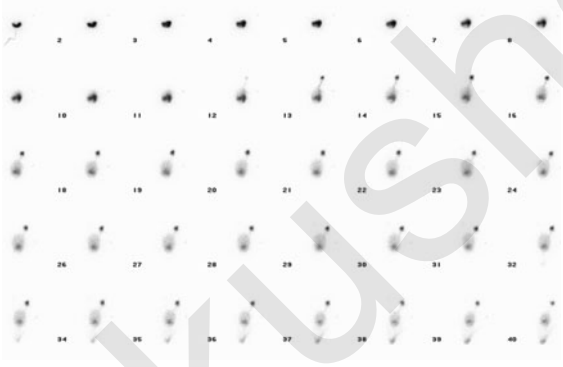


Figure 92.6 Direct isotope cystogram in a 16-month-old girl, showing clear evidence of right-sided VUR.

Functional imaging

Radioisotopes examinations provide an *in vivo* evaluation of the global and regional renal cortical function, with a precise estimate of the contribution of each kidney to the total renal function. Moreover, the dynamic radionuclide renography shows how each kidney drains, with identification of possible hold-ups.

TRACERS AVAILABLE

The main tracers available are the Tc-99m dimercapto-succinic acid (DMSA), the Tc-99m mercapto-acetyl-triglicine (MAG3) and the Tc-99m diethylenetriaminepentacetic acid (DTPA). Some centers use ^{123}I ortho-iodo-hippuran (OIH), but the labeling with ^{123}I (cyclotron produced) makes it an expensive and not readily available tracer. The DMSA is taken up by the proximal renal tubules and, once in the renal parenchyma, approximately 60% sticks within the tubules, while approximately 30–40% of the tracer leaves the kidney with the urine. The DMSA is the current gold standard for the evaluation of the differential renal function (DRF) and the evaluation of renal parenchymal integrity. The MAG3 and the OIH are secreted by the proximal tubules into the lumen and leave the kidney via the collecting ducts and the renal collecting system. The DTPA is filtered by the glomerulus and leaves the kidney via the collecting system. Tc-99m MAG3 has a higher extraction fraction than Tc-99m DTPA and therefore is a better tracer, especially in the neonate. The tracers used for dynamic renography can evaluate DRF almost as accurately as the DMSA. They can also provide an evaluation of renal parenchymal integrity (although small scars can be missed) and assess drainage.

PATIENT'S PREPARATION

The child should be appropriately hydrated. This allows normal flow of urine throughout the renal parenchyma and pelvi-calyceal system. If the child is suboptimally hydrated, the tracer will progress slowly through the renal parenchyma and collecting system, thus giving a false impression of obstruction. In some centers, i.v. fluids (saline 10–15 mL/kg) are given, starting 30 minutes prior to the tracer injection. In other centers, oral hydration is preferred. It is also essential that the child is immobile during the examination: this is achieved with sandbags at both sides of the neonate and velcro straps. If the neonate has been fed prior to the start of the examination, it is likely that he will fall asleep and keep still. Sedation/general anesthesia are not necessary and should not be used.

EVALUATION OF THE DIFFERENTIAL RENAL FUNCTION

This is achieved by drawing regions of interest (ROI) around each kidney at a time after tracer injection when the parenchyma-to-background ratio is optimal and no significant tracer has reached the collecting system (normally between the first and the second minute after tracer injection in the case of tracers used in dynamic renography). In the case of DMSA scintigraphy, the split function is usually calculated between 2 and 4 hours after tracer injection, when the tracer has been taken up by the renal parenchyma. ROI around each kidney to subtract background activity are also drawn. A precise estimate of the DRF can be challenging in the neonate, with immature kidneys and consequent reduced tracer uptake and relatively high background activity, even more so if there is also chronic renal failure (for example, due to posterior urethral valves), because the kidneys extract the tracer much less avidly. Another challenging clinical situation is when one of the kidneys is much bigger than the other, for example, in a neonate with prenatally diagnosed severe hydronephrosis.

In a neonate with antenatally diagnosed hydronephrosis, functionally imaging is normally deferred until the child is two or three month old, with better, even if not complete, renal maturation. Occasionally, a functional study may be requested in a younger infant: the clinical question then is whether a kidney shows any significant function at all, leading to the consideration of a possible nephrectomy versus more conservative treatments.

EVALUATION OF DRAINAGE

Drainage can be influenced by several different factors, especially in the neonate: the function of the kidney, the hydration status, the size of the renal pelvis, the bladder status, the effect of gravity (supine versus upright position). Therefore, an accurate evaluation of drainage has to take into account all these factors. Intravenous furosemide administration (5 mg in neonates and infants up to six months of age) can help to distinguish between an obstructed renal pelvis and a dilated non-obstructed one. It may happen that the neonate voids in the nappy during the dynamic renography, especially after administration of furosemide: this can be helpful as it shows the drainage pattern with an empty or almost empty bladder and it can even demonstrate the possible presence of VUR. An image after change of position (from supine to upright) at the end of the dynamic renography is essential to differentiate an obstructed pelvis from a dilated non-obstructed one.

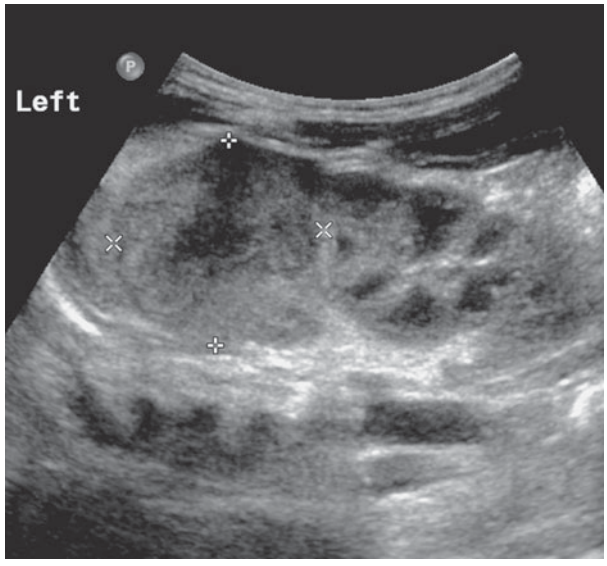
There are computerized methods to assess drainage. The half-time diuretic wash-out method calculates how long it takes to halve the counts within the renal pelvis following furosemide administration. This method is only reliable if it gives a normal value (<10 minutes half-time). If it is prolonged, it cannot differentiate between a dilated pelvis and an obstructed one, as it does not take into account the size of the renal pelvis, the bladder status, the gravity effect, and the hydration status and therefore in the context of antenatally diagnosed hydronephrosis it should not be relied upon. Methods such as the pelvic outflow excretion efficiency (PEE) or the normalized residual activity (NORA) evaluate how much tracer has left the kidney as a percentage of what has come into the kidney (PEE) or how much tracer has remained in the kidney as a percentage of the amount that has left the kidney.

DEFINITION OF OBSTRUCTION

It is important to bear in mind that slow drainage via a dilated collecting system on dynamic radionuclide renography does not necessarily mean obstruction in the context of an asymptomatic infant with an antenatally diagnosed hydronephrosis. A dilated pelvis and/or ureter in an asymptomatic infant can be due to a number of conditions: PUJ or VUJ obstruction, PUJ dilatation with no obstruction, VUR, hydro-ureteronephrosis, megaureter with or without VUJ dysfunction, a complex duplex system with a dilated upper moiety. All these conditions can give slow drainage on dynamic radionuclide renography. Urinary stasis within a dilated renal pelvis/ureter does not necessarily cause suffering of the renal parenchyma. Even a mild stenosis at the PUJ may not cause sufficient resistance to urinary outflow to cause suffering of the renal parenchyma. Therefore, the only definition of obstruction that has been accepted at present is 'a condition of resistance to urinary outflow that, left untreated, will cause deterioration of renal function'. As it can be seen, unfortunately this definition is a retrospective one. Therefore, on a single dynamic renography examination showing slow drainage and urinary stasis either at the PUJ or at the VUJ, obstruction cannot be reliably diagnosed, as it is not known whether this condition will cause a fall in function of that kidney or not.

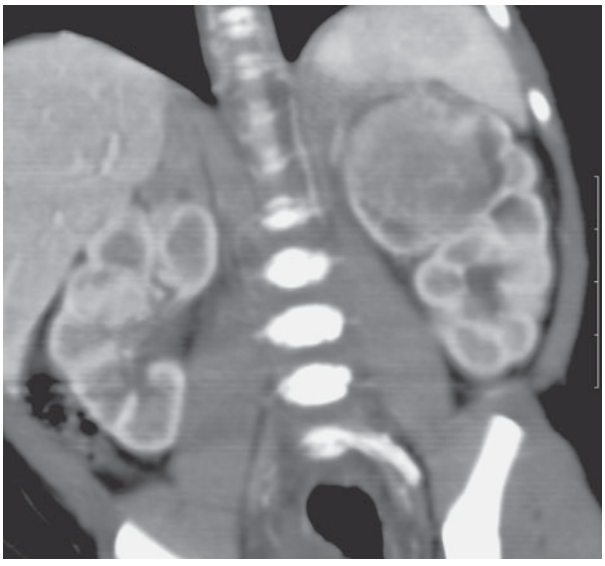
MRI and CT: cross-sectional imaging

In the presence of a transonic lesion on US, there is no indication for cross-sectional imaging as cystic lesions can be followed with US. Solid lesions will usually require further imaging after the initial US. The major differential diagnosis of renal tumors in the neonate is that of a mesoblastic nephroma (Fig. 92.7), as Wilms' tumors (Fig. 92.8) are rare in the neonatal period. Neuroblastoma (in the adrenal) can sometimes be confused with a renal mass lesion and should also be considered. MRI is the optimal technique to assess mass lesions as it does not use radiation and has better inherent tissue contrast resolution than CT. CT has good spatial resolution and is fast to acquire, but carries a heavy radiation dose penalty. Furthermore, the neonate has little fat

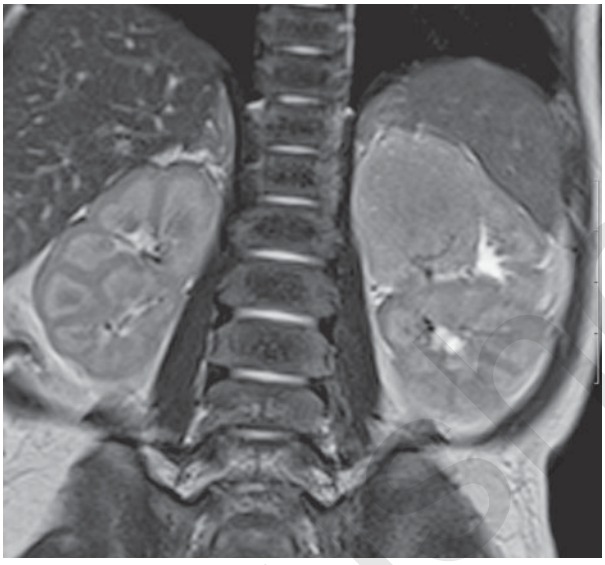


(a)

Figure 92.7 (a) Ultrasound in a 6-day-old male patient showing a mass at the upper pole of the left kidney. Histology subsequently confirmed mesoblastic nephroma; (b) computed tomographic scan in the same patient; (c) magnetic resonance image with T_2 weighting showing the displacement of the collection system around the mass and demonstrating the normal corticomedullary differentiation in the rest of the left kidney and in the right kidney.



(b)



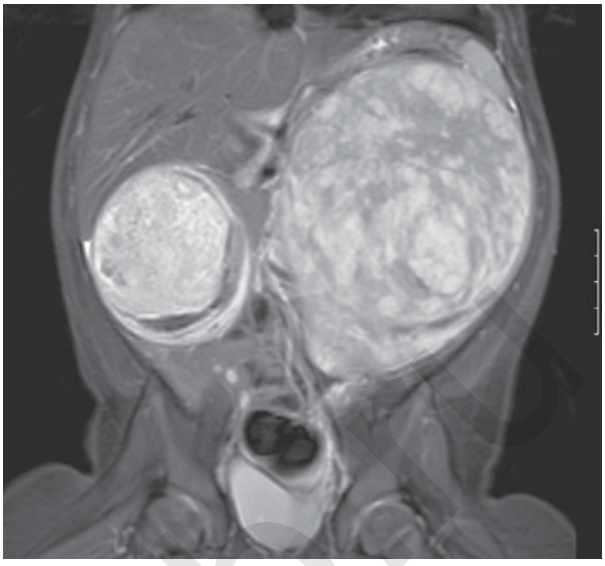
(c)

Figure 92.7 *Continued*

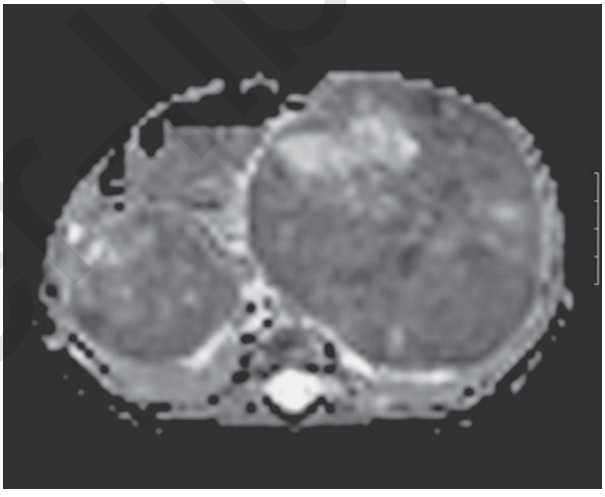
to provide contrast between tissues and thus CT images may be suboptimal.

MRI can also provide exquisite depiction of the urinary tract, especially if it is dilated, as specific sequences will show water, and hence urine-containing structures, in great detail. This examination is also termed magnetic resonance urography (MRU) (Fig. 92.9). It is therefore increasingly useful in supplementing the information obtained by US regarding dilatation, anatomy, and in some cases the function, of the renal tract.

The use of MRI in the neonatal age group was previously limited by the length of time to acquire various sequences (up to 10 minutes each) and therefore the risk of patient movement degrading the images, but the sequences are now much faster and techniques are available to counteract the effects of breathing and cardiac movement. MRI can be performed under general anesthetic if the 'feed and wrap' technique fails.



(a)



(b)

Figure 92.8 Magnetic resonance image in a three-month-old infant with bilateral Wilms' tumors: (a) STIR sequence in coronal plane showing the marked distortion of the normal anatomy due to the bulk of the tumors; (b) ADC sequence showing extensive areas of low signal (dark gray) within the tumors which represent densely packed tumor cells. The area of high signal (white) anteriorly in the larger left-sided tumor indicates an area of necrosis.

SPECIFIC CONDITIONS IN THE NEONATAL PERIOD

Hydronephrosis

Hydronephrosis in the neonatal period is most commonly imaged subsequent to an antenatal diagnosis of renal pelvic dilatation being made at a routine antenatal US scan. It is important to clarify if the dilatation is bilateral and how dilated the renal pelvis is. Imaging will always be by US. Bilateral pelvic dilatation (>7 mm) necessitates close inspection of the bladder (for bladder wall thickening and ureteroceles) and in boys will prompt MCU to exclude

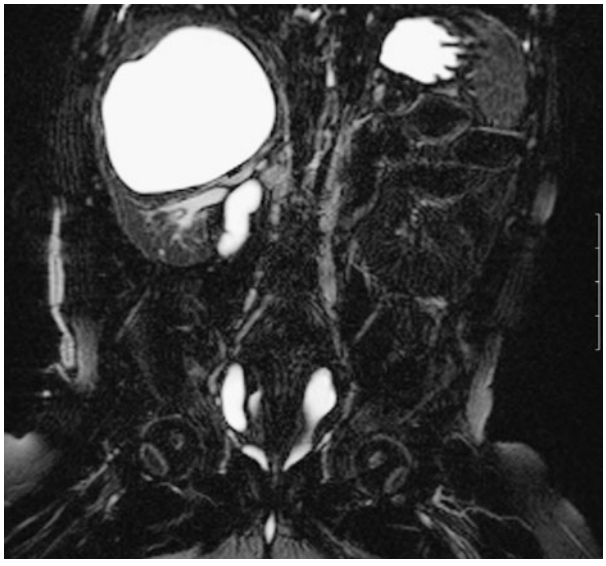


Figure 92.9 Magnetic resonance image in a six-month-old female patient in whom ultrasound had been unable to differentiate between a right-sided pelvi-ureteric junction obstruction and a dilated moiety of a duplex kidney. This heavily T_2-weighted sequence shows that the right kidney is in fact duplex with a very dilated upper moiety and a small and compressed lower moiety. Incidental note was also made of a didelphus uterus.

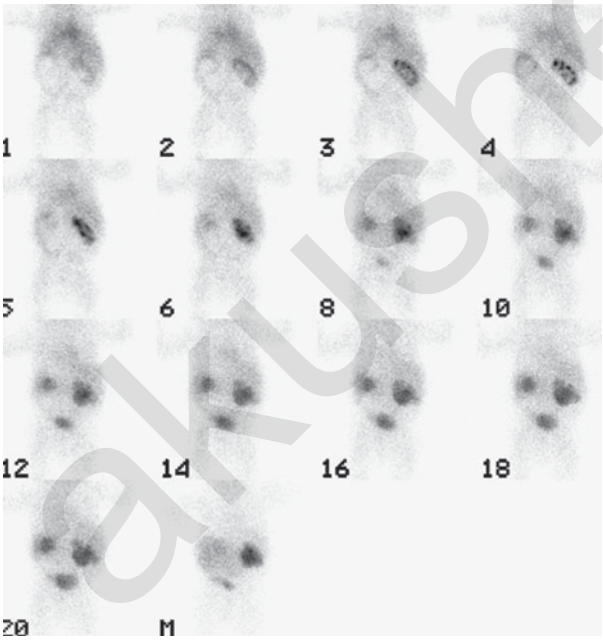
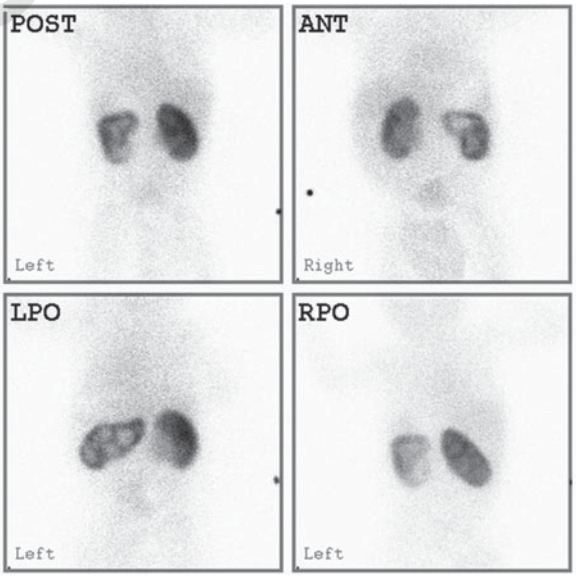
posterior urethral valves. A unilateral antenatally diagnosed hydronephrosis requires functional evaluation, normally with a MAG3 renography, to assess the split function of the hydronephrotic kidney and its drainage. It is important to realize that slow drainage does not necessarily mean obstruction. Follow up of a hydronephrotic kidney is normally performed with US, the frequency of which is controversial. Significant increase in renal pelvis dilatation on US will prompt a repeat functional study. A very significant unilateral dilatation at diagnosis may indicate an intrinsic severe PUJ obstruction, and a functional study (often with MAG3, but also DMSA can be used – especially if the kidney is very enlarged with a very stretched renal parenchyma) will be indicated to establish if the affected kidney has any useful function. A very enlarged and stretched kidney may still have function, or potentially recover its function if prompt intervention is instigated (Fig. 92.10).

'Bright' kidneys

In an unwell neonate, US may be requested by way of a baseline and to exclude any related renal cause for the infant's condition. On these occasions, the observation of 'bright' kidneys may sometimes be made. 'Bright' in this context implies that the parenchyma (both cortex and medulla) is



(a)



(b)

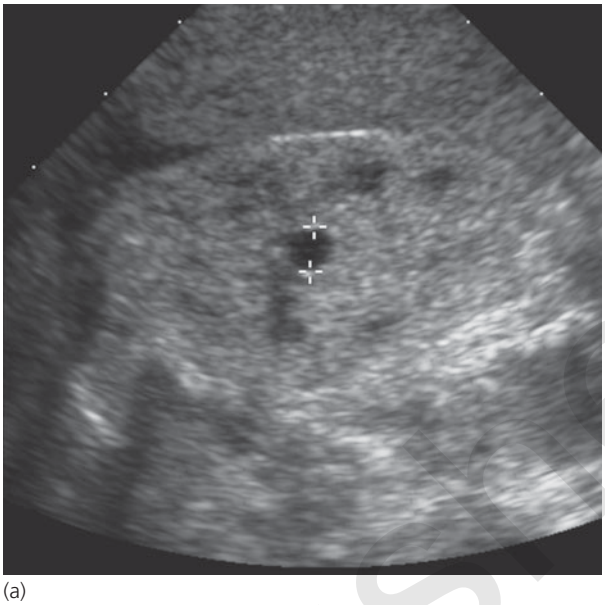
Figure 92.10 Two-month-old boy, presenting with massive left hydronephrosis. On ultrasound, the left kidney measured 11 cm in length, the left renal pelvis measured 8.4 cm, no left ureteric dilatation was seen. (a) Tc-99m MAG3 renogram. The split function of the left kidney is virtually impossible to measure accurately, as the kidney appears grossly enlarged and the region of interest around the left kidney together with the background region extends partially outside the body contour. However, there is tracer uptake within the left kidney suggesting some maintained function. Drainage from the left kidney is very slow, with urinary stasis in the very large renal pelvis seen even following change of posture and micturition. The child underwent an urgent left nephrostomy followed by a left pyeloplasty. (b) A DMSA scan performed a few days following pyeloplasty shows very good function in the left kidney (41% contribution to total renal function), with the kidney appearing much less stretched. On a follow-up MAG3 nine months later (not shown) the split function of the left kidney was unchanged. This case illustrates that prompt intervention on a massively enlarged kidney in an infant due to a PUJ obstruction can still restore good renal function.

more echo bright than the parenchyma of the adjacent liver or spleen. The kidneys may also be small, normal-sized, or large depending on the underlying cause (Figs 92.2 and 92.3).

The differential diagnosis of enlarged hyperechoic kidneys in the neonate includes acute tubular necrosis, renal vein thrombosis, polycystic kidney disease (autosomal dominant or autosomal recessive), autosomal dominant glomerulocystic kidneys, dysplastic kidneys (with or without an associated syndrome, Figs 92.11a and 92.12a) and, rarely, an underlying metabolic disorder (Fig. 92.2). In the case of renal vein thrombosis, a functional study can be useful once the acute episode has resolved to assess if the kidney drained by the thrombosed vein has lost significant function.

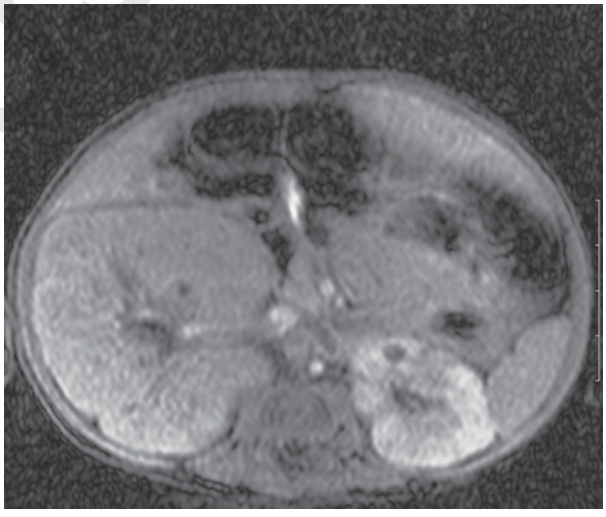
Cystic kidneys

Cystic kidneys will usually present in the neonate either because the infant is in renal failure, or because bilateral mass lesions can be felt in the flanks, or because the patient has an US scan for another reason. The main groups of cystic disease are listed above (see above under 'Bright' kidneys). A multicystic dysplastic kidney (MCDK) may be diagnosed antenatally, but may be picked up in the neonatal period or later (Fig. 92.13). Tuberous sclerosis may also give rise to multiple cysts in the kidneys, but it would be unusual for this to present in the neonatal period (Figs 92.12a and 92.14). US will always be the first examination and usually no other



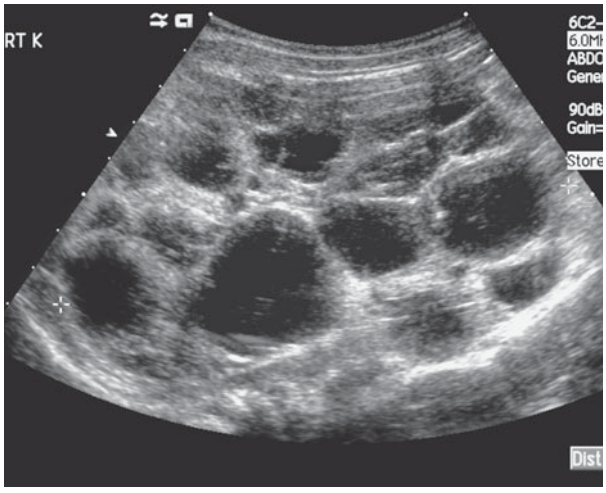
(a)

(b)

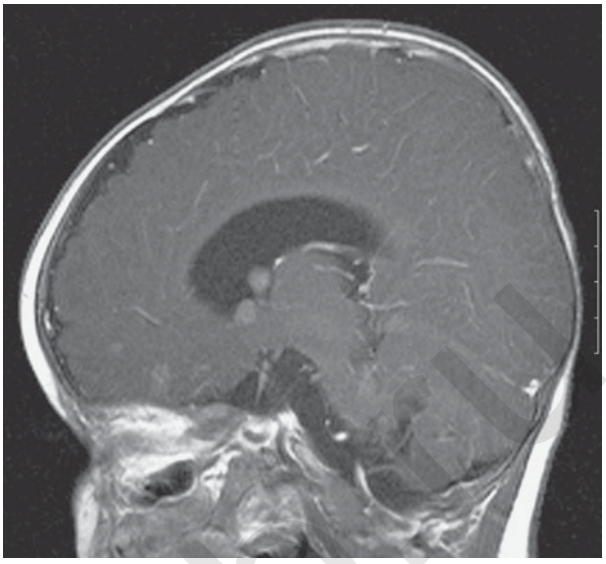


(c)

Figure 92.11 (a) Ultrasound in a one-month-old patient with dysplastic kidneys. Note the small cysts in an otherwise featureless parenchyma; (b) magnetic resonance image in the same patient at the same time: this coronal STIR sequence shows the enlargement of the kidneys and the very abnormal renal architecture, with a typical striated appearance; (c) axial T_1-weighted sequence following gadolinium demonstrating the small cysts seen on ultrasound and poor enhancement.



(a)



(b)

Figure 92.12 (a) Ultrasound in a two-month-old with large palpable kidneys showing multiple cysts; the differential diagnosis would lie between autosomal dominant polycystic kidney disease (ADPKD) and tuberous sclerosis. (b) Brain magnetic resonance image in the same patient demonstrates the presence of tubers (shown adjacent to the lateral ventricle), thus confirming the diagnosis of tuberous sclerosis.

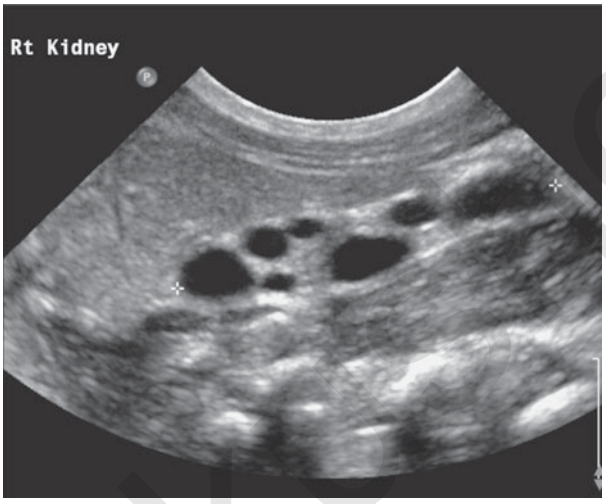


Figure 92.13 Right-sided multicystic dysplastic kidneys on ultrasound in a newborn patient. The cysts may vary in size, but are usually seen throughout the kidney(s) and the intervening parenchyma is echo bright. A true multicystic dysplastic kidney has no function on DMSA.

imaging would be necessary at the neonatal stage. Functional imaging may be performed later.

Tumors

Renal tumors in the neonatal period are rare, but the most likely type would be a mesoblastic nephroma. On US, this mass lesion would generally be mainly solid, if not entirely so (Fig. 92.7). Usually, no further imaging is required and surgery in the neonatal period is curative. Occasionally, the surgeon may wish for further cross-sectional imaging before operating and in this instance MRI would be the modality of choice if it is available. There is no indication for functional imaging for the affected side, but functional imaging may be indicated to assess the function of the contralateral kidney before surgery.

Renal anomalies

Duplex kidneys (Fig. 92.15), cross-fused ectopic kidneys (Fig. 92.16), horseshoe kidneys, and other anomalies are usually first detected by US. US will also be used for monitoring, and for searching for other related anomalies, for example spinal anomalies in patients with the VATER spectrum. Functional imaging is essential as it informs on the function of the upper and the lower moieties of the duplex kidney and on the drainage. Occasionally, it can also inform on the presence of VUR (Fig. 92.17). MRI may be very useful in the most complicated cases, being able to demonstrate the whole of the urinary tract in any desired plane, and giving some information about function and drainage. Unless there are specific complications requiring further intervention all of the secondary imaging may be delayed until the patient is older.

Infection

Infection in the neonatal period may be acquired at the time of delivery, or be secondary to an underlying urinary tract anomaly, or as a result of instrumentation/catheter placement. If imaging were required, then US would be the first modality. If the urinary tract is anatomically normal, US may not demonstrate any abnormal findings, however echogenic

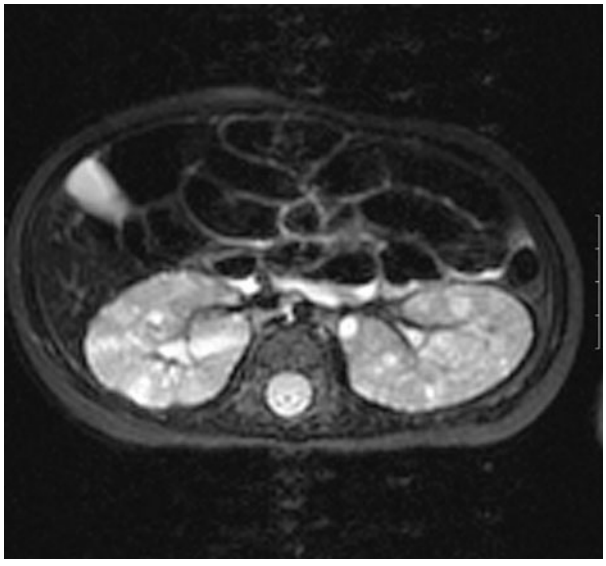

Figure 92.14 Magnetic resonance image in a five-month-old with tuberous sclerosis. This axial STIR sequence shows multiple cysts in both kidneys. These are easily demonstrated by ultrasound, but magnetic resonance imaging is also performed to exclude liver or pancreatic involvement.

debris may be seen throughout the urinary tract, and if the upper tracts are involved (pyelonephritis) it may be possible to demonstrate focal areas of low echogenicity, or the kidneys may simply be enlarged. If the patient has been systemically ill (eg. requiring i.v. antibiotics as an inpatient) functional imaging may be required. If the clinical question is to confirm whether the child has an acute pyelonephritis with renal parenchymal inflammatory involvement and how much of the renal parenchyma has been involved by the inflammatory process, then a DMSA performed during the infection will answer the question. If the question is whether

Figure 92.16 Ultrasound in a two-month-old male infant demonstrating a cross-fused ectopic kidney. The two kidneys lie in the right flank and are fused obliquely.

the infant has developed renal scarring as a consequence of the infection, then a DMSA scan will have to be performed between four and six months after the infection.

Renal calculi and nephrocalcinosis

Calculi are rare in the neonatal period but nephrocalcinosis may be seen in patients with an inherited underlying metabolic abnormality, such as primary hyperoxaluria (Fig. 92.2). It is most commonly asymptomatic. Nephrocalcinosis is well demonstrated on US and is described as medullary, cortical, or parenchymal. Initially, there is a mild increase in echogenicity and ringing of the pyramids, which may

(b)

Figure 92.15 (a) Ultrasound (US) of the kidney in a newborn male showing dilatation of both moieties in a duplex kidney; (b) US of the spine, also performed in the same patient (due to other anomalies in the VATER group), which shows a normal appearance. Spine US needs to be performed in the first few weeks of life before ossification of the spine becomes established.

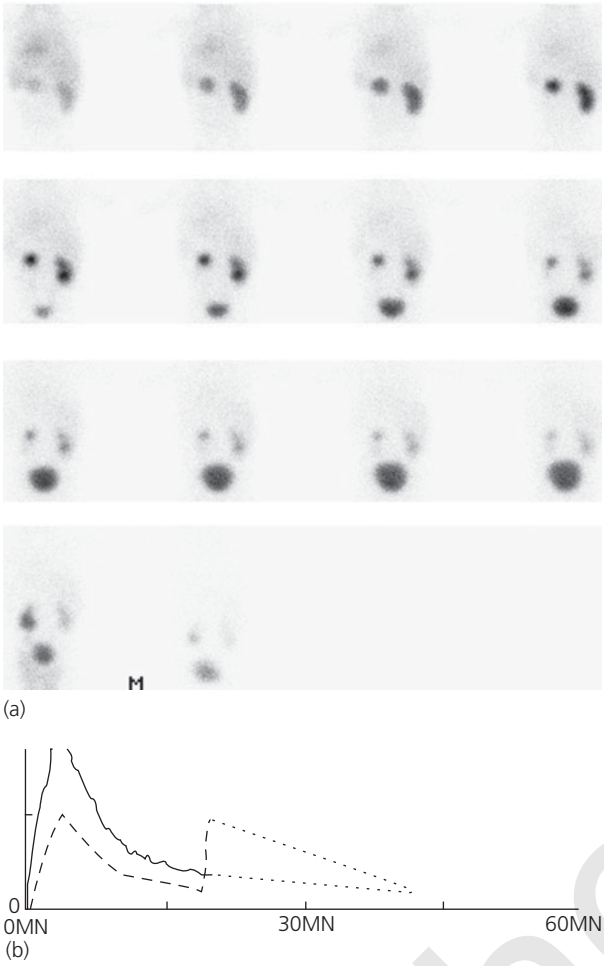

Figure 92.17 Four-month-old boy with an antenatal diagnosis of a left hydronephrosis. The upper moiety appears normal on ultrasound; the lower moiety shows a dilated pelvis of 11 mm and a thin rim of cortex surrounding it. (a) The MAG3 renogram shows good function in the left upper moiety and no function in the left lower moiety. The split function of the left kidney is 36% (right kidney, 64%). There is good drainage from the left upper moiety. The child partially voided in the nappy at the end of the study, with VUR clearly seen in the left lower moiety in the dynamic renography. The right kidney shows good function and drainage. The drainage pattern from the right suggests an uncomplicated duplex system. (b) The time activity curve clearly shows a spike corresponding to the episode of VUR in the left lower moiety. Following the functional study, which demonstrated no function in the left lower moiety, the child underwent a left lower pole heminephrectomy.

eventually progress to filling in of the medullae with acoustic shadowing.

Other causes of focal echogenicity mimicking nephrocalcinosis in the neonatal period include the use of furosemide (calcification seen at the tips of the pyramids, sometimes associated with stone formation), and Tamm Horsfall protein deposition in the medullae (which is a transitory event related to fluid regulation around the time of birth).

CONCLUSION

The US examination should always be the first imaging examination in the neonate. This may be supplemented by functional studies (DMSA or MAG3) or further anatomical studies (including MCU and MRI (or CT)) as determined by the underlying findings on US.

Management of antenatal hydronephrosis

JACK S ELDER

INTRODUCTION

An abnormality involving the genitourinary tract is detected in one in 50 to one in 100 pregnancies, depending on the sonographic criteria.[1,2] The goal of management is to recognize and treat congenital anomalies that may adversely affect renal function or cause urinary tract infection (UTI) or sepsis. Many structural abnormalities of the urinary tract are characterized by hydronephrosis, which frequently is assumed to be obstructive. However, often antenatal hydronephrosis is not caused by obstruction; examples include vesico-ureteral reflux (VUR), multicystic kidney, and certain abnormalities of the ureteropelvic and ureterovesical junction.

DEVELOPMENT OF THE KIDNEY AND RENAL FUNCTION

The kidney is derived from the ureteral bud and the metanephric blastema. During the 5th week of gestation, the ureteral bud arises from the mesonephric (Wolffian) duct and penetrates the metanephric blastema, which is an area of undifferentiated mesenchyme on the nephrogenic ridge. The ureteral bud undergoes a series of approximately 15 generations of divisions, and by 20 weeks' gestation forms the entire collecting system, that is, the ureter, renal pelvis, calyces, papillary ducts, and collecting tubules. Under the inductive influence of the ureteral bud, nephron differentiation begins during the 7th week of gestation. By 20 weeks' gestation, when the collecting system is completely developed, approximately one-third of the nephrons are present. Nephrogenesis continues at a nearly exponential rate and is complete at 36 weeks' gestation.

Throughout gestation, the placenta functions as the fetal hemodialyzer, and the fetal kidneys play a minor role in the maintenance of fetal salt and water homeostasis. Formation of urine begins between the 5th and 9th weeks of gestation. The rate of urine production increases throughout gestation, and at term, volumes have been reported to be 51 mL/h.[3] The glomerular filtration rate (GFR) has been measured at 6 mL/min/1.73 m^2 at 28 weeks' gestation, increasing to 25 mL/min/1.73 m^2 at term, and thereafter triples by three months of age.[4] The main factors responsible for this increase in GFR after birth include an increase in the capillary surface area available for filtration, changes in intrarenal vascular resistance, and redistribution of renal blood flow to the cortical nephrons, which are much more numerous than the medullary nephrons. A congenital obstructive lesion of the urinary tract may have a deleterious effect on renal function. Severe early obstructive uropathy disrupts nephrogenesis and results in renal dysplasia.

MANAGEMENT OF THE FETUS WITH ANTENATAL HYDRONEPHROSIS

When a fetus is identified with a suspected urinary tract abnormality, the goals of management include determining the differential diagnosis, assessment of associated anomalies, and determining the fetal and postnatal risk of the anomaly.

Hydronephrosis is recognized by demonstrating a dilated renal pelvis and calyces. The ureter and bladder may be dilated also. The likelihood of having a significant urinary tract abnormality is directly proportional to the severity of hydronephrosis.[2,5,6] In general, if the renal pelvic diameter is more than 2 cm, 94% have a significant abnormality of the urinary tract requiring surgery or long-term urologic follow up. If the fetal renal pelvic diameter is between 1.0 and 1.5 cm, 50% have an abnormality, and if the dilated renal pelvis is less than 1 cm, only 3% have a significant abnormality.[2,7,8] Currently, a renal pelvic diameter of at least 4 mm before 33 weeks' gestation and at least 7 mm after 33 weeks' gestation is considered significant.[9] The later the sonogram is performed, the more likely an existing abnormality will be detected, because the obstructed renal pelvis gradually enlarges throughout gestation. In addition, *in utero* the fetus is usually upside down in the uterus and urine is draining uphill. For example, Fugelseth and colleagues[10] reported that only one-third of a series of women carrying babies with a urologic anomaly had an abnormal ultrasound study at 15–21 weeks' gestation.

The differential diagnosis of antenatal hydronephrosis is provided in Table 93.1. Virtually all of these conditions can cause bilateral hydronephrosis. A distended bladder and bilateral hydronephrosis is suggestive of bladder outlet obstruction, such as posterior urethral valves or a large ectopic ureterocele obstructing the bladder neck, but fetuses with non-obstructive conditions, such as high-grade VUR or prune belly syndrome, also may have bilateral hydroureteronephrosis and a distended bladder.[11]

In fetuses with a urologic anomaly, associated abnormalities are common. For example, in one series of fetuses with bilateral hydronephrosis and oligohydramnios, 16 of 31 (55%) had an associated structural or chromosomal abnormality.[12] Congenital heart disease and neurologic deformities can often be detected, if they are present. In contrast, large bowel abnormalities, such as imperforate anus, are more difficult to detect by prenatal sonography, whereas recognition of small bowel anomalies, such as atresia, are usually straightforward.

The main considerations in determining fetal management include overall fetal well-being, gestational age, whether the hydronephrosis is unilateral or bilateral, and the volume of amniotic fluid. There are no guidelines for determining how frequently to image the fetus or whether specific intervention is necessary. If hydronephrosis is unilateral, usually no specific fetal therapy is necessary. For example, if the hydronephrosis is secondary to a ureteropelvic junction

Table 93.1 Genitourinary anomalies detectable by prenatal ultrasonography.

Condition	Sex (ratio)	Frequency	Kidney(s)	Ureter(s)	Bladder	Amniotic fluid	Prognosis
Ureteropelvic junction obstruction (unilateral)	M/F (3–4:1)	1:2000	Hydronephrosis	Not seen	Normal	Normal	Good after surgical correction
Multicystic kidney (unilateral)	M/F (1:1)	1:3000	Large with cysts of variable size	Not seen	Normal	Normal	Normal
Primary obstructive megaureter	M/F (3:1)	1:10 000	Hydronephrosis	Dilated	Normal	Normal	Good after surgical correction
Ectopic ureterocele or ureter	M/F (1:6)	1:10 000	Large cyst; possible duplex kidney	Dilated	Normal or enlarged	Normal	Good after surgical correction
Posterior urethral valves	Male	1:8000	Bilateral hydronephrosis; possible cortical cysts	Dilated	Enlarged	Variable; diminished or absent in severe obstruction	Usually good after surgical correction or drainage; poor if oligo?hydramnios is present
Prune belly syndrome	Nearly always male	1:40 000	Bilateral hydronephrosis; possible cortical cysts	Dilated	Enlarged	Variable; diminished or absent if severely affected	Usually fair to good; may need surgical drainage; poor if oligo?hydramnios is present
Vesico-ureteral reflux	M/F (1:5)	1:100	Hydronephrosis if reflux high grade	Variable	Normal; dilated if reflux high grade	Normal	Good; may need surgical correction
Infantile polycystic kidney disease	M/F	1:6000–1:14 000	Large, echogenic	Not seen	Small or not seen	Usually absent or severely diminished	Poor
Renal agenesis	M/F (2.0–2.5:1)	1:4000 (bilateral)	Not seen	Not seen	Not seen	Severely diminished or absent	Stillbirth
		1:1500 (unilateral)	Not seen	Not seen	Normal	Normal	Normal
Hydrocolpos	Female		May have hydronephrosis	Not seen	Normal	Normal	Good after surgical correction
Ovarian cyst	Female		Normal (cyst may be confused with kidney or bladder)	Not seen	Normal	Normal	Good after surgical correction

(UPJ) obstruction, even if function is poor, the kidney has a significant capacity for improvement in function following neonatal pyeloplasty. Even with bilateral UPJ obstruction (characterized by bilateral hydronephrosis and a normal bladder), the amniotic fluid volume and pulmonary development typically are normal. Consequently, specific intervention, such as percutaneous drainage of the fetal kidney or early delivery to allow immediate urologic surgery, are unwarranted. These same principles apply to primary obstructive megaureter.[13]

The primary life-threatening congenital urologic anomalies include posterior urethral valves, urethral atresia, and prune belly syndrome, which are usually characterized by bilateral hydro-ureteronephrosis and a distended bladder that does not empty in a male fetus. Approximately one-third of infants with urethral valves eventually develop renal insufficiency or end-stage renal disease.[14,15] Although prune belly syndrome is considered non-obstructive, neonates with this condition frequently have renal insufficiency, in large part because of congenital renal insufficiency and also from renal deterioration in children with repeated episodes of pyelonephritis.[16] Urethral atresia is nearly always fatal, because the kidneys are usually dysplastic. A severe adverse prognostic factor is oligohydramnios, which prevents normal pulmonary development. In fetuses with severe obstructive uropathy and renal dysplasia, neonatal demise usually results from pulmonary hypoplasia rather than chronic renal failure.

Intuitively, it would seem that treatment of the obstructed fetal urinary tract by diverting the urine into the empty amniotic space might allow normal renal development to occur and restore amniotic fluid dynamics, stimulating lung development. Indeed, experimental procedures have been performed, including percutaneous placement of a vesico-amniotic shunt, creation of a fetal vesicostomy or pyelostomy, and even percutaneous urethral valve ablation through a miniscope.[17] Unfortunately, the complication rate is high, including shunt migration, urinary ascites, stimulation of preterm labor, and chorioamnionitis.[4,18] Furthermore, in most cases, irreversible renal dysplasia has already occurred, and although the procedure may be successful technically, often the baby is stillborn, dies of pulmonary hypoplasia, or is alive with end-stage renal disease.[18,19] Nevertheless, some fetuses may benefit from aggressive intervention if the kidneys do not have irreversible dysplasia. Unfavorable prognostic factors include:[4,13]

- prolonged oligohydramnios;
- renal cortical cysts;
- urinary Na >100 mEq/L, Cl >90 mEq/L, and osmolarity >210 mOsm/L;
- beta$_2$-microglobulin >6 mg/L;
- reduced lung area and thoracic or abdominal circumference.

Unfavorable urinary electrolytes may reflect stale urine in the fetal urinary tract. Consequently, many perinatal centers obtain two or three sequential samples, as subsequent samples yield fetal urine that is more reflective of true fetal renal function.[20,21]

MANAGEMENT OF THE NEWBORN WITH ANTENATAL HYDRONEPHROSIS

Management in the nursery

At birth, the abdomen is inspected to detect the presence of a mass, which most often is secondary to a multicystic dysplastic kidney or UPJ obstruction. In male newborns with posterior urethral valves, often a walnut-shaped mass, representing the bladder, is palpable just superior to the pubic symphysis. Newborns should also be evaluated for anomalies involving other organ systems. Renal function should be monitored with serial serum creatinine levels, particularly in infants with bilateral hydronephrosis. At birth, the serum creatinine level is identical to the mother's, but by 1 week of age, the creatinine should decrease to 0.4 mg/dL. The exception is premature infants, in whom the creatinine may not decrease until these children reach 34–35 weeks' conceptional age because of the immaturity of renal function before that age.

Neonates with hydronephrosis who are at risk for UTI should be placed on antibiotic prophylaxis with either amoxicillin 50 mg daily or cephalexin 50 mg daily.[22] There is evidence that children with vesico-ureteral reflux, ectopic ureter and ureterocele, and posterior urethral valves benefit from prophylaxis, but that those with hydronephrosis secondary to an abnormality of the ureteropelvic junction or ureterovesical junction are not at increased risk.[23] At two months beyond term, the prophylaxis is usually changed to trimethoprim-sulfamethoxazole. In addition, circumcision should be considered in male neonates to minimize the likelihood of urinary tract infection.

INITIAL RADIOLOGIC EVALUATION

Radiologic evaluation should be performed before infants are discharged to delineate the abnormality responsible for changes on prenatal sonography. Serial renal sonograms, a voiding cystourethrogram (VCUG), and a diuretic renogram usually provide the diagnostic information necessary to guide management, although all of these studies are unnecessary in many children.

Renal ultrasound

A renal and bladder sonogram should be obtained first. Typically, this study is obtained shortly after delivery or the following day. However, because neonates have transient oliguria, a dilated or obstructed collecting system may appear normal for the first 24–48 hours of life (Fig. 93.1). Ideally, if unilateral hydronephrosis was present prenatally, the renal sonogram should not be obtained until 72 hours to maximize its sensitivity, but with mothers being discharged within 24–48 hours of delivery, it seems impractical to have the baby brought back to the hospital after discharge for sonography. Inexperienced radiologists may misinterpret a normal neonatal kidney with hypoechoic pyramids for caliectasis.

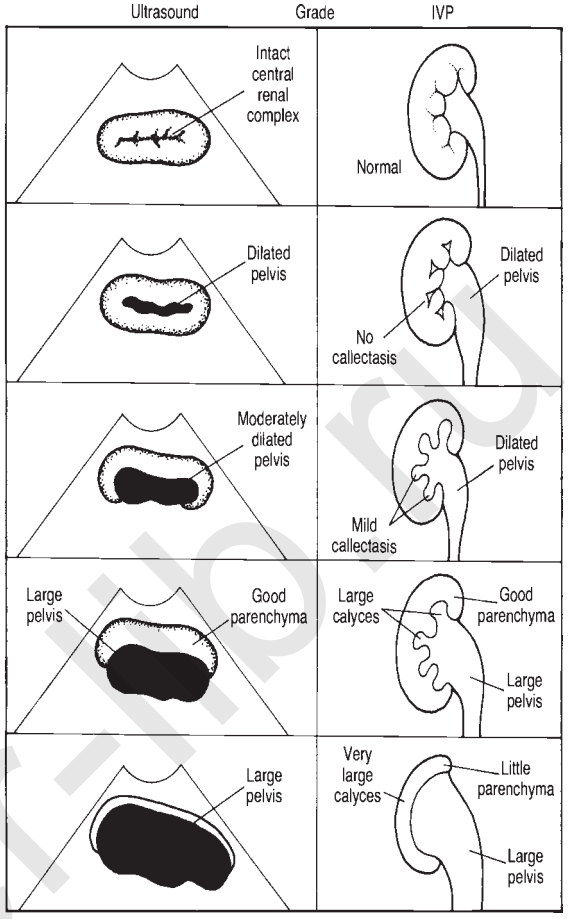

Figure 93.2 Grading system for hydronephrosis. Reproduced with permission from the Society for Fetal Urology.

Renal length, degree of caliectasis and parenchymal thickness, and presence or absence of ureteral dilation should be assessed. The severity of hydronephrosis can be graded from 1 to 4 using the Society for Fetal Urology (SFU) grading scale (Fig. 93.2).[24] Most significant urologic anomalies that require surgical correction or long-term urological follow up are associated with grade 3 or 4 hydronephrosis.[25] More sophisticated analyses, such as the renal resistive index, as well as urinary studies have been assessed, but efforts to demonstrate obstruction have been inconsistent.

The degree of pelvocaliectasis correlates closely with the likelihood that a significant urological condition is present. Lee *et al.*[26] performed a meta-analysis of reports of antenatal hydronephrosis and determined that the risk of finding postnatal pathology was 11.9% with mild antenatal hydronephrosis, 45.1% for moderate, and 88.3% for severe antenatal hydronephrosis. Their definitions of mild, moderate, and severe hydronephrosis depended on gestational age at the time of diagnosis. Similarly, Sidhu *et al.*[27] performed a meta-analysis and found that when postnatal hydronephrosis was SFU grade 1 or 2, there was stabilization or resolution of pelviectasis in 98%, whereas when there was SFU grade 3 or 4, there was stabilization or resolution in 51%.

The bladder should be imaged to detect a dilated posterior urethra (urethral valves), bladder wall thickening, ureteral dilation, inadequate bladder emptying, or a ureterocele. Perineal sonography may demonstrate a dilated prostatic urethra, which is consistent with posterior urethral valves.[28]

Voiding cystourethrogram

Next, a VCUG should be performed. This study may demonstrate VUR, posterior urethral valves, or a bladder diverticulum. A radiographic cystogram is preferred over a radionuclide cystogram because the latter does not provide sufficient delineation of bladder and urethral anatomy and because VUR, if present, cannot be graded.

In a recent analysis by the American Urological Association Pediatric Vesicoureteral Reflux Guidelines Committee, an overall VUR detection rate of 16.2% was found.[29] The mean incidence of VUR into a non-dilated kidney was 4.1%. In cases with antenatal hydronephrosis and a normal postnatal sonogram, the incidence of VUR was 17%. The prevalence of VUR was significantly higher in girls than boys with antenatal hydronephrosis. The likelihood is highest if there is SFU grade 3 or 4 hydronephrosis or if a dilated ureter

is identified. The chance of identifying VUR on a VCUG is less if there is only SFU grade 1 or 2.[30]

WHAT IF THE INITIAL SONOGRAM IS NORMAL?

A common dilemma is whether a full evaluation is necessary if the initial renal sonogram is normal. Assuming a significant degree of fetal renal pelvic dilatation (i.e. 4 mm anteroposterior pelvic diameter <33 weeks, 7 mm diameter after 33 weeks) was present, the child may have VUR. This issue is unresolved. For example, Blane and colleagues[31] reported that 12% of children with grade V, 31% with grade IV, and 80% with grade III VUR had a normal renal sonogram. However, the AUA Reflux Guidelines determined that the mean incidence of VUR into a non-dilated kidney was 4.1%.[29] Because VUR may cause intermittent renal pelvic dilation, theoretically babies with prenatal hydronephrosis and a normal postnatal sonogram may have VUR, and early diagnosis and medical treatment of VUR may reduce the likelihood of developing reflux nephropathy.[32] On the other hand, others have advocated performing a VCUG only if the postnatal sonogram were abnormal;[33] however, in these reports, neonates with a normal postnatal renal sonogram were not systematically evaluated to determine the real incidence of VUR in this group. This author generally recommends that VCUG not be performed unless the postnatal renal sonogram is abnormal.

Follow-up evaluation and treatment

If bilateral hydronephrosis or unilateral hydronephrosis in a solitary kidney is present, then close monitoring of the serum creatinine and electrolytes is necessary. If the hydronephrosis is caused by posterior urethral valves, then valve ablation should be performed before hospital discharge. If the hydronephrosis is secondary to VUR, the infant should be placed on prophylaxis and managed, as described later in this chapter. If the hydronephrosis is grade 3 to 4 and bilateral UPJ or ureterovesical junction obstruction is suspected, prompt evaluation with diuretic renography is indicated.

If unilateral hydronephrosis and a normal contralateral kidney are present, abnormalities in serum creatinine or electrolytes are uncommon. Nevertheless, these serum studies should be drawn to document that renal function is normal. Usually, follow-up functional radiographic studies can be delayed until 4–6 weeks of age, when renal function is more mature and studies of renal function and obstruction are more likely to be accurate.

If the sonogram and VCUG are normal, then only a follow-up sonogram in 6–8 weeks is necessary. In general, if hydronephrosis is discovered on the initial postnatal sonogram, pediatric urologic or nephrologic consultation is advisable to direct subsequent radiologic evaluation and plan therapy.

Diuretic renogram

The diuretic renogram is used to determine whether upper urinary tract obstruction is present. It is used to assess differential renal function and efficiency of drainage of the kidneys. Infants with grade 3 and 4, and occasionally grade 2, hydronephrosis should undergo this study. Mercaptoacetyl triglycine (MAG-3) is generally used, and is primarily secreted by the renal tubules. It provides excellent images with little background activity. Another option is diethylene triamine pentaacetic acid (DTPA), which is excreted by glomerular filtration, but there is much more background with this radiopharmaceutical.

During a diuretic renogram, a small dose of a radiopharmaceutical is injected intravenously. During the first 2–3 minutes, renal parenchymal uptake is analyzed and compared, allowing computation of differential renal function. Subsequently, excretion is evaluated. After 20–30 minutes, furosemide is injected intravenously, and the rapidity and pattern of drainage from the kidneys to the bladder are analyzed. If no upper urinary tract obstruction is present, then normally half of the radionuclide is cleared from the renal pelvis within 10–15 minutes, termed the $t_{½}$. In the presence of significant upper tract obstruction, the $t_{½}$ is greater than 20 minutes. A $t_{½}$ between 15 and 20 minutes is indeterminate. The images generated usually provide an accurate assessment of the site of obstruction.

The renal scan is considered superior to the i.v. pyelogram (IVP) in infants and children with hydronephrosis. The diuretic renogram may be unreliable, however, if certain important variables are not controlled.

Numerous variables affect the outcome of the diuretic renogram. For example, newborn kidneys are functionally immature, and in some cases even normal kidneys may not demonstrate normal drainage following diuretic administration. Dehydration prolongs parenchymal transit and can blunt the diuretic response. Giving an insufficient dose of furosemide may result in inadequate drainage. In addition, a full bladder may impede bladder drainage. Furthermore, if VUR is present, continuous catheter drainage is mandatory to prevent radionuclide from refluxing from the bladder into the dilated upper tract, prolonging the washout phase. Consequently, a urethral catheter should be inserted and bladder drainage measured.

Because of the limitations of the diuretic renogram in newborns with hydronephrosis, and because the methodology for performing diuretic renography varies substantially, the Society for Fetal Urology and the Pediatric Nuclear Medicine Club jointly developed a standardized methodology for performing diuretic renograms in infants.[34]

Magnetic resonance urography

The newest study used to evaluate suspected upper urinary tract pathology is magnetic resonance urography (MRU) (Fig. 93.3). The child is hydrated and given i.v. furosemide. Next, gadolinium-DTPA, which is filtered and excreted, is injected intravenously and routine T_1-weighted and fat-suppressed fast spin-echo T_2-weighted imaging is performed through the kidneys, ureters, and bladder. This study provides superb images of the pathology, and methodology is being developed to allow assessment of differential renal function and drainage.[35] There is no radiation exposure, but younger children need strong sedation or anesthesia. It is

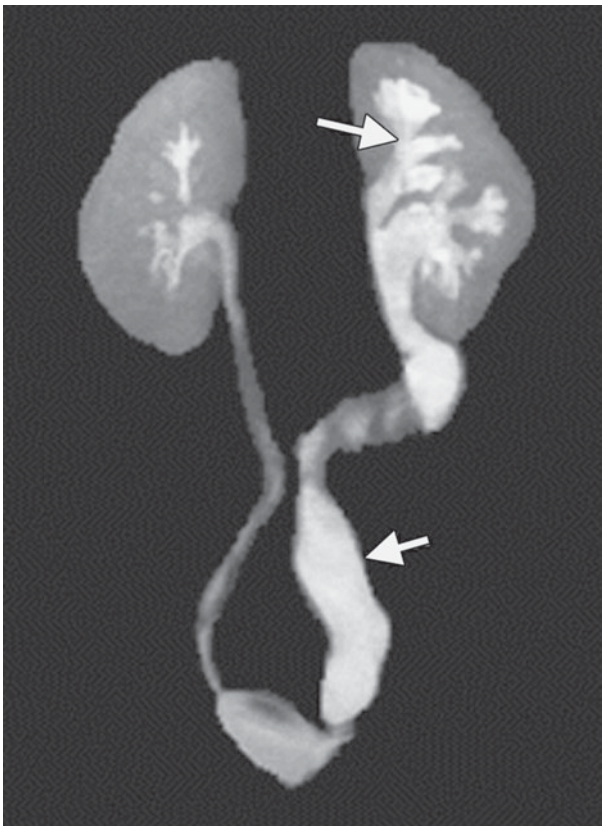

Figure 93.3 Magnetic resonance urogram in a one-year-old demonstrating left obstructive megaureter. The right kidney is normal.

used primarily when renal sonography and nuclear imaging fail to delineate complex pathology, and is the procedure of choice for complex genitourinary pathology.

Ancillary studies

In most cases, a renal sonogram, VCUG, and diuretic renogram provide sufficient information to establish a diagnosis and establish a plan of management. In particularly complicated cases, however, cystoscopy with retrograde pyelography, computed tomography (CT) scan, antegrade pyelography, or a Whitaker antegrade perfusion test is necessary.

CONGENITAL ANOMALIES CAUSING ANTENATAL HYDRONEPHROSIS

UPJ obstruction or anomalous UPJ

The most common cause of severe hydronephrosis without a dilated ureter or bladder in newborn infants is UPJ obstruction, which results from an intrinsic fibrotic narrowing at the junction between the ureter and renal pelvis (Fig. 93.4). At times, an accessory artery to the lower pole of the kidney also causes extrinsic obstruction, but this finding is rare in newborns with hydronephrosis. In kidneys with a UPJ obstruction, renal function may be significantly impaired from pressure atrophy. The anomaly is corrected by performing a pyeloplasty, in which the stenotic segment is excised and the normal ureter and renal pelvis are reattached. Success rates are 91–98%.

Lesser degrees of UPJ narrowing may cause mild hydronephrosis, which is usually non-obstructive, and typically these kidneys function normally. The spectrum of UPJ abnormalities has been referred to as 'anomalous UPJ'. Another cause of mild hydronephrosis is fetal folds of the upper ureter (Fig. 93.5), which also are non-obstructive.

Hydronephrosis in many newborns gradually diminishes or resolves over months to years. The goal of early evaluation is to determine whether a true anatomic obstruction is present that should be corrected or whether it is safe to follow the infant non-operatively. Defining what constitutes obstructive and non-obstructive hydronephrosis is a constant source of debate in pediatric urology.

Cartwright and colleagues[36] studied 80 neonates with suspected UPJ obstruction. Of 39 with unilateral hydronephrosis and at least 35% differential renal function who were managed non-operatively, only six (15%) later underwent pyeloplasty, primarily because of deteriorating differential renal function on renal scintigraphy. Following pyeloplasty, the differential renal function returned to its initial level in these patients. One might question whether early pyeloplasty in these patients would have allowed renal function to improve to 50% (normal). The remaining patients managed non-operatively maintained differential function greater than 40%.

Koff and Campbell[37] reported 104 consecutive neonates with unilateral hydronephrosis managed non-operatively, with follow up as long as five years. In follow up, only seven (7%) underwent pyeloplasty because of reduction in differential renal function of more than 10% or progression of hydronephrosis. Pyeloplasty returned differential renal function to prepyeloplasty levels in all cases. Of 16 patients with significantly reduced renal function on initial scan and grade 4 hydronephrosis, rapid improvement was noted on follow-up diuretic renography in 15 and the washout curve became non-obstructive in six. In addition, hydronephrosis disappeared in six, improved in six, remained stable in three, and deteriorated in one. The physiology of the resolution or reduction in hydronephrosis and the improvement in differential renal function in these babies is unknown. In another more recent report from the same institution, of 19 newborns with bilateral grade 3 or 4 hydronephrosis, a total of 13 kidneys were subjected to pyeloplasty.[38] Of those managed non-operatively, 21 kidneys were grade 0 to 2 and grade 3 in two kidneys. The mean follow-up time to achieve maximum improvement in hydronephrosis was ten months.

Although these studies suggest that it is safe or appropriate to manage neonates with a suspected UPJ obstruction non-operatively, an infant's kidney has much greater capacity for improvement in differential renal function than an older child's. In addition, all of these studies base 'differential renal function' on the uptake during the first 2–3 minutes of the study, and there is substantial variability in the way this percentage is calculated.[39] Finally, these studies have not reported the pattern of washout on diuretic renography.

In a review of renal biopsies obtained at pyeloplasty at the author's institution, 63% showed minimal or no obstructive

The voiding cystourethrogram was normal. (b,c) MAG-3 diuretic renogram (left kidney on the left side of image) shows minimal drainage on the left side. The differential function left:right was 46:54%. Patient underwent left pyeloplasty at two months of age. (d) Follow-up sonogram of left kidney at five months of age demonstrates reduction in hydronephrosis.

Figure 93.5 Excretory urogram in infant with bilateral grade 2 hydronephrosis shows bilateral fetal folds of upper ureters (arrows). Note sharp calyces (normal).

histologic changes; however, of those with differential function greater than 40%, 21% showed significant histopathologic changes, including reduced glomerular number, glomerular hyalinization, interstitial inflammation, and dysplastic glomeruli.[40] Of the kidneys with a low differential function (less than 40%), 33% showed minimal or no histologic changes. Overall, in 25% of the patients the findings on renal biopsy did not correlate with the computed differential renal function and reflect the need for more sensitive markers of obstruction.

The approach of most pediatric urologists to neonates with a suspected UPJ obstruction is as follows. The hydronephrosis is graded from 1 to 4 using the SFU grading scale and a VCUG is obtained. Nearly all infants requiring pyeloplasty have grade 3 or 4 hydronephrosis,[24] and those with grade 1 or 2 hydronephrosis do not seem to be at significant long-term risk.[41–43] If a neonate has an abdominal mass from a hydronephrotic kidney, bilateral severe hydronephrosis, or a solitary kidney, a prompt MAG-3 diuretic renogram is obtained. If signs of obstruction are apparent, prompt pyeloplasty is performed. Otherwise, the newborn is placed on amoxicillin 50 mg daily for prophylaxis, and the diuretic renogram is obtained at 6 weeks of age. The study is not obtained right away in these cases because renal function in the newborn is immature. If diuretic renography shows at least 35–40% differential renal function and there is some drainage on the diuretic renogram, the child is managed nonoperatively, regardless of the drainage pattern (Fig. 93.4). At two months, prophylaxis is changed to trimethoprim-sulfamethoxazole suspension 1.25 mL daily. A follow-up renal sonogram is performed three months later. If the hydronephrosis is unchanged from baseline, a repeat MAG-3 diuretic renogram is obtained. If there is deterioration in differential renal function or worsening of the diuretic washout curve, pyeloplasty is recommended. However, if these parameters remain stable or improved and the child does not develop a UTI, follow up three to six months later with another renal sonogram or MAG-3 diuretic renogram is performed, and management is individualized. It is incumbent on clinicians caring for these infants to have a good understanding of the vagaries of the diuretic renogram and to monitor infants with a suspected UPJ obstruction closely. In addition, review of the radiologic studies (not just the radiology report) by the pediatric urologist is strongly encouraged.

There has been significant progress in the development of minimally invasive techniques in pediatric pyeloplasty, even in infants. Although infant pyeloplasty is performed through a small incision (lumbotomy or flank muscle-splitting) in many centers,[44] an increasing number of pediatric urologists are performing the procedure with traditional laparoscopic techqniques,[45,46] or the daVinci robot.[47,48] Success rates are being compared to series of open surgical repair;[49] hospital stay and narcotic use are less with the minimally invasive approach. Generally, a transperitoneal approach has been used, with mobilization of the colon. However, on the left side, the pyeloplasty can be performed with a transmesenteric approach.

MULTICYSTIC DYSPLASTIC KIDNEY

A multicystic dysplastic kidney is composed of multiple noncommunicating cysts of varying sizes with a stromal component that is composed of dysplastic elements. These kidneys do not function. Although multicystic kidney is the most common cause of an abdominal mass in neonates, the vast majority of multicystic kidneys are detected by prenatal sonography. Some clinicians incorrectly assume that multicystic kidney and polycystic kidney are synonymous terms. Polycystic kidney disease is an inherited disorder and has an 'adult form' (autosomal dominant) and an 'infantile form' (autosomal recessive) and affects both kidneys. In contrast, a multicystic kidney is almost always unilateral and is usually not an inherited disorder.

Sonography of multicystic kidneys is often diagnostic, demonstrating multiple echolucent cysts of varying sizes with no discernible cortex (Fig. 93.6). Occasionally, the cysts may resemble a severe UPJ obstruction with minimal parenchyma, termed the 'hydronephrotic variant'. The contralateral kidney is abnormal in 5–10% of cases. Renal scintigraphy (MAG-3 or DMSA (dimercaptosuccinic acid) scan) shows nonfunction and generally should be performed to confirm the diagnosis. On occasion, there is a segmental multicystic kidney, in which there is a complete duplication anomaly of the upper urinary tract, with the upper pole being multicystic.[50] Many also recommend obtaining a VCUG, because as many as 15% have contralateral VUR,[51] although this recommendation is not universally accepted.

The management of a multicystic kidney is becoming less controversial. If an abdominal mass that is symptomatic is present, early nephrectomy is indicated. However, left untreated, most multicystic kidneys become smaller relative

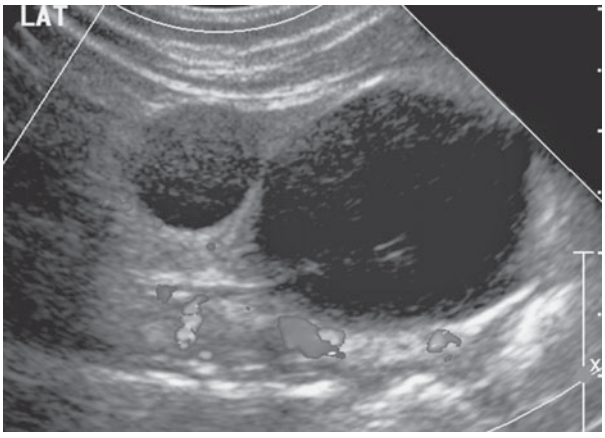

Figure 93.6 Left multicystic dysplastic kidney.

to total body size, and complete cyst regression is common. Potential complications include malignancy, and nodular renal blastema, which is a precursor to Wilms' tumor, and hypertension. In a review of 26 clinical series, no cases of Wilms' tumor were reported among 1041 children, and the maximum estimated risk was 3.5 per 1000 affected children.[52] Tumors arise from the stromal, not the cystic, component of multicystic kidneys. Consequently, even if the cysts regress completely, the likelihood that the kidney could develop a neoplasm is not altered. With regard to hypertension, in a review of 29 studies, six cases were reported among 1115 eligible children, and the mean probability was 5.4 per 1000 affected children (95% confidence interval (CI) 1.9 to 11.7 per 1000).[53]

Generally, a follow-up sonogram is recommended at six months of age. If the cysts enlarge, the stromal core increases in size, or hypertension develops, laparoscopic (or possibly open) simple nephrectomy is recommended. However, further follow-up sonography is unnecessary unless there is concern regarding the contralateral kidney, because finding a Wilms' tumor incidentally would be extremely rare. Because of the occult nature of hypertension, annual blood pressure measurement is recommended, and if hypertension occurs, nephrectomy should be considered.

Primary obstructive megaureter (non-refluxing)

A megaureter refers to a wide ureter and may be (1) primary or secondary, (2) obstructive or non-obstructive, and (3) refluxing or non-refluxing. Non-refluxing megaureter results from an aperistaltic segment of the distal ureter that does not allow normal propulsion of urine (Fig. 93.3). In this condition, sonography shows a dilated ureter and renal pelvis with variable renal parenchymal atrophy. VCUG shows no VUR in most cases. Before the sonography era, most patients with this condition presented with flank pain, flank mass, pyelonephritis, hematuria, or stone disease. Surgical correction consists of excision of the aperistaltic segment, tailoring (also known as tapering) of the ureter, and reimplantation of the ureter into the bladder.

Although severe hydronephrosis may be present, there is often a tendency to gradual reduction in hydronephrosis over a period of several years (Fig. 93.7). For example, in one series of 40 neonates with 57 non-refluxing megaureters, only four underwent early repair because of diminished renal function.[54] With a mean follow up of 6.8 years, only one demonstrated late worsening of hydronephrosis at 14 years. Chertin *et al.*[55] reported on a series of 79 children with follow up as long as 18 years. Overall, 31% underwent surgical correction at a mean age of 14 months. Independent predictive factors for surgery included differential renal function $<30\%$, ureteral diameter >1.33 cm, and grade 3 or 4 hydronephrosis. Consequently, most of these patients may be followed non-operatively on antibiotic prophylaxis and serial monitoring of renal function and drainage.

In these neonates, a renal sonogram and VCUG should be obtained before discharge. Early management is identical to that of neonates with suspected UPJ obstruction. If an abdominal mass, solitary kidney, or bilateral hydro-ureteronephrosis is present, then a MAG-3 diuretic renogram should be obtained promptly. Otherwise, the study is deferred until 6–8 weeks of age. In some centers, the diuretic-stimulated drainage from the renal pelvis and ureter are measured separately. If the differential renal function is at least 40%, the child generally is managed non-operatively, even with grade 4 hydronephrosis, and a follow-up renal sonogram or diuretic renogram is obtained every three to six months.

Early repair of megaureter has a higher complication rate than in older children. For example, Peters and colleagues[56] reported on megaureter repair in 42 infants operated on at a mean age of 1.8 months. In that series, early complications occurred only in those less than 6 weeks of age and included transient apnea in three, UTI in one, hyponatremia in one, and meningitis in one. VUR occurred postoperatively in six infants, and none developed postoperative obstruction. The VUR resolved spontaneously between 18 and 36 months in three patients, and the remainder underwent secondary ureteroneocystostomy. Greenfield and colleagues[57] reported on repair of 11 megaureters in infants less than six months old. Of these children, two had transient ureteral obstruction immediately after stent removal and persistent grades 1 and 2 VUR in two children. In a series of older children who underwent tapered ureteral reimplantation, the success rate was 90% for obstructive megaureter.[58] The results were slightly better for intravesical compared with extravesical reimplantation.

There are two other reasonable treatment options if surgical repair seems necessary in the neonate or young infant. The first is to perform a temporary cutaneous ureterostomy, allowing the ureter to decompress over a period of 12–18 months. Subsequently, the ureterostomy can be taken down and ureteral reimplantation with or without tapering is performed. In a series of children who underwent this procedure, when undiversion and ureteral reimplantation was performed, only five of 23 ureters required tapering.[59] The other option is to insert a double J ureteral stent through the ureterovesical junction and leave it interposed between the bladder and the kidney. Castagnetti

Figure 93.7 Female newborn with non-refluxing left megaureter discovered by prenatal ultrasound. (a,b) Newborn ultrasound shows grade 4 hydronephrosis and dilated ureter. Diuretic renogram, 8 weeks of age, showed 50% differential renal function in left kidney. Obstructive drainage pattern was noted following administration of furosemide. Patient managed non-operatively. (c) Ultrasound six months later shows grade 1 hydronephrosis. Diuretic renogram later showed normal drainage pattern.

et al.[60] reported ten infants, of whom five required open surgery for stent insertion. A total of seven had stent-related complications, including UTI in five and early stent removal was performed in two patients. Of the five who underwent subsequent surgical repair, none required ureteral tapering.

In summary, if differential renal function remains normal and the child is asymptomatic, it seems safe to follow these patients with renal sonograms and diuretic renography to monitor hydronephrosis, and renal function and drainage. If renal functional deterioration, slowing of upper urinary tract drainage, or UTI occurs, ureteral reimplantation is recommended. These infants should receive prophylactic antibiotics while stasis is present in the upper ureter and kidney.

URETEROCELE AND ECTOPIC URETER

A ureterocele is a cystic dilatation of the distal end of the ureter and is usually obstructive. In children, they usually extend through the bladder neck, termed 'ectopic', but may remain entirely within the bladder, termed 'intravesical' or 'orthotopic'. Ectopic ureteroceles and ectopic ureters occur more commonly in girls than in boys and usually are associated with the upper pole of a completely duplicated collecting system. In boys with a ureterocele, however, 40% drain a single collecting system. Prenatal sonography typically shows either hydro-ureteronephrosis or upper pole hydronephrosis with a dilated ureter. These conditions are bilateral in 10–15% of patients.

Early evaluation consists of:

- **Sonography** shows a hydronephrotic upper pole connected to a dilated ureter; the ureterocele typically is visualized in the bladder (Fig. 93.8a,b).
- **VCUG** often visualizes the ureterocele and demonstrates whether VUR is present, either into the lower pole moiety or contralateral collecting system (Fig. 93.8.c); an ectopic ureter that inserts into the bladder neck also typically refluxes into the upper pole obstructed ureter.
- **DMSA renal scan** shows whether the moiety drained by the ectopic system functions; this study may be done at 1–2 weeks of age because the result does not change with functional maturity. A DMSA renal scan is recommended rather than a diuretic renal scan, because there is not generally a question regarding 'obstruction' and the DMSA provides excellent cortical imaging. Alternatively, a CT or MRU demonstrates the anatomy adequately, although it may not provide functional information regarding the function of the obstructed upper pole (Fig. 93.8c).

The management of neonates with a ureterocele is highly individualized.[61] The least invasive initial form of therapy is transurethral incision (TUI), which can be performed either with a 3-F Bugbee electrode or the holmium:YAG laser (Fig. 93.8d,e). The ureterocele is punctured several times at its junction with the bladder mucosa. If the ureterocele is ectopic, it must be punctured both in the bladder and in the urethra.

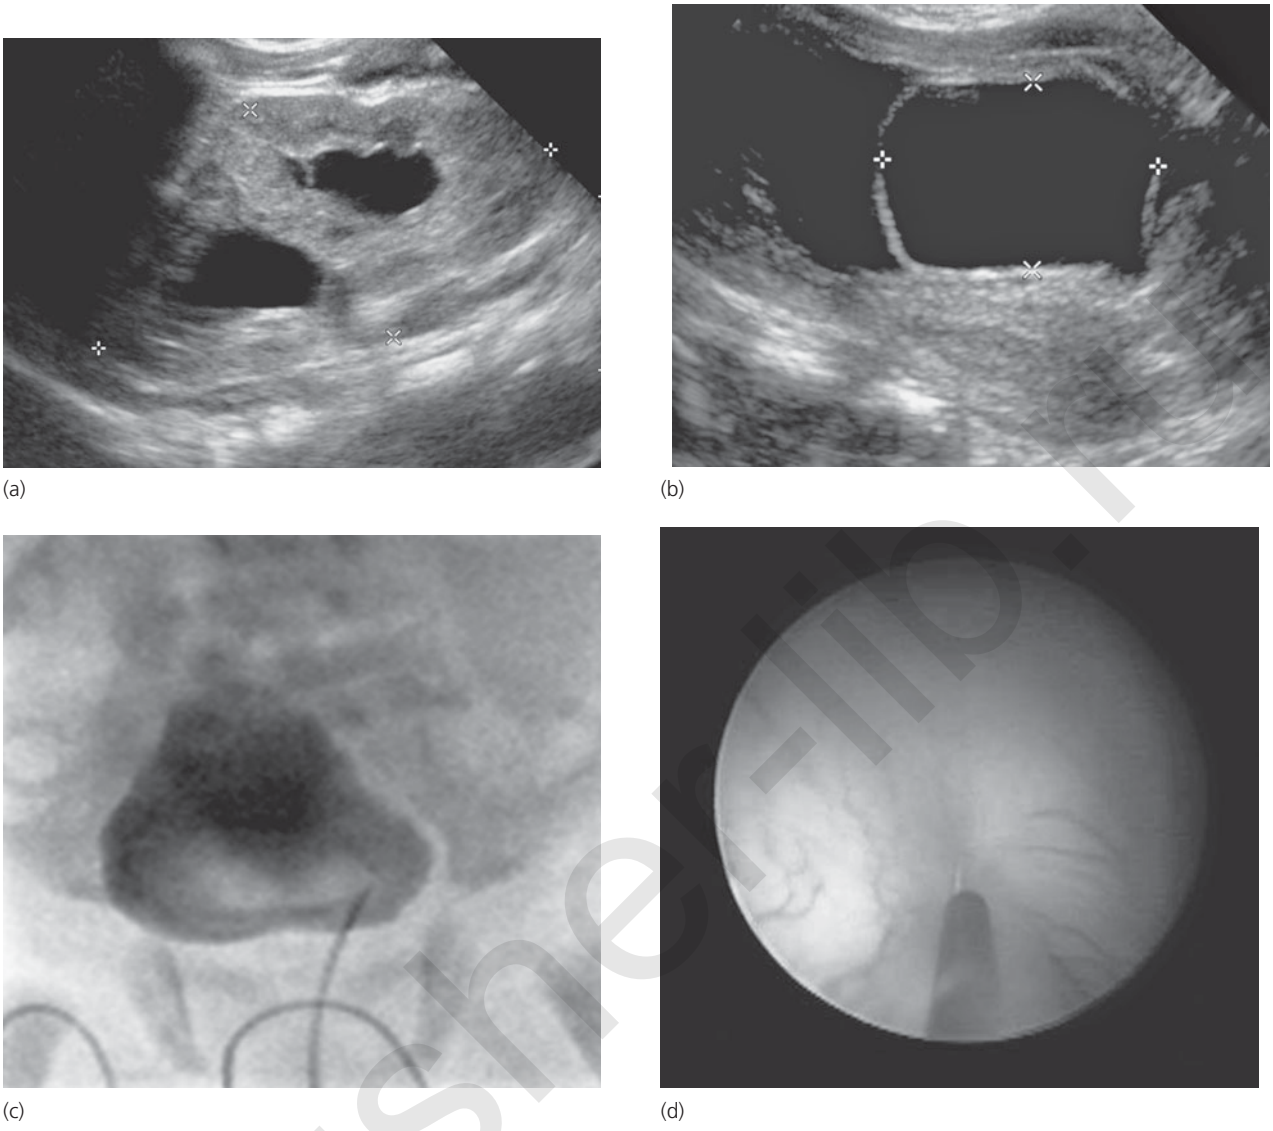

Figure 93.8 Infant with ureterocele and duplex collecting system, right side. (a) Sonogram of right kidney demonstrating echogenic right kidney with duplex collecting system and hydronephrosis involving both upper and lower pole. (b) Ureterocele in bladder. (c) Voiding cystourethrogram shows ureterocele in bladder, and no vesico-ureteral reflux. (d) Patient underwent transurethral incision; endoscopic view of ureterocele. (e) Appearance after transurethral incision. (f) Follow-up renal sonogram shows normal right kidney. (g) Bladder shows decompressed ureterocele.

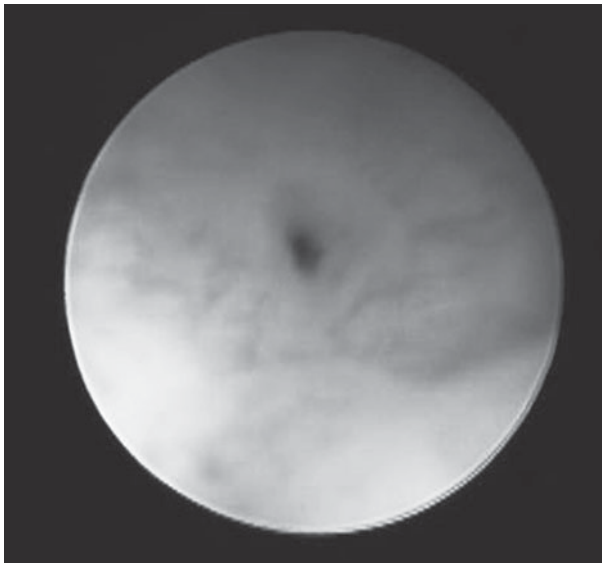
TUI provides satisfactory upper tract decompression with a single procedure in >90% of cases. However, there is a significant risk of post-operative VUR through the ureterocele into the upper pole moiety, which may require subsequent definitive treatment. If the ureterocele is orthotopic, approximately 30% show VUR following TUI, whereas if it is ectopic, 75% have VUR following TUI.[62,63] TUI is often the only procedure necessary.[64]

TUI of a ureterocele draining a non-functioning moiety will not result in the development of any significant degree of function. Although the risk for subsequent VUR into the ureterocele is significant, TUI is an appropriate minimally invasive alternative to an open partial nephrectomy. However, in recent years many centers have been performing minimally invasive (laparoscopic) upper pole heminephrectomy. These procedures have been performed either with a retroperitoneal[65,66] or transperitoneal[67] approach. One recent series with a laparoscopic retroperitoneal approach reported an overall conversion rate to open surgery of 21%, although the authors stated that they had only one conversion in their most recent 20 cases.[68] Common complications include perirenal urinoma and, in some cases, devascularization of the lower pole moiety. The latter complication is most common in infants. Another option is to perform transperitoneal laparoscopic partial nephrectomy with robotic assistance.[69] Consequently, if the hydronephrotic upper pole does not function, this author maintains the infant on antibiotic prophylaxis and laparoscopic upper pole heminephrectomy (or nephrectomy, if the entire kidney does not function) with or without robotic assistance performed electively at six months of age, assuming the upper pole system remains hydronephrotic. If the DMSA scan shows significant



(e)

(g)

Figure 93.8 *Continued*

upper pole function, however, ureteropyelostomy or ureteroureterostomy, in which the upper pole ureter is anastomosed to the lower pole renal pelvis or ureter, is recommended. This procedure can be performed either at the level of the kidney, with removal of part of the redundant distal ureter,[70] or low, through an inguinal incision.[71] Total urinary tract reconstruction in neonates and infants is not recommended because of the high complication rate caused by the small size of the infant bladder.

POSTERIOR URETHRAL VALVES

The most common cause of severe obstructive uropathy in children is posterior urethral valves (PUV), which are tissue leaflets fanning distally from the prostatic urethra to the external urinary sphincter (Fig. 93.9). Typically, the leaflets are separated by a slit-like opening. Approximately one-third ultimately develop chronic renal failure or severe renal insufficiency. Prognosis is significantly better if the antenatal sonogram before 24 weeks' gestation was normal. In one study, nine of 17 patients with PUV whose hydronephrosis was discovered before 24 weeks' gestation developed renal failure, whereas only one of 14 recognized after 24 weeks' gestation developed end-stage renal disease.[72] Favorable prognostic factors include a serum creatinine level of less than 0.8–1.0 mg% after bladder decompression, unilateral VUR into a non-functioning kidney ('VURD syndrome'), ascites, and identification of the corticomedullary junction on renal sonography.

Early delivery of infants with an antenatal diagnosis of suspected PUV is not recommended, unless there is oligohydramnios. If severe bilateral renal dysplasia is present, pulmonary hypoplasia is often also present, and problems with ventilation may result. Initially, a small feeding tube should be passed into the bladder for urinary drainage until electrolyte imbalances can be corrected. A Foley catheter is not recommended because the balloon may cause significant bladder spasm and impede upper tract drainage. Care should be taken passing the catheter, as the prostatic urethra is dilated and there is bladder neck hypertrophy; the feeding tube may coil in the prostatic urethra and not drain the

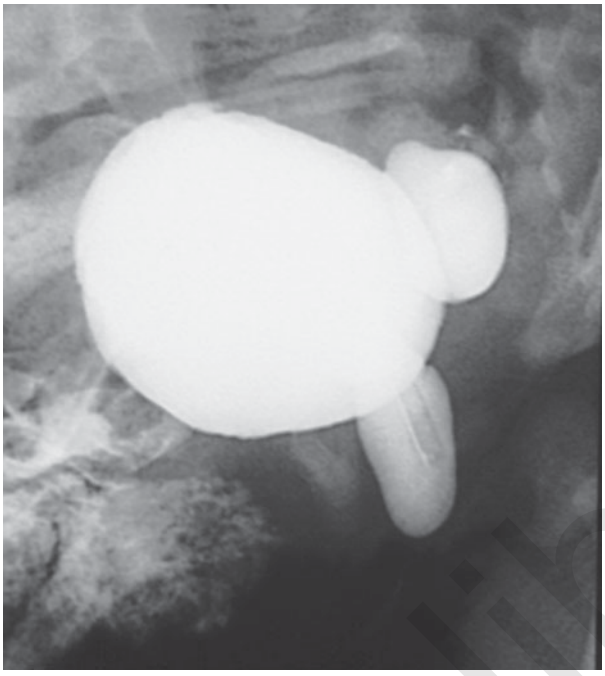
Figure 93.9 Newborn with posterior urethral valves and abdominal distension secondary to urinary ascites. (a) Plain film of abdomen showing ascites. (b,c) Renal sonogram showing bilateral hydronephrosis and urinary ascites. (d) Voiding cystourethrogram. Note dilated prostatic urethra proximal to the valve leaflets and bladder diverticulum on left side. Patient managed with upper tract drainage and transurethral incision of valve leaflets. (e,f) Renal sonogram, left and right kidneys at six months of age shows minimal hydronephrosis. At 17 years, patient had nearly normal renal appearance on ultrasound.

bladder. In this setting, catheter irrigation typically results in fluid coming out of the urethra next to the catheter. A VCUG should be obtained to confirm the diagnosis, and a DMSA renal scan should be performed to evaluate the upper tract differential renal function.[15]

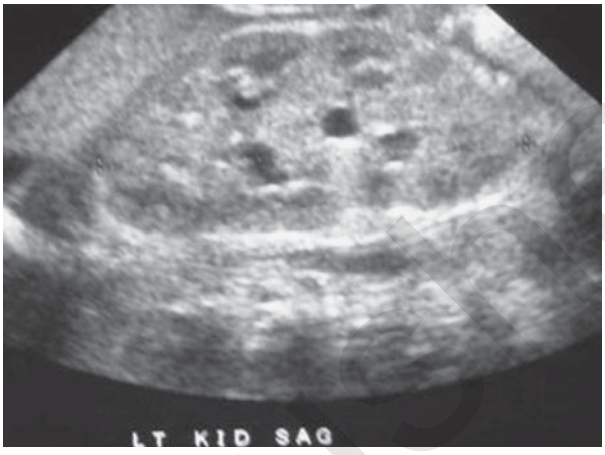
In newborns, alternative treatments include transurethral endoscopic ablation of PUV, cutaneous vesicostomy, and high diversion (cutaneous pyelostomy). The ideal initial treatment is valve ablation with a small Bugbee electrode, as is used with TUI, or the holmium:YAG laser. In small neonates, the 8 or 9 Fr resectoscope may be too large for the urethra, and a temporary vesicostomy may be necessary. A vesicostomy also should be considered for those with a serum creatinine level that remains significantly elevated after bladder decompression. Cutaneous pyelostomy rarely affords better drainage compared with cutaneous vesicostomy and diverts urine away from the bladder, which may prevent normal bladder growth.[73] However, in selected cases the Sober-en-T cutaneous ureterostomy is useful. In this procedure, the upper ureter is brought out to the abdomen and transected, and the distal segment is anastomosed to the renal pelvis; this option allows urine to drain both through the ureterostomy, as well as to the bladder.[74]

VESICO-URETERAL REFLUX

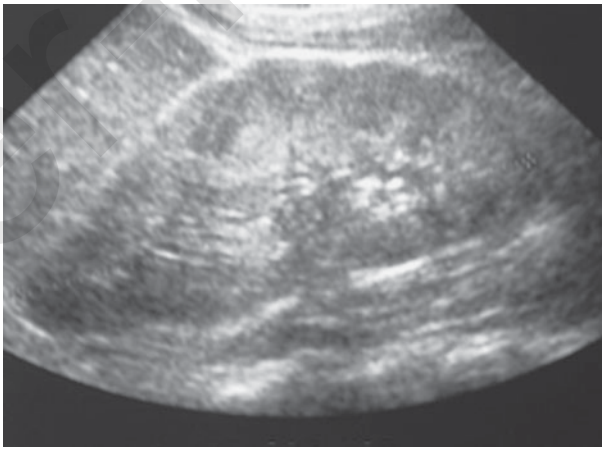
Some neonates with medium- and high-grade VUR are detected following the finding of antenatal hydronephrosis. Approximately 80% of such patients are boys. In the most severe cases of massive VUR, the bladder may also become distended from aberrant micturition into the upper



(d)



(e)



(f)

Figure 93.9 *Continued*

tracts, termed the 'megacystis-megaureter syndrome'. In the American Urological Association analysis, reflux-related renal scarring was present in 47.9% of those with grades IV–V VUR, but only 6.2% of those with grades I–II VUR. Consequently, in neonates with grades III–V VUR, a DMSA scan is recommended to determine whether reflux-related renal scarring is present.

Initially, neonates with prenatally diagnosed VUR are managed medically. Most are placed on amoxicillin prophylaxis for two months, followed by nitrofurantoin or trimethoprim-sulfamethoxazole prophylaxis, and circumcision is recommended for male neonates to decrease the risk for UTIs.

Neonates with VUR are more likely to show spontaneous resolution than are older children. Indeed, 20–35% of ureters with grade IV or V VUR have reflux resolution within two years; however, a significant proportion develop a breakthrough UTI, and antireflux surgery is recommended in these cases. The success rate for open surgical correction of VUR in infants can be as high as in older children.[57] Another option is subureteral injection of the ureterovesical junction with dextranomer microspheres, in which the success rate is 69% with a single injection.[75]

SUMMARY

Approximately 1–2% of newborns have an antenatal diagnosis of hydronephrosis or significant renal pelvic dilation. Hydronephrosis is often caused by non-obstructive conditions. The likelihood of significant urologic pathology is directly related to the size of the fetal renal pelvis, and 90% with an anteroposterior diameter more than 2 cm need surgery or long-term urologic follow up. Following delivery, antibiotic prophylaxis should be administered and a renal

sonogram and voiding cystourethrogram should be obtained. If there is grade 3 or 4 hydronephrosis, a diuretic renogram is usually also recommended. Pediatric urologic or pediatric nephrologic consultation is helpful in planning evaluation and treatment. Antenatal recognition of hydronephrosis allows postnatal diagnosis and treatment of urologic pathology, preventing complications of pyelonephritis and obstruction. In the past decade, significant progress has been made in the development of minimally invasive treatment options.

Multicystic dysplastic kidney

DAVID FM THOMAS AND AZAD S NAJMALDIN

INTRODUCTION

Before the introduction of routine antenatal ultrasonography, multicystic dysplastic kidney (MCDK) was regarded as an uncommon anomaly which generally presented as an abdominal mass in the newborn period. Nephrectomy was the standard form of management.

It has become clear, however, that the prevalence of asymptomatic unilateral multicystic kidneys in the general population is far higher than was previously suspected, with an estimated incidence of around 1:3000 to 1:4000.[1,2] The majority of MCDKs are small, clinically undetectable and would have been destined to remain unrecognized in the neonatal period (and indeed throughout the individual's lifetime) if they had not been identified on antenatal ultrasonography.

ETIOLOGY

Although MCDK is almost invariably associated with atresia of the proximal ureter, it can rarely occur in conjunction with ureteral dilatation and a ureterocele. In both instances, however, the underlying mechanism is believed to be an obstructive insult to the developing metanephric mesenchyme at an early stage in gestation. Bilateral cases are invariably lethal and, when detected prenatally, usually lead to termination of pregnancy. Most cases of unilateral MCDK occur on a sporadic basis, although familial occurrence has been reported. MCDKs comprise an irregular collection of tense, non-communicating cysts of different sizes, lined by cuboidal or flattened tubular epithelium. Any renal parenchyma is limited to small islands or flattened plates of dysplastic tissue interposed between cysts.

It is important to note, however, that occasional variants of renal dysplasia which include a cystic component in addition to solid dysplastic tissue can create diagnostic confusion. Indeed, it is likely that some of the reports of hypertension and malignancy have been incorrectly attributed to MCDKs when they have, in fact, arisen in these variants.

PRESENTATION

Patterns of presentation include:

- Prenatal ultrasound detection (the majority).
- Clinical presentation, involving large multicystic kidneys, generally presenting as a firm, 'knobbly', abdominal mass which is apparent at birth or early in the neonatal period.
- Incidental finding during the investigation of some unrelated illness.
- Symptomatic complications (very rare).

INVESTIGATIONS

Ultrasound

The ultrasound features which characterize MCDK are now well defined in the radiological literature (Fig. 94.1).[3,4]

These important diagnostic criteria comprise:

- multiple oval or round cysts which do not communicate;
- presence of interfaces between the cysts;
- non-medial location of the largest cyst (a large fluid-filled component located medially is more likely to represent the dilated pelvis of a severely hydronephrotic kidney);
- absence of solid parenchymal tissue;
- complete absence of function (0% differential function) on ^{99m}Tc-DMSA (technetium-99m dimercaptosuccinic acid) scintigraphy.

Other causes of a renal mass in the neonatal period, such as mesoblastic nephroma or infantile polycystic kidney, can readily be excluded from the differential diagnosis. However,

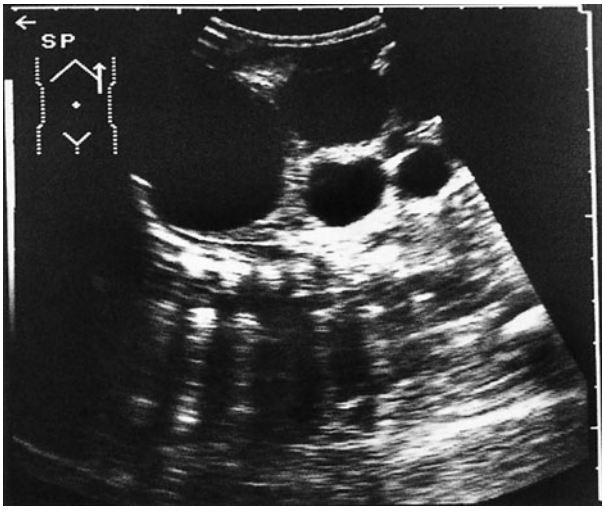

Figure 94.1 Typical ultrasonographic appearance of neonatal multicystic dysplastic kidney, i.e. non-communicating cysts of varying size, demonstrable septa between cysts, no visible rim or cortical tissue.

diagnostic difficulty can arise in distinguishing between MCDK and and gross hydronephroses due to pelvi-ureteric junction obstruction. Similarly, as already indicated above, other forms of renal dysplasia can be mistakenly diagnosed as MCDK by those unfamiliar with the diagnostic criteria. The bladder, ureters, and contralateral kidney should also be carefully evaluated by ultrasound for dilatation associated with vesico-ureteric reflux, contralateral pelvi-ureteric obstruction, or some other urological abnormality.

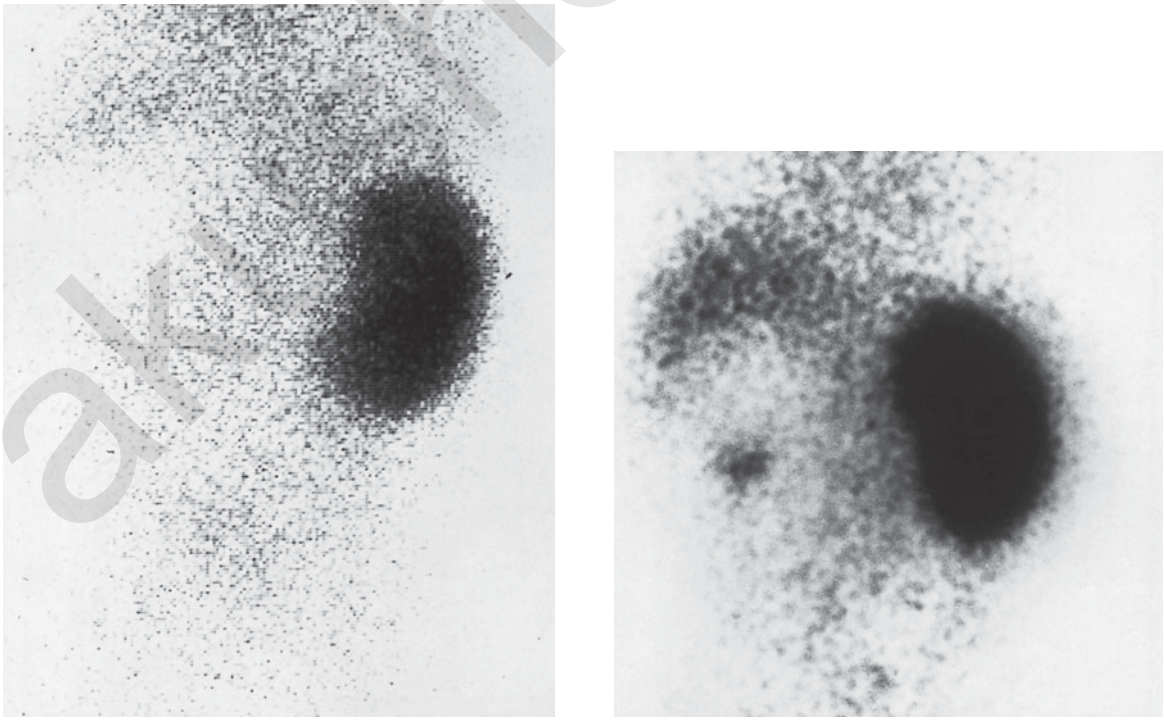
Isotope imaging

The main purpose of isotope imaging is to distinguish between MCDK and a grossly hydronephrotic kidney or a variant of renal dysplasia. MCDKs are entirely non-functioning, whereas even grossly hydronephrotic kidneys almost invariably demonstrate some degree of isotope uptake, corresponding to a small percentage of differential function. Similarly, some rare variants of cystic dysplasia have demonstrable function (although this is also usually apparent as an area of solid parenchymal tissue on ultrasound). In equivocal cases, nephrectomy is justified to establish a histological diagnosis and to obviate the possible risk of complications, notably hypertension.

^{99m}Tc-DMSA is the most reliable modality for demonstrating low levels of function (Fig. 94.2a,b). Nevertheless, ^{99m}Tc-MAG3 (technetium-99m mercapto-acetyl-triglycine) may be preferable if there is any suggestion of contralateral pelvi-ureteric junction obstruction (which is present in 5–10% of cases). Ideally, imaging should be deferred until after the fourth week of life.

Other investigations

Although voiding cystourethrography (VCUG) is undoubtedly indicated if postnatal ultrasonography reveals ipsilateral



(a) (b)

Figure 94.2 (a) ^{99m}Tc-DMSA scan demonstrating normal isotope uptake and renal morphology on the left, and no uptake or isotope in the right (multicystic) kidney. (b) A focus of poor, but discernible, uptake of ^{99m}Tc-DMSA in a grossly hydronephrotic right kidney. Ultrasound could not distinguish with certainty between gross hydronephrosis and multicystic kidney.

ureteric dilatation or contralateral upper tract dilatation, it is doubtful whether this invasive investigation is routinely necessary if the ultrasound appearances of the urinary tract are otherwise normal. In the absence of ureteric dilatation on ultrasound, any coexisting contralateral or ipsilateral vesicoureteric reflux (VUR) is invariably low grade, self-limiting, and rarely gives rise to infection. Miller and associates[5] studied the outcome of reflux into the contralateral kidney of 75 children with MCDK and found a high incidence of spontaneous resolution over a relatively short period. There was no difference in the growth between kidneys which were associated with VUR and those that were not. If a routine VCUG is not performed, it is nevertheless important that parents and general practitioners are aware that the occurrence of a documented or suspected urinary tract infection (UTI) or an unexplained febrile illness requires further investigation to look for possible VUR.

INDICATIONS FOR SURGERY

The following are widely accepted as definite indications for nephrectomy:

1. A large multicystic kidney giving rise to an obvious, visible, and readily palpable abdominal mass. In this situation, there is usually considerable parental anxiety. In addition, there may be apparent discomfort or other symptoms attributable to the size of the mass.
2. Diagnostic uncertainty. Despite the combination of ultrasound and isotope imaging, it may occasionally be impossible to distinguish with certainty between an MCDK, a poorly functioning hydronephrotic kidney or a rare cystic variant of renal dysplasia. The presence of demonstrable function in what otherwise appears to be an MCDK should be viewed with suspicion and represents a valid indication for nephrectomy. Isotope function equates with perfusion and it can be reasonably argued that perfused tissue imparts a greater risk of renal hypertension. Likewise, a cystic anomaly which is also seen to contain a solid parenchymal component or which does not fulfil the other diagnostic criteria listed above is not an MCDK and is, therefore, best removed.

Issues surrounding surgery for asymptomatic MCDKs

The overwhelming majority of prenatally detected MCDKs are asymptomatic and clinically undetectable. Nevertheless, some surgeons have advocated the 'prophylactic' removal of asymptomatic, prenatally detected MCDKs, justifying this policy on the basis of the perceived risk of complications – notably hypertension and malignant transformation. When MCDKs were first diagnosed prenatally, the extent of these perceived risks was, of necessity, based upon historical case reports. However, closer analysis of the historical literature sheds doubt on the accuracy of the diagnosis of MCDK in some of the reported cases. Fortunately, it is no longer necessary to resort to historical data since the last two decades have witnessed the publication of an extensive body of literature specifically devoted to prenatally detected MCDK. In addition, there have been a number of authoritative literature reviews. For example, Narchi[6,7] undertook a detailed review of 26 published series totaling 1041 children with conservatively managed MCDKs. Information on duration of follow up was available in 18 publications and was between 1.25 and 6.5 years, with a maximum of 23 years. No cases of Wilms' tumor were identified by Narchi's literature review.[7] Cambio and associates[8] reviewed data reported by 105 publications on prenatally detected MCDK, to which they added unpublished data from the MCDK Registry on approximately 900 MCDKs. From their extensive analysis of the literature, these authors identified three cases of Wilms' tumor arising in a prenatally detected MCDK – none of which occurred after four years of age. There were no cases of Wilms' tumor arising in involuted MCDKs. Seven cases of Wilms' tumor arising in a purported MCDK were identified from the historical literature, but Cambio and associates highlighted uncertainties regarding accuracy of the diagnosis of MCDK in historical case reports. The Trent and Anglia MCDK Study Group[1] systematically collected prospective data on 202 children with prenatally detected MCDK born between 1985 and 2004. The mean duration of follow up was 8.1 years (0.1–19.7 years), with 43 children being followed beyond ten years. No Wilms' tumors were encountered in these patients. Similarly, no Wilms' tumors occurred in 325 children with prenatally detected MCDKs managed conservatively at Great Ormond Street Hospital, London. Of these, 180 children with MCDKs had been followed prospectively for more than ten years (unpublished data, Dhillon HK, personal communication, 2009).

Using published data on the prevalence of MCDK, the risk of Wilms' tumor has been calculated to lie in the range 0.0001%[9] to 0.0005%.[10]

Anecdotally, there have been cases of malignancy arising in prenatally detected MCDKs which have not been reported in the literature. Although the accuracy of the diagnosis of MCDK in anecdotal cases has not been subject to scrutiny in the peer-review process, it could reasonably be argued that calculations based upon the number of published cases of malignancy understate the true magnitude of the risk. However, the risk of malignancy can also be approached from a different perspective by asking 'how frequently does MCDK feature in published series of Wilms' tumor?'

The respected pediatric pathologist, JB Beckwith,[10] addressed this question by studying data on 7500 Wilms' tumors reported to the National Wilms' Tumour Study Pathology Centre over an 18-year period. Of the 7500 Wilms' tumors, five had arisen in MCDKs. On the basis of these data, coupled with published data on the prevalence of MCDKs, Beckwith calculated the individual life-time risk of developing Wilms' tumor in an MCDK as approximately 1:2000 (0.0005%). If anything, this calculation probably overstates the risk because more recent published information indicates that overall prevalence of MCDK in the pediatric population is somewhat higher than the original figure on which Beckwith's calculation was based. Beckwith also questioned the diagnostic accuracy of historical reports, observing that

'the literature concerning renal tumors in multicystic dysplastic kidney is burdened with poorly documented or unconvincing cases'.

The risk of hypertension has also been cited by the proponents of 'prophylactic nephrectomy'. There is now a growing body of evidence with which to quantify the scale of this risk. No cases of hypertension were encountered in the 202 children with prenatally detected MCDK followed prospectively by the Trent and Anglia MCDK Study Group[1] and no instances of hypertension were recorded in 441 children with prenatally detected MCDKs enrolled on the MCDK registry.[9]

Narchi's literature review did, however, reveal a published incidence of hypertension of 0.5%.[6] However, it is important to recognize that confirming a reliable diagnosis of hypertension in this age group can be problematic because of the difficulties inherent in obtaining accurate, reproducible blood pressure readings in fractious infants and young children.

As with malignancy, the risk of hypertension can also be viewed from a different perspective. MCDK is now known to be a relatively common anomaly with a birth incidence in the range of 1:3000–1:4000.[1,2] By contrast, hypertension is a relatively rare condition in the pediatric population. If MCDKs were resulting in hypertension on any appreciable scale, it could be expected that they would account for a sizeable proportion of children with hypertension. This is not the case. For example, in a series of 21 children with renal hypertension managed by nephrectomy at Great Ormond Street Hospital between 1968 and 2003, there was only a single case of MCDK.[11]

Removing a MCDK may not entirely obviate the risk since there are well-documented cases of hypertension arising in the contralateral kidney.[12] Moreover, there is also some evidence that individuals with a solitary kidney are at an increased lifetime risk of developing hypertension.

It must also be acknowledged that information on the possible long-term risk of hypertension (i.e. beyond ten years) is still very limited and the risk of later-onset hypertension cannot be entirely discounted. Nevertheless, the evidence of the adult nephro-urological literature suggests this risk is very low.

A more extensive review of the large body of published information on prenatally detected MCDKs is beyond the scope of this chapter, but, in summary, the best evidence currently available puts the risk of developing hypertension associated with a prenatally detected MCDK at less than 1% (probably significantly less) and the risk of malignant transformation at 0.0001–0.0005%.

With regard to malignancy, the risk of mortality associated with general anesthesia in this age group is probably of the same order (or higher) than the risk of dying from Wilms' tumor arising in a prenatally detected MCDK. In summary, cystic renal anomalies which do not fulfill the diagnostic criteria set out above are not MCDKs, and nephrectomy is reasonable in such cases – particularly if there is evidence of solid dysplastic tissue on ultrasound or demonstrable function on renography. By contrast, there is now a substantial body of evidence that the risk of complications arising in genuine MCDKs (the overwhelming of prenatally detected cystic anomalies) is exceedingly small and the natural history is generally one of spontaneous involution.

Surgeons must assess the arguments for themselves, but those who advocate routine 'prophylactic' nephrectomy should be aware that this approach will inevitably expose large numbers of healthy asymptomatic infants to the risks inherent in unnecessary general anesthesia and surgery.

Timing of surgery

Large multicystic kidneys associated with a sizeable mass should be removed electively in the first few weeks of life. Smaller lesions for which surgery is nevertheless thought to be appropriate can safely be left until 6–12 months of age or later. It is important to obtain an ultrasound scan shortly before surgery to confirm that the MCDK is still visible and has not undergone involution in the period since the decision was taken to operate.

SURGICAL OPTIONS

Nephrectomy can be performed as a conventional open procedure or laparoscopically, depending on such factors as the surgeon's expertise in minimally invasive surgery, availability of suitable pediatric instrumentation, and the preference of the parents.

Open nephrectomy

Dorsal or posterior lumbotomy has the advantage of simplicity, good cosmesis, reduced postoperative pain, and shortened hospital stay. The major drawback is the more limited exposure of the kidney offered by this incision and difficulty in extending it if the surgeon is faced with an unforeseen problem. For a small MCDK, the dorsal lumbotomy incision is ideal and even for larger lesions nephrectomy should not pose problems, provided that the bulk of the multicystic kidney is reduced by cyst aspiration. For an account of operative technique and an assessment of the place of the dorsal lumbotomy in pediatric renal surgery, readers are referred to the articles of Orland *et al.*[13] and Wise and Snow.[14]

Those unacquainted with the dorsal lumbotomy incision are advised to employ the more familiar loin approach, described in detail below.

OPERATIVE DETAILS

Position of the patient

A full lateral position is employed (Fig. 94.3). Lateral flexion of the spine is best achieved in this age group by the use of a sandbag under the contralateral loin rather than by a bridge or 'break' in the table. Once the required position has been achieved, adhesive strapping is used to maintain it. The strapping is fixed first to one side of the operating table,

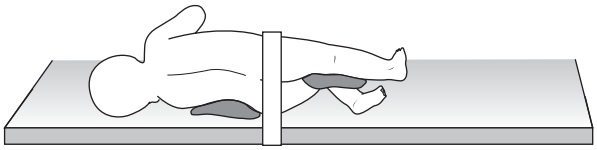


Figure 94.3 Lateral position of the patient.

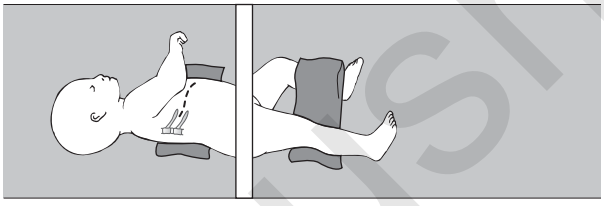
taken across the abdomen at the level of the iliac crests and then is secured firmly on the other side of the table.

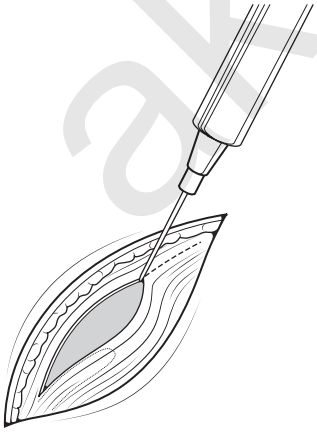
The incision

The 12th rib is identified by palpation. If available, a preoperative plain x-ray is helpful in determining the length of the 12th rib. An incision of modest length above the 12th rib nevertheless affords good access for nephrectomy if the procedure is combined with intraoperative cyst aspiration. Care should be taken to base the incision on the 12th rib (Fig. 94.4a), as an inadvertent incision above the 11th rib often results in the pleura being opened.

Once the skin and subcutaneous fat have been incised, cutting diathermy is used to deepen the incision to the tip of the 12th rib. The muscles attached to the superior border of the 12th rib (latissimus dorsi intercostal muscles) are incised along their insertion. The rib, thus mobilized, is deflected caudally to allow the surgeon to insert a finger which can be advanced anteriorly in the line of the rib to sweep the peritoneum medially and anteriorly from the overlying abdominal wall muscles. The incision can then be extended forwards in the line of the rib using the diathermy to divide the external oblique, internal oblique, and transversus abdominis muscles (Fig. 94.4b). Care is needed to avoid damaging the neurovascular bundle, as this can result in a visible obvious (but usually self-limiting) postoperative weakness of the relevant segmental abdominal musculature. When the incision has been completed, a self-retaining retractor can be inserted. A bent or 'offset' ring retractor is suitable for this purpose, but a conventional flat ring is not usually effective as it does not correspond to the marked curvature of the loin.



(a)



(b)

Figure 94.4 (a,b) The incision.

Mobilization of the kidney

Small MCDKs (particularly in older infants) are sometimes difficult to locate in the retroperitoneum. In this situation, it is necessary to dissect carefully through the retroperitoneal and perirenal fat, maintaining proximity to the posterior abdominal wall until the multicystic kidney is identified. More commonly, the MCDK is encountered without difficulty in the renal fossa. A combination of blunt and scissor dissection is commenced to develop a plane between the most superficial cysts and adjacent tissues (Fig. 94.5). It should be noted that the peritoneum is usually applied extensively over the anteromedial aspect of a large multicystic kidney. The phase of the dissection intended to identify and develop a plane around the multicystic kidney is best achieved with the cysts intact.

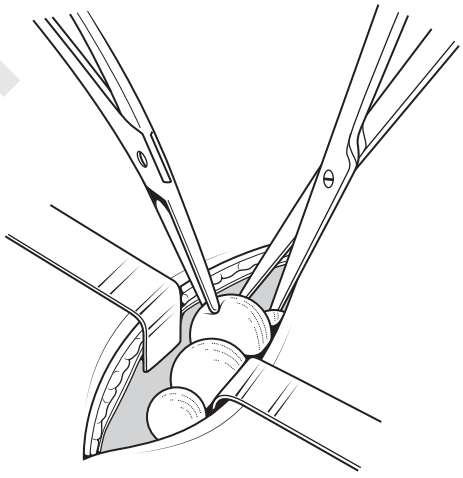


Figure 94.5 Mobilization of the kidney.

Aspiration of cysts

Once a portion of the kidney has been exposed and mobilized in this fashion, it is helpful to aspirate the visible cysts with a syringe and needle (Fig. 94.6). The decompressed cyst wall can then be grasped, e.g. with Allis tissue forceps, so that gentle traction can be applied to deliver the kidney out of the incision. By sequence of dissection around the intact cysts followed by aspiration and mobilization through the incision, it is possible to remove a MCDK through a much smaller incision than would have been required if the cysts were left intact.

Dissection of hilum

As the dissection is deepened, a malleable retractor is inserted to retract the peritoneum and expose the ureter and hilar

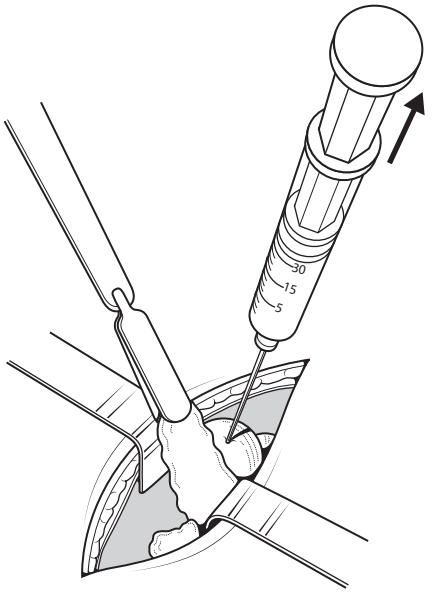

Figure 94.6 Aspiration of cysts.

vessels. A vascular sling or tape is placed around the ureter and gentle traction is applied to facilitate the final dissection of the hilum (Fig. 94.7). The ureter is then ligated with a 4-0 absorbable suture and divided. While it is good practice to ligate the renal arteries and veins individually (to prevent the risk of arteriovenous fistula formation), this may prove impossible in an MCDK since the vessels are usually small and frequently non-patent. Once identified, the vessels are ligated in continuity, then divided between ligatures. By this stage, mobilization of the decompressed multicystic kidney is usually complete and it can removed following division of any remaining attached tissue.

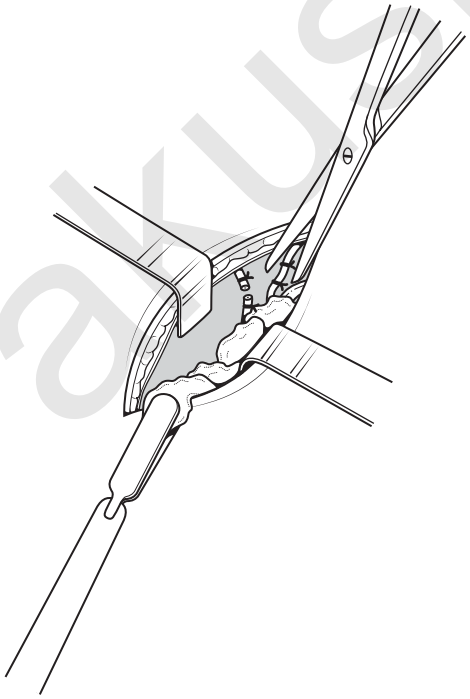

Figure 94.7 Dissection of the hilum.

The renal bed is inspected carefully and further diathermy hemostasis is performed, if required. Likewise, the peritoneum is inspected and any defect closed with a continuous suture of 4-0 absorbable suture. Drainage of the renal fossa is not necessary. This incision is closed either in two layers using continuous 3-0 PDS or vicryl, or alternatively by a series of interrupted mass sutures encompassing the rib. The skin is then closed with a subcuticular suture of 5-0 vicryl.

POSTOPERATIVE CARE

Postoperative recovery is usually rapid. Feeding is re-established within 24 hours and the child can generally leave hospital within 1–2 days.

Laparoscopic nephrectomy

Laparoscopic nephrectomy can be performed either transperitoneally[15–17] or extraperitoneally,[18] with the former being more widely practiced.

EQUIPMENT AND INSTRUMENTS

In addition to a set of instruments for open technique laparosocopy[19] and laparotomy in case of emergency or conversion to open surgery, the following equipment and instruments are required:

- Camera, light source, insufflator, and one or preferably two monitors with appropriate attachments.
- Diathermy unit (monopolar and bipolar) with appropriate cables and hand probes. Ultrasonic shears, ligasure, or plasma kinetic coagulation devices may be used as an alternative.
- Three or four, 2.5–12 mm cannulae and trocars with appropriate converters.
- A 30° or 45°, 2.5–10 mm, angled telescope (0° scope may be adequate).
- An appropriate retractor may prove helpful. Often, a simple instrument, such as an atraumatic grasper, may be used as a retractor.
- Two atraumatic, preferably insulated, relatively fine curved or angled double action jaw grasping forceps (an additional forceps with ratchet can be useful).
- One insulated, curved, double-action jaw scissors with appropriate diathermy lead.
- Suction/irrigation apparatus and probe.
- A single- or multi-load automatic clip applicator and clips (alternatively, suture ligatures may be used).
- One long needle to compress cysts, if necessary.
- Balloon dissector may be required for an extraperitoneal approach.

The size and length of instruments depend on the size of patient, surgeon's preference and availability of instruments.

PREPARATION AND POSITION OF THE PATIENT

General anesthesia with endotracheal intubation and full muscle relaxation are essential. A small nasogastric tube and a urinary catheter only if the bladder is palpable and cannot be expressed manually, may improve access. The infant is placed and strapped securely in the semilateral position with soft towels under the contralateral loin/lower chest to allow lateral flexion and the bowel to fall medially under gravity (Fig. 94.8).

TECHNIQUE FOR TRANSPERITONEAL NEPHRECTOMY

Theater layout, position of the surgeons, and the placement of the cannulae are illustrated in Figure 94.8. The primary cannula is place in the peri-umbilical region using an open technique laparoscopy.[19] A pneumoperitoneum is created with CO_2 insufflation through the primary cannula at a flow rate of 0.2–1 L/min and pressure of 8–10 mm mercury.[20] A telescope is then placed through the cannula and under direct vision, the working cannulae are placed in the direction of the kidney. The sites and sizes of the working 'secondary' cannulae are dependent on the size of the patient, the size of the instruments to be used, and the surgeon's preference.[21] Often, two (2.5–5 mm) working cannulae, in addition to the primary cannula provide adequate access to remove MCDKs. An additional cannula may be placed for retraction if necessary. A few centimeters long opening in the peritoneum, lateral to the upper border of the colon and directly over the lower part of the kidney allows adequate exposure.[15] A true mobilization of the colon is not necessary in pediatric patients. The kidney is then mobilized by blunt and sharp dissection and traction on the cysts may facilitate exposure (Fig. 94.9). The vessels, which are small and attenuated, are exposed usually close to the kidney and divided between clips or ligatures. Alternatively, diathermy, uni- or bipolar, ultrasound shears, ligasure or plasma kinetic may be used to secure hemostasis. A non-atretic ureter is clipped or ligated and divided at a convenient level. If necessary, the size of the specimen can be reduced by needle aspiration. The specimen is then removed via the largest cannula or site of a cannula with or without 1–2 cm extension. A retrieval bag is usually difficult to accommodate in infants and often not necessary. A change of telescope and/or instruments from one cannula to another may facilitate viewing and dissection during the procedure.[21] A drain is not necessary. In infants, cannula sites greater than 2.5 mm are closed with absorbable sutures. The peritoneal opening is covered by colon as the patient is returned to the supine position at the end of the procedure, thus leaving very little, if any, raw surface that might promote adhesion formation.

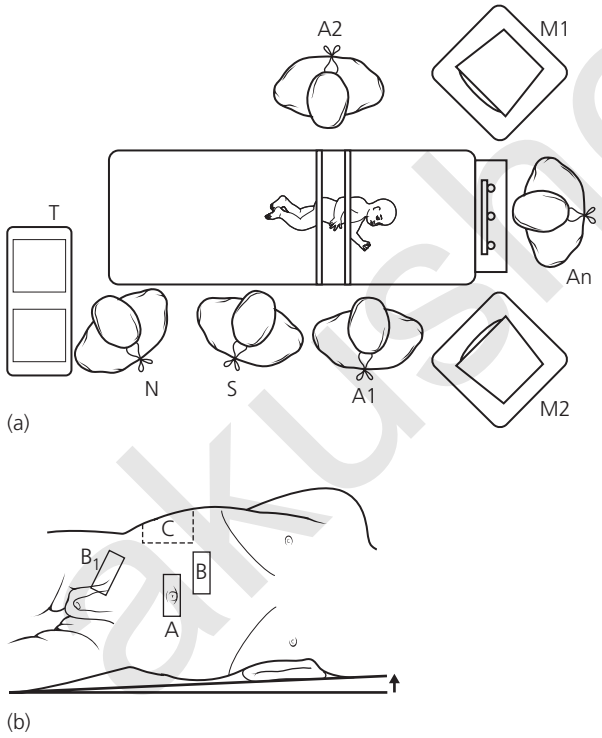

Figure 94.8 Laparoscopic transperitoneal right nephrectomy for multicystic dysplastic disease. (a) Theater layout. Note how the patient is fully supported and strapped in a semilateral position. S, surgeon; A1/A2, assistants; N, scrubbed nurse; An, anesthetic apparatus; M1/M2, monitors; T, instrument trolley. (b) Position of cannulae. A, peri-umbilical or lateral abdominal wall site for the primary cannula; B, working cannula 1; B1, working cannula 2 in the lower abdominal skin crease which may be extended to retrieve the specimen if necessary; C, an accessory cannula for hand instruments and/or retractor, if necessary.

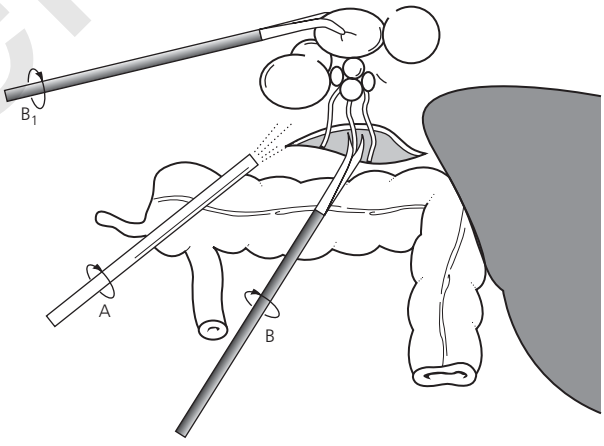

Figure 94.9 Laparoscopic transperitoneal nephrectomy. A, 2.5 to 10-mm angled or 0° telescope; B and B_1, two working instruments. Note how a few centimeter-long high paracolic peritoneal incision directly over the cystic kidney without colon mobilization allows full mobilization of the specimen and hemostasis.

POSTOPERATIVE CARE

At the end of the procedure, the nasogastric tube and/or urinary catheter are removed. Local infiltration of the cannula sites with an appropriate anesthetic agent provides adequate pain relief. Opiate analgesia is usually not required. However, i.v. paracetamol may be used for several hours postoperative, if thought to be necessary. The patient is usually ready to go home within 8–24 hours.

APPROACH FOR RETROPERITONEAL NEPHRECTOMY

In infants, extraperitoneal nephrectomy is a challenge but can be performed within a space created by breaking up the loose connective tissue binding the extraperitoneal space with either the tip of the telescope and direct CO_2 insufflation or a balloon dissector.[18,22]

This technique avoids the morbidity that may be associated with traversing the peritoneal cavity. However, its drawback is the more restricted exposure of the kidney offered by this approach and the possibility of peritoneal tear and extension pneumoperitoneum that makes extraperitoneal surgery difficult to achieve. Furthermore, published data indicate no significant difference between the two approaches in terms of clinical outcome.[23]

FOLLOW UP

Follow up is determined by the nature of any coexistent abnormalities. In an otherwise normal child who has undergone nephrectomy for a MCDK, follow up is limited to an occasional precautionary ultrasound scan of the solitary remaining kidney, until such age as the child could reasonably be relied upon to localize symptoms in the unlikely event of developing symptomatic pathology (e.g. pelvi-ureteric junction (PUJ) obstruction) in the remaining kidney. For reasons outlined above, lifelong annual blood pressure measurement may also be advisable for any individual with a solitary kidney.

Upper urinary tract obstructions

PREM PURI AND BORIS CHERTIN

INTRODUCTION

With the widespread use of maternal ultrasound, the incidence of hydronephrosis has increased significantly, altering the practice of urology. A recent review of the trends in the prenatal sonography use and subsequent urological diagnoses in the United States demonstrated significant increase in the overall ultrasound use over the last two decades. Moreover, the mean number of ultrasounds per pregnancy also increased significantly from 2.7 in 1998 to 4.2 in 2005.[1] Pelvi-ureteric junction obstruction is the most common cause of hydronephrosis detected antenatally.[2,3] The next most common cause of prenatally detected hydronephrosis is obstruction at the uretero-vesical junction.[2] Management of these patients after birth remains controversial. The decision to intervene surgically has become more complex because spontaneous resolution of antenatal and neonatal upper urinary tract dilatations is being increasingly recognized.[2,4–6] The recognition and relief of significant obstruction is important to prevent irreversible damage to the kidneys.[7] Differentiating urinary tract dilatations that are significantly obstructive and require surgery from those that represent mere anatomical variants with no implications for renal function is not a simple task especially in newborns. It has been shown that the changes in the function of the involved kidney should be used as a measure of degree of obstruction and indication for surgical intervention.[4,5,7–10]

PELVI-URETERIC JUNCTION OBSTRUCTION

The overall incidence of pelvi-ureteric junction (PUJ) obstruction approximates 1 in 1500 births. The ratio of males to females is 2:1 in the neonatal period, with left-sided lesions occurring in 60%. In the newborn period, a unilateral process is most common, but bilateral PUJ obstruction was found in 10–49% of neonates in some reported series.[7] PUJ obstruction is classified as intrinsic, extrinsic, or secondary.

Intrinsic obstruction results from failure of transmission of the peristaltic waves across the PUJ, with failure of propulsion of the urine from the renal pelvis into the ureter, which results in multiple ineffective peristaltic waves, eventually causing hydronephrosis due to the incomplete emptying of the pelvic contents.[8–11] Tainio *et al.*[12] have shown the abnormalities of peptidergic innervation with dense innervation of neuropeptide Y (NPY) and vasoactive intestinal polypeptide (VIP) and proposed that these may have a role in intrinsic obstruction. Absence or reduction of smooth muscle with replacement by collagen fibers has been demonstrated histologically.[13,14] Some researchers proposed that downregulation of Cajal cells is responsible for the development of PUJ obstruction.[15] Extrinsic mechanical factors include aberrant renal vessels, bands, adventitial tissues, and adhesions that cause angulation, kinking, or compression of the PUJ. Extrinsic obstruction may occur alone, but usually coexists with intrinsic ureteropelvic junction pathology. Secondary PUJ obstruction may develop as a consequence of severe vesico-ureteric reflux (VUR) in which a tortuous ureter may kink proximately.[16] Previous reports have described VUR in 9–15% of children with PUJ obstruction, although the fractions that are secondary to reflux is difficult to determine.[9,16]

Prenatal diagnosis

The bladder is visualized by 14 weeks of gestation. The presence of a full bladder provides evidence of renal function. The ureters are usually not seen in the absence of distal obstruction or reflux. The fetal kidney may be visualized at the same time as the bladder. If not, they are always visualized by the 16th week of gestation. However, it is not until 20–24 weeks of gestation, when the fetal kidney is surrounded by fat, that the internal renal structures appear distinct.[16] Renal growth can then be assessed easily.[17] Beyond 20 weeks, fetal urine production is the main source of amniotic fluid. Therefore, major abnormalities of the urinary tract may result in oligohydramnios.

Because of the distinct urine–tissue interface, hydronephrosis can be detected as early as 16 weeks' gestation. An

obstructive anomaly is recognized by demonstrating dilated renal calyces and pelvis. A multitude of measurements and different gestational age cut-off points have been recommended in the assessment of fetal obstructive uropathy.[18–22] Routine estimation of the anteroposterior (AP) diameter of the renal pelvis in the fetus with hydronephrosis is considered as a useful marker for the classification of renal dilatation and possible obstruction. AP renal pelvis threshold values ranged between 2.3 and 10 mm. Positive predictive values for pathological dilatation confirmed in the neonate ranged between 2.3 and >40% for AP renal measurements of 2–3 and 10 mm, respectively. A study which included more than 46000 screening patients published the standards regarding renal pelvic measurement.[17] This study clearly demonstrated that only fetuses exhibiting third-trimester AP renal pelvis dilatations >10 mm would merit postnatal assessment. In order to standardize postnatal evolution of prenatal hydronephrosis, a grading system of postnatal hydronephrosis was implemented in 1993 by the Society for Fetal Urology (SFU).[23] Under SFU system, the status of calices is paramount, while the size of the pelvis is less important. Following the SFU grading of hydronephrosis, there is no hydronephrosis in grade 0. At grade 1, the renal pelvis is only visualized; grade 2 of hydronephrosis is diagnosed when a few (but not all) renal calices are identified, in addition to the renal pelvis; grade 3 hydronephrosis requires that virtually all calices are depicted; grade 4 hydronephrotic kidneys will exhibit a similar caliceal status with the involved kidney exhibiting parenchymal thinning. Often, this classification is also applied on prenatal hydronephrosis. We have recently published our data regarding prenatal findings with the special emphasis on the natural history of hydronephrosis during the postnatal period.[7] Our data show that SFU grade of prenatal hydronephrosis is not a significant predictive factor for surgery in unilateral hydronephrosis. However, SFU grade 3–4 prenatal bilateral hydronephrosis indicates that the majority of children will require surgical correction during the postnatal period.

In case of severe prenatal bilateral hydronephrosis, severe hydro-ureteronephrosis or severe impairment of the solitary kidney, fetal bladder aspiration for urinary proteins and electrolytes may be performed in order to predict the renal injury secondary to obstructive uropathy. Fetal urinary sodium level less than 100 mmol/L, chloride level of less than 90 mmol/L, and an osmolality of less than 210 mOsm/kg are considered as prognostic features for good renal function.

Clinical presentation

The clinical presentation of PUJ obstruction has dramatically changed since the advent of maternal ultrasonographic screening.[3–7] Before the routine fetal ultrasonography, the most common presentation was with abdominal flank mass. Fifty percent of abdominal masses in newborns are of renal origin with 40% being secondary to PUJ obstruction. Some patients present with urinary tract infection. Other clinical presentations include irritability, vomiting, and failure to thrive. Between 10 and 35% of PUJ obstructions are bilateral and associated abnormalities of urinary tract are seen in about 30%.[23] Pelvi-ureteric junction problems are often associated with other congenital anomalies, including imperforated anus, contralateral dysplastic kidney, congenital heart disease, VATER (vertebrae, anus, trachea, esophagus, and renal) syndrome, and esophageal atresia. In patients with such an established diagnosis, a renal ultrasound examination should be performed.[24] Although the majority of cases occur sporadically, familial cases have been reported. It has been suggested that hereditary pelvi-ureteric obstruction is an autosomal dominant trait with variable penetrance and Izquierdo *et al.*[25] proposed one of the loci to short arm of chromosome 6 as responsible for the development of PUJ obstruction. Moreover, the importance of angiotensin II and its type 2 receptor (AT2) in the development of congenital urinary tract abnormalities has begun to be appreciated.[24–26] Nishimura *et al.*[27] reported an association of a polymorphism of intron 1 of the AT2 gene (the A-1332G transition, which caused AT2 mRNA splicing) in patients with multicystic dysplastic kidneys and/or PUJ obstruction.

Diagnosis

With the increasing number of cases of antenatally diagnosed hydronephrosis, it is difficult to interpret the underlying pathology and its significance. Severe obstructive uropathies are detrimental to renal function. However, on the other hand, hydronephrosis without ureteral or lower tract anomaly is common. The important aspect of postnatal investigations is to identify the group of patients who will benefit from early intervention to those who need to be carefully followed up.

Ultrasound

Follow-up ultrasound examination is necessary in the postnatal period in antenatally detected hydronephrosis. If the bilateral hydronephrosis is diagnosed *in utero* in a male infant, postnatal evaluation should be carried out within 24 hours, primarily because of the possibility of posterior urethral valves. If the ultrasound scan is negative in the first 24–48 hours in any patient with unilateral or bilateral hydronephrosis, a repeat scan should be performed after 5–10 days, recognizing that neonatal physiological dehydration may mask a moderately obstructive lesion.

If hydronephrosis is confirmed on the postnatal scan, further careful scan of the kidney, ureter, bladder, and the posterior urethra in boys is essential. Ultrasonography depicts the dilated calyces as multiple intercommunicating cystic spaces of fairly uniform size that lead into a larger cystic structure at the hilum, representing the dilated renal pelvis (Fig. 95.1a). Peripheral to the dilated calyces, the renal parenchyma is usually thinned with normal or increased echogenicity.

In order to standardize the postnatal evolution of prenatal hydronephrosis, the SFU grading system of postnatal hydronephrosis mentioned above, is used.

Typically, the ureter is of normal caliber and not seen.[22] However, if it is dilated, the size of the ureter is also assessed ultrasonographically and graded 1–3 according to ureteral width <7, 7–10, >10 mm, respectively.

Clearance curve for left kidney confirming the high-grade obstruction on this side; (c) 20 minute full-length film from an i.v. urogram (IVU) series showing left-sided high-grade PUJ obstruction in the same patient; (d) magnetic resonance urography (MRU) showing PUJ obstruction in the same patient (left arrow shows PUJ obstruction on the left side; right arrow shows normal urinary bladder with balloon of the Foley catheter).

Radionuclide scans

Diuretic renograms using ^{99m}Tc-DTPA augmented with furesemide were useful in the diagnosis of urinary tract obstructions over a long period.[28,29] DTPA is completely filtered by the kidneys, with a maximum concentration of 5% being reached in 5 minutes, falling to 2% at 15 minutes. However, in the last decade, it has been reported that use of the tracers that rely on tubular extraction such as ^{123}I-Hippuran and ^{99Tc}-MAG3 (Fig. 95.1b) may improve diagnostic accuracy.[30–32] The kidney of the young infant is immature; renal clearance, even when corrected for body surface, progressively increases until approximately two years of age. Therefore, renal uptake of the tracer is particularly low in infants, and there is a high background activity. Thus, traces such as ^{123}I-Hippuran and ^{99Tc}-MAG3 with a high extraction rate provide reasonable images, enabling estimation of differential kidney function during the first few weeks of life. It is also helpful in assessing the size, shape, location, and function of the kidney. Diuretic augmented renogram is a provocative test and is intended to demonstrate or exclude obstructive hydronephrosis by stressing an

upper urinary tract with a high urine flow. Obstruction is usually defined as a failure of tracer washout after diuretic stimulation. If unequivocal, it eliminates the need for further investigations. In equivocal cases, F15, in which furosemide is given 15 minutes after injection of the radionuclide trace, provides a better assessment of the drainage of the upper urinary tract. Forced hydration prior to scan increases the predictive value of non-obstructed pattern up to 94%.[31] Since glomerular filtration and glomerular blood flow are still low in the newborn, the handling of the isotype is unpredictable and can be misleading. Koff *et al.*,[32] therefore, feel that the risk of making a misdiagnosis of obstruction in this age group far outweighs the potential damage to renal function that might result from delaying surgery for a few weeks until the diagnosis can be made more accurately. Therefore, the timing of radionuclide studies is of crucial importance.

In those cases where DTPA is used as an isotype, radionuclide study should be postponed until 6–8 weeks after birth allowing the kidney to multiply the number of the functioning glomeruli. When ^{99Tc}-MAG3 is utilized in the diagnosis of the obstruction, the radionuclide study may be performed as early as 2 weeks of age in those cases where prompt diagnosis is required.

Diagnosis of pelvi-ureteric junction obstruction can be made by i.v. urography. Although this investigation can show a dilated renal pelvis with clubbed calyces, it is often not helpful as the concentration of contrast is unreliable and, nowadays, it has no place in the in the diagnostic armamentarium (Fig. 95.1c).

Recently, the value of magnetic resonance urography (MRU) has begun to be appreciated in the diagnosis of upper tract obstructions.[33,34] The advent has facilitated the assessment of both function and morphology of the urinary tract, thereby increasing the accuracy of diagnostic work-up. The advantages of this relatively new modality reside not only in not using ionizing radiation, but especially in the acquisition of images with higher contrast and spatial resolution in any orthogonal plane, compared with conventional techniques. Certain pathological conditions, such as neoplasms, infections, parenchymal ischemias, and hemorrhage, as well as obstructions and anomalies, can be accurately identified. The addition of new rapid magnetic resonance imaging (MRI) techniques with high temporal resolution has allowed quantification of cortico-medullary perfusion along with the renal excretory function (Fig. 95.1d).[34]

PRESSURE-FLOW STUDY

In ambiguous cases and in the presence of impaired function, the pressure flow study (Whitaker test) and antegrade pyelography may be necessary to confirm or exclude obstruction.[35] Whitaker test is based on the hypothesis that if the dilated upper urinary tract can transport 10 mL/min without an inordinate increase in pressure, the hydrostatic pressure under physiological conditions should not cause impairment of renal function and the degree of obstruction, if present, is insignificant. However, it is an invasive test and is seldom required. Antegrade pyelography may be performed with ultrasound guidance in patients where diagnosis is difficult.[36] Retrograde pyelography is seldom required to determine the status of ureters. The disadvantages include difficulty in ureteral catheterization in neonates, and trauma and edema may change partial to complete obstruction. In patients where diagnosis is equivocal, serial examinations may be necessary.

Treatment

Considerable controversy exists regarding the management of newborn urinary tract obstructions. Some authors advocate early surgical intervention to prevent damage to maturing nephrons,[37] while others feel that early surgery carries no specific benefit.[4–7] During late prenatal and early postnatal life, there is a progressive increase in the glomerular filtration rate.[5] Additionally, this transition is associated with an abrupt decline in urine output from what appears to be a quite high *in utero* output to a rather low early neonatal level of urine production.[38] These physiological observations may explain the common observation of hydronephrosis detected antenatally, which on postnatal follow up reverts to an unobstructed pattern.[1,5,10] In 1990, in a pioneering manuscript, Ransley *et al.* reported the results of non-operative treatment in newborns with non-refluxing hydronephrosis and differential renal function $>40\%$.[4] At six-year follow up, only 23% needed surgical correction. The most common indication for surgery in this group of children was deterioration of renal function. Subsequently, Koff and Cambell[5] reported that out of 104 neonates with prenatally diagnosed unilateral hydronephrosis who had been followed conservatively, only 7% required pyeloplasty on long-term follow up. Furthermore, the same group reported results of initial conservative management of children with severe unilateral hydronephrosis due to PUJ obstruction.[39] Only 22% of these children required pyeloplasty. All children who required surgery were younger than 18 months and had progressive hydronephrosis and/or reduction in renal function. Therefore, immediate postnatal surgical intervention is unnecessary in the majority of newborn children with pelvi-ureteric junction obstruction. These babies should be followed up with serial examinations to observe anatomical and functional improvement. Surgery is undertaken in infants with deteriorating renal function.[3–57,39,40] We have recently reported over a 16-year period (1988–2003) experience with 343 children (260 males and 83 females) with antenatal diagnosis of hydronephrosis, which led to postnatal diagnosis of PUJ obstruction, who were followed conservatively. Of these, 110 had right-sided hydronephrosis and 233 had left-sided hydronephrosis. According to the Society for Fetal Urology classification, none had grade 0 postnatal hydronephrosis, 20 had grade 1, 118 grade 2, 147 grade 3, and the remaining 58 children grade 4 postnatal hydronephrosis. Relative renal function (RRF) on radionuclide scans revealed 235 children with RRF of more than 40%, 68 with RRF between 30 and 40%, and 40 patients with RRF less than 30%. Renal function deterioration of greater than 5% served

as a main indication for surgery.[7] We have found that 179 (52.2%) children required surgical correction in the course of conservative management. Average age at surgery was 10.6 months (range, 1 month–7 years). Of those, 50% underwent surgery during the first two years of life and the majority of the remaining patients underwent surgery between the second and fourth years of age; only two patients required surgery later than this. Univariate analysis revealed that child sex, side of hydronephrosis, and SFU grade of prenatal hydronephrosis are not significant predictive factors for surgery. However, SFU grade 3–4 of postnatal hydronephrosis and RRF less than 40% were significant independent risk factors which led to the surgical correction.

Pyeloplasty

Pathological variations in PUJ obstruction necessitate the surgeon to be conversant with the various techniques of the pyeloplasty.[41–47] The objective of the pyeloplasty is to achieve a dependent, adequately calibered, watertight PUJ. There are different approaches for open pyeloplasty. The classical traditional approach is an extraperitoneal approach via a lateral flank incision. The infant is placed on the operating table in a supine position with the affected side elevated on a roll (Fig. 95.2a). Muscles are either cut or split (Fig. 95.2b–d) and Gerota's fascia is opened (Fig. 95.2e). In the past, it was recommended that an appropriate size silicone tube be passed from the opened PUJ down the ureter to the bladder, in order to check for distal obstruction. However, we have abandoned this approach due to the possibility of the development of subsequent ureterovesical junction (UVJ) obstruction as a result of the injury to the fragile UVJ area from the passing catheter. The current diagnostic modalities almost certainly exclude existence of any double pathology. In those cases where suspicion to the distal to PUJ area has arisen, antegrade or retrograde study of the ureter upon or during surgery is recommended.

In some cases, the posterior lumbotomy may be applied.[41,42] The use of muscle splitting, rather than muscle cutting, makes it an almost minimally invasive procedure. The location of the incision just under and parallel to the 12th rib has a cosmetic advantage. The bilateral procedure is possible, if indicated, under the same anesthesia without changing position. This approach should not be used in older children or those who are significantly obese.

The various techniques of pyeloplasty are divided into dismembered and non-dismembered pyeloplasty.

DISMEMBERED PYELOPLASTY

Anderson–Hynes pyeloplasty

The renal pelvis, pelvi-ureteric junction, and proximal ureter are freed of perirenal fat. Three stay sutures are placed: (1) at the superomedial aspect of the pelvis, (2) at the inferolateral aspect of the pelvis, and (3) on the ureter about 5 mm below the pelvi-ureteric junction. The ureter is divided obliquely above the ureteric stitch and the redundant pelvis trimmed (Fig. 95.3a). The superior two-thirds of the pelvis is closed by using continuous 6/0 maxon stitch (Fig. 95.3b). An oval-shaped anastomosis between the ureter and lower part of the pelvis is carried out from the posterior to the anterior layer over a silastic stent using 6/0 maxon continuous stitch (Fig. 95.3c,d). After the anastomosis is completed, a radivac drain is inserted. Gerota's fascia is closed with interrupted 3/0 chromic catgut sutures. Muscles are approximated in layers using subcuticular 5/0 dexon. We have used a Pippi-Salle stent nephrostomy tube (Cook, Bloomington, IN, USA) for dismembered pyeloplasty. In order to avoid passing of the distal end of the Pippi-Salle stent nephrostomy through the UVJ in small children, we cut the distal tail of the tube and leave a distal end in the ureter below the anastomosis. The proximal end of the stent is positioned in the renal pelvis. The nephrostomy end is opened for drainage for the next 48–72 hours after surgery. Then the nephrostomy is closed and the patient is discharged home following removal of the drain. The tube is usually removed in the office 4 weeks after surgery.

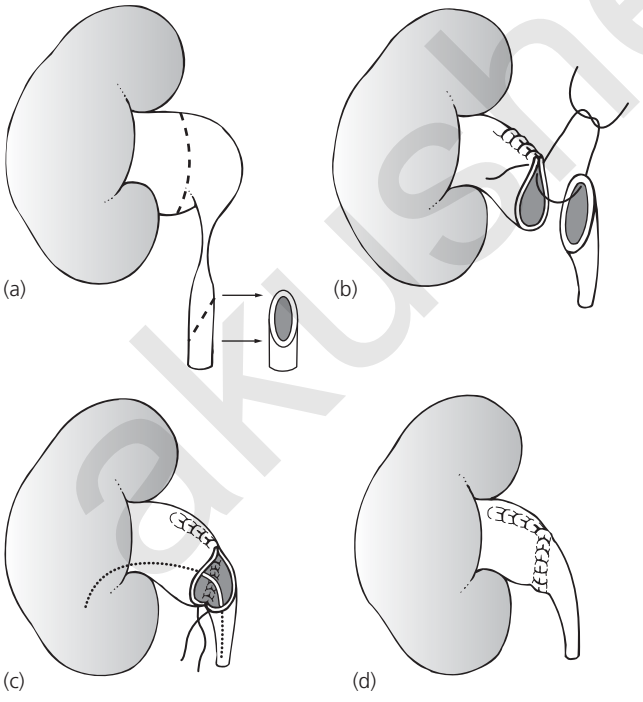

Figure 95.3 Anderson–Hynes pyeloplasty. (a) Vertical *en bloc* resection of the pelvis, pelvi-ureteric junction, with oblique division of the ureter; (b) superior part of the pelvis is closed and start of the posterior layer anastomosis between ureter and pelvis; (c) posterior layer anastomosis completed and anterior layer anastomosis commenced over a stent; (d) an oval-shaped anastomosis completed between ureter and renal pelvis.

NON-DISMEMBERED PYELOPLASTY

The Y plasty (Foley)

This is based on the principle of a Y–V flap. This operation is suitable when the ureter inserts high on the pelvis. A V-shaped incision is made on the pelvis on the anterior and posterior surface. The tail of the incision is on the lateral surface of the ureter well below the obstruction. The pelvic flap is brought down, and posterior and anterior anastomosis of the flap and ureter performed using 6/0 maxon.

The spiral flap (Culp)

The spiral flap (Culp) is suitable for long, dependent, stenotic ureteropelvic obstruction. The incision on the ureter must be adequate covering the stenotic area. A flap of equal length is based on a broad base (Fig. 95.4a). The posterior layer of the ureter and flap is sutured using 6/0 maxon (Fig. 95.4b). The anterior layer is crossed over the stent and anastomosed using 6/0 maxon (Fig. 95.4c).

The endoscopic technique has gained some popularity in the surgical treatment of PUJ obstruction.

Endopyelotomy

Endopyelotomy can be performed using either the percutaneous antegrade approach or endoscopic retrograde procedure.[43] Even experienced surgeons do not recommend this procedure in neonates, infants, or young children.[44] Percutaneous endopyelotomy is performed by making an incision

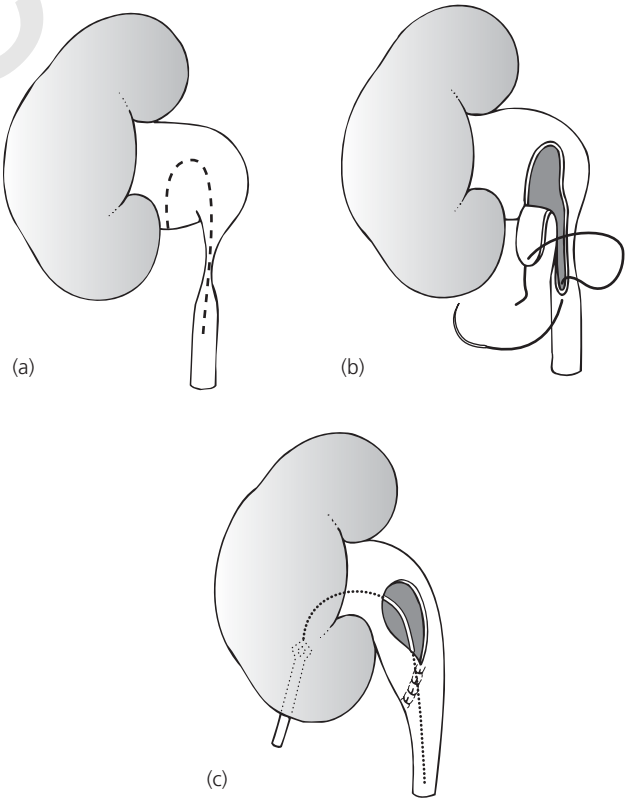

Figure 95.4 The spiral flap (Culp) pyeloplasty. (a) Spiral fashioning of the flap; (b) the flap brought down and the first suture positions the rounded tip of the flap distally to the ureter; (c) anterior layer closed over a stent.

on the posterolateral wall using a smaller endoscope and using a 3F or 5F electrocautery probe and followed by separating the cut edges using a balloon. A ureteral stent is placed for drainage for 6 weeks and nephrostomy tube for between 3 days to 6 weeks. Kavoussi *et al.*[45] have shown that this procedure is also safe and effective in treating secondary PUJ obstruction.

Figenshau and Clayman[46] used a retrograde technique for older children and combined antegrade-retrograde for young children. The incision in the PUJ segment was performed using an Accucise balloon under fluoroscopic control. They concluded that the technique has an 86% success rate and should be offered to pediatric patients with PUJ obstruction. Balloon dilatation of PUJ has also been reported in infants and young children. This consists of dilatation of the PUJ segment using a dilating balloon catheter (12–24 Fr), which is positioned, confirmed, and inflated for 3 minutes under fluoroscopic control. The success rate has been reported as 63% with a follow up to 23 months.

LAPAROSCOPIC PYELOPLASTY

Laparoscopic Anderson–Hynes dismembered pyeloplasty has recently gained wide popularity in the pediatric population.[47–49] A decade ago, Yeung *et al.*[48] reported the results of initial experience with retroperitoneal dismembered pyeloplasty in 13 infants and children. The authors concluded that laparoscopic Anderson–Hynes dismembered pyeloplasty is feasible and safe in infants, but stressed that the long-term results are awaited in order to prove that this method is durable in the long term in children. Since then, the visibility of the laparoscopic approach has found support in numerous publications.[49] Surgery may be performed through either retroperitoneal or transperitoneal approaches. The retroperitoneal approach is safe, but technically more demanding due to the smaller operating space and additional difficulties in facilitating intracorporal suturing. Moreover, it is more difficult to teach residents to perform laparoscopic surgery, while using the retroperitoneal approach. In order to facilitate a laparoscopic pyeloplasty, some technical steps may be employed. Taking a transperitoneal approach allows the operative space to be increased especially in small children. Laparoscopic pyeloplasty on the left side may be performed through the transmesenteric approach. The placement of the stay suture on the renal pelvis prior to suturing the anastomosis between the renal pelvis and the ureter stabilizes the suture line and allows precise placement of the sutures, therefore eliminating the risk of reobstruction.

The final development in laparoscopic reconstructive surgery in children was the employment of robot-assisted surgery. The currently available system (DaVinci, Intuitive Surgical, Sunnyvale, CA, USA) is a robotic manipulative device which permits the surgeon to have better control over the instruments. The impression with robot-assisted surgery is that suturing is easier and less operating time is required to perform laparoscopic pyeloplasty. Furthermore, it is much easier to teach a surgeon without prior laparoscopic experience to perform laparoscopic pyeloplasty while using a robot-assisted suturing technique. However, the high initial cost of robotic equipment and expensive maintenance of the working system cannot be ignored.

NEPHRECTOMY

Because the recovery potential of the kidney is greater in neonates, extreme conservation is justified. Salvage pyeloplasty should be considered, as renal function as shown on renal scintigraphy can recover.[50] At operation, an assessment should be made of the renal cortex after emptying the pelvis. Severe cystic dysplasia is an indication for nephrectomy, otherwise every effort should be made to salvage the kidney.

BILATERAL PELVI-URETERIC OBSTRUCTION

Surgical correction of the symptomatic side (or the side with better function) should take precedence. If a nephrectomy is considered on one side, the pyeloplasty should precede this.

Postoperative complications

Postoperative complications include infection, adhesive obstruction (transperitoneal approach), temporary obstruction at the anastomosis resulting in excessive urine leakage and failure due to postoperative stricture at anastomotic sites. An overall reoperation rate of 8.2% was reported in the early series.[44] However, when temporary double-J stents or stent nephrostomy tubes were used, the reoperation rate was negligible.

Follow up and results

Follow up ultrasound may be performed three to six months after operation when maximum improvement can be seen.[7] Radionuclide scans are useful to monitor the postpyeloplasty function and drainage. Pyeloplasty in the neonatal period, when indicated, gives excellent results.

MEGAURETER

Megaureter is a ureter, which is dilated out of all proportion to the rest of the urinary tract and above the norms. Cussen[51] and later Hellstrom et al.[52] have established the normal measurement of the ureteral diameter in infants and children from 30 weeks of gestation to 12 years of age. Normal ureteral diameter in children is rarely greater than 5 mm, and ureters large than 7 mm can be considered megaureters.

Classification

In 1976, the Paediatric Urology Society[53] adopted a standard nomenclature for categorizing megaureters, which is a useful guide for management. There are three types described:

1. **Refluxing ureter**, which may be primary or secondary to distal obstruction or pathology
2. **Obstructive ureter**, which may be primary and include intrinsic obstruction, or secondary due to distal obstruction or extrinsic causes

3. **Non-refluxing, non-obstructed ureter**, which may be primary, idiopathic type or secondary to diabetes insipidus or infection.

In 1980, King[54] subsequently modified this classification by adding a fourth group consisting of the refluxing, obstructed megaureters.

URETERO-VESICAL JUNCTION OBSTRUCTION

The presence of an adynamic distal ureteral segment is the most common cause of primary obstructive megaureter. The presence of a narrowed terminal portion of ureter will not convey the peristaltic wave or dilate enough to permit free passage of urine. This results in excess boluses of urine which coalesce and cause ureteral dilatation. The contraction waves become smaller and are unable to coapt the walls of dilated ureters. This along with infection could damage the renal parenchyma. The proposed etiologies include:

- **Alteration in muscular orientation**: Tanagho *et al.*[55,56] noted in the fetal lamb that the muscle coats of the distal ureter develops last and that late arrest in development results in absence of longitudinally oriented musculature that conducts the peristaltic wave. This results in hypertrophy of the circular fibers causing obstruction.
- **Muscular hypoplasia with fibrosis**: McLaughlin *et al.*[57] found that 69% of narrowed terminal ureteric segments showed muscular hypoplasia which were separated by fibrotic sheets thus affecting the transmission of peristalsis. This fibrotic ring prevents expansion and free urinary drainage.
- **Excessive collagen deposition**, resulting in a discontinuity of muscular coordination is another hypothesis.[58] Lee *et al.*[59] examined the histology of ureteric smooth muscle and collagen in obstruction employing computer-assisted color image analysis. They found that the tissue matrix collagen ratios (collagen–smooth muscle) were significantly higher in patients with megaureters compared to the control.
- **Disturbance in the electric syncytium**, along with the nexus injury, has been suggested to precede pathological innervation.[60] Dixon *et al.*[61] showed dense non-adrenergic innervation in a smooth muscle collar surrounding the terminal ureter in cases of obstructed megaureter associated with ectopic ureteric insertion. Recently, it was reported that the myocyte apoptosis and decrease of the interstitial Cajal cells in the longitudinal muscular layer of the intravesical part of the ureter may lead to the development of the aperistaltic segment and subsequently to the UVJ obstruction.[62,63]

Prenatal diagnosis

Usually, the ureter is not seen in fetal scans. Visualization of the dilated ureter to the level of the vesico-ureteric junction without an abnormal bladder may suggest obstruction or reflux. However, this may be a transient phenomenon. Fetal urine flow is four to six times greater before birth than after and is due to differences in renal vascular resistance, glomerular filtration, and concentrating ability. This high outflow contributes to ureteral dilatation. Another contributing factor is increased compliance of the fetal ureter.[64]

Clinical features

The widespread use of maternal ultrasound has changed the age of presentation of congenital uropathies, including megaureter. Currently, about half of the cases are asymptomatic and discovered on prenatal ultrasound. The most common mode of clinical presentation is urinary tract infection.[65,66] Microscopic hematuria is frequent and may occur in the absence of infection. This is presumably caused by the disruption of mucosal vessels of the ureter secondary to ureteric distension. Primary obstructive megaureter is more common in males than females and the left ureter is more likely to be involved than the right. Between 17 and 34% patients have bilateral megaureters. Contralateral renal agenesis is found in 10% of the patients.[64–69]

Diagnosis

Antenatally diagnosed ureteral dilatation needs further evaluation to confirm or exclude obstruction, reflux or both. Clinicians are confronted with the two basic problems in assessing the dilated ureter in a neonate.[6,65,66,70–72] First, it is a real challenge to differentiate between obstructive and non-obstructive urinary tract dilatations. Second, there is no study that can determine accurately the potential of the kidney to recover after relief of obstruction.

Ultrasound

In antenatally detected cases, ultrasonography should be performed between 3 and 5 days after birth. If no dilatation is seen, repeat ultrasound should be performed after a few weeks as neonatal oliguria can mask dilatation. If dilatation persists on a repeat ultrasound, further work-up can be postponed for a few weeks unless bilateral disease or a serious abnormality, such as obstruction in a solitary kidney or urethral valves, is suspected. Such an approach allows for the expected changes of transitional renal function in the newborn period that might otherwise cause inaccuracies with many diagnostic studies. Ultrasonography classically shows hydroureter and variable hydronephrosis, with hyperperistalsis of a lower ureter that terminates shortly above the bladder in a narrow, adynamic segment (Fig. 95.5a).[73] However, the narrow segment may not always be visualized and therefore micturating cystourethrogram is necessary to exclude vesico-ureteric reflux.

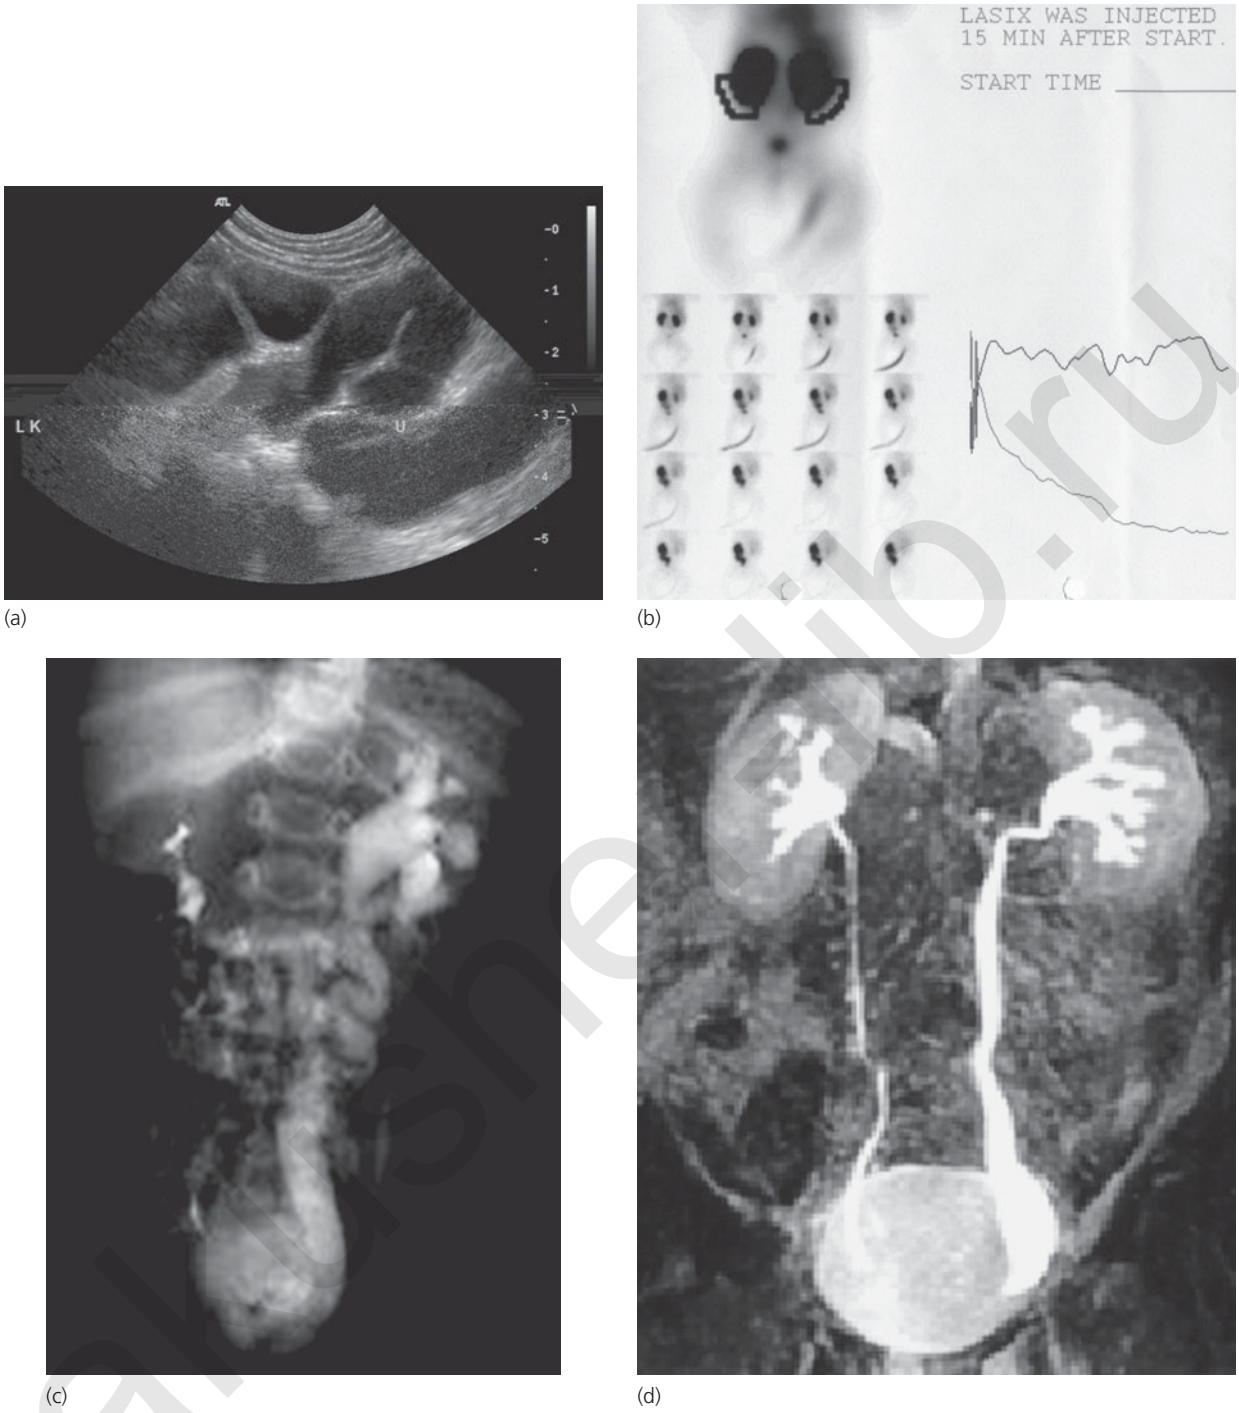

Figure 95.5 (a) Longitudinal scan to the left of the midline through the bladder demonstrates dilatation of the left lower ureter to the level of the vesico-ureteric junction; (b) MAG3 renal scan showing clearance curve for left kidney demonstrating obstructive pattern; (c) 30-minute full-length film from the i.v. urogram series shows obstructed megaureter of the same patient; (d) magnetic resonance urography image showing obstructive left megaureter.

Renal scintigraphy

A radionuclide scan is required to assess the urinary flow and stasis along with determination of the differential function and glomerular filtration rate. For the evaluation of neonatal hydronephrosis and hydroureter, MAG3 is the most frequently used (Fig. 95.5b).

Intravenous urography

Intravenous urography may be necessary in equivocal cases to establish the diagnosis. It delineates the anatomy showing dilated, obstructed ureter (Fig. 95.5c). However, it is better to wait for a few weeks for renal maturation to allow concentration of contrast reliability. Occasionally, Whitaker

test and antegrade pyelography may be required to establish the diagnosis.

Fung *et al.*[74] explored ureteral opening pressure as a novel parameter for evaluating pediatric ureterohydronephrosis. Renal pelvic pressure is assessed while simultaneously documenting the passage of contrast material from the distal ureter into the bladder. A pressure increase of 14 cmH_2O within the renal pelvis is consistent with distal ureter obstruction.

As in the diagnosis of PUJ obstruction, MRU has gained wide popularity in the diagnosis of UVJ obstruction (Fig. 95.5d).

Management

It is being increasingly recognized that many antenatal and neonatal ureteral dilatations improve over time.[5,65,66,72] Surgery is indicated in patients with progressive ureteral dilatation and deterioration in renal function. We have recently published our experience of over 18 years in 79 children (64 boys and 15 girls) with antenatal diagnosis of hydronephrosis, which led to postnatal diagnosis of megaureter, and tried to determine criteria for those who are at risk for surgery.[72] According to the SFU classification of hydronephrosis, eight renal units (RU) were grade 1, 57 were grade 2, 29 were grade 3, and 11 were grade 4 of postnatal hydronephrosis. Mean ureteral diameter was 1.2 cm. Relative renal function (RRF) was more than 40% in 82 RU, between 30 and 40% in 18, and less than 30% in 5 RU. Only a combination of renal function deterioration of the hydronephrotic kidney greater than 5% and worsening of hydronephrosis (considered as upgrade of SFU) served as main indications for surgery. Twenty-five (31%) children required surgical correction. Mean age at surgery was 14.3 months (range, 3–60 months). Univariate analysis revealed SFU grade 3–4 of postnatal hydronephrosis, RRF less than 30%, and ureteral diameter more than 1.33 cm were significant independent risk factors leading to reimplantation.

Operation

There are various techniques for reimplanting the ureter in a non-refluxing manner after excision of adynamic, narrow segment. The initial approach to the ureter can be either intravesical, extravesical, or combined.[75] The most commonly used techniques for intravesical approach are Cohen's transtrigonal reimplantation and the Politano–Leadbetter operation.

INTRAVESICAL APPROACH

Position

The patient is anesthetized and placed in supine position (Fig. 95.6a).

Incision

A low transverse suprapubic skin crease incision is made (Fig. 95.6a).

Exposure

The skin flaps are raised by diathermy dissection (Fig. 95.6b). The rectus sheath is cut and two recti are separated in the midline. The peritoneum is pushed upwards. The bladder is opened vertically between two stay sutures. A Denis-Brown retractor is placed over the gauze inside the bladder to improve exposure. The ureter openings are inspected. A 3 or 5 Fr infant feeding tube is passed into the ureter and a stay suture is placed around the tube. This facilitates the handling of the ureter during dissection. An incision is made circumferentially along the ureter opening and the distal ureter is dissected from mucosa and trigonal muscle. The ureter is freed keeping away from the adventitia and mesentery to avoid damage to the blood supply (Fig. 95.6c). Bladder opening is narrowed with interrupted absorbable sutures.

COHEN'S METHOD

This method is simpler and easier to perform, and an especially useful technique in infants in whom the bladder is small. An incision is made in the mucosa above and a little lateral to the opposite ureteric orifice. A submucous tunnel is made by inserting the closed blades of scissors and performing an opening and cutting movement. The ureter is threaded through the tunnel (Fig. 95.6d). The tunnel should be adequately wide for the ureter and two to three times the ureteric diameter in length to prevent reflux. The terminal narrow portion of the ureter is excised and sent for histology. If the ureter is very dilated, remodeling is necessary, which may be performed by one of the following methods:

- A non-excisional tapering technique has the advantage of avoiding a suture line with potential urinary leakage. However, it is inappropriate for very dilated ureters as it reduces the diameter by only 50% and in neonates it can become too bulky for the tunnel.
  - Folding (Kalikinski) where a 10–12 Fr catheter is placed into the ureter and a running mattress suture placed proximally and continued distally. The lateral excluded segment is folded posteriorly and its edge fixed to the medial wall with another running suture.
  - Plication (Starrr) of the ureteral wall is achieved by multiple mattress sutures in the anti-mesenteric border.
- Excisional tapering technique, where part of ureteral wall is excised by using a knife and scissors, or Hendren clamps. The remaining ureteral strip is tubularized over 8 Fr double-J stent or feeding tube utilizing a running absorbable suture. The distal end of the ureter is closed with interrupted absorbed sutures to allow for any shortening that might be necessary. The proximal segment of the tailored ureter should stay outside the bladder after completion of the reimplantation, in order to avoid a dilated obstruction of the tailored segment. The cuff of the ureter is then sutured into position. First, a 4/0 dexon suture is inserted laterally through the full thickness of the ureter and also through the full thickness of the bladder muscle, so as to prevent the ureter retracting. Next, bladder and ureteral mucosa are approximated using

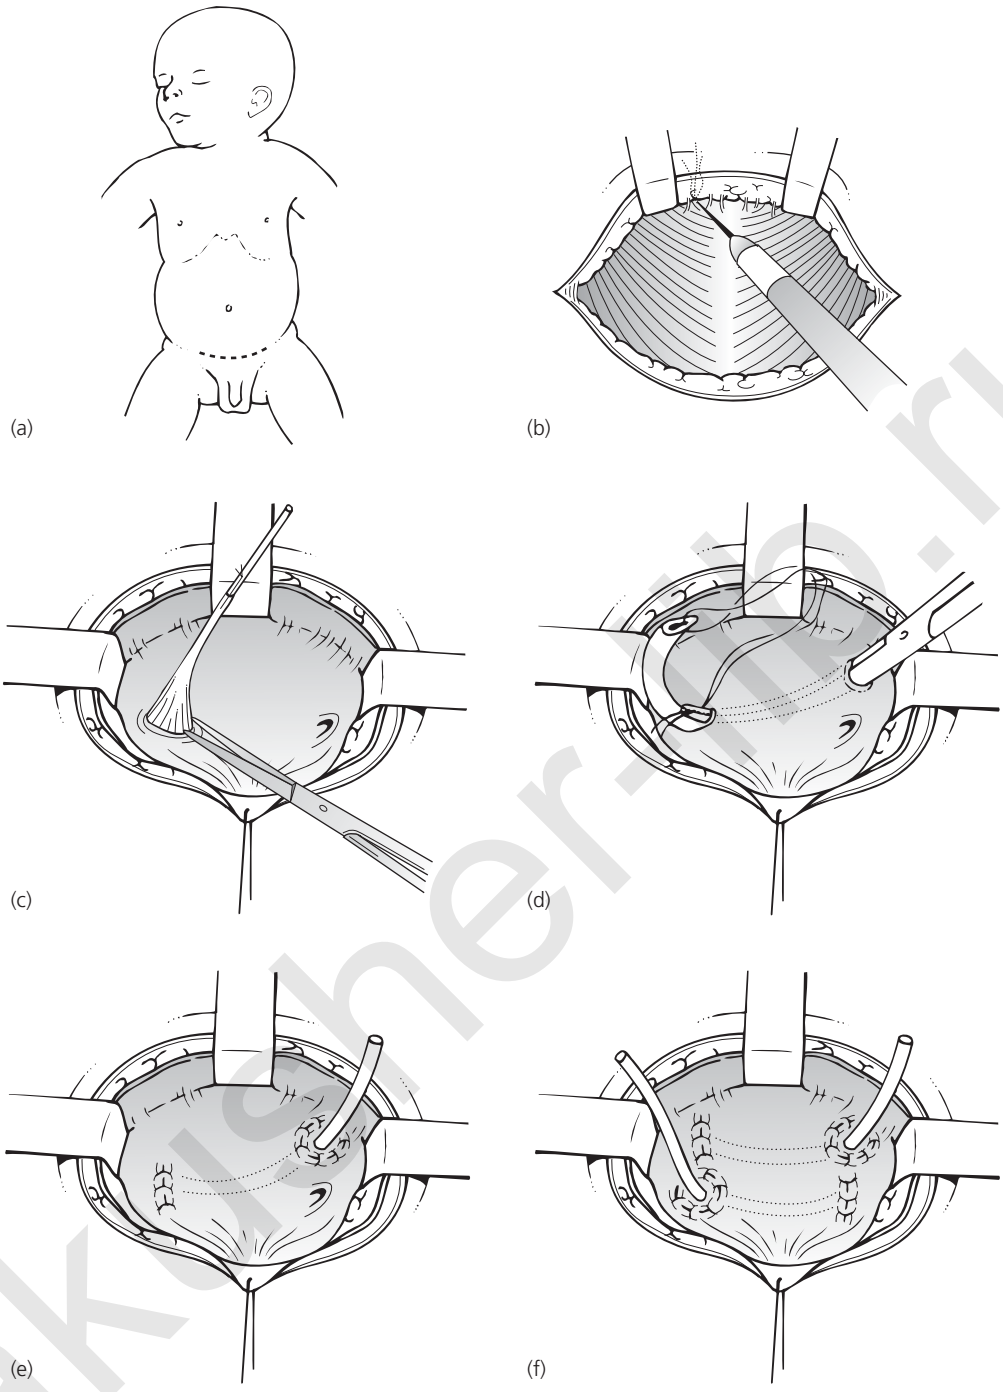

Figure 95.6 Reimplantation of ureter. (a) Position of patient on the operating table and line of incision; (b) skin flaps being raised; (c) opened bladder is retracted by Denis-Browne retractor and the stented ureter is dissected free; (d) the tunnel is commenced just above and lateral to the opposite ureteric orifice and continued to the original orifice. The ureter is threaded through the tunnel; (e) cuff of the ureter is sutured in position, while the original orifice in the bladder is closed; (f) in bilateral reimplantation, the second separate tunnel is parallel to the first and ends in the opposite orifice.

interrupted 5/0 dexon. The stents are placed into the ureter (Fig. 95.6e). In bilateral reimplantation, the second ureter has its tunnel below and parallel to the first ending in the orifice of the opposite side (Fig. 95.6b).

- Politano–Leadbetter technique: The ureter is further freed up to the dome of the bladder. The new opening for the entrance of the ureter is made on the posterolateral aspect of the bladder. The new submucosal tunnel is formed from there to the old ureteric orifice. Then, the stay suture of the ureter is passed and gently threaded through the new tunnel. The narrow terminal portion of ureter is excised and the ureter narrowed by one of the above techniques if needed and the neo-ureter opening fixed at the old opening with 5/0 dexon. Stents are put in place. A suprapubic catheter is left in the bladder and the bladder is closed in two layers, the mucosa with 4/0 plain catgut

and the muscles with 4/0 dexon. A retropubic drain is brought out through a separate incision and the muscles approximated with 3/0 dexon. The rectus sheath is sutured with 3/0 dexon and the skin approximated with a 5/0 dexon subcuticular stitch.

ENDOSCOPIC REPAIR OF THE URETER

Recent progress in endoscopic tools (such as miniscopes, balloons, and guide wires) has led to widespread use of endoscopy for ureteral repair.[76,77] Some suggest that a simple insertion of the double-J stent into the obstructive ureter for six months may solve the problem.[78] Barat *et al.*[79] recently reported preliminary results with endo-ureterotomy for congenital megaureter. The technique consists of incision of the obstructive segment of the ureter which is inserted into the ureteral orifice ureteroscope. All of the layers of the ureter are incised in the long axis through the entire obstructive segment, to expose the peri-ureteral areolar tissue. A double-J stent is inserted for 3 weeks after the procedure. The risk of secondary reflux, which is a main concern after this type of procedure has not been systematically checked. The role of endo-ureterotomy in the treatment of megaureters in children has not been widely established.

In some small children with severe obstructive megaureter, refluxing ureteric reimplantation was suggested as a novel method to temporize an obstruction.[80] The treatment consists of anastomosing the ureter proximal to the obstruction to the dome of the bladder in a freely high-grade refluxing fashion. This technique allows time for the child to mature, while accurately establishing renal function and preparing for a definitive surgical solution.

LAPAROSCOPIC REIMPLANTATION

In recent years, laparoscopic reimplantation has gained popularity in some medical centres.[81–83] Use of robot-assisted laparoscopic techniques in pediatric urology led to even wider application of laparoscopic reimplantation to the surgical armamentarium. Three procedures have been attempted laparoscopically: extravesical reimplantation, Gil-Vernet procedure, and the Cohen crosstrigonal reimplantation. Some difficulties were noticed with this approach: long operative time, steep learning curve, and the technical challenges in the creation of a submucosal channel without injury to the intact bladder mucosa, and suturing aspects of the procedure. Use of the robot-assisted technique is supposed to overcome these difficulties. However, the current port size is not suitable for small children.

POSTOPERATIVE COURSE

Patients are fasted for 24 hours in case of development of ileus. In the intravesical approach, the drain is removed after 24–48 hours. Stents are removed after 7–10 days followed by the suprapubic catheter. Ureteral reimplantation using the extravesical approach can be performed without stenting.[84,85] An indwelling urethral catheter is put in place usually for 3–5 days to avoid urinary retention.

Complications

Complications include wound infection, vesico-ureteral reflux due to short tunnel with no effective flap valve mechanism, or obstruction due to a fibrotic distal end secondary to ischemia.

FOLLOW UP AND RESULTS

Radiologic studies are used to assess the initial and long-term surgical results and to monitor renal growth. These include ultrasound, i.v. urography, or radionuclide scans. The success is measured by normal urinary drainage with no reflux and control of urinary infections.

Ureteral duplication anomalies

PREM PURI AND HIDESHI MIYAKITA

INTRODUCTION

Duplication of the ureter and renal pelvis is the most common upper urinary tract anomaly with a reported incidence of 0.8 in the population and in 1.8–4.2% of pyelograms.[1–5] The vast majority of these anomalies have normally developed renal moieties and cause no functional problems. However, they can challenge the diagnostic acumen with a wide variety of manifestations. Vesico-ureteral reflux (VUR) is the most frequently associated anomaly found in duplex systems. A small proportion of ureteral duplications is associated with ureteroceles, ectopic ureter, and pelvi-ureteric junction obstruction.

EMBRYOLOGY

The ureteric bud appears at 5 weeks' gestation from the point where the Wolffian duct bends centrally and medially to the cloaca and pushes into the pelvic metanephrogenic mass and eventually forms the ureter and renal pelvis. Premature division of the ureteral bud gives rise to incomplete duplication. If two ureteral buds arise from the Wolffian duct and if both are incorporated into the urogenital sinus, then complete duplication occurs. The upper pole ureter is more closely associated with the Wolffian duct, while the lower pole ureteric bud is closest to the urogenital sinus and incorporated first. The upper pole ureter is carried medially and caudally along with the Wolffian duct. Therefore, the upper pole ureter opens more medially and inferiorly than the lower pole ureter, according to the Weigert–Mayer law.[6–8] Sometimes, this upper pole ureter has an abnormally prolonged or close attachment to the Wolffian duct which will migrate into the segment of urogenital sinus that is destined to become the urethra.

Occasionally in males, a separate opening into the urogenital sinus is not established and the bud continues to be linked to the Wolffian duct much longer and the ureter inserts into the male genital tract, for example in the seminal vesicles, vas deferens, or even epididymis.

Stephens[9] proposed that, in females, the fused Müllerian ducts after penetrating the urogenital sinus undergo significant epithelial activity and incorporate any Wolffian duct remnants, and thus the ureteral bud along with the Wolffian duct may be carried along as part of caudal Müllerian migration and this in turn would lead to drainage sites into the vestibule, vagina, cervix, and uterus.

CLASSIFICATION

A standard set of definitions used to describe ureteral duplication anomalies now exists. These definitions were established by the Urologic Section of the American Academy of Pediatrics Committee on Terminology, Nomenclature and Classification.[10] The following are the different types of ureteropelvic duplications, the recognition of which is important in understanding the pathophysiology, clinical manifestations, and management.

- Incomplete ureteral duplication, where two ureters unite and enter the bladder through a common orifice.
- Complete ureteral duplication:
  - Intravesical: Two ureters drain separately into the bladder. The upper pole opens caudal and medial to the lower pole ureter and has a longer ureterovesical course and therefore less risk of reflux.
  - Extravesical: where the ureter opens into the urethra or genital tract.
- Inverted Y ureteral duplication. Two distal ureters fuse to drain a single kidney; one of the limbs may be ectopic, blind-ending, or atretic.
- Blind bifid ureter. One branch ends blindly and this is thought to be because one ureteral bud does not join the metanephrogenic mass.

- Ureteral triplication and even quadruplication has been reported and is due to formation and/or division into three or four buds.[11–13]

CLINICAL MANIFESTATION

Most often, ureteral duplication anomalies are discovered incidentally unassociated with any symptoms. Infants may come to medical attention because of the complications of obstruction of the upper moiety or infection. VUR is common, occurring much more frequently in the lower segment and is present in 70% of children with duplex systems who present with urinary tract infections.[5,14]

Duplication affects both sides equally, while 15% of patients have bilateral duplications. It is more common in females, who are more likely to exhibit pathological complications. There is a familial tendency with the risk of duplication in a sibling up to one in eight and is suggestive of autosomal dominant inheritance with incomplete penetration.[3,15] A recent study reported prevalence of duplex systems in familial VUR.[16] Duplex systems were present in 39 (7.6%) of the 513 siblings with VUR. Families with exclusively boys affected with VUR had a significantly higher rate (15%) of duplex systems than in families with mixed affected siblings and girls.

Ureterocele, a cystic dilatation of the terminal intramural segment of the distal ureter, is classified as either simple or ectopic.[10] The ectopic variety is symptomatic in infants far more commonly than simple ureterocele and is nearly always with an obstructed upper segment of a duplex kidney. The bulging ureterocele protrudes into the intravesical space and terminates ectopically at the bladder neck or in the urethra. Whether associated with single or duplex systems, the problems of ureterocele are much more common in girls than boys.

Ureteral duplication can present with diverse clinical manifestations and include:

- Urinary tract infection, which may be due to reflux or obstruction. This can vary from overwhelming sepsis to asymptomatic bacteria.
- Epididymo-orchitis as a result of an ectopic ureter opening into the male genital tract or
- Incontinence, which is due to an ectopic ureter opening beyond the sphincter and is thus more common in females or because of infection causing urge incontinence.
- Urinary retention. A ureterocele occupying the bladder neck can cause urinary retention and overflow incontinence. Rarely, it may prolapse through the urethra (Fig. 96.1).
- Abdominal mass. Hydronephrosis secondary to obstruction may present with abdominal mass.
- Failure to thrive, because of chronic persistent urinary infection.

Prenatal diagnosis

The kidneys can be imaged at the 12th gestational week by abdominal ultrasound. With the increased availability and use of maternal ultrasonography, the incidence of urinary tract disorders diagnosed *in utero* has increased considerably. Oligohydramnios or anhydramnios in the mother is usually due to diminished amniotic fluid. Because amniotic fluid after 18 weeks of gestation is voided urine, it suggests bilateral renal agenesis or outflow obstruction. In order to be certain that renal development is normal, ultrasound at or beyond 20 weeks of gestation is necessary. An obstruction anomaly is recognized by demonstrating a dilated renal pelvis, calyces, or ureter. However, it is not possible to detect an uncomplicated duplex anomaly prenatally.[17]

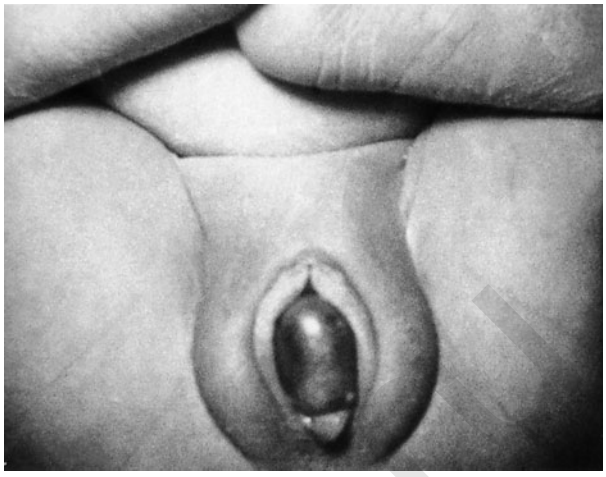

Figure 96.1 Ureterocele prolapsing through the urethra in a newborn.

Postnatal diagnosis

Ultrasonography, which does not visualize the excretory pathway, may be unable to differentiate between kidneys with and without pyeloureteral duplication, but is able to recognize thick transverse intermediate cortical mass (1 cm) in the latter group and also on the basis of the ratio between the longitudinal and transverse diameter which is greater than in kidneys without duplication.[18] An obstructed or refluxing system and ureteroceles can be visualized on the ultrasound scans (Fig. 96.2).

Micturating cystograms will delineate reflux and ureteroceles. Despite its declining role in the routine evaluation of infants with urinary tract infections (UTIs), intravenous urography is a useful and easily available modality of investigation.[19] It accurately defines the anatomy, while in the non-functioning segment the remaining pole will exhibit the 'drooping lily' sign (Fig. 96.3). Radionuclide scans are useful in determining the differential function.[20] Computed tomography and magnetic resonance imaging (MRI) may help to define the anatomy of kidneys and MRI is particularly useful in cases where conventional imaging fails to delineate occult dysplate renal moieties, ectopic ureters,

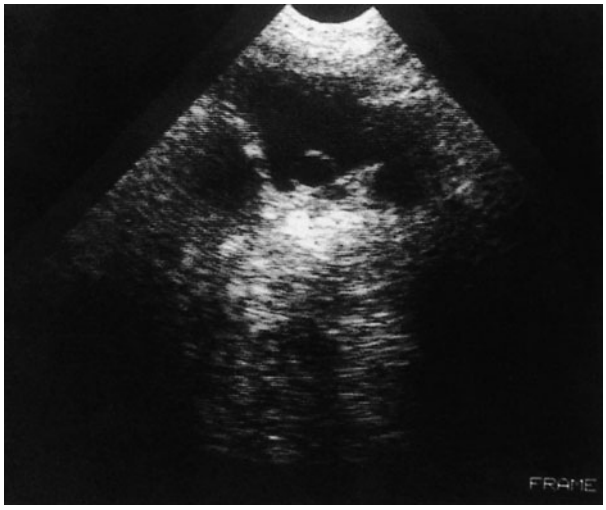

Figure 96.2 Sonographic appearance of a ureterocele within the bladder.

Figure 96.3 Twenty-minute film from urogram showing 'drooping lily' sign on the left as a consequence of an obstructed non-functioning upper moiety on this side due to a large ureterocele.

and ureteroceles. Diagnosis is usually confirmed by cystoscopy and endoscopic visualization of the ureteric orifices. It also helps to assess the extent of ureterocele.

MANAGEMENT

Asymptomatic uncomplicated ureteral duplications do not require active clinical management.

Vesico-ureteric reflux

VUR is the most common problem associated with ureteral duplication and is more common in lower poles than in upper poles. Most of the recent reports suggest that there is no difference in the rate of spontaneous resolution of minor grades of reflux into single ureters or lower pole ureters in duplex systems.[20–23] Medical surveillance should be continued in these patients to prevent renal scarring. High-grade VUR in duplex systems is unlikely to resolve and generally considered an indication for surgical treatment.[14,21] Afshar *et al.*[14] compared the outcome of VUR in duplex systems with VUR in single system and found that only 7% of refluxing units with grade III and none of those with grades IV and V resolved at a median follow up of 33 months. The reported rates of spontaneous resolution of grades I and II reflux in duplex systems vary from 22 to 85%.[21–23]

In the newborn period, conservative antimicrobial treatment combined with full urological investigation is the management of choice. Infants with grades I–III reflux should continue on chemoprophylaxis. High grades of reflux in infants associated with ureteral duplication, breakthrough infections in spite of prophylaxis and progressive renal scarring and poor function constitute indications for antireflux operation[24,25] or endoscopic correction.[26]

Polar nephro-ureterectomy is performed in patients who have one pole ureter reflux with poorly functioning segment of kidney, while nephro-uterectomy may be necessary if both poles are involved. Recently, the role of laparoscopic heminephrectomy in pediatric patients has begun to be appreciated.[27–30] Both transperitoneal and retroperitoneal laparoscopic techniques have been used for heminephrectomy in infants and children. The transperitoneal approach for moiety excision is technically simple and offers the added advantage of complete ureterectomy. The retroperitoneal approach, although technically more challenging, offers the advantages of a direct access to the kidney, minimal mobilization of kidney and surrounding structures, and a decreased risk of intraperitoneal organ injury and postoperative adhesions.

In patients with lower pole reflux only in complete ureter duplication, Ahmed and Boucout[25] and Bivens and Palken[31] recommend ipsilateral uretero-ureterostomy when there is no abnormality on the contralateral side, or there is history of bladder operation or abnormality-thickened bladders. They propose that this operation has fewer complications, requires shorter hospitalization, no postoperative bladder catheters are required and, as the non-refluxing ureteral orifice and submucosal tunnel are not disturbed, there is no risk of creating reflux. This can be undertaken either by suprapubic incision or extraperitoneal iliac fossa incision. Lashley *et al.*[32] reported excellent results of uretero-ureterostomy in 94 children with complete ureteral duplication associated with VUR, obstructing ureterocele, and ectopic ureters. The significant discrepancy in ureteral size did not preclude uretero-ureterostomy.

Another surgical option is reimplantation of ureters. Only a refluxing ureter may be undertaken if it can be safely separated. In patients with reflux into both ureters and those where the refluxing ureter cannot be safely separated, common

sheath ureteric reimplantation is undertaken. Ellsworth *et al.*[33] reported ten-year experience with common sheath reimplantation in 54 refluxing units. Common sheath reimplantation yields a 98% success rate with minimal morbidity. Recently, Lopez and colleagues[34] described their experience with laparoscopic extravesical transperitoneal approach following the Lich–Gregoin procedure in 60 refluxing duplicated collecting systems. All procedures were successfully completed laparoscopically and reflux was corrected in all children.

In incompletely duplicated ureters, surgical options include reimplantation of the common distal ureter if the junction is proximal or when junction is close to bladder excision of the common segment, with reimplantation of both ureters in the bladder or uretero-ureterostomy with reimplantation of one ureter. However, if the function is poor, nephro-ureterectomy is necessary to avoid a diverticulum-like defect.

Minimally invasive endoscopic technique for the correction of VUR has become an established alternative to long-term antibiotic prophylaxis and surgical treatment. Endoscopic subureteric Deflux® injection is effective in treating duplex reflux of higher grades in complete and incomplete systems.[24,35,36] The technique of endoscopic injection of Deflux is simple and straighforward. With an incomplete duplex system, the technique is the same as in a single system. All cystoscopes available for infants and children can be used for this procedure. The disposable Puri flexible catheter (Storz, Tuttlingen, Germany) or a rigid metallic catheter can be used for injection. A 1-mL syringe filled with Deflux is attached to the injection catheter. Under direct vision through the cystoscope, the needle is introduced under the bladder mucosa 2–3 mm below the affected ureteral orifice at the 6 o'clock position. In children with grade IV and V reflux with wide ureteral orifices, the needle should be inserted not below but directly into the affected ureteral orifice. The needle is advanced about 4–5 mm under the mucosa and the injection started slowly. As the Deflux is injected, a bulge appears in the floor of the submucosal ureter. A correctly placed injection creates the appearance of a nipple on the top which is a slit-like or inverted crescent orifice (Figs 96.4 and 96.5).

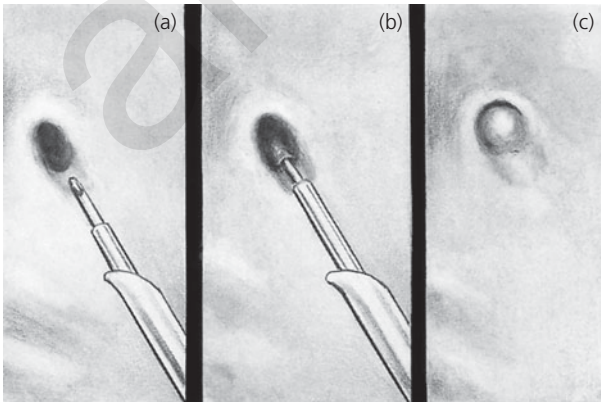

Figure 96.4 Technique of subureteric injection in an incomplete duplex system.

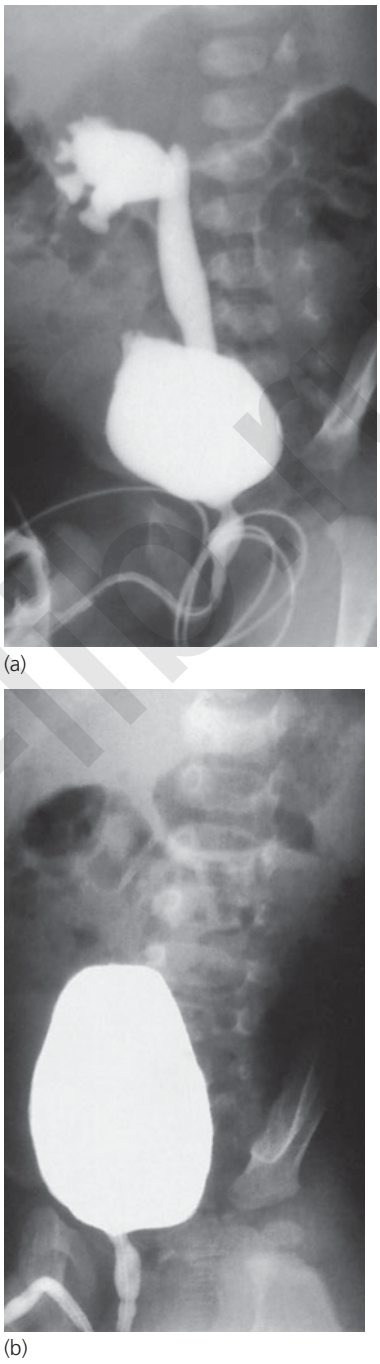

Figure 96.5 (a) Micturating cystogram in an 8-week-old boy shows grade IV vesico-ureteric reflux into the lower moiety of the right duplex system. (b) Micturating cystogram in the same boy following endoscopic correction of reflux.

In the case of a complete ureteral duplication, the needle is introduced 2–3 mm below the lower ureteric orifice at the 6 o'clock position, but the entire length of the needle (8 mm) is advanced behind the two ureters. During injection, the needle is slowly withdrawn until a 'volcanic' bulge of paste is seen and the two ureteric orifices look slit-like (Fig. 96.6). Patients are treated as day cases and a voiding

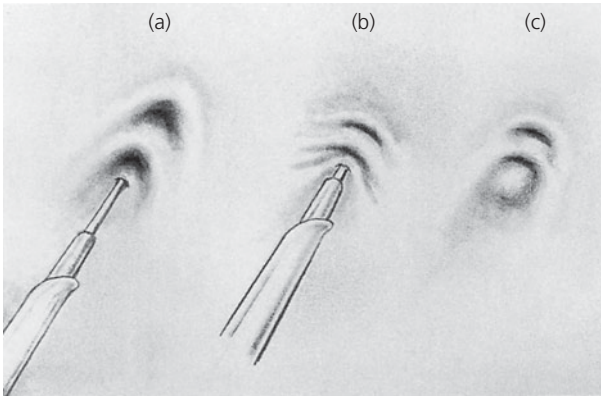

Figure 96.6 Technique of subureteric injection in a complete duplex system.

cysto-urethrogram and ultrasound are performed 6–12 weeks after discharge.

Ureteropelvic obstruction

In the bifid system, obstruction commonly involves the lower pole.[30–33] Upper pole ureteropelvic junction obstruction is uncommon (Fig. 96.7a,b). In patients with low bifurcations and who have long ureteral segments, a standard pyeloplasty can safely be performed. If the lower pole ureteral segment is short, an end-to-end anastomosis of the lower pole pelvis to the upper pole ureter, eliminating the short lower pole ureter, may be necessary. Alternatively, the short lower pole ureter is retained and incorporated into a wider anastomosis. In patients with incomplete duplications, it is possible to widen the narrowed junction of the lower pole segment to the upper pole ureter by making a vertical incision in the anterior wall and suturing it transversely.[37] If there is nonfunction of the obstructed segment, a heminephro-ureterectomy to the level of the bifurcation is necessary to avoid leaving a ureteral stump into which uretero-ureteral reflux can occur.[37]

The management of ureterocele is complex.[38–40] Consideration of ureterocele as intravesical or extravesical is important because the technique of surgical reconstruction can be different. If the function is good, endoscopic incision of the ureterocele may be tried. The advantages of this procedure are that this is straightforward management, especially in septic babies. The obstruction can be solved by simple puncture of ureterocele rather than endoscopic incision. The reflux rate to the ureterocele moiety following endoscopic puncture is negligible. In all our patients, we have used a stylet of the 3-Fr ureteral catheter for endoscopic puncture. The puncture hole is made high enough and lateral on the ureterocele in order to avoid reobstruction and to create postpuncture flap sufficient to preserve the flap-valve antireflux mechanism. If the reflux developed after endoscopic puncture, it is usually a low grade and does not require any treatment. If the child develops breakthrough infections or high-grade reflux, endoscopic correction of reflux can be easily performed.[26]

Vesico-ureteral reflux

PREM PURI

INTRODUCTION

Primary vesico-ureteral reflux (VUR) is the most common urological anomaly in children. It occurs in 1–2% of the pediatric population and in 30–50% of children who present with urinary tract infection.[1,2] The association of vesico-ureteral reflux, urinary tract infection, and renal damage is well known. Marra *et al.*[3] reviewed data on children with chronic renal failure who had high-grade VUR in the Italkid project, a database of Italian children with chronic renal failure and found that those with VUR accounted for 26% of all children with chronic renal failure. Parenchymal injury in vesico-ureteral reflux occurs early, in most patients before the age of three years. Kidneys of young infants are more vulnerable to renal damage. Most renal scars are present when reflux is discovered at initial evaluation for urinary tract infection.

The hereditary and familial nature of vesico-ureteral reflux is now well recognized and several studies have shown that siblings of children with vesico-ureteral reflux have a much higher incidence of reflux than the general pediatric population. Prevalence rates of 27–51% in siblings of children with VUR and a 66% rate of VUR in offspring of parents with previously diagnosed reflux have been reported.[4–8]

ETIOLOGY

The uretero-vesical junction (UVJ) acts as a valve and closes during micturition or when the bladder contracts. The UVJ is structurally and functionally adapted to allow the intermittent passage of urine and prevent the reflux of urine in the bladder. The main defect in patients with VUR is believed to involve the malformation of the UVJ, in part due to shortening of the submucosal ureteric segment due to congenital lateral ectopia of the ureteric orifice. Since VUR primarily involves abnormalities of the ureter and ureteric orifice, it has been suggested that the timing and positioning of branching of the ureteric bud from the Wolffian duct may be related to VUR. The underlying abnormality could be due to mutations in one or more developmental genes that control these processes.

Mechanism of renal scarring

The association between VUR and renal scarring is now widely recognized. Scarring is directly related to the severity of reflux. Belman and Skoog[9] assessed renal scarring in 804 refluxing units and found renal scars in 5% of those with grade I reflux, 6% of those with grade II reflux, 17% of those with grade III reflux, 25% of those with grade IV reflux, and 50% of those with grade V reflux.

The mechanism by which reflux produces renal scars is still not clear. It is essential to distinguish between the commonly acquired segmental scarring associated with VUR and infection, and the primary scarring seen congenitally, in which the etiology is very different and linked to abnormal metanephric development. There is no doubt that bacterial pyelonephritis produces renal scars experimentally and clinically. Dimercaptosuccinic acid (DMSA) scans have allowed us to follow sequentially the evolution of a scar from an area of decreased blood flow during the acute inflammatory phase to a parenchymal defect indicative of a mature scar. Yet only half of patients with acute pyelonephritis will have such a scar. What converts an acute inflammatory process into a scar in some patients and not in others is not clearly understood. Factors implicated in the formation of a mature scar include magnitude of the pressure driving the organisms into the tissues, the intrinsic virulence of the organism itself, and the host defense mechanisms. Furthermore, some of the worst examples of renal injury associated with VUR are those that are present at birth. As renal damage at that time cannot be the consequence of infection, such injury is assumed to be developmental in origin, but the pathophysiology of this is not entirely clear.

The three mechanisms considered potential etiologies for renal scar formation are (1) reflux of infected urine with interstitial inflammation and damage, (2) sterie, usually

high-grade reflux, which may damage the kidney through a mechanical or immunological mechanism, and (3) abnormal embryological development with subsequent renal dysplasia. Patients in the latter group may also have urinary tract infection in the postnatal period, resulting in extensive parenchymal damage. It is well recognized that in the first two groups of renal parenchymal damage, it is essential to discover reflux early before damage can be initiated. In the third group, it is clear that congenital damage currently cannot be prevented. However, in these patients, it is mandatory to discover reflux at the early stages to prevent exposure to urinary tract infection and avoid the possible progression of renal parenchymal damage.

DIAGNOSIS

Antenatally diagnosed reflux

Prenatal ultrasonography has resulted in a dramatic increase in the number of infants detected with significant asymptomatic uropathology, allowing treatment before the potential devastating consequences of UTI occur.[10] An incidental anomaly is detected by antenatal ultrasonography in about 1% of studies and 20–30% involving the urinary tract.[11] By far the most common abnormal finding is hydronephrosis, comprising over 90% of the urological abnormalities detected. Underlying diagnoses include pelvic-ureteric junction obstruction, vesico-ureteric junction obstruction, posterior urethral valves, and VUR.

Although antenatal hydronephrosis is generally considered to represent an obstructive lesion, VUR is not an uncommon cause. Najamaldin and colleagues[12] performed micturating cystography in the first six months of life in 97 of 102 patients with renal abnormalities detected *in utero* and found that 18 males and 12 females had VUR. In the series of Gordon and associates,[13] of 25 cases of primary VUR suspected *in utero* and confirmed in the neonatal period, 21 (84%) were males. In another series, prenatal hydronephrosis was due to VUR in 34 of 309 cases (11%).[14]

Natural history of prenatally diagnosed VUR

The vast majority of infants found to have VUR following detection of antenatal hydronephrosis are males. The male preponderance is reported to range from 2:1 to 5:1 in various series.[15–17] This is in total contrast to the female preponderance that has been consistently reported in later childhood. In approximately two-thirds of the cases, the reflux is bilateral. VUR diagnosed prenatally tends to be of high grade.[15–17]

It has also been reported that boys are more vulnerable to UTI, especially in the first six months of life, where different factors play a significant role.[18] Host factors, such as the inner non-keratinized epithelium of the foreskin, create a moist reservoir for uropathogens and contribute to the first contact between the host and the bacteria. Once the prepuce has been colonized, the bacteria can ascend the urinary tract, causing cystitis or pyelonephritis. Rushton and Majd[18] showed a clear predominance of males among infants less than six months old with febrile UTI, and a disproportionately high frequency of uncircumcised male infants. Cascio *et al.*[19] showed a pure growth of a uropathogen in 48% of uncircumcised infants with VUR despite the use of prophylactic antibiotics.

At birth, between one-third and a half of refluxing kidneys may have reduced renal function on DMSA scintigraphy, even in the absence of UTI.[20,21] In the series of Anderson and Rickwood,[14] 75% of the kidneys with grade V reflux, 80% with grade IV reflux, 46% with grade III reflux, and 0% with grade I or II reflux exhibited reduced isotope uptake with an overall 18% of renal function.

Yeung *et al.*[20] studied 155 infants with prenatal hydronephrosis and postnatally diagnosed VUR. They observed renal parenchymal damage in 42% of the 135 infants (101 males and 34 females) without history of UTI.[20] Furthermore, Nguyen *et al.*[21] reported renal parenchymal abnormalities in 65% of predominantly male infants with sterile high-grade reflux. The resolution rate of antenatally diagnosed high-grade VUR (grade IV or V) is approximately 20% by the age of two years.[10,11] However, in approximately 25% of boys followed non-operatively, UTIs developed by the age of two years, despite antimicrobial chemoprophylaxis.[11]

CLINICAL PRESENTATION

It is obviously important to diagnose VUR at the earliest possible age, preferably in infancy. There are a number of clinical presentations, which should raise the suspicion of VUR in an infant. As antenatal ultrasound becomes increasingly routine, many cases will be suspected before birth and should be investigated within the first month of life. Infants with a poor urinary stream as in posterior urethral valves or infants with spina bifida have a high incidence of VUR, while early investigations are indicated in the first-degree relatives of patients with high-grade VUR.

In most cases, VUR is discovered clinically after investigations for urinary tract infection. The incidence of VUR in infants with febrile UTI is 30–50% with even higher incidence in male infants. Cascio *et al.*[22] found VUR in 33% of the 57 neonates investigated for first hospitalized UTI. Sixteen had bilateral VUR and three unilateral with 91% having high-grade VUR. Another study evaluated the incidence of renal damage by DMSA in 141 consecutive male infants with grade III–V VUR.[23] Renal parenchymal damage was detected in 44% of infants.

RADIOLOGICAL INVESTIGATIONS

Ultrasound

Sonography should be performed in any infant with suspicion of VUR. The kidneys and upper ureters should be examined both in B-mode and real time. The bladder and lower ureters are assessed by real-time examination at each uretero-vesical junction for dilatation, configuration, peristalsis, and continuity with the bladder base. VUR is

suspected in the presence of a dilated pelvicaliceal system, upper or lower ureter, unequal renal size, or cortical loss and increased echogenicity (Fig. 97.1a–d). Sonography is not sufficiently sensitive or specific for diagnosing VUR.[17,24,25] The intermittent and dynamic nature of VUR probably contributes to the insensitivity of routine renal sonography in the detection of even higher grades of reflux.

Micturating cystography

VUR is a dynamic process. Bladder filling and voiding are necessary for its elucidation which requires catheterization for adequate documentation. Micturating cystogram remains the gold standard for detecting VUR (Fig. 97.2). Despite the unpleasant nature of the procedure, it has a low false-negative rate and provides accurate anatomical detail, allowing grading of the VUR (Fig. 97.3a–c). It is commonly performed as a first-line investigation, together with ultrasound.

Some investigators employ nuclear cystography for diagnosing VUR. This can be either direct or indirect using technetium-labeled diaminotetra-ethyl-pentaacetic acid (DTPA). In direct nuclear cystography, DTPA is instilled into the bladder by urethral catheter or suprapubic injection and the ureters and kidneys are observed on camera during bladder filling and voiding. In indirect nuclear cystography, DTPA is injected intravenously. After the bladder is filled, the

Figure 97.2 Four-week-old male infant with bilateral grade V vesico-ureteric reflux (note normal urethra and bladder wall).

patient is instructed to void and the counts taken over the ureters and kidneys are used to assess the presence of VUR. Indirect nuclear cystography requires a cooperative patient and therefore is of no value in infants. The main disadvantage of nuclear cystography is that it does not give anatomical detail and VUR cannot be graded according to international classification.

According to the international classification of reflux, there are five grades of reflux:

1. grade I, ureter only
2. grade II, ureter, pelvis, and calices – no dilatation, normal caliceal fornices
3. grade III, mild dilatation and/or tortuosity of the ureter and mild dilatation of the renal pelvis – minor blunting of the fornices
4. grade IV, moderate, dilatation and/or tortuosity of the ureter and moderate dilatation of the renal pelvis and calices – complete obliteration of the sharp angle of fornices but maintenance of the papillary impressions in the majority of calices
5. grade V, gross dilatation of the renal pelvis and calices (Fig. 97.4).

DMSA scan

DMSA is the most sensitive technique for detecting renal scarring. When performed in the course of acute urinary tract infection, the DMSA scan is currently the most reliable test for the diagnosis of acute pyelonephritis. Several reports have suggested that a normal[26–28] acute DMSA scan rules out the possibility of high-grade VUR. However, others have reported that acute DMSA scintigraphy has limited overall ability in revealing VUR after first febrile UTI in infants.[25,29] This was true even when the findings of the acute DMSA scan were combined with those of renal ultrasonography.

MANAGEMENT

Management of VUR has been controversial. The various treatment options currently available in the management of VUR are: (1) long-term antibiotic prophylaxis, (2) intermittent antibiotic therapy for UTI, (3) antibiotic prophylaxis and anticholinergics, (4) open or laparoscopic reimplantation of ureters, and (5) minimally invasive endoscopic treatment.

Medical management

This strategy is based on three important assumptions: (1) Sterile VUR in most cases is not harmful to the kidneys and has no relevant affect on kidney function. (2) Children can outgrow VUR, at least the lower grades. (3) Continuous low-dose antibiotic prophylaxis can prevent infection for many years while VUR is still present.

The patient is required to take low-dose daily antibiotics and annual ultrasound and VCUG are performed to assess whether the reflux has resolved. The European arm of the International Reflux Study Group, in children at ten-year follow up showed that half of the children with grade III and IV reflux randomly allocated to medical treatment still had reflux after ten years.[30] In those with bilateral reflux, 61% had persistence of reflux after ten years. In a long-term study, Schwab *et al.*[31] reported spontaneous resolution rates of 13% yearly for grade I to III reflux and only 5% for grade IV to V reflux. Additionally, long-term antibiotic prophylaxis has the risk of bacterial resistance accompanied by potential breakthrough UTIs.

Surgical treatment

OPEN ANTIREFLUX PROCEDURES

Open surgical treatment of reflux has been the gold standard. However, surgery is not without risk, and in infants it is technically more challenging. The majority of the open antireflux procedures entail opening the bladder and performing a variety of procedures on the ureters, such as transvesical reimplantation (Politano–Leadbetter technique) and transtrigonal advancement of the ureters (Cohen technique). These procedures, although effective, involve open surgery, prolonged in-hospital stay, and are not free of complications, even in the best hands. Although open surgery achieves a success rate of 92–98% in grade II–IV VUR, the American Urological Association report on VUR reported persistence of VUR in 19.3% of ureters after reimplantation of ureters for grade V reflux.[32] The rate of obstruction after ureteral reimplantation needing reoperation reported by the American Urological Association in 33 studies was 0.3 to 9.1%.

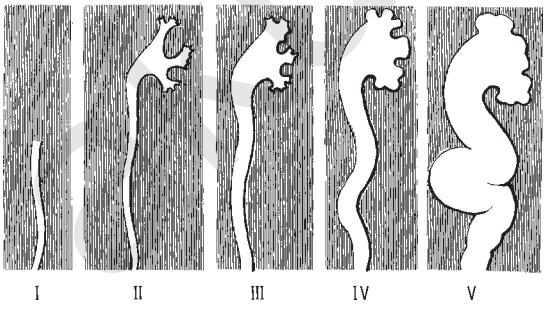

Figure 97.4 International classification of vesico-ureteric reflux (grades I–V).

LAPAROSCOPIC URETERAL REIMPLANTATION

In recent years, several authors have reported their experience of ureteral reimplantation with laparoscopic extravesical transperitoneal approach, as well as pneumovesical approach.[33–35] This technique results in a shorter hospital stay and less postoperative discomfort compared to open operation.

ENDOSCOPIC TREATMENT OF VUR

Minimally invasive endoscopic technique for the correction of VUR has become an established alternative to long-term antibiotic prophylaxis and open surgical treatment. Endoscopic treatment has several advantages over the two other options. In contrast to long-term antibiotic prophylaxis, it offers immediate cure of reflux with a high success rate, its success does not rely on patient or parent compliance and the procedure is virtually free of adverse side effects. Long-term administration of antibiotics implies the danger of bacterial resistance with promotion of breakthrough UTIs and antibiotics are usually needed for years. In 2001, Deflux was approved by the Food and Drug Administration (FDA) as an acceptable tissue augmenting substance for subureteral injection therapy for VUR. Since then, endoscopic treatment has become increasing popular worldwide for managing

VUR and Deflux is the most widely used tissue augmenting substance.

During the last two decades, the author has performed endoscopic correction of high-grade VUR in infants as the first line of treatment because it provides early resolution of reflux at a time when infants are at a higher risk for renal scarring.[36–38]

The technique of endoscopic injection of Deflux is simple and straightforward.[37,38] All cystoscopes available for infants and children can be used for this procedure. The disposable Puri flexible catheter (Storz, Tuttlingen, Germany) or a rigid metallic catheter can be used for injection. A 1-mL syringe filled with Deflux is attached to the injection catheter. Under direct vision through the cystoscope, the needle is introduced under the bladder mucosa 2–3 mm below the affected ureteral orifice at the 6 o'clock position (Fig. 97.5). In children with grade IV and V reflux with wide ureteral orifices, the needle should be inserted not below but directly into the affected ureteral orifice. The needle is advanced about 4–5 mm under the mucosa and the injection started slowly. As the Deflux is injected, a bulge appears in the floor of the submucosal ureter. A correctly placed injection creates the appearance of a nipple on the top which is slit-like or inverted crescent orifice. Patients are treated as day cases and a voiding cysto-urethrogram and ultrasound are performed 6–12 weeks after discharge.

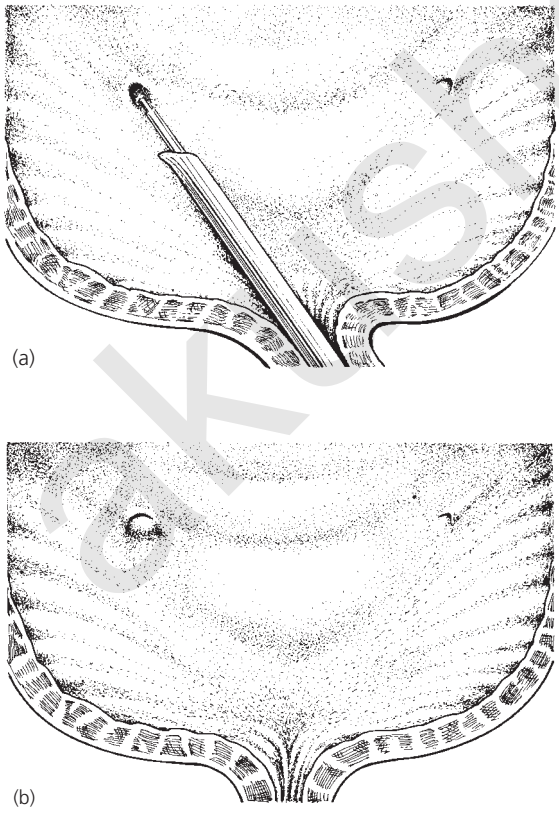

Figure 97.5 Technique of endoscopic subureteric injection: (a) the site of insertion of the needle; (b) appearance of ureteric orifice at completion of injection.

Endoscopic subureteral injection of Deflux is excellent first-line treatment in children with 87% success in high-grade vesico-ureteral reflux after one injection. This 15-minute outpatient procedure is safe and simple to perform, and it can be easily repeated in failed cases.

Ureteroceles in the newborn

JONATHAN F KALISVAART AND ANDREW J KIRSCH

INTRODUCTION

Ureteroceles are congenital, cystic dilations of the terminal, intravesical portion of the ureter. The associated ureteral orifice, often extremely difficult to visualize, may be partially or totally obstructed, resulting in variability in size from small to very large. They can also vary in location from intravesical to ectopic. The use of fetal ultrasonography has improved the diagnosis of ureteroceles, however, they often remain difficult to diagnose and require complete postnatal evaluation when suspected.

PATHOGENESIS

The pathogenesis of the ureterocele remains unclear, although several theories have attempted to explain it. Chwalla[1] and Ericsson[2] attributed the ureterocele formation to the persistence of an epithelial sheet (Chwalla's membrane) separating the lumen of the distal portion of the Wolffian duct and the urogenital sinus. Chwalla's membrane is a normal embryologic structure that disappears spontaneously approximately two months after conception. If it persists, it can balloon out and form the ureterocele. Stephens,[3] on the other hand, postulates that the terminal ureter becomes involved in the growth of the bladder and undergoes extensive enlargement, resulting in the formation of the ureterocele. Tanagho[4] suggests that the ureterocele forms secondary to local dilatation of the ureteral bud prior to its migration from the Wolffian duct. Tokunaka and colleagues[5] demonstrated poor muscle development in the dome of the ureterocele and suggest that ureterocele formation is based on a segmental embryonic arrest of the development of the most distal portion of the ureter. These theories regarding the pathogenesis of ureteroceles are still only speculation.

Pathological anatomy and associated pathology

Ureteroceles can be associated with the ureter draining of the upper moiety of a duplex collecting system or with the ureter of a single system. Duplex system ureteroceles occur in approximately 85% of diagnosed cases and can vary in size and position. The upper renal moiety is non-functional and dysplastic in over 80% of cases.[6,7] Occasionally, ureteroceles are small and well demarcated from the bladder wall, but often they present as very large subtrigonal masses. The ureterocele may also protrude towards the contralateral ureteral orifice or the bladder neck causing contralateral ureteral or bladder outlet obstruction. More commonly, the ipsilateral orifice of the ureter draining the lower pole is pushed upwards by the distended ectopic ureterocele, shortening the intratrigonal tunnel, leading to reflux and hydronephrosis. On the contralateral side, reflux and secondary hydronephrosis can be seen, likely due to the disruption of the normal trigonal anatomy. Less commonly, reflux can be seen to occur into the ureterocele itself.

Ureteroceles are attached to single collecting systems in approximately 15% of cases, often in males.[6,7] The cystic swelling tends to be asymmetric with the ureteral orifice located in an eccentric position. The single system ureterocele is usually smaller in size than the ectopic ureterocele and the size of the ureterocele is generally related to the degree of obstruction caused by the pinpoint orifice.[8]

Single-system ureteroceles rarely prolapse and cause bladder neck obstruction, and reflux is extremely uncommon. Although the ureter and pelvicalyceal structures are hydronephrotic to varying degrees, function of the renal unit is often preserved.

CLASSIFICATION

In 1954, Ericsson[2] classified ureteroceles into orthotopic or simple ureteroceles if the ureter forming the ureterocele ends in a normal site in the bladder or ectopic ureteroceles if the ureter ends in an ectopic location. However, confusingly, a simple ureterocele can also mean a ureterocele involving a single system and an ectopic ureterocele can describe a ureterocele associated with a duplicated system. Stephens[3] classified ureteroceles based on the anatomic location and appearance of the orifice into stenotic (narrowed opening

found in the bladder), sphincteric (an orifice distal to the bladder neck), sphincterostenotic (a narrowed opening distal to the bladder neck), and a cecoureterocele (intravesical orifice with a submucosal extension into the urethra). These traditional classifications, based on the location of the ureteral orifices or on the anatomical description, can be quite confusing. The modern classification system is based on the report of the Committee on Terminology, Nomenclature and Classification of the Urology Section of the American Academy of Pediatrics.[9] It subdivides ureteroceles based on:

1. Number of ureters that drain the kidney ipsilateral to the ureterocele
2. Location and extent of the ureterocele
3. Any additional anatomic distortions of the ureterocele resulting from eversion, prolapse, or secondary incompetence or obstruction of the other ureteral orifice or the bladder neck.

Thus, a duplex-system ureterocele is when the ureterocele is attached to the upper pole ureter of a completely duplicated collecting system, and a single-system ureterocele is when the ureterocele is attached to a single ureter draining the kidney. If the ureterocele and its orifice are located entirely within the bladder, the term 'intravesical' is used and if the ureterocele and its orifice extend beyond the trigone to the bladder neck or outside the bladder to involve the urethra, the term 'ectopic' is applied. Single-system ureteroceles are generally intravesical and ectopic ureteroceles are usually associated with the upper pole ureter of a duplex-system (Fig. 98.1).[10]

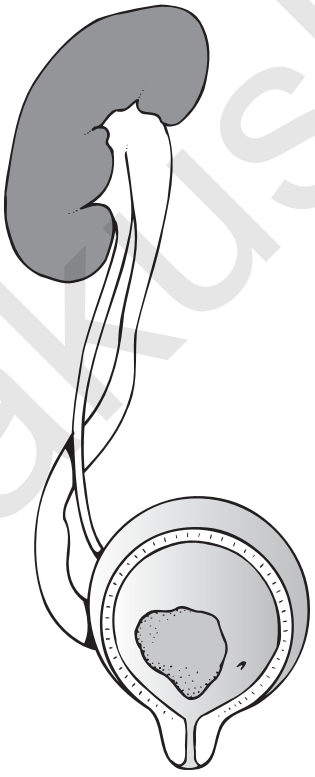

Figure 98.1 Ectopic ureterocele in relation to the upper moiety of a duplex collecting system.

INCIDENCE

The incidence of ureteroceles varies between 1:1500 and 1:12 000 pediatric admissions, depending on the study[11,12] and in 1:4000 autopsies.[13] Ureteroceles occur most frequently in females with a 4:1 ratio and are more common in Caucasians.[14] Duplex-system ureteroceles are four to seven times more common in females than in males,[15] and single-system ureteroceles appear to have a slightly male predilection.[10]

There does not appear to be a predilection towards laterality as both kidneys are equally affected[16] and bilateral ureteroceles are found in approximately 10% of cases.[8]

CLINICAL PRESENTATION

The clinical presentation of ureteroceles in infants and children is a febrile urinary tract infection in 39–73.5% of cases.[7,17–19] Sepsis, hematuria, urinary incontinence, and/or flank pain can be present. Non-specific symptoms, such as failure to thrive, irritability, urinary retention or recurrent vomiting, should also lead to further investigation of the urinary tract. In cases of severe obstruction and consequent gross megaureter and hydronephrosis, a palpable mass may be present in the abdomen or in the pelvis. Severe electrolyte disturbances, such as hyperkalemia may occur, and in very rare cases of hyponatremia and hyperkalemia, pseudohypoaldosteronism should be suspected.[20]

In baby girls, the ureterocele may prolapse through the urethra and can be seen as an apparent vaginal or vulvar mass (Fig. 98.2).

Figure 98.2 Prolapsing ureterocele in a female newborn.

DIAGNOSIS

Ureteroceles can be diagnosed in the antenatal period as part of a screening ultrasound. After the 30th week of pregnancy, the ureterocele may be demonstrated in the fetal bladder (Fig. 98.3). More often, however, the antenatal ultrasound

Figure 98.3 Antenatal ultrasonography. Ureterocele in the fetal bladder as seen in the 30th gestational week.

performed after the 16th gestational week shows only hydronephrosis. The causative pathology of this hydronephrosis can generally only be established by immediate postnatal investigations. These investigations have traditionally consisted of ultrasonography, voiding cysto-urethrogram (VCUG), and cystoscopy. In addition, DMSA, DTPA, MAG3 renal scintigraphy, or magnetic resonance urography (MRU) should be used to detect renal cortical defects, evaluate renal function and the degree of ureteral obstruction (Fig. 98.4).

Figure 98.4 Isotope scan (DMSA) demonstrating the ureterocele (uptake defect in the bladder) and the non-function of the upper renal moiety.

Although inferior in many ways, i.v. urogram (IVU) may be used in cases where other imaging modalities are unavailable.

Ultrasonographic findings are of a cystic mass within the bladder, often with dilatation of the associated ureter and pelvicalyceal structures (Fig. 98.5). VCUG shows a filling defect within the bladder varying in size and position. The ectopic ureterocele is seen as a filling defect placed eccentrically along the bladder wall extending into the bladder neck or into the posterior urethra. The intravesical ureterocele is generally surrounded by contrast medium demonstrating most of its circumference. If the images are taken when the bladder is full, the ureterocele may evert, mimicking a bladder diverticulum (Fig. 98.6).

With the VCUG, reflux into all renal units can also be assessed. Studies have estimated that 50% will have reflux into the ipsilateral lower pole, 25% into the contralateral ureter, and 10% into the ureterocele-bearing ureter.[21]

MRU has also been used to diagnose ureteroceles in both fetal life and in infants with a sensitivity of 89–100%.[22,23] The advantages of MRU include anatomic images of both the upper and lower tracts, and with the correct sequences, functional data of the upper tract can also be delineated.[24] This information can be useful both in decision-making and in surgical planning (Fig. 98.7).

Once the diagnosis is suspected based on imaging, cystoscopy can confirm the diagnosis and help with surgical planning.

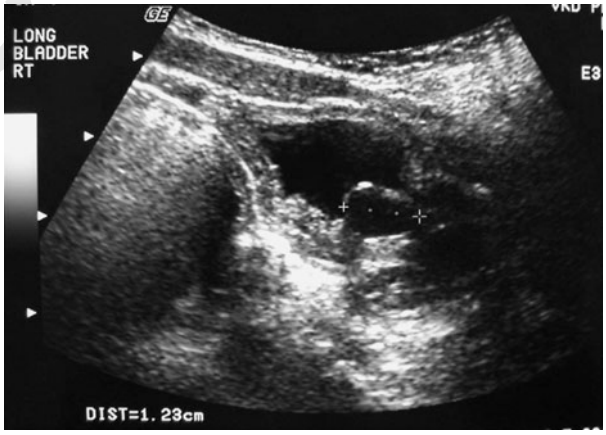

Figure 98.5 Postnatal ultrasonography. Ureterocele within the bladder.

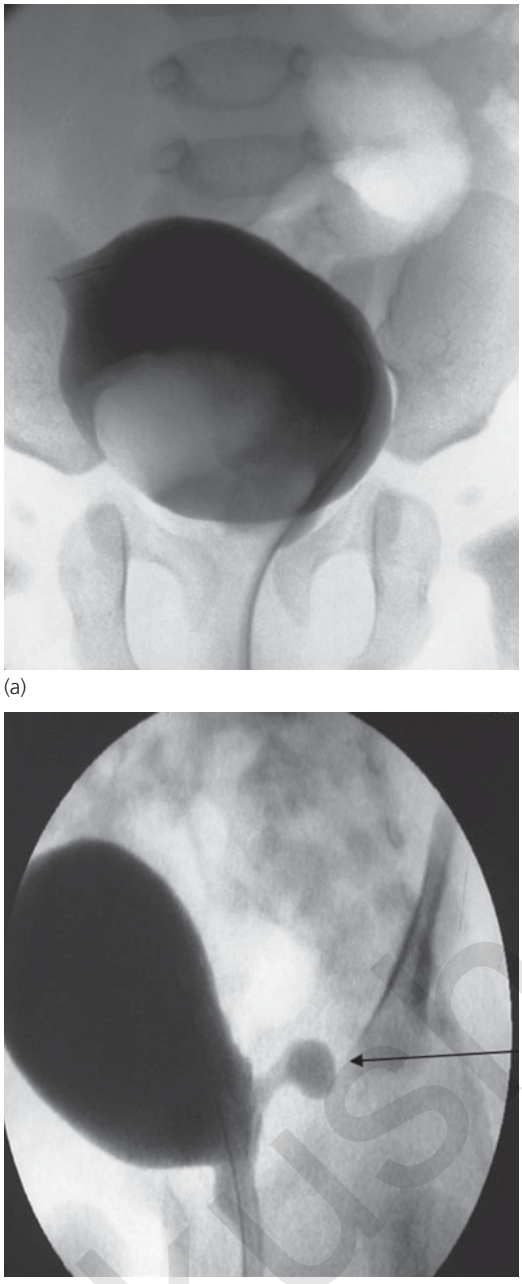
TREATMENT

Ureteroceles are often complex anomalies. Although considerable controversy still exists regarding the best treatment, the final aims of the surgical management of the ureterocele are to relieve obstruction, prevent urinary infection, prevent or correct vesico-ureteral reflux, and preserve renal function. The latter goal may be considered secondary as the upper pole moiety serving the ureterocele is often dysplastic with marginal function.

As a result of these goals, four aspects have to be taken into account in the planning of the correct surgical treatment:[25]



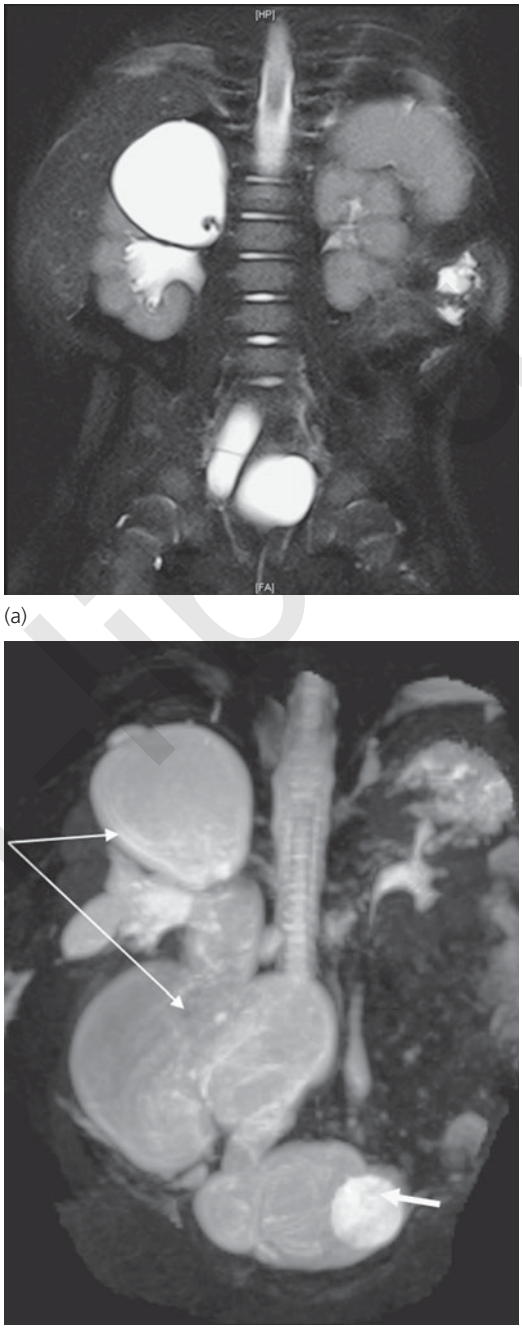
(a)

(b)

Figure 98.6 Voiding cysto-urethrogram (VCUG) showing (a) ureterocele in the bladder and (b) eversion of the ureterocele with filling of the bladder (arrow).

1. Degree of renal dysplasia and its resulting loss of renal function
2. Presence of reflux into the ureterocele-bearing ureter, the ipsilateral ureter, and/or the contralateral ureter
3. Altered trigonal anatomy, as well as the weakness of the detrusor muscle backing the ureterocele
4. Degree of obstruction caused by the prolapsing or ballooning ureterocele.

A standardized approach is probably impossible and it seems reasonable to individualize the management according to the aspect of each particular case.



(a)

(b)

Figure 98.7 T_2-weighted magnetic resonance urography (MRU) showing (a) the dilated upper pole associated with the ectopic ureterocele and (b) the characteristic appearance of the ureterocele (thick, white arrow) with the associated dilated renal upper pole and ureter (thin, white arrows).

Conservative management

Patients meeting specific criteria have been successfully managed with prophylactic antibiotics only. These criteria are:

- either a well-functioning renal moiety associated with the ureterocele or a completely non-functioning renal unit associated with the ureterocele;

- no evidence of obstruction on functional renal imaging;
- no other pathology (i.e. bladder outlet obstruction).

Between 60 and 70% of these highly selected patients managed conservatively had resolution of reflux and hydronephrosis[26,27] showing that, in this highly selected group, surgery may be avoided. However, the long-term potential sequelae of small persistent ureteroceles, such as urolithiasis and infection, have not been evaluated.

Endoscopic puncture or incision

With improvements in urologic endoscopic technology, a more conservative approach in the surgical management of the ureterocele is feasible. Several authors have demonstrated the advantages of the endoscopic incision or puncture of ureteroceles in the preservation of renal tissue,[28–31] and in the case of the septic or acutely ill child with an obstructing ureterocele, endoscopic puncture should be considered to be the first-line treatment. This procedure can be performed with the patient under general or regional anesthesia, on a same-day surgery or outpatient basis.[32] Satisfactory postoperative urinary tract decompression has been reported in 85–100% of cases of endoscopic decompression,[32–34] and recovery of renal function following endoscopic puncture or incision has been reported.[32,33]

Several techniques of endoscopic puncture or incision of ureteroceles exist, but the most common technique consists of a small 2–3-mm incision or puncture made just above the distal junction of the ureterocele with the bladder using a Bugbee electrode[35] or a sharp electrode[28] through a pediatric cystoscope (Fig. 98.8). This avoids leaving a flap of ureterocele that might obstruct the bladder outlet and works to preserve a flap valve of the collapsed ureterocele. All these techniques bear the risk of interfering with the structures of the lower pole orifice and an attempt to visualize the lower pole orifice should be made to prevent such damage. Postincision imaging should be performed to detect reflux in all renal segments and to determine the need for further surgery. A second puncture should be considered in cases where a large ureterocele persists postoperatively and the degree of hydroureteronephrosis on ultrasound remains unchanged or worsened.

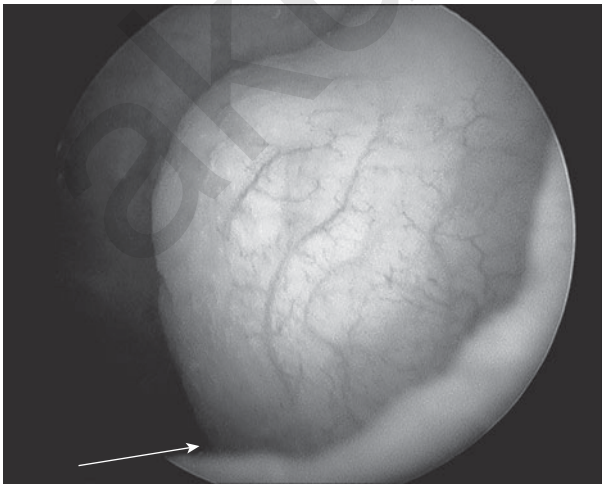


Figure 98.8 Cystoscopic view of a ureterocele. The arrow indicates the target for endoscopic puncture. Image courtesy of Dr Edwin Smith.

Controversy still exists regarding the advantages of the endoscopic puncture or incision of ureteroceles as a 'first-stage' treatment, principally due to the high association of postoperative reflux and secondary operations.[21,36–38] Surgeons in favor of the endoscopic puncture or incision 'first-stage' treatment in neonates with ureteroceles, suggest that:

- Approximately one-third of these patients will be definitively treated by this technique.
- Early renal and ureteral decompression will allow improvement or stabilization of renal function, as well as a decreased risk of pyelonephritis.
- It allows for a delay in definitive surgical correction, if necessary, and a technically easier operation after the neonatal period due to bladder growth, and decreased distention of the affected ureter.[21,28,29,36,37,39,40]

A recent meta-analysis found that, among patients undergoing endoscopic puncture of their ureterocele, risk factors for repeat surgery included an ectopic versus an intravesical ureterocele (RR, 2.78), ureteroceles draining the upper pole of a duplex system versus those draining a single system (RR, 3.93), and patients with preoperative reflux versus those without reflux (RR, 1.56).[41,42] Thus, the anatomy of each individual patient needs to be taken into account prior to any attempt at endoscopic puncture as a primary treatment.

Duplex system ureteroceles

For the treatment of duplex system ureteroceles, three definitive surgical options are available:

1. Heminephrectomy with partial or total ureterectomy, allowing the ureterocele to collapse ('upper-tract approach').
2. Excision or marsupialization of the ureterocele, reconstruction of the bladder, and reimplantation of the ureter(s) ('lower tract approach').
3. Combination of heminephrectomy and excision or marsupialization of the ureterocele ('combined upper and lower tract approach').

Ureterocele excision or marsupialization

The traditional open surgical approach involves the complete excision of the ureterocele with reconstruction of the bladder and bladder neck to create a functional bladder neck mechanism. Potential problems with this approach involve injury to adjacent structures, primarily the bladder neck, sphincteric mechanism, or creation of a vesicovaginal fistula. An alternative involves the marsupialization of the ureterocele which leaves the floor of the ureterocele intact and adhered to the bladder mucosa. This prevents the potential

injury to the surrounding structures due to the decreased dissection needed. One study has found no statistical difference between these two techniques.[43]

Procedure

Using a modified Pfannenstiel incision, the skin and the anterior rectus sheath are opened transversally. The recti are bluntly separated in the midline and the bladder is well mobilized laterally. Over the bladder dome the peritoneal covering has to be carefully stripped off, avoiding entry into the peritoneal cavity.

The previously filled bladder is incised longitudinally, taking care to avoid injury to the bladder neck. The lower end of the incision can be secured with a holding stitch to prevent tearing into the bladder neck or urethral sphincter and to make for easy identification when closing. The edges of the incised bladder are suspended and held open with holding sutures over the Denis-Browne ring retractor. Several sponges are placed into the superior bladder (the exact number varies depending on the size of the bladder) and the cranial blade is positioned inside the bladder dome over the sponges, pulling it upwards and forwards, exposing the trigonal area. The ureterocele, the orifice of the lower renal pole ureter and the contralateral ureter are visualized (Fig. 98.9). Each ureter is catheterized with an infant feeding tube or a ureteral catheter. Stay sutures are placed in the dome of the ureterocele and the urothelium is incised in an elliptical fashion (Fig. 98.10a,b).

If the ureterocele is to be completely excised, a dissection plane between the wall of the ureterocele and the urothelium and the detrusor muscle is found and the ureterocele is dissected off the urothelium (Fig. 98.10c). Once the ureterocele is freed completely, the remaining intramural ureter is mobilized as with a standard intravesical ureteral reimplantation (Fig. 98.10d). If the ureterocele reaches into the bladder neck or the posterior urethra, this procedure can be extremely difficult to perform and care has to be taken not to damage the urethral sphincter or its nerve supply. Once the ureterocele is resected, its backing detrusor muscle must be carefully reconstructed using resorbable monofilament sutures (Fig. 98.10e). This is to minimize diverticulum formation.[44] In girls, damage to the underlying vagina, and in boys, damage to the ipsilateral vas deferens, has to be avoided during this procedure.

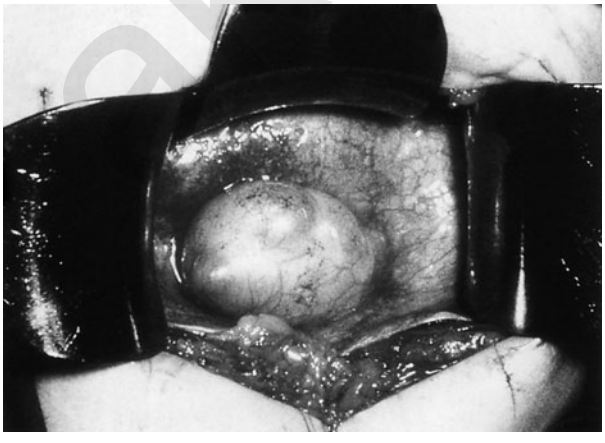

Figure 98.9 Operative treatment: intraoperative findings of a duplex system ectopic ureterocele.

Alternatively, the ureterocele can be marsupialized by excision of the anterior and lateral walls of the ureterocele using cautery. This leaves the posterior wall in continuity with the detrusor muscle behind it. The edges of the ureterocele are then reapproximated to the surrounding mucosa using absorbable sutures.

At this stage, the ureters are reimplanted according to Cohen's technique,[45] creating a cross-trigonal submucosal tunnel. Stenting of the reimplanted ureter can be performed according to the surgeon's preference. We generally do not stent the ureter, unless there is a specific reason, i.e. a solitary kidney, an abnormally small ureter, etc.

The bladder is then closed in a standard two-layer technique using resorbable sutures. The bladder is drained with a transurethral catheter. The urethral catheter is generally removed between 1 and 7 days after surgery depending on the surgeon's preference. Prophylactic antibiotics are administered perioperatively and are continued until absence of reflux is confirmed with postoperative imaging.

Heminephro-ureterectomy

This procedure can be performed either in the traditional open technique, or laparoscopically. The laparoscopic partial (or polar) nephrectomy has had good results reported, but is widely considered to be one of the hardest laparoscopic procedures to perform.[46] As a result, it is generally reserved for the skilled laparoscopist. It is less technically demanding in older, larger children, although it has been done successfully in infants.[47,48] The open surgical approach will be covered here.

Procedure

The upper pole nephrectomy is performed through a flank incision just off the tip of the 12th rib. The incision is extended to a length of 3–4 cm.

The muscle layers are incised using cautery down to the level of the retroperitoneum. The retroperitoneum is entered and the peritoneum is gently dissected anteriorly. The wound is held open with a retractor. Gerota's fascia is exposed and opened posteriorly. The upper pole ureter can then be identified, generally quite easily due to its size. The upper pole ureter is dissected free from the surrounding tissue. The lower pole ureter needs to be identified and dissected free, being careful to leave a sufficient amount of peri-ureteral tissue in place to avoid devascularization. The dilated upper pole ureter is then followed up towards the renal hilum. It is brought under the renal vessels being careful not to injure them. Once this is accomplished, the ureter can be followed to the upper pole segment which can be dissected free from the remainder of the renal parenchyma. There is generally a renal groove between the upper and lower pole segments which can assist in the dissection. The different color and

consistency of the dysplastic upper renal pole can be of additional help in the anatomical definition of the two segments (Fig. 98.11). Alternatively, the upper pole system can be entered and can be dissected away from the lower pole from the inside of the collecting system. Extreme care must be taken to preserve the lower renal vasculature.

It is important to remove the entire pelvicocalyceal structures of the upper renal pole and to carefully inspect the remaining kidney for opened lower pole calyces, which need to be closed meticulously with absorbable sutures.

Once hemostasis is achieved, the renal capsule is approximated and sutured with absorbable sutures (Fig. 98.11b). Hemostatic agents, such as Floseal®, Tisseel®, or Surgicel® can be of additional help to control hemostasis.

Heminephrectomy is now accomplished without having interrupted the circulation to the lower moiety.

Following this procedure, the upper pole ureter is dissected towards its distal portion as far as possible. The dissection line is kept close to the diseased ureter in order not to disturb the lower pole ureter blood supply. If the ureter

refluxes, it is ligated and transacted, but if it is obstructed it is transacted without ligation to prevent infection.

Once the heminephro-ureterectomy is completed, a drain can be placed according to the surgeon's preference and the muscular layers are approximated using continuous 3-0 or 4-0 resorbable sutures. The subcutaneous tissues are approximated and the skin closed with a subcuticular suture.

Percutaneous drainage

Percutaneous drainage of systems with ureteroceles is generally only indicated in cases in which the patient is acutely ill and endoscopic puncture is not an option due to small urethral size or the inability to undergo anesthesia.

SUMMARY

Ureteroceles are a fairly common urologic finding. The management of the ureterocele can be quite complex and needs to be individualized for the patient and their condition, as well as the findings of imaging and functional studies.

Posterior urethral valves

PAOLO CAIONE AND VALENTINA DE PASQUALE

INTRODUCTION

The main cause of urethral obstruction in neonates and infants is related to posterior urethral valves (PUV) and these continue to be a significant cause of morbidity and mortality in the pediatric age patients.[1,2] In males, children born with bladder obstructive uropathy and renal dysplasia represent the single largest group undergoing renal dialysis and transplantation under five years of age. End-stage renal disease develops in a significant proportion, varying from 30 to 42%.[1–3] In 2003, the Italkid Project, consisting of a prospective population-based registry assessing the epidemiology of chronic renal failure (CRF) in 1197 children recruited over ten years, showed that renal hypodysplasia, with identified congenital uropathy, was the most common cause of CRF (43.6%): in this group, PUV was second only to vesico-ureteral reflux (VUR), accounting for 23.8%.[4]

HISTORICAL NOTES

Congenital obstruction of the posterior urethra has been recognized for almost 200 years, and the earliest description of this condition in infants was by an Italian anatomist in 1717, Giovanni Battista Morgagni.[5] At the beginning of the nineteenth century, Langenbeck described infravesical urethral obstruction in 1802 in his monograph on stone disease,[6] and a few years later, in 1832, Velpeau coined the term 'valves'.[7] Subsequently, many reports of posterior urethral obstruction can be found in the literature. The most important contribution to define the anatomical aspects of the valves was made by Hugh Hampton Young in 1919[8] and 1929.[9] Young was the first to clearly describe the features of PUV. The description included the first classification of this entity based on his initial report of 12 patients, and a review of the literature.[8] The Young classification distinguished congenital obstruction of the posterior urethra on three types of valves (types I, II, and III), and which he described in detail (Fig. 99.1). In more recent years, some criticism arose from the analysis of Young's original work, revealing disagreement with his original conclusions.[10–15] In fact, recent post-mortem dissection studies from different authors have suggested that congenital obstruction of the posterior urethra is due to a membrane with a posterior defect and paramedian reinforcements.[16–18] Contribution to a better anatomical definition of PUV and urethra diaphragm was given more recently by Dewan *et al.*,[19,20] who identified the morphological evidence of the congenital membrane obstructing the male posterior urethra (see below under Classification). However, Young's classification, although not anatomically precise, is known worldwide and is still in current use.

EPIDEMIOLOGICAL DATA

Epidemiology of PUV is difficult to define, as most authors believe that only those with typical appearance on voiding cystourethrograms (VCUG) should be included. The incidence of PUV is often reported as 1:5000–8000 infant males.[18,19,21] A multicenter review in the United Kingdom between 1970 and 1980 estimated the incidence to be approximately one in 25000 live births,[22] but this value seems to be an underestimate. The point is that the true incidence of congenital posterior urethral obstruction is difficult to ascertain.

The lesion could be more common than previously thought: this is due to the fact that the widespread use of prenatal and postnatal ultrasonography and of VCUG during the recent decades led to recognition of a higher number of congenital valves, diaphragms, or strictures on the male posterior urethra, not always recognized as classic 'valves'.

Moreover, the frequent observation at endoscopy or at VCUG of 'mild' or 'minor' forms of inframontanal 'plicae' or mucosal folds, responsible for partial or little urinary outflow impairment, is nowadays a more common observation in male children and infants, as a consequence of the increasing use of cysto-urethroscopy. Thus, the full spectrum of congenital posterior obstruction is probably twice as frequent than previously thought.[21]

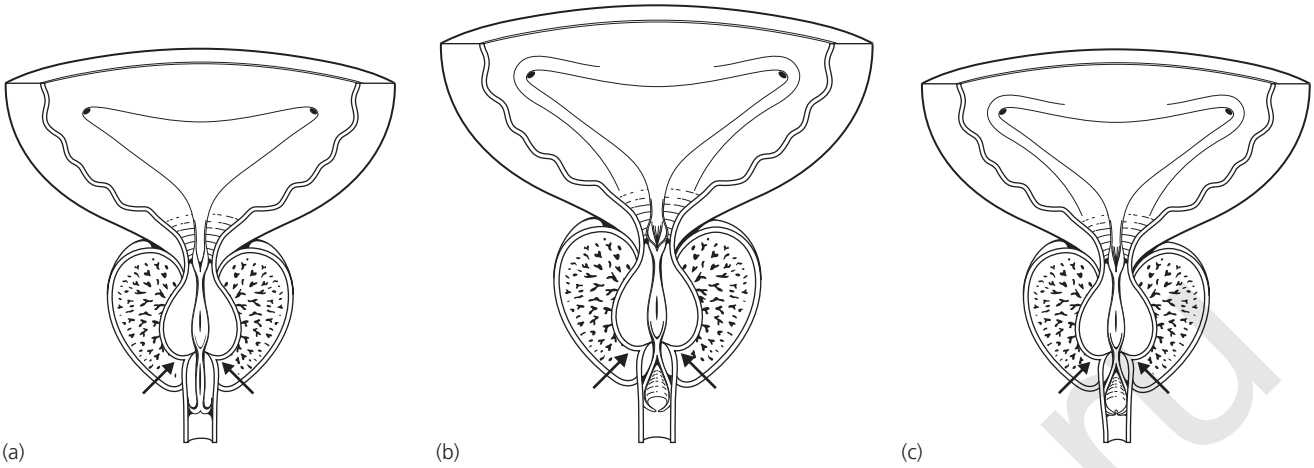

Figure 99.1 Posterior urethral valves: the original classification proposed by Young in 1919 as three types.[8,9] Reproduced with permission from Macpherson RI, Leithiser RE, Gordon L, Turner WR. Posterior urethral valves: an update and review. *Radiographics* 1986; **6**: 753–91.

EMBRYOLOGY

Obstruction of the male posterior urethra is a congenital abnormality, which is considered to have no genetic basis and no pattern of inheritance. There is no agreement as regards the true embryogenesis. It has been argued that posterior valves could originate from an abnormality of development during formation of the urogenital sinus.[23] Livne *et al.*[24] proposed that the embryogenesis of the valves arise from the plicae colliculi diverging from the distal end of the verumontanum appearing at 11 weeks' gestation (mesonephric Wolffian duct). Field and Stephens[25] believed that valves could be vestiges of the receding Wolffian ducts, which migrated posterolaterally to converge on the posterior wall of the urethra, creating the inferior urethral crests. Fusion of these folds anteriorly would explain the formation of a membranous obstruction with a posterior deficit, as described by Dewan.[20] A detailed review of the literature has been recently undertaken by Krishnan *et al.*,[26] better elucidating the precise origins regarding the anatomy, classification and embryology of PUV. Anyway, the embryological development of the congenital posterior urethra obstruction in male fetuses and infants remains uncertain. With the advent of more accurate imaging techniques, such as ultrasonography, VCUG, and fetal/infant magnetic resonance imaging (MRI), the obstructive membranes of posterior male urethra are now better defined. It has been hypothesed that the severity of the congenital diaphragm obstructing the urethra is variable, consistent with the differential clinical presentation of PUV. In some cases, the membrane only partial obstructs, whereas in other situations it may totally obstruct, as in infants with severe renal sequelae.[26] When a feeding tube or catheter is passed into the newborn urethra, the oblique membrane could be ruptured ventrally, modifying the appearance into the Young's classic valves.[26]

CLASSIFICATION

Classically, Young and colleagues in 1919 divided PUV into types I, II, and III, based primarily on autopsy findings.[8] Young described type I valves as sails or strong plicae colliculi, which extend distally from either side of the verumontanum to attach to the anterolateral walls of the urethra; type II valves are folds that arise from the verumontanum and pass proximally towards the bladder neck where they divide into fin-like membranes; type III valves are diaphragms with a central perforation located distal or proximal to the verumontanum, but not attached to it (Fig. 99.1).

Most authors agree that Young's classification is incorrect. In particular, the existence of type II valves has been questioned, as these plicae should be considered as normal mucosal folds.[13–18]

The type I valves are the most commonly recognized. The clinical description of a valve with two separate leaflets is derived from autopsy specimens in which the urethra is laid open by cutting through the anterior wall. However, when viewed endoscopically, it is seen to be a single structure originating from the inferior margin of the verumontanum, the lateral folds fusing anteriorly to form a slit-like aperture. Dewan and colleagues, in accurate endoscopic studies, demonstrated that the commonly defined PUV are represented by a single membrane with a posterior defect, distal to the verumontanum, but connected to it by mucosal folds. Dewan proposed the term 'congenital obstructive posterior urethral membrane' (COPUM) to define this lesion.[19,20,27,28]

Type III valves are considered very uncommon and represent a severe form of urethral obstruction.[16] In a review of cysto-endoscopies of boys with urethral obstruction, Dewan described a fibrous membrane without attachment to the verumontanum, with a central defect below the verumontanum in the bulbar urethra.[19,20] These lesions are known as a Cobb's collar,[29] Moormann's ring,[30] or congenital

bulbar urethra stricture, but should be distinguished from the COPUM or misnamed type III valves, that have a posterior defect at the level of the lower aspect of the prostatic urethra.[27,28]

In conclusion, nowadays we consider PUV as a spectrum of anatomical and pathological entities, presenting different severity of urinary outflow obstruction and having probably only two structural features:

1. a membrane at the level of the posterior urethra distal to the verumontanum, with connecting folds and a posterior defect (COPUM);
2. a fibrous membrane in the bulbar urethra with a central defect (Cobb's collar).

PATHOPHYSIOLOGY AND SECONDARY CONSEQUENCES

Congenital posterior urethral obstruction interferes with all the lower and upper urinary tract, causing significant anatomical and functional changes. In pediatric urology, PUV could represent a severe congenital uropathy, with lifelong consequence.

Urethral pathology

Valves of the posterior urethra represent a spectrum of lesions within the male urethra, grouped under the more extensive term of congenital obstructive posterior urethral membrane.[20,28] The macroscopic appearance has been described above under Classification. The severity of the obstruction varies from small folds without obstruction to unyielding and hard membranes with a small deficit, causing a high degree of outlet obstruction.[31] The valves cause a mechanical and functional obstruction in the urethral conduit, leading to sequential secondary pathological changes. The heaviness of the secondary pathological changes on the upper urinary tract will depend on the degree and timing of the primary obstruction.

Proximally to the obstructive valves, high back-pressure prenatally determined, is responsible for significant changes on the anatomical appearance. The prostatic urethra is enlarged and elongated and the verumontanum is much more evident; the posterior aspect of the bladder neck is very pronounced, as a consequence of muscular hypertrophy, and it could also cause impaired bladder emptying after removal of the urethral obstruction.

The severity of the pathological changes on the urethral and bladder structures and on the upper tract, depends on the degree and timing of the primary urethral obstruction that is considered to have an early onset during the embryological life (16–18 weeks of gestion).[26]

Secondary pathology on bladder and upper urinary tract

Not only does the posterior urethra dilate and elongate secondarily to the congenital urethral obstruction, but also the bladder, the ureter, and the kidneys will present significant structural and functional consequences.

Bladder secondary changes

The congenital urethral obstruction is responsible for significant changes on the bladder reservoir, with consequences on the upper urinary tract and on the renal parenchyma. These changes may persist, although the primary urethral obstruction could be fully solved. As the valves are formed very early in fetal life, the abnormal condition of high endoluminal pressure and overdistension of the urinary structures leads to a pathological development and dysfunctional activity of the entire urinary tract and of the renal parenchyma.[29] Experimental studies on fetal lambs demonstrated the induction of renal parenchyma dysplasia and significant histological and functional bladder changes.[32] Bladder dysfunction may present a variety of forms, changing over the years, before and after puberty.[33]

Macroscopically, the bladder wall presents trabeculations as a consequence of hypertrophy of the muscular components and of the high-pressure regimen. Histologic studies of the bladder wall have shown increased collagen and connective tissue elements within the muscular cells. The collagen/muscular ratio could be increased with reduced muscular components of the bladder wall. The overall structural and functional changes of the bladder, that persist after urethral obstruction release, was named 'valve bladder syndrome'.[34]

Ureteral pathology

Dilatation of one or both ureters is often seen in newborns or infants presenting with PUV. Ureteric dilatation may be due to vesico-ureteric reflux, vesico-ureteric junction obstruction, or inefficient ureteric drainage secondary to high vesical pressures. These changes may persist following valve removal[35] and the ureters may remain enlarged and tortuous, with thickened and rigid walls (Fig. 99.2).

Vesico-ureteric reflux

Reflux is frequently associated with PUV. It has been reported in 19–78% of children[36–40] and is thought to be due to the high-pressure regimen in the prenatally obstructed bladder (Fig. 99.3). Once the urethral obstruction has been resolved, a significant proportion of patients is expected to have resolution of their reflux.[41] Thus, a conservative approach to VUR in children with previous valves or diaphragm on posterior urethra is strongly recommended in infancy and early childhood. The incidence of bilateral and unilateral reflux is almost equal; however, bilateral reflux and posterior urethral obstruction denotes a more severe disease with a higher grade of renal parenchymal involvement and risk of CRF.[41]

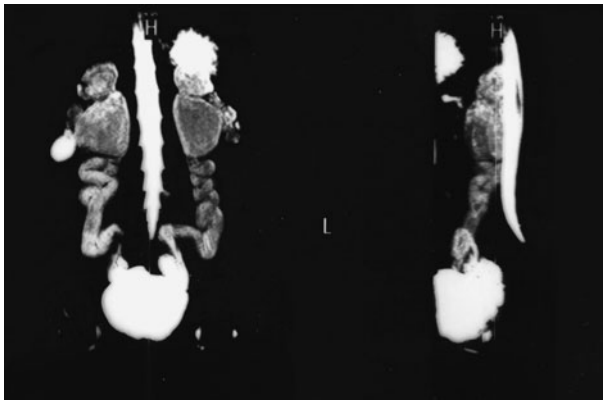

Figure 99.2 Magnetic resonance image of urinary tract in a five-year-old boy, born with posterior urethral valves ablated shortly after birth: the pyelocaliceal system remains bilaterally dilated, with ureters enlarged and tortuous.

'VURD' syndrome

John Duckett and others focused on the protective factors in PUV, stating that unilateral reflux denotes less severe disease, although the VUR is usually high grade and ipsilateral renal parenchyma is very damaged and dysplastic.[38,42] In fact, in such cases, the contralateral side is protected by the 'pop off' mechanism which keeps bladder pressures low.[42,43] The kidney on the side affected with reflux is usually non-functioning as a result of dysplasia (Fig. 99.4). VUR and renal dysplasia in posterior urethral obstruction could be a primary event due to abnormal location of the ureteric bud arising from the Wolffian duct. More probably, the pathogenesis of unilateral renal dysplasia in the VURD (vesico-ureteral reflux and dysplasia) syndrome is due to the high-pressure regimen of the upper urinary tract, which starts very early during the fetal life, with consequent impairment of the renal parenchymal maturation.[43]

Renal dysplasia and hydronephrosis

Renal damage is very frequent in PUV and it can be attributed to a variety of reasons:

- primary renal dysplasia;
- renal dysplasia induced by early intrauterine bladder outlet obstruction;
- VUR or uretero-vesical obstruction;
- postnatal urinary tract infection;
- persistent bladder dysfunction.

Association between renal dysplasia and hydronephrosis can be seen as a consequence of severe obstructive posterior valves or urethral diaphragm. Renal dysplasia is typically associated with abnormal histology and is not reversible. Hydronephrosis and stasis secondary to obstructive uropathy has normal renal histology and is reversible with treatment. Whether renal dysplasia is a primary event, or is secondary to urinary obstruction, has not been established. Using a fetal lamb model, Beck[44] has given experimental evidence that

early obstruction of the developing kidney results in dysplastic changes, while obstruction in the latter half of embryogenesis results in hydronephrosis.

On the other hand, Hoover and Duckett[43] described that frequent association of posterior urethral obstruction, reflux, and renal dysplasia suggested a common embryological error. Henneberry and Stephens[45] proposed that renal dysplasia associated with posterior urethral obstruction is not secondary to reflux or high pressures, but a primary embryologic malformation that is the result of an abnormal position of the

(c) Poor functioning left kidney at DMSA scan.

primitive urethral bud. This pathogenetic theory may be the reason why the long-term outcome does not depend on management but on congenital embryological status.[2,3,36]

Early bladder outlet obstruction, as in PUV, can also produce impaired tubular function. Pediatric nephrologists and urologists from the Great Ormond Street Children's Hospital in London observed that defective urine concentration occurs in as many as 60% of boys with urethral obstruction, and is severe in 15%.[46] The resultant concentrating defect causes high urinary output and sodium loss and the severe polyuria carries a risk of dehydration and electrolyte imbalance. Furthermore, high urine output may increase the overload of work of lower tract and enhance the bladder dysfunction, causing incontinence and further renal damage in an attempt to obtain dryness in toilet-trained boys and adolescents.[35] This clinical picture was named 'valve bladder' syndrome.[47]

These secondary consequences on pathophysiology of kidneys and lower urinary tract in boys with previous valves have a significant role in the management of these patients after obstruction removal.[47]

Pulmonary hypoplasia

During the pregnancy, oligohydramnios secondary to decreased fetal urine output produces an abnormally small

uterine cavity. This compresses the fetus and interferes with the normal growth and expansion of the fetal thorax, resulting in pulmonary hypoplasia. The kidneys themselves have an important role in early lung growth, while the presence of amniotic fluid contributes to growth later in gestation. The amniotic fluid index (AFI) is an important marker of renal physiology during pregnancy. If severe oligohydramnios is present in early fetal life (19–26 weeks' gestation), repeated maternal amnioinfusions or fetal bladder shunting may be considered, in an attempt to prevent lung maldevelopment. Preliminary hypoplasia represents the main cause of postnatal death in newborns with severe PUV or other congenital obstructions of the urethra.

CLINICAL FEATURES

Over the last three decades, advances in antenatal diagnosis have resulted in an increase in the number of babies with urinary tract obstruction being diagnosed either *in utero* or within the first few days of life, some of whom have posterior urethral obstruction. The ultrasonographic features of bilateral hydronephrosis in a male newborn with dilated and winding ureters, associated with enlarged and poor emptying bladder with thickened walls is very suspicious for PUV or urethral diaphragm (Fig. 99.5).

Nowadays, the picture of a very sick newborn, who is admitted as an emergency into the neonatal intensive care unit, is uncommon, as urethral obstruction is usually suspected by the pre- and postnatal ultrasonographic screenings which are offered in the more developed countries.[18,23] Classically, in the neonatal period, the baby may present with urinary tract infection, septicemia, uremia, and metabolic acidosis. Urinary symptoms may include a poor urinary stream, which can be an unreliable sign as some infants with severe obstruction have developed detrusor hypertrophy, enabling them to have a good stream. Quite often, the bladder and/or kidneys are palpable in infants with bladder outlet obstruction.

More commonly, infants with PUV can present with chronic urinary stasis and upper tract changes, vomiting, failure to thrive, and loss of weight. Rarely, they may present

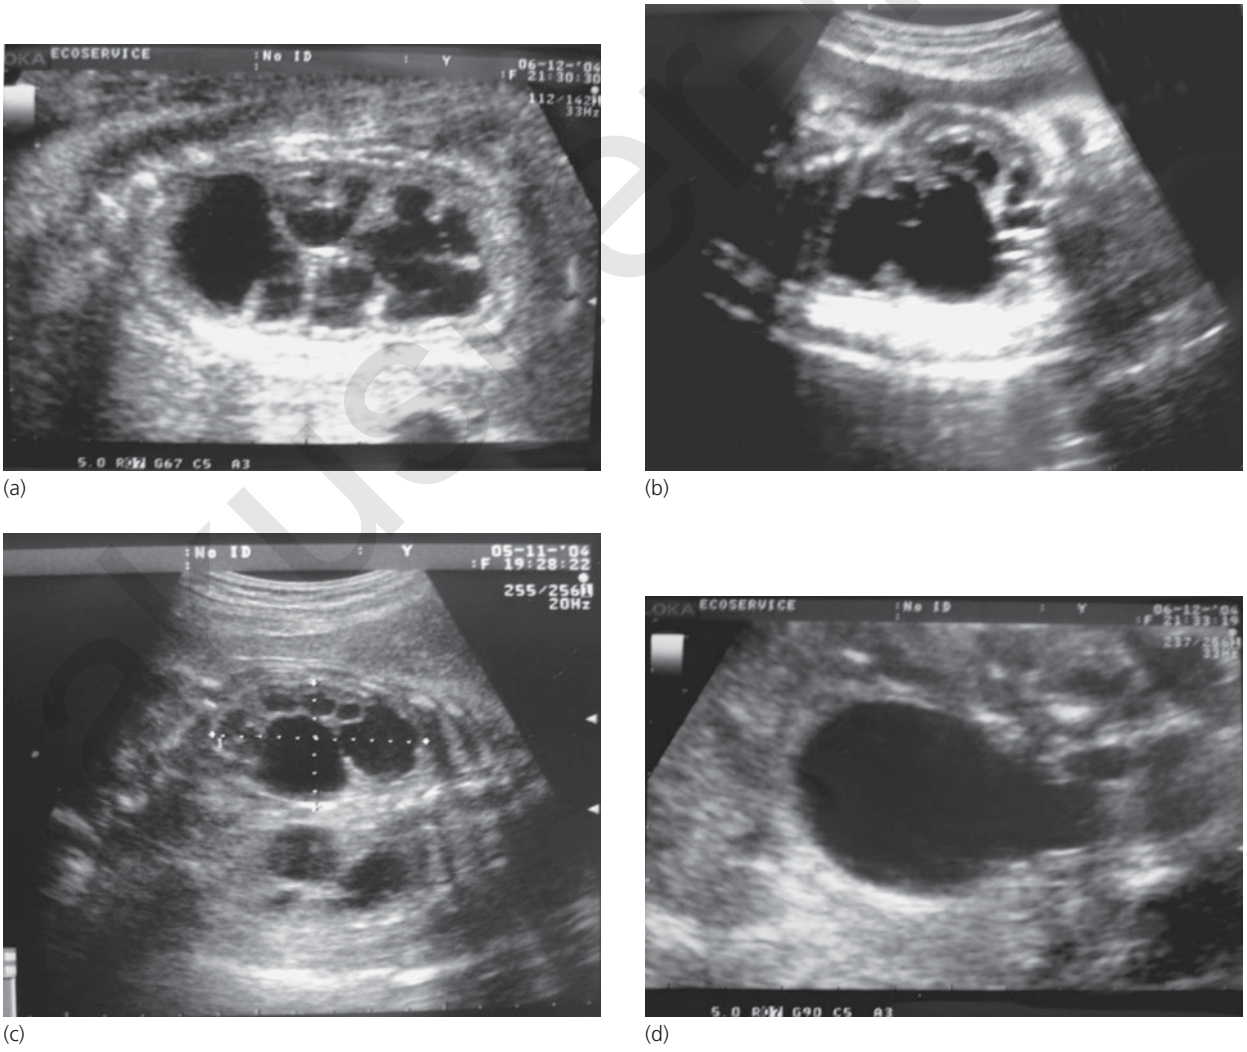

Figure 99.5 Prenatal ultrasonographic pictures of fetal urethra obstruction. (a,b,c) Bilateral hydronephrosis in a male newborn, with dilated ureters. (d) Enlarged and poorly emptying bladder, presenting thickened walls and wide bladder neck.

Figure 99.6 Picture of a very sick newborn, with severe abdominal distension due to urinary ascitis from congenital posterior urethral obstruction.

with abdominal distension due to urinary ascites or perirenal urine collection. Urinary ascites is usually a result of perforation of the kidney and in many instances the site of actual leak is not obvious radiologically. The newborn may present with severe abdominal distension, due to urinary tract dilatation and/or urinary ascitis (Fig. 99.6). A dyspneic or polypneic breathing is often observed, as a consequence of pulmonary dysplasia, metabolic acidosis, and abdominal distension.

INVESTIGATIONS

Ultrasound scan is the first diagnostic step, that is often suggested by the prenatal sonographic studies during pregnancy. The ultrasound should be perfomed at the earliest opportunity. The kidneys are scanned to determine the severity of hydronephrosis and to identify any perineal collections of urine. The dilated ureters can be traced down to the bladder. In an uncatheterized patient, a dilated posterior urethra can be demonstrated by a perineal sagittal scan. The bladder is thick-walled and with irregular edges, caused by the presence of pseudodiverticula (Fig. 99.7).

After birth, once the infection has been brought under control, the diagnosis can be confirmed by a **micturating cystogram** that is the gold standard for the diagnosis of posterior urethral obstruction. The examination should be performed to record the micturition in the lateral oblique position. The following features can usually be demonstrated (Fig. 99.8): trabeculated bladder walls, poorly emptying, and dilatation and elongation of the posterior urethra, with prominence of the bladder neck, particularly the posterior lip. VUR may be present in many infants (Figs 99.3 and 99.4).

Intravenous pyelogram is no longer performed in infants and young children, as it has been replaced by ultrasound and radionuclide studies. Useful anatomical information on ureters for boys requiring upper tract surgery or bladder enlargement can be obtained by **magnetic resonance imaging** studies (Fig. 99.2).

Radionuclide studies should not be performed in the neonatal period, but are very useful to assess the later functional status of both kidneys and to guide the urologist's

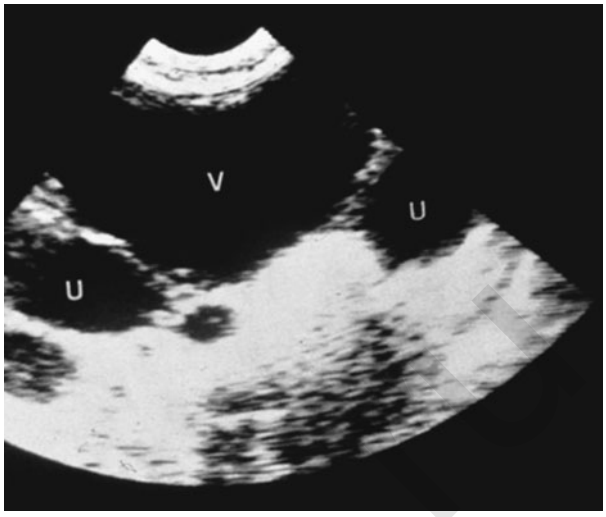

Figure 99.7 Ultrasonographic findings in an infant with posterior urethral valves: bilateral hydronephrosis, enlarged ureters with distended bladder.

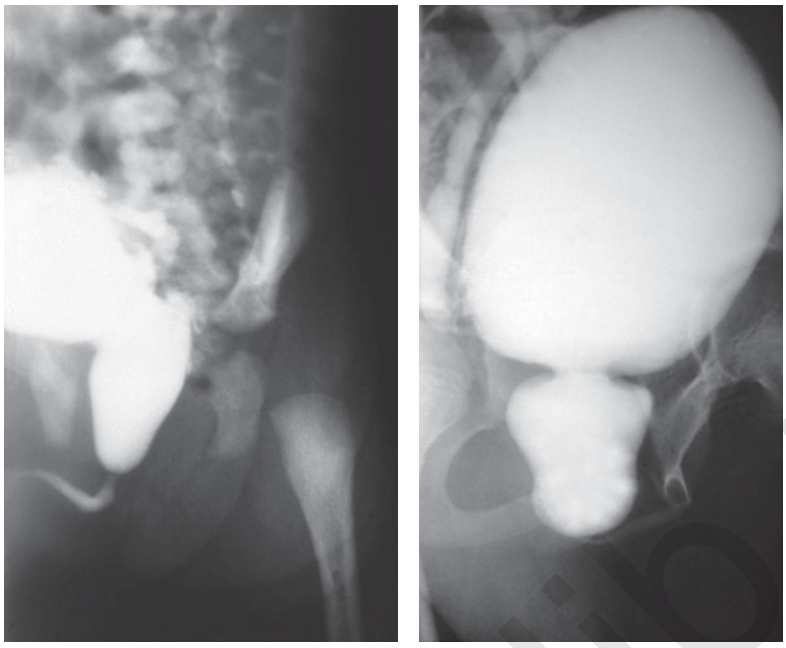
decision on upper tract repair and on the decision for nephrectomy (VURD syndrome). In infants in whom a postoperative ultrasound scan shows no improvement, a MAG3 scan may help to distinguish between persistent obstruction and cystic dysplasia. The uptake is negligible in dysplasia. A renogram should be performed to assess the differential glomerular filtration rate, and the uretero-vesical or pyelo-ureteral junction obstruction.

Urodynamic investigations are not usually performed in the neonatal age or before valve ablation, but are essential for the outcome evaluation of bladder changes over time.[48] Urodynamic studies are necessary to investigate the functional manifestation of the valve bladder syndrome and their relationship with urinary incontinence, voiding dysfunction and upper tract persisting dilatation. From initial patterns of hypercontractility in infancy and early childhood, bladder activity may gradually change to hypocontractility in many boys, expecially after puberty (Fig. 99.9).[49] The overdistended bladder in adolescence may lead to decompensation and increasing post-micturition residual and maximum bladder capacity. Upper tract persisting dilatation is a possible severe consequence, necessitating drug manipulation and/or intermittent catheterization.[35]

PRENATAL DIAGNOSIS AND MANAGEMENT

The prenatal suspicion of urethral obstruction in a male fetus has enabled evaluation and treatment to begin before the onset of infection, electrolyte abnormalities, and renal failure in the newborn. With the introduction of screening ultrasonography and improvement of technology, an increased level of expertise in detecting fetal urological abnormalities has been reached. A more frequent *in utero* diagnosis of PUV is now feasible.[50] Classic sonographic findings of PUV include a combination of megacystis, thickened bladder wall, dilated posterior urethra with the 'keyhole sign', and bilateral hydronephrosis in a male fetus (Fig. 99.10). Oligohydramnios may be associated in more severe forms.[51]



(a) (b)

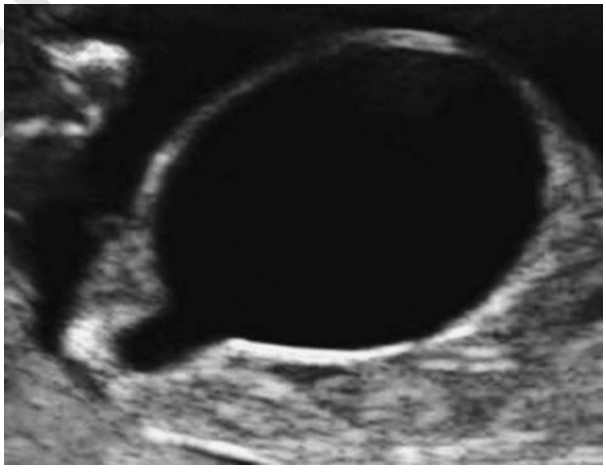

Figure 99.10 The 'key-hole sign' of the fetal bladder at prenatal ultrasonography: poorly emptying megacystis, with thickened bladder wall and dilated posterior urethra in a male fetus.

Even in the absence of these signs, antenatal diagnosis of urethral obstruction can be considered, especially in the presence of a constellation of findings including oligohydramnios and evidence of spontaneous urinary tract decompression (ascites, perirenal urinoma) (Fig. 99.11).

Urethral obstruction *in utero* produces a wide variety of clinically significant effects in addition to obvious obstructive uropathy. Fetal urine is produced by the 13th gestational week, a decreased production of which results in an abnormally small uterine cavity. This compresses the fetus and interferes with normal growth and expansion of the fetal thorax, resulting in pulmonary hypoplasia. Bladder distension and urinary ascites expand the fetal abdomen and compromise the development of the abdominal wall muscle, resulting in the prune belly appearance. In conclusion, prenatal ultrasound can accurately detect fetal lower urinary tract obstruction, with a sensitivity of 95% and a specificity of 80%.[52,53] MRI may be increasingly used in the diagnosis and assessment of fetuses with lower urinary tract obstruction, enhancing the ultrasound findings.

Pulmonary and renal consequences vary in severity with the degree of urethral obstruction *in utero*; where high-grade oligohydramnios and pulmonary hypoplasia develop this leads to postnatal respiratory insufficiency and death. In less severe cases, enough urine passes to give a sufficient amniotic fluid volume to allow adequate pulmonary growth.

The advantage of prenatal diagnosis is considerable. The maternal and fetal management can be planned early, which usually results in maternal transport to a tertiary

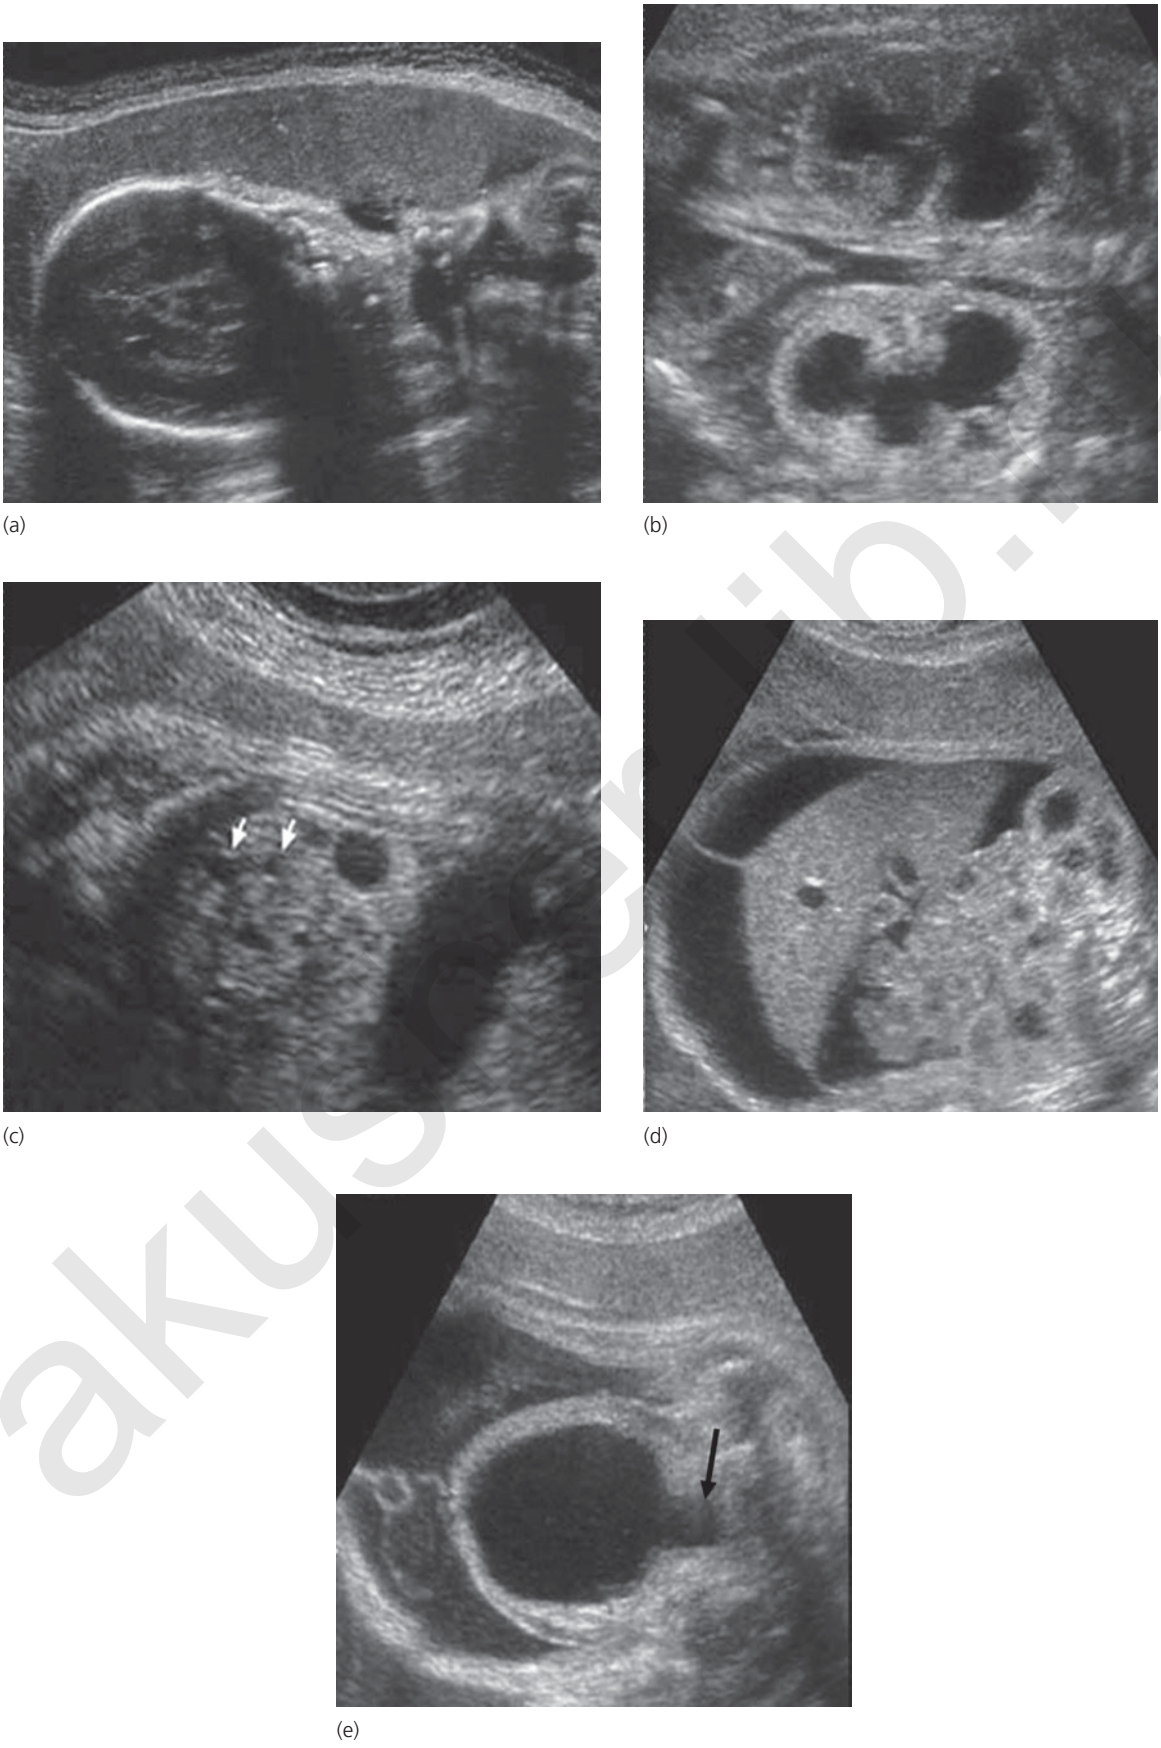

Figure 99.11 Prenatal ultrasonographic pictures. (a) Severe oligohydramnios; (b) bilateral hydronephrosis; (c) dysplastic kidneys; (d,e) fetal urinary ascites with enlarged thickened bladder.

center where the newborn can receive optimal treatment immediately after birth. A flow chart on the prenatal management of PUV is presented in Fig. 99.12.

Fetal lower urinary tract obstruction is a condition of high mortality and morbidity, associated with progressive renal dysfunction, oligohydramnios, and secondary pulmonary hypoplasia. Intrauterine intervention is now possible and was developed from the pioneering research of Harrison and co-workers.[46–48] The most difficult problem has been the selection of the fetus with obstructive uropathy, who might benefit from *in utero* treatment. Studies of the natural history of untreated congenital hydronephrosis have shown that the fetus with mild bilateral hydronephrosis and normal amniotic fluid volume requires no *in utero* intervention. Also, the fetus who presents with severe oligohydramnios and severely dysplastic kidneys sonographically is unlikely to benefit from antenatal intervention. Between the two groups, cases with obstructive uropathy can be observed, where potentially fatal renal and pulmonary damage may be averted by intervention. Prognostic criteria have been developed by Glick *et al.*[54] (Table 99.1). Fetal urine analysis may provide improvement in prenatal determination of renal prognosis. However, precise criteria to guide prenatal management remain uncertain.[55] Further predictors of renal dysplasia have been examined in fetal obstructive uropathy, as bladder pressure and beta$_2$-microglobulin assessment, to achieve prenatal evaluation of fetal renal function.[55,56]

Table 99.1 Favorable prognostic criteria of prenatally detected posterior urethral valves.

Urinary electrolytes	$Na^+ < 100$ mmol/L $Cl^- < 90$ mmol/L
Fetal osmolarity	< 2/0 mOsm/L
Beta$_2$-microglobulin	< 5 mg/L
Renal parenchyma ultrasound	Preserved appearance or mild hyperechogenicity. No cortical cysts
Amniotic fluid (AFI)	Normal or slightly reduced
Diuresis	> 2 mL/h

Modified from Ref.[54]

It is now possible to decompress the obstruction *in utero*, through percutaneous vesico-amniotic shunting or cystoscopic techniques.[57] Quintero and colleagues[58] focused technique and results on the insertion of a vesico-amniotic shunt passed either percutaneously using ultrasound or via a fetoscope, allowing the bladder to decompress into the amniotic cavity. The International Fetal Surgery Register of

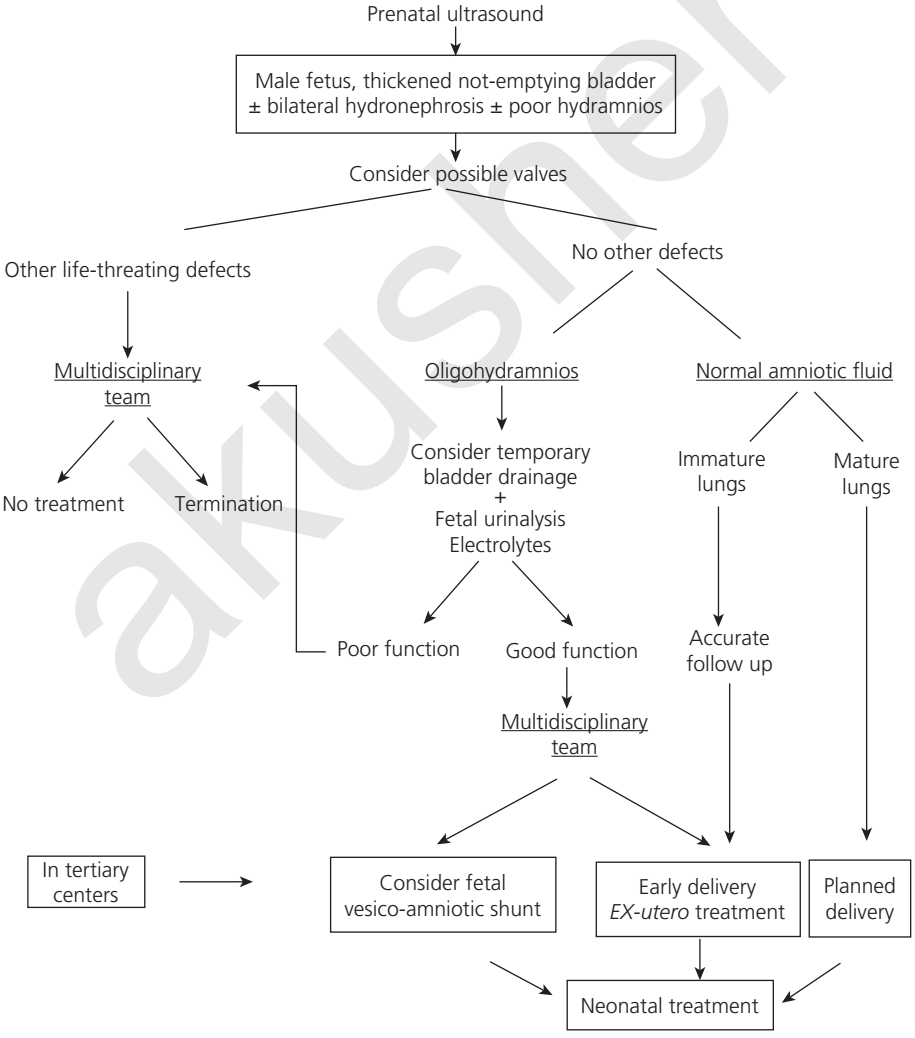

Figure 99.12 Posterior urethral valves: prenatal diagnosis and management.

1985 reported 73 cases of fetal obstructive uropathy treated by *in utero* placement of a vesico-amniotic shunt. The shunts are not satisfactory for long-term fetal urinary tract decompression due to the high incidence of catheter obstruction, displacement, and risk of chorio-amnionitis.[59] Today, it has been demonstrated to be possible to perform endoscopic ablation of PUV *in utero*.[60]

In conclusion, in appropriately selected fetuses, prenatal intervention may improve perinatal survival, but long-term renal damage remains mostly unsolved. Randomized multicentric studies are warranted.[61] Currently, the initial enthusiasm has been reduced by the poor ability to modify the long-term outcome for the severely affected newborns. Open decompression for fetal obstructive uropathy is still in the experimental stage, awaiting further control trials to establish its efficacy.[59,61]

POSTNATAL MANAGEMENT OF NEONATES WITH POSTERIOR URETHRAL VALVES

Infants born with posterior urethral obstruction may often have upper tract dilatation and renal damage that varies with the severity and duration of obstruction *in utero*. Most neonates with PUV when first seen are acutely ill with electrolyte abnormalities, metabolic acidosis, renal insufficiency, and septicemia (Fig. 99.6). They may have respiratory distress, the severity of which will depend on the degree of associated pulmonary hypoplasia. Improved management of these neonates has resulted in a better outcome for the treatment of posterior urethral obstruction in the last two decades.

The treatment strategy in neonates with PUV can be divided into three stages:

1. Immediate management and confirmation of diagnosis
2. Surgical treatment of the obstructing valves
3. Long-term follow up and treatment of associated pathology and complications.

Immediate management

The initial resuscitation of the sick neonate and confirmation of clinical impression by ultrasound and micturating cystogram is mandatory. Almost all neonates presenting with posterior urethral obstruction will need i.v. rehydration and electrolyte replacement. At the same time, blood samples can be obtained for:

- full blood count, including platelet count that may be low or high in septicemic babies;
- urea, creatinine, and electrolytes which should be estimated as baseline values;
- blood and urine should be sent for culture and sensitivity tests prior to starting antibiotic therapy;
- arterial blood samples to determine the degree of acidosis, to treat by sodium bicarbonate infusion.

Temporary vesical drainage can be achieved by passing a fine feeding tube (size 5 or 6 Fr gauge) transurethrally. Balloon catheters are not suitable for vesical drainage in posterior urethral obstruction. If the bladder is not emptying, a suprapubic catheter can decompress the urinary tract without interfering with the congenital urethra obstruction and its radiological study. A sample of urine obtained on catheterization should be sent for microscopy and culture.[62]

Once urine and blood samples are obtained for culture and sensitivity tests, the baby should be treated by antibiotic therapy. An aminoglycoside or cephalosporin is suitable initially and changes can be made once the urine and blood culture results are available. Respiratory insufficiency should be considered, and information on the respiratory states is given by means of a chest x-ray and blood gas estimation, and treated aggressively as and when necessary. A multidisciplinary team in the neonatal intensive care unit is often needed.

The confirmation of diagnosis usually involves a micturating cystogram, performed when the general condition of the patient is improved and the infection is brought under control (Fig. 99.8). However, an ultrasound scan can be done even in a sick neonate, by a sagittal perineal scan. The 'keyhole sign', although specific, cannot always be observed.[63]

Surgical treatment of congenital posterior urethral valves

To release the congenital obstruction in a male newborn with PUV should be considered as early as possible, because the indwelling transurethral catheter is only very transient, due to the risk of serious urinary tract infections and of defunctionalized bladder retraction. There is no consensus as regards the optimum method of treatment of posterior urethral obstruction, and its management constitutes an ongoing challenge in pediatric urology practice. The range of opinion varies from primary ablation alone to upper renal tract drainage, followed by delayed ablation. Ideally, the treatment option should be individualized, depending on the condition of the baby, the state of the upper renal tracts, and the size of the baby's genitalia.

PRIMARY TRANSURETHRAL RETROGRADE ABLATION

It can be performed under endoscopic view or blindly, depending on the preference of the surgeons and the available instrumentation.

Retrograde endoscopic ablation

It is the treatment most widely utilized, thanks to appropriate neonatal cystoscopes and resectoscopes now available, that may reduce the risk of secondary urethral damage and strictures in the newborn.[64,65] Fulguration can be undertaken once the infant's overall condition and renal function have stabilized. The development of smaller endoscopic equipment, as well as improved fiberoptics, has permitted transurethral endoscopic incision or fulguration of posterior urethral obstruction in virtually all but the most premature

patients. In most cases, primary ablation is sufficient to decompress the bladder and upper renal tracts.

Bugbee electrodes, available for use with the 8 Fr cystoscope, can be used for fulguration of PUV. One satisfactory alternative is to use a 3 Fr ureteric catheter with a metal stylet that can be used to coagulate. This can be passed through the side channel of an 8 Fr cystoscope. The obstructing membrane is incised at the 5, 7, and 12 o'clock positions. The neonatal resectoscope is commonly used in term newborns, as the caliber is 8 Fr (Fig. 99.13). This instrument allows the valve leaflets to be hooked and cut with more precision than the Bugbee catheter. It must be stressed that the valves or the congenital obstructive membrane should not be resected, but a full section of the leaflets should be undertaken at 5, 7, and 12 hours (Fig. 99.14). The section is enough to release the bladder outlet obstruction and avoiding the main severe complication that is postoperative urethral stricture. The reported incidence of strictures following endoscopic ablation is between 3.6 and 25%,[65] but an incidence of 0% has been reported with improved delicate maneuvers.[66]

Blind transurethral ablation

Particularly in very small newborns or premature babies, the transurethral endoscopy cannot be accomplished without the risk of urethral injury. Blind ablation of valves and urethral diaphragm can be performed, utilizing different instrumentation and techniques:

- **Fogarty balloon catheter**. The baby is anesthetized and a 6 Fr urethral catheter is passed transurethrally. The bladder is filled with contrast material until the posterior urethra is filled and an obstructing membrane identified. The catheter is then removed and, under fluoroscopic control, a No. 4 Fr Fogarty balloon catheter is placed into the bladder and inflated with approximately 0.75 mL of saline. With gentle withdrawal, the operator visualizes engagement at the level of the balloon. Sharp withdrawal of the catheter ruptures the valves or the membrane without injuring the sphincter.[67,68] Postoperative catheter drainage is recommended for 48–72 hours.
- **Mohan's valvotome**. This simple instrumentation may solve the problem of valve ablation in small infants. The advantages of the technique are its suitability in small neonates and the fact that it can be performed in areas of the world where pediatric endoscopic equipment is not easily available. However, a significant number of children have shown urethrorrhagia and periurethral extravasation of contrast in a post-ablation cystourethrogram.[69]
- **Whitaker–Sherwood diathermy hook**. Innes Williams successfully used a diathermy hook to ablate posterior urethral obstruction.[11] Whitaker and Sherwood[70] have modified the hook to its present form, which is fully insulated, except for the inside of the hook itself where the metal is bare for application of the diathermy. The advantages are its small caliber, 6–7 Fr, and applicability without the need for a general anesthetic. However, the proximal end of external stricture is above the obstruction, putting the sphincter at risk.[67] The sterile lubricated hook is passed up the urethra, pointing to the 12 o'clock position, with the bladder full of contrast medium. The obstructive membrane is immediately engaged by rotating it to either side and often it will not disengage until the diathermy is applied. The obstructing membrane is destroyed with the smallest effective diathermy current at the 3 and 9 o'clock positions, and elsewhere if it can be re-engaged.

With the advances in small cystoscopes, all these relatively blinded techniques are less favored over recent years.

Primary antegrade ablation

A percutaneous antegrade ablation technique was proposed by Zaontz and Firlit,[71] combining the techniques of antegrade urethral obstruction ablation and percutaneous endoscopy. The disadvantages of urethral instrumentation are avoided and the technique is applicable even in small premature infants.

Antegrade laser ablation in newborns has been proposed by some authors.[72,73] The Nd:YAG laser can be used via antegrade or retrograde access. The main advantage should be the limited inflammatory response of the injured tissue, with a reduced risk of bleeding and of secondary stenosis.

(a) The obstructing membrane; (b) dilated prostatic urethra; (c) diathermic hook; (d,e) the valve flaps are hooked at 12, 5, and 7 o'clock; (f) final appearance after posterior urethral valves fulguration.

INITIAL URINARY DIVERSION FOLLOWED BY SECONDARY TRANSURETHRAL ABLATION

There is general agreement on some indications for temporary diversion in neonates, including prematurity, small body size, and/or small urethral caliber with massive VUR.

Vesicostomy

In 1974, Duckett described the use of cutaneous vesicostomy as an alternative to primary ablation in a neonate.[74] By creating a vesicostomy, urethral instrumentation is avoided, high voiding pressures causing persistent high-grade reflux are managed, and hydroureteronephrosis due to poor

ureterovesical drainage is relieved. The bladder should be closed at the time of the subsequent diathermy of the urethral obstruction. However, vesico-ureteric junction obstruction and shrinkage of a defunctionalized hypertrophied bladder may occur, if it is proposed that the vesicostomy is long term.

Upper tract diversion

Upper tract diversion in posterior urethral obstruction is practiced in some limited indications. Primary ablation or temporary vesicostomy will be enough for hydroureteronephrosis to resolve in most cases. However, for severe or late presentation cases, and if significant dilatation of upper tract persists, in spite of lower tract drainage and ablation, non-intubated upper tract drainage may be beneficial. However, we know that dilatation does not mean obstruction and that temporary nephrostomy diversion on the use of double J catheters may ameliorate the hydronephrosis. In work by Krueger *et al.*,[75] infants treated with high-loop cutaneous ureterostomy ultimately had better outcome with regard to renal function and growth than the group managed by primary transurethral ablation of the valves. In 79% of patients who were treated initially with high diversion, Reinberg *et al.*[2] demonstrated that mild to severe renal failure developed versus 47% with primary ablation. Although no controlled study has been conducted, unilateral low ureterocutaneostomy could be useful in case of VURD syndrome with refluxing ureter and non-functioning kidney, allowing urinary tract decompression without interfering with bladder cycling and maturation in the small infant (Ransley, personal communication, 2009).

Temporary nephrostomy diversion on insertion of double J stents

Temporary nephrostomy with an insertion of double J stents may be useful in patients with vesico-ureteric junction obstruction or severe dilated upper tract. The insertion of double J stents prevents dry bladder and maintains bladder cycle, which is needed for normal bladder development.

EARLY POSTOPERATIVE MANAGEMENT

After valve ablation, the urethral catheter is left *in situ* for 48–72 hours, to allow the edema to subside and the urinary output to be measured. Accurate hydro-electrolytic balance is monitored by i.v. fluids and electrolyte solutions. Serial serum creatinine, electrolytes, and urinalysis are monitored after the patient is discharged with antibiotic prophylaxis. Post-void residual urine volume is frequently checked by ultrasound, and sonographic appearance of kidneys and upper tract is observed at four to six months intervals. If the post-void residual urine volume is significant (greater than 10% of expected bladder capacity), alpha-1 adrenergic blocker drug treatment can be started (terazosin 0.04–0.4 mg/kg per day), after obtaining informed consent.[76] Blood pressure must be routinely monitored.

The first micturating cystogram is usually performed at three months from valve ablation, and a 'second-look' cystoscopy is indicated if residual valves or leaflets are suspected, to guarantee complete removal of the urethral obstruction. A simple measurement that allows quantitative assessment of valve ablation is the 'urethral ratio' on micturating cystogram.[77] A post-fulguration urethral ratio of 2.5–3.0 represents positive results postoperatively. Renal radionuclide scan (MAG3 or DMSA) is suggested at 6–12 months from valve ablation to check parenchymal function.

FOLLOW UP AND TREATMENT OF LONG-TERM SEQUELAE AND COMPLICATIONS

Urethral stricture

It can be a significant complication following the transurethral approach for the treatment of PUV, as a consequence of mechanical trauma on posterior urethral wall. The stricture can happen where the lesion on the urethral wall is deeper and the corpus spongiosum could be injured. The incidence of urethral strictures following PUV ablation is reducing from 25 to almost 0%, but it can be avoided, utilizing small endoscopes and delicate maneuvers.[65,66,78]

Dysfunctional voiding and urinary incontinence

THE 'VALVE BLADDER' SYNDROME

At least 30% of children with previous PUV have different degrees of dysfunctional bladder. It often presents with daytime and night-time urinary incontinence at the toilet-trained age. Initially, it was thought to be secondary to external sphincter incompetence, depending on the primary maldevelopment of the sphincteric urethra, rather than iatrogenic injuring of this structure during endoscopic manipulations. Further urodynamic studies showed the presence of vesical dysfunction which does not resolve after complete urethral obstruction removal.[48]

A number of different voiding dysfunction pictures may be present after primary valve ablation in children born with PUV. The incidence of voiding dysfunction in posterior urethral obstruction has been reported to occur in 13–38% of all patients treated, of which incontinence is the most common problem.

The main bladder anomalies causing incontinence are detrusor overactivity, reduced compliance, and myogenic failure. Detrusor overactivity and reduced compliance are treatable with anticholinergic pharmacotherapy, but bladder augmentation may be necessary in selected cases. Myogenic failure may be most effectively treated with clean intermittent catheterization and nocturnal bladder emptying.[47]

Early valve ablation allows the bladder to fill and empty with normal cycling, starting shortly after birth. The restored bladder cycling is crucial for regaining normal bladder function and dynamics.[79,80] Mitchell[35] suggested the term 'valve bladder syndrome' to denote the association of a non-compliant bladder and upper tract dilatation in boys with a history of previous PUV.

The evolution along the years of this severe bladder dysfunction may result in upper tract dilatation and renal

function deterioration.[34,35,47] Serial urodynamic studies, with pressure-flow analysis and evaluation of post-voiding residual urine are necessary. Bladder activity may change over time from hyperactive, low-compliant, and reduced functional volume bladder to hypocontractile, high capacity, and poorly emptying behaviour (decompensated bladder with myogenic failure).[48,49,81]

Early valve ablation, even in patients with severe bladder changes, could provide better bladder function results, with a higher resolution rate of VUR and hydronephrosis.[80] Bladder neck incision, performed simultaneously to valvulotomy or later in infancy or childhood, has been advocated to increase low-pressure bladder outlet if pharmacological treatment by α-1 adrenergic blocker drugs has not been efficacious.[78,82]

VESICO-URETERAL REFLUX AND HYDRONEPHROSIS

The incidence of VUR in boys with PUV ranges from 26 to 72%.[83] More recently, bilateral VUR was observed in 37% and unilateral VUR in 27% of patients.[84] Children born with bilateral high-grade VUR are at greater risk for CRF than those with unilateral or no VUR. Unilateral VUR may confer a protective pop-off effect in the contralateral kidney.[43,85]

A high rate of reflux resolution is expected after valve ablation, even in the presence of vesical diverticuli, with a consistent follow up. VUR resolution is correlated with bladder dysfunction normalization. In a recent series of Heikkila *et al.*,[84] VUR resolved spontaneously in 62%, was corrected by antireflux surgery in 21%, and required nephrectomy in 17% of boys with previous PUV. Indications for ureteral reimplantation remain undefined today, but the recent experience tends to support a less aggressive surgical approach than in the past.

Pyelo-ureteral dilatation persisting after treatment of an obstructing membrane is either due to vesico-ureteric junction obstruction or ureteral atony. Diuretic renograms may be helpful in the differentiation between the two conditions, although temporary drainage of the upper tract may be necessary to make the diagnosis. A conservative approach, with care to bladder dysfunction treatment, is often recommended today.

Renal dysplasia

Unilateral renal dysplasia with a nonfunctioning kidney should be treated by nephro-ureterectomy, if there is a risk of blood hypertension or urinary tract infections. Bilateral renal dysplasia will go on to develop end-stage renal disease and will require dialysis and renal transplantation.

PROGNOSTIC FACTORS IN PUV

Congenital lower urinary tract obstruction is a disease of high mortality and morbidity in newborns. With the widespread use of prenatal ultrasound, most children with PUV are now recognized prenatally and confirmed at birth. Several prognostic factors have been underlined to better define the long-term outcome of an infant born with PUV.

- Prenatal prognostic factors for better postnatal outcome have been presented and discussed above under Prenatal diagnosis and management. Poor prognosis is related to reduced amniotic fluid volume, presence of cortical renal cystis, and other congenital or structural anomalies of the fetus.[57]
- Ultrasound findings of reduced parenchymal thinness, increased renal echogenicity, and cystic changes in infancy are usually correlated with severe renal damage and dysplasia, evolving into CRF.[50,52]
- Urinary extravasation with or without ascites in the prenatal or neonatal age, large bladder diverticula, and VURD syndrome are all factors decompressing the urinary tract and related to a better renal function outcome.[42,43]
- Delayed presentation of patients with PUV (after two years of age) are at higher risk of developing CRF on long-term follow up.[86] Early vesicostomy or other urinary diversion is not confirmed to give better outcome.[87]
- Early primary valve ablation of PUV seems to lead to better outcome than urinary diversion, reducing bladder dysfunction.[79,80]
- Unilateral gross VUR, associated with poor functioning ipsilateral kidney, may give a protective effect in the contralateral kidney ('pop-off' valve syndrome).[43,85]
- Patients with bilateral high-grade VUR are at greater risk for renal insufficiency, although this is not always confirmed.[84]
- Severe bladder dysfunction ('valve bladder' syndrome) may jeopardize the upper tract and renal function at long-term follow up.[47–49]
- Proteinuria, blood arterial hypertension, and febrile urinary tract infections do not correlate significantly with the ultimate functional outcome.[88] The nadir creatinine values of 0.8 mg/dL or higher within the first year of life is reported as the most significant prognostic factor correlated with poor renal function over the long term.[89,90]
- Renal transplantation can be offered to children with a history of previous PUV or congenital obstruction of posterior urethra, with the same good results as other pediatric candidates, with pre-emptive urological repair of the lower urinary tract.[91]

CONCLUSIONS

Congenital obstruction of male posterior urethra represents a spectrum of lesions, of which PUV is the most common. PUV often remains a severe structural cause of urinary outflow obstruction in newborn age and in infancy. It still represents one of the most significant causes of end-stage renal failure before the age of two years.[4,89] The prognosis of children born with PUV has improved significantly over the past two decades, but until now a large number of patients enter CRF and progress to end-stage renal insufficiency by adolescence, with the need for the dialysis and/or progression

to the renal transplant program.[90,91] A precise multidisciplinary approach may further increase the outcome of these children, providing a more pathogenetic and appropriate treatment at long-term follow up, until adulthood.

Neurogenic bladder in the neonate

YVES AIGRAIN AND ALAA EL GHONEIMI

INTRODUCTION

The prevalence of neonates with neurogenic bladder dysfunction has decreased due to the wide prenatal ultrasonographic screening and the prophylactic use of folic acid during pregnancy. Nevertheless, there are still newborns presenting with spina bifida or other forms of spinal dysraphism or sacral agenesis.

Although the management of these children has been significantly modified over the last few decades, the main goal of the treatment has not changed, i.e. preventing urinary tract deterioration, which concerns the upper urinary tract as well as the bladder.

PRENATAL DIAGNOSIS AND COUNSELING

Despite the progress of the ultrasonographic evaluation and the information provided by fetal magnetic resonance imaging (MRI), it is almost impossible to predict prenatally the precise degree of bladder dysfunction. Urinary and anal incontinence are among the main disturbances in the life of these children, particularly in those with a low lesion without or with minor motor involvement. The treatment of the urinary tract involvment has to be started early in life,[1] which is why the participation of the pediatric surgeon (or urologist) is of utmost importance in the counseling of parents before the birth. It will help the parents to be prepared for the need for immediate neonatal management of bladder emptying by clean intermittent catheterization (CIC).

ANATOMY AND MICTURATION PHYSIOLOGY

The autonomic and somatic nervous systems are involved in the innervations of the bladder and sphincter. The parasympathetic component of the autonomic innervations is derived from the sacral segments of the spinal cord. These fibers emerge as preganglionic fibers within the pelvic nerve, which then joins the hypogastric nerve to form the bladder's plexus. The post-ganglionic fibers emerge from synapses close to the bladder and urethra, where they have the overall effect of producing sustained bladder contraction. Acetylcholine is the neurotransmitter for both the pre- and post-ganglionic fibers, although there is certainly more than one principal neurotransmitter. Within the bladder, the parasympathetic cholinergic receptors are largely muscarinic (M_2). Other neurotransmitters documented to be present in the bladder include vasoactive intestinal peptide, neuropeptide Y, substance P, somatostatin, calcitonin gene-related peptide, cholecystokinin, dopamine, serotonin, histamine, and tyrosine hydroxylase. The exact roles of these neurotransmitters, as well as their complex interactions, remain unclear.

The sympathetic component of the autonomic innervation arises from spinal cord segments T11–L2 with preganglionic fibers traveling to the hypogastric and inferior mesenteric ganglia, where they synapse with the noradrenergic, post-ganglionic fibers, which in turn travel to the bladder and urethra via the hypogastric nerve. Sympathetic input is mediated by both α- and β-adrenoreceptors. The α-adrenoreceptors are more densely represented at the bladder base and produce contraction, while the β-adrenoreceptors, which are more common in the bladder body, produce relaxation. Thus α-activity promotes outlet resistance, while β-activity promotes urine storage and opposes cholinergic tone.

Somatic motor innervations arise from the S2–S4 segments and pass via the pudendal nerve to the striated muscle of the external sphincter. While the external sphincter is voluntary muscle, in infancy external sphincter tone is mediated via spinal cord reflex. It is only as the child matures that cortical inhibitory influences develop that allow voluntary relaxation and contraction, which contribute to the development of continence.

Normal bladder sensation is relayed via pelvic and hypogastric nerves, with parasympathetic visceral afferent fibers transmitting information from pain, temperature, and stretch receptors.

In the newborn and infant, voiding occurs as a result of a spinal reflex secondary to bladder distension, which stimulates the efferent limb of the reflex arc, resulting in spontaneous detrusor contraction. Initially, as the bladder fills, the peri-urethral striated muscles make the external urinary sphincter contract to prevent urine loss. The act of micturition occurs with subsequent relaxation of the external sphincter, resulting in the bladder emptying at low pressure. During the first year of life, the number of voiding episodes per day remains constant at about 20, occurring during both sleep and while awake; with increased age, there is a reduction in the voiding frequency that relates to the relative increase in bladder volume and decreasing proportion of the caloric intake associated with fluid.

CLASSIFICATION

There are many classifications describing neurogenic bladder dysfunction. Most of these classifications depend on the site of the neurological lesions, well adapted to adult pathology, but not to congenital spinal lesions. In fact, in children, there is poor correlation between the spinal level of lesion and the clinical impact. For this reason, classification based on clinical disorders and urodynamic findings are more practical for use in children. The main dysfunctions are due either to detrusor or to urethral sphincter dysfunction.[2] The four main anomalies are defined as: overactive bladder, underactive detrusor, overactive sphincter, or underactive sphincter. Many patterns may be the result of combinations of these four anomalies.[3] The most common is the detrusor sphincter dyssynergia (DSD), which is often associated with both overactive bladder and overactive sphincter. DSD is the main characteristic of neurogenic bladder in children.

URODYNAMIC INVESTIGATION

Urodynamic investigation has become an integrated part of any discussion of the management of neurogenic bladder even in neonates. It is mandatory to understand the definition and specificity of urodynamic findings as they relate to children. The International Children's Continence Society has established the standardization of the terminology to be used in children's bladder dysfunction.

Performing a urodynamic evaluation in a neonate should be undertaken under optimal conditions, including treatment of the associated constipation and emptying of the rectum on the day of examination.[4] The common basic principles specific to children are the following: smaller catheter, rectal pressure measurement, and measurement of urethral profile (even if its interpretation needs caution). Most importantly, the rate of bladder filling should be adapted to the expected bladder capacity (usually divided by 10/min). Surface patches measure the electrical activity of the external sphincter. Video urodynamometry has gained popularity over the last decade. Visualization of the bladder and the bladder neck during filling, and the urethra during voiding, add more accuracy in the determination of voiding dysfunction. In case of associated reflux, its visualization allows a proper interpretation of the bladder pressure and compliance.

DIAGNOSIS OF NEUROGENIC BLADDER IN THE NEONATE

The most common cause for neuropathic bladder dysfunction in the neonate is the congenital spinal anomalies. Prenatal occurrence of a tumor with intracanal expansion is another rare cause of paraplegia and neurogenic bladder dysfunction in the neonate. The expected findings and the modalities of follow up of the most common of these pathologies during the first months of life are discussed below.

Myelodysplasic patient

In the event of myelomeningocele (MMC), the workup is performed in the neonatal period, usually after the surgical closure of the defect. The initial workup will serve as the baseline information for the follow up of the child. It will include renal and bladder ultrasound (US), urodynamic study, voiding cystourethrogram (VCUG) (or a video urodynamic study). These initial studies will help to identify children at risk for urinary tract deterioration: poor compliant or overactive bladder, or outflow obstruction as a part of DSD. The identification of such risk factors will justify initiating the prophylactic measures before deterioration of the upper urinary tract. It is not enough to look at the radiological appearance of the upper urinary tract. Detailed functional screening of the lower urinary tract is necessary to allow an early preventive therapy, before the later appearance of upper tract deterioration. It will also help to preserve bladder compliance, and to avoid or delay as far as possible bladder augmentation procedures.

The neurological lesion produced by MMC can be variable. The bony vertebral level provides little or no clue to the exact neurological level or lesion produced.

Three categories of lower urinary tract dynamics may be detected: (1) synergic (26%), (2) dyssynergic with and without detrusor compliance (37%), and (3) complete denervation. Bauer reports that 15% of neonates have abnormal urinary tract that developed *in utero*.[5]

Within the first three months of life, 71% of newborns with DSD have deterioration of bladder compliance or upper tract, by comparison to the initial evaluation, whereas 17% of synergic children and 23% of those completely denervated developed similar changes. Outlet obstruction is a major contributor to the development of urinary tract deterioration in MMC children. The leak point pressure is not the only pejorative prognostic factor; so is the filling pressure, which should remain lower than 30 cm H_2O, while voiding pressure should not exceed 100 cm H_2O. If this is not the case, CIC and anticholinergic medications are mandatory.

Anal incontinence is unpredictable and is not correlated with urinary incontinence. Anal incontinence is not a problem during the first year of life, but treatment of constipation should be undertaken as soon as needed.

Other spinal dysraphisms

This group of congenital defects affects the formation of the spinal column, but does not result in an open vertebral canal. In young infants, the vertebral bones have not ossified, thus a window exists for ultrasound to screen spinal cord lesions. Many of these lesions are now detected by an accurate prenatal US screening, raising the question of a prophylactic surgical treatment before the onset of symptoms.

Occult spinal dysraphism

Lipomeningocele, intradural lipoma[6,7] and other rare anomalies of filum terminale are increasingly being diagnosed by prenatal ultrasound screening. The majority of these children have a normal neurological examination, but Keating reports that the urodynamic evaluation reveals anomalies in one-third of infants younger than 18 months. These anomalies produce different neurologic findings. Satar *et al.*[6] report that lipomas invariably cause upper motor neuron either alone or in combination with lower motor neuron defect. Neonates and infants with various occult dysraphism may have skin lesions, varying from a small dimple or a skin tag to a hair's tuft, a dermal vascular malformation, subcutaneous lipoma, or an asymmetrical curving gluteal cleft.

SACRAL AGENESIS

Sacral agenesis is defined as the absence of part or all of two or more lower vertebral bodies. Curarino syndrome associates in complete forms: sacral agenesis, a presacral mass, and an anorectal malformation. This is a familial disease with dominant inheritance, due to a deletion in chromosome 7 in the *HLXB9* gene.

In 1999, Wilmhurst *et al.*[8] reported that more than three-quarters of the cases were detected either prenatally or in early infancy. Most of these children have normal skin sensation and no abnormalities in the lower extremities. On clinical examination, palpation of flat buttocks and absence of vertebrae in the sacrococcygeal area may be observed. A plain x-ray will confirm the diagnosis of sacral agenesis, while the spinal cord-associated anomalies are explored by US and MRI. One typical finding is the sharp cut-off of the cone at T12 as shown by Diel *et al.* (2001).[23]

The urodynamic findings may be either an overactive bladder, with exaggerated sacral reflex and DSD, with a thick and trabeculated bladder on the VCUG with a closed bladder neck or an acontractile detrusor with open bladder neck and a small, thin-walled bladder. These neurological findings are stable and rarely progress with time. Urodynamic evaluation and VCUG are mandatory to tailor the management of these neonates and infants.[9]

NEUROLOGIC BLADDER ASSOCIATED WITH ANORECTAL MALFORMATION

Spinal cord anomalies (tethered cord, filum terminale anomalies, or lipomas) may be found in up to 50% of cases, especially in the high type of anorectal malformation (ARM). Intraspinal imaging at least by US is mandatory since not all patients with spinal cord anomalies and ARM have a vertebral body defect. The timing of the urodynamic evaluation in ARM infants is discussed. To perform these investigations in ARM children with proven spinal cord anomalies before the definitive pull-through procedure will help to distinguish between the congenital and acquired anomalies, secondary to the surgical procedure. Most of these infants with spinal cord anomalies have upper motor lesions with DSD and are at high risk of upper urinary tract deterioration.

CEREBRAL PALSY

Cerebral palsy is a non-progressive injury of the brain occurring in the perinatal period. Most children with cerebral palsy will develop total urinary control. As Karaman *et al.* reported in 2005,[10] when they explored the urodynamic anomalies in every child with cerebral palsy, urinary symptoms were not the major concern of these neonates and no screening is recommended in this group of patients.

MANAGEMENT OF NEUROGENIC BLADDER

The first goal of the treatment of a neonate with a neurogenic bladder is the preservation of a normal upper urinary tract. The second goal will be to improve the urinary and fecal continence of these children to improve their social life and their quality of life. These objectives would ideally need a reservoir, the bladder, with adequate capacity and a low storage pressure, able to empty itself with a normal micturition profile. In a child with a neurogenic bladder, none of these characteristics is present. As mentioned above, the urodynamic evaluation done in the neonatal period will help to tailor the treatment to each individual child. Later, the motor and intellectual capacities of the children will also influence the choice of treatment.

Clean intermittent catheterization

Lapides introduced CIC in 1971.[11] CIC is the most important tool in the management of a child with neurogenic bladder. It is a clean, but not sterile procedure. It allows the emptying of the complete bladder, lowering the risk of urinary tract infection and protecting both the upper urinary tract against high bladder pressure and the deterioration of the bladder wall and compliance in relation to DSD and obstruction. CIC may be sufficient to induce dryness of the child if the bladder capacity and the sphincter pressure are correct, but this is not the main objective in the newborn. CIC is enhanced by the availability of single use lubricated catheters, but it may be realized with classical Nelaton catheter kept in an antiseptic solution in less developed countries.

Everyone agrees that there is no longer a role for Crédé and Valsalva maneuvers in children with congenital neurogenic bladder since these may induce reflux, worsened the high bladder pressure and the upper urinary tract deterioration.[1] We advocate the introduction of CIC as early as

possible in the neonatal period. This is mandatory in infants with overactive or low compliant bladder and DSD. In neonates with low sphincter pressure and no risk of deterioration of the upper urinary tract and bladder compliance, the age at which CIC should be started may be discussed, taking into account the burden of CIC to the parents of the handicapped child and the ease of starting CIC in a neonate by comparison to a two- or three-year-old child.

The authors do not have experience of urethral dilation for lowering the leak pressure as published by Kiddo *et al.*[12] These authors report a favorable outcome in 19 infants with upper tract deterioration (dilation or reflux) and urinary tract infection. When CIC is not applicable due to the familial condition or to associated anomalies, the authors would rather consider the construction of a tubeless vesicostomy to decompress the bladder and avoid deterioration of the upper urinary tract.[13] The surgical technique of vesicostomy should be precise to allow a correct decompression of the urinary tract. The incision should be done halfway between the umbilicus and the pubis exposing the rectus fascia, which is incised transversally. The rectus muscles are retracted and the inferior fascial edge is incised vertically. The peritoneum is reflected superiorly from the bladder (this may be helped by filling the bladder with a catheter). The urachus is identified and excising the urachus opens the bladder. The detrusor edge is anchored to the fascia to avoid the opening being too wide with the risk of bladder prolapse, or too small with resulting poor decompression. Suturing the full thickness of the detrusor to the skin and subcuticular layer creates the cutaneous stoma. A catheter is left in place for 2 or 3 days.

In selected cases, where despite CIC urinary tract deterioration occurs, the overnight catheter drainage of the bladder may be successfully attempted as shown by Koff *et al.*[14] and Nguyen *et al.*[15] These authors have shown that overnight drainage may increase bladder compliance and capacity, avoiding augmentation in some children.

CIC will have to be done for the full extent of the life of the child. Later in childhood, when CIC is difficult through the urethra, a Mitrofanoff[16] channel may be constructed, allowing catheterization through a continent abdominal stoma. The location of this stoma will be either at the umbilical site or in the lower abdominal wall depending on the child's motor disability. The continent channel is either realized as a specific procedure or together with a bladder augmentation or outlet procedure. Many variations of the original procedure described by Mitrofanoff, using the appendix as the channel have been reported. Use of one ureter, a refashioned ileal conduit (Monthy), or a flap from the bladder wall have to be known.

BLADDER CAPACITY AND COMPLIANCE

When CIC and sometimes overnight drainage fail to maintain normal bladder capacity and compliance, the preservation of the reservoir and the upper tract may need either pharmacological manipulation or surgery.

During the first year of life, a bladder augmentation procedure is very seldom, if ever, indicated.

Pharmacologic treatment of neurogenic bladder overactivity

Oxybutinin, an anticholinergic agent, is the reference treatment of bladder overactivity. Even if it has not been approved for use in children younger than five years, oxybutinin is in most cases well tolerated and may be introduced after the initiation of CIC, at an early stage, if the urodynamic evaluation shows bladder overactivity. The use of an oxybutinin solution helps the administration in infants. Oxybutinin should be administered at regular intervals during the nyctemer, starting with minimal dose increases according to the child's tolerance and the effects upon the overactivity. In older children, side effects of oxybutinin include mouth dryness, constipation, and headaches or eye trouble. These side effects may be reduced or suppressed by direct instillation of the oxybutinin within the bladder during CIC, but the sterile solution is not universally available. There is no report on the use of other anticholinergic agents during the neonatal period or in infancy.

Botulinum toxin A has been shown by many authors to be very effective in reducing the bladder overactivity, enhancing the bladder capacity and compliance.[17,18] Botulinum toxin A is injected in the detrusor muscle under cystoscopic guidance at 5–10 IU/kg body weight with a maximum dose of 300 IU. The site of injections are spread through the detrusor, respecting the trigone so as not to induce a vesico-ureteric reflux. The effects of Botulinum toxin A last for six to nine months, but the procedure is minimally invasive and may be repeated on an outpatient basis after ruling out any allergologic reaction. Most authors now consider Botulinum toxin A as an alternative to bladder augmentation procedure in children.

Alpha-blocking agents have a very limited place in the management of neurogenic bladder.

Guys *et al.*[19] introduced sacral neuromodulation in the treatment of neurogenic bladder dysfunction in children from five years of age. These authors showed a significant improvement in bladder compliance and capacity at six and nine months of treatment. These results have to be confirmed in a larger group of patients. Interestingly, the intestinal transit improved in many of these patients.

As already mentioned, bladder augmentation is rarely if ever indicated in neonates and infants. In older ones, the surgical increase in bladder capacity and compliance in order to preserve both the upper urinary tract and to allow a social continence between catheterizations may be done by bladder autoaugmentation or detrusorectomy,[20,24] or by intestinal augmentation, in most cases using the ileum. In some instances, the stomach (El Ghoneimi et al 1998) and the sigmoid may be an alternative to the use of ileum. These augmentation procedures may be associated with a reinforcement of the outlet resistance and/or with a continent cystostomy using Mitrofanoff's principle. The augmentation per se causes many complications, some being preventable, and others having to be identified during the life-long follow up of these patients. They are mainly infections, stone formation, and metabolic complications, including acidosis or vitamin B_{12} deficiency,[29] perforation,[28] and cancer. They explain why bladder augmentation should be avoided or delayed as much as possible. The neonatal

introduction of CIC and oxybutinin is in the event of severe dyssynergia, which is mandatory to prevent fast bladder deterioration.[22]

OUTLET RESISTANCE

There is obviously no need to increase the outlet resistance in a neonate or an infant where dryness is not relevant for the child and his parents. Nevertheless, the child's family will need information and the various possibilities should be known in order to provide the complete picture.

Increasing the outlet resistance may be obtained by the periurethral or pericervical injection of bulking agents, an open cervicoplasty, a sling suspension of the bladder neck, an artificial urinary sphincter, or closure of the bladder neck.

The injection of bulking agents has the advantage of being a non-invasive technique. Various agents have been tested including dextranomer (Deflux®) or silastic particles.[21] We have recently published our experience with dextranomer injections in 61 patients. The incidence of dryness or improvement at six months was 51% and this result was maintained during long-term follow up.[20] Similar results have been published with silastic particles by Guys *et al.*[19] They suggested the combined injections of Botulin toxin A and pericervical injection of silastic particles, combining in a non-invasive procedure the treatment of bladder overactivity and the increase of outlet resistance. These techniques are the only ones to be used in a young child. The neonatal management of neurogenic bladder and other possibilities that are reserved for older children will not be discussed in this chapter. This is obvious given the complications of the surgical procedures used to increase the outlet resistance. Any of these, including to some extent the injection of bulking agents, may induce bladder and upper urinary tract deterioration. The main goal of the neonatal management should be preservation of these structures.

URINARY DIVERSION

Despite the widespread acceptance of CIC, there are families with social conditions which make them unable to comply or simply to have access to any form of bladder catheter. As already discussed, in the neonatal period, urinary diversion is realized by a tubeless cystotomy. Later in life, quadriplegia, limited dexterity, devastating cognitive impairment, or lack of ancillary support are the main factors leading to the decision of urinary diversion. The urinary diversion is most often realized by an ileal conduit (Bricker's procedure).[25]

BOWEL MANAGEMENT

Constipation is a usual feature of babies with neurogenic bladder. It should be managed both to improve the infant's comfort and to reduce the risk of urinary tract infection. Later in life, the quality of life of a child born with a neurogenic bladder is even more altered by feces incontinence as by the leak of urine. It is then important to consider bowel management, including either retrograde enemas or antegrade colonic washing as described by Malone.

CONCLUSION

The management of a neonate with neurogenic bladder requires a multidisciplinary team and has to be tailored to each particular child and family. CIC is the most important part of the treatment and should be started as early as possible after birth and repair of the spinal defect. It will not always be sufficient to achieve continence, but is mandatory to protect the upper urinary tract, which is the main goal of the treatment.

Hydrometrocolpos

DEVENDRA K GUPTA AND SHILPA SHARMA

HISTORICAL BACKGROUND

Although the historical literature on hydrometrocolpos is sparse, there are records of hydrometrocolpos dating back to the mid-nineteenth century. Godefroy in 1856 first described a case of a two-month-old infant with 5 mL of viscid mucoid fluid imprisoned behind a 2.0 mm thick, vascular hymen.[1] In 1899, Von Winckel found an atretic vagina containing 180 cc of fluid at autopsy in a stillborn infant.[2] In some instances, the baby with hydrometrocolpos was associated with such urogenital and hindgut grotesque abnormalities that the specimens were considered to be embryologic curiosities. These findings emphasize that hydrometrocolpos, when associated with other congenital anomalies, has a poor prognosis. A major undertaking, such as panhysterectomy, even in infants, was reported as long ago as the mid-twentieth century, even before the diagnosis could be established.[3,4] This kind of aggressive treatment for a simple benign vaginal obstruction in an infant is now obsolete and unethical. The diagnosis and treatment of hydrometrocolpos has now been revolutionized completely.[5]

DEFINITION

Hydrometrocolpos is a condition in which the uterus and vagina are grossly distended with retained fluid other than blood, usually in the presence of distal vaginal outflow obstruction.

INCIDENCE

The incidence of hydrometrocolpos is reported as 1 in 10000–30000 live births.[5,6] The condition is now being increasingly diagnosed prenatally, with the use of ultrasound and fetal magnetic resonance imaging.[7] The incidence is reported higher in communities with consanguinity.[8] The rarity of this anomaly was probably due to high mortality resulting from infections and associated anomalies.[9] Many of those affected are stillbirths due to serious associated anomalies and obstructive uropathy.

EMBRYOLOGY

The Müllerian ducts develop as tubular invaginations of the coelomic mesothelium parallel to the mesonephric ducts during the second month of gestation. The caudal ends (which form the uterus and vagina) fuse in the midline and join the urogenital sinus. The distal portion of the fused Müllerian ducts is temporarily completely occluded by a solid cord of cells, the Müllerian tubercle, the caudal end of which becomes the hymen. Failure of degeneration of the epithelial plate in the Müllerian tubercle results in imperforate hymen, and persistence of a portion of the solid cord of cells in the fused Müllerian ducts above this level results in atresia of the vagina. A transverse septum of the vagina might result from incomplete coalescence of the vacuoles that develop as the epithelial cord begins to degenerate.

ETIOPATHOGENESIS

The condition occurs at the two extremes of childhood – in the neonatal period, when there is a high level of maternal hormones, and in early puberty, when the patient herself begins to produce estrogenic hormones. The reason being that for hydrometrocolpos to develop there should be both an accumulation of excessive fluid in the female genital tract due to estrogenic stimulation, as well as vaginal obstruction. Thus, if there is a low level of maternal hormones in the presence of vaginal obstruction, the obstruction remains unnoticed until puberty and presents as hematocolpos at the time of the menarche. The common causes of distal vaginal obstruction are imperforate hymen, transverse vaginal septum, and vaginal atresia with or without persistence of a urogenital sinus or cloaca. The distal vaginal outflow obstruction is usually imperforate hymen (60–70%) that forms a thin translucent membrane bulging between the

labia. Atresia of the vagina is the next common cause. These anomalies may result from either a local error of development or as an inherited disorder, e.g. McKusick–Kaufman syndrome.

TYPES

Secretory

This is the most common type, consisting of mucoid material secreted mainly by the cervical part of uterine glands in response to maternal estrogenic hormones, mainly due to prenatal stimulation. The fluid is viscid, pearly gray in color, and may accumulate even up to one liter in volume. The retained fluid is usually acidic and serous or mucoid with large numbers of desquamated epithelial cells and leukocytes.

Urinary

In urinary hydrometrocolpos, urine collects in the vagina as a backwash during the act of micturition, although there is no complete distal vaginal mechanical obstruction. This is usually in association with urogenital sinus or cloaca. The size of the communication varies. It is usually valvular, allowing only one way flow of urine to the vagina.

The terms 'hematometrocolpos' and 'pyometrocolpos' are used for presence of blood or pus.[10] The collected fluid in the vagina often become infected very soon, resulting in pyometrocolpos. As the obstruction gets established, there is pyosalpinx and even peritonitis.

CLASSIFICATION

On the basis of the level of obstruction and the association with urogenital sinus (UGS) or cloaca, hydrometrocolpos has been classified into five types (Fig. 101.1).[5]

- I Low hymenal obstruction
- II Mid-plane transverse membrane or septum at the level of lower one-third and upper two-thirds of the vagina
- III IIIa, high obstruction with distal vaginal atresia; at the level of upper one-third and lower two-thirds of the vagina
  IIIb, high obstruction with distal vaginal atresia and gluteal swelling
- IV Vaginal atresia with persistence of the UGS
- V Vaginal atresia with cloacal anomaly

ASSOCIATED ANOMALIES

Almost 50% of newborns with hydrometrocolpos have associated anomalies. A large number of these are delivered as stillborns. Rare variants may be seen with fused labia or ipsilateral hydrometrocolpos in patients with uterus didelphys and septate vagina.[11] It may be associated with congenital heart disease, genitourinary and gastrointestinal anomalies.

Associated gastrointestinal anomalies include anorectal malformation, esophageal atresia, duodenal atresia, paraesophageal hiatus hernia, and congenital intestinal aganglionosis.[12] Associated genitourinary anomalies are most common and most serious. These include bicornate uterus and double

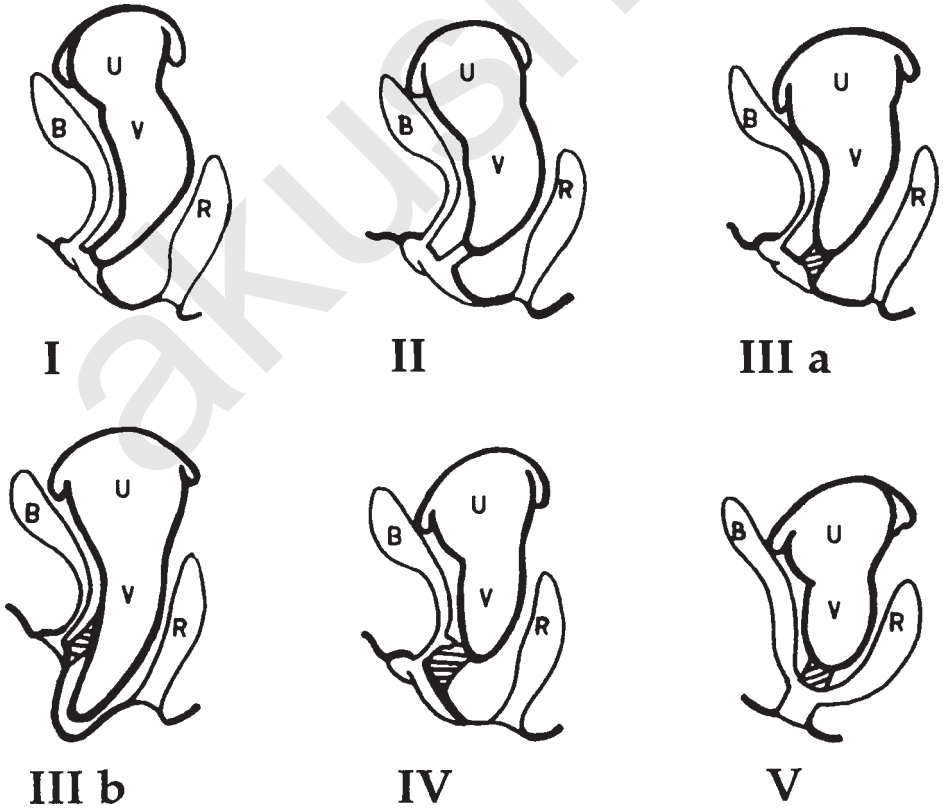

Figure 101.1 Classification of hydrometrocolpos.

vagina, duplication of the uterus and vagina, bifid clitoris, congenital urethral membrane, double ureter, ureteral stenosis, urethral atresia, absence of vulva, renal agenesis, and ambiguous genitalia.[13] Rare associations include Müllerian dysgenesis syndrome, staphyloma of the left eye, and severe hydrops.[14–16] Other additional findings include vertebral segmentation anomalies, lung hypoplasia, corpus callosum hypoplasia, and single umbilical artery.[17]

Patients with multiple congenital anomalies have a bad prognosis, thus awareness about associated anomalies is necessary for proper diagnosis and treatment.[18]

SYNDROMIC ASSOCIATIONS

Hydrometrocolpos may be associated with inherited disorders, such as McKusick–Kaufman syndrome (MKKS) and Bardet–Biedl syndrome (BBS).[19,20]

McKusick–Kaufman syndrome

This is a rare, autosomal recessive disorder characterized by dysmorphic features, hydrometrocolpos, post-axial polydactyly, and congenital heart disease and less often urinary and gastrointestinal anomalies. Fewer than 100 cases had been reported in the English literature until 2005, mainly in the Amish population.[21] McKusick–Kaufman syndrome is difficult to diagnose prenatally and requires postnatal phenotyping and molecular studies before a definitive diagnosis can be established.[22]

Bardet–Biedl syndrome

This is an autosomal recessive multisystemic disorder characterized by a combination of primary and secondary clinical features that include retinal dystrophy or retinitis pigmentosa (appearing usually between 10 and 20 years of age), post-axial polydactyly, obesity, nephropathy, and mental disturbances, or, occasionally, mental retardation. The phenotypic overlap of Bardet–Biedl syndrome and McKusick–Kaufman syndrome, both autosomal recessive syndromes, including hydrometrocolpos and post-axial polydactyly in the neonatal stage and this may cause diagnostic confusion initially.[23]

The presentation of Bardet–Biedl syndrome in an adolescent, 13-year-old girl with retinitis pigmentosa, obesity, polydactyly, learning disabilities, precocious puberty, hypertension, renal cysts, and Hirschprung's disease has been reported.[24] Based on the frequent association of Bardet–Biedl syndrome with hydrometrocolpos and also the recent findings in some mouse models of BBS, it has been suggested that hydrometrocolpos may be considered as an additional diagnostic criterion for BBS to be used in females in parallel with the criterion of hypogonadism in males, thereby improving diagnostic sensitivity.[24]

Typically, MKKS is diagnosed in very young children, whereas the diagnosis of BBS is often delayed to the teenage years. A series of nine patients diagnosed in infancy with MKKS because of the presence of vaginal atresia and post-axial polydactyly, who later developed obesity and retinal dystrophy, thus turning out to be instances of BBS has been reported.[20] Thus, some authors recommended that all children seen in infancy with a diagnosis of MKKS be re-evaluated for other signs of BBS, including mental retardation, obesity, and retinitis pigmentosa.[20,23] MKKS may be considered as a variant of BBS.[23] It has been postulated that mutations in MKKS cause Bardet–Biedl syndrome.[25]

In the inherited type of hydrometrocolpos, obstruction is mainly due to transverse vaginal septum or vaginal atresia, without a urogenital sinus.

ANTENATAL DIAGNOSIS

In recent years, prenatal diagnosis has been made possible by routine antenatal ultrasound scan.[26,27] Antenatal hydrometrocolpos may be associated with oligohydramnios. It may be initially misdiagnosed as a large bladder, representing the dilated proximal vagina.[17] Ultrasonographic findings include a large retrovesical septate hypoechogenic mass in the fetal abdomen. Fetal female urogenital anomalies are often difficult to evaluate by ultrasonography, especially in late gestation. However, when sonographic findings are inconclusive, magnetic resonance imaging (MRI) is a useful complementary tool for assessing fetal urogenital anomalies. It has been useful to diagnose a hydrometrocolpos with septate vagina and uterus didelphys.[7]

CLINICAL FEATURES

The condition has two peaks: during the neonatal period and around puberty.

Neonatal period

About 80% of the cases present at less than three months age. The newborn female infant under the effect of maternal hormones, in addition to having enlargement of the breasts, usually displays swollen vulva and a slight mucoid leukorrhea with a low pH and many Doederlein's bacilli. The vagina has thick, stratified squamous epithelium consisting of an active basal layer and 20–30 layers of large vacuolated cells containing abundant glycogen. By the age of one month, the vaginal secretion becomes scanty and alkaline. The epithelium is thin, the individual cells are small and devoid of glycogen, and the basal layer comparatively inactive.

Rarely, hematocolpos will develop in the newborn infant with estrogen-withdrawal bleeding from the uterus. Secondary infection of the vaginal fluid, usually with colonic organisms like *Escherichia coli* is not uncommon.

The typical presentation in a neonate is as a surgical emergency with lower midline mass, associated with abdominal distension. The female baby is usually sick due to the

gross distension. The upper vagina becomes enormously distended, usually producing a palpable abdominal mass arising from the pelvis. The uterus, with its less distensible and thick muscular wall, is involved to a lesser degree, but is always larger than normal. Examination of the abdomen reveals a tensely cystic, rounded mass arising from the pelvis and occasionally reaching as high as the costal margin. The tumor may seem lobulated because of the distended bladder anteriorly and the moderately enlarged uterus surmounting the vagina. The Fallopian tubes are usually normal, although occasionally they may be distended, even allowing escape of fluid into the peritoneum. Quite often, the fluid gets infected very soon with life-threatening generalized sepsis.

Compression of adjacent structures may cause acute respiratory distress that becomes life threatening. The patient may also have respiratory infection, neonatal sepsis, and fever.

Extensive squamous cell peritonitis has been described to result from vaginal atresia with hydrometrocolpos and squamous cell reflux through the genital system.[17]

Associated features include urinary retention with obstructive uropathy causing scanty and infrequent urination. The upward pull of the enlarging vagina elongates and angulates the urethra, producing dysuria and acute urinary retention. Pressure of the vagina on the ureters crossing the pelvic brim results in hydronephrosis and hydroureter, usually on both sides. Even low lesions may present with urinary retention and bilateral hydronephrosis. However, bilateral hydrosalpinx is extremely rare in the neonatal period.[28]

Besides abdominal distension and sepsis, renal failure is also a common presentation in hydrometrocolpos.[18,29] In addition, there may be presence of abdominal ascites.[29] Compression of the vena cava and iliac vessels will cause cyanosis, edema, and ecchymosis of the perineum, lower extremities and abdominal wall.

The rectum is less commonly involved, but constipation, ribbon stools, and intestinal obstruction may complicate hydrometrocolpos. The perineal examination in lithotomy position under adequate illumination may help to identify a bulging hymenal membrane. Rectal examination reveals the pelvic component of the mass. The translucent bulge of an imperforate hymen will be seen to increase in size when the infant cries or when pressure is exerted on the abdominal mass. In vaginal atresia, the upward pull of the enlarging vagina rising out of the pelvis may retract the atretic lower portion of the vagina up into the pelvis and make the examination difficult. If a major portion of the vagina is absent, the external genitalia may seem quite normal, and the diagnosis will be missed unless the vaginal orifice is deliberately looked for.

In some cases, a transverse septum higher in the vagina will be seen to protrude through a normally perforated hymen, apparently representing a congenital diaphragm. In the absence of clearly demonstrable patency of the vagina, the mass should be considered to be vagina until proven otherwise.[9]

In atresia of the vagina, the appearance of the external genitalia differs markedly from that seen with imperforate hymen. Instead of a bulging membrane protruding from the labia, with unusual prominence of the vulva and perineum, the area normally occupied by the vaginal orifice may be retracted upward into the pelvis, as a result of the enlarging upper vagina escaping from the small pelvis into the more capacious abdominal cavity. Rarely, the abdominal mass may be quite large and associated with gluteal swellings or acute abdomen with paralytic ileus.

In McKusick–Kaufman syndrome, hydrometrocolpos is always associated with post-axial polydactyly and less often congenital heart disease, and urinary and gastrointestinal anomalies.

For obstruction at a higher level, identification and probing of perineal orifices, endoscopy, and radiological studies are essential. When three perineal orifices are present, it is a type II anomaly; with two orifices it is type III or IV; and with one orifice it is type V. Type IIIb will have cystic gluteal bulge. In type II anomaly, there is mild depression at the vaginal site with a small orifice, which can be dilated. Types III and IV can be differentiated by endoscopy and radiological studies.

Around puberty

Rare cases presenting in the prepubertal group from 12 to 15 years may present with complications like leukorrhea through a pinpoint opening in the hymen. In asymptomatic hydrometrocolpos, the diagnosis is made only after accidental discovery of a bulging membrane. The early symptoms attributed to this condition are non-specific indications of discomfort followed by urinary, venous, or intestinal obstruction, respiratory distress, or superimposed infection of the urinary tract or of the fluid retained in the vagina.

Adolescent patients may present with abdominal pain, voiding dysfunctions, and backache.[30] Adults may present with the inability to consummate and infertility.[30]

DIFFERENTIAL DIAGNOSIS

These include congenital, inflammatory, or neoplastic cyst. The mass has also been confused with a presacral mass, such as a sacrococcygeal teratoma, rectosigmoid duplications, or an abdominal mass, such as ovarian cyst or teratoma. When the diagnosis is in doubt, exploratory laparotomy gives the definitive diagnosis.

INVESTIGATIONS

In addition to routine investigations, special preoperative investigations are necessary to differentiate hydrometrocolpos from other neonatal pelvic masses and also to confirm the type of hydrometrocolpos and plan surgery.

These include:

1. Plain skiagram abdomen – anteroposterior view and lateral view to identify the location and size of mass. The small intestinal loops will be displaced into the epigastrium by a rounded homogenous mass in the lower abdomen. Neonatal peritoneal calcifications along with the ascites have also been described in cases of hydrometrocolpos secondary to imperforate hymen, without evidence of gastrointestinal tract obstruction.[31]

2. Abdominal ultrasonography to identify dilated vagina and upper urinary tract anomalies, especially ipsilateral renal agenesis. Transperineal ultrasonography can help to measure a caudally placed obstructive septum in vaginal atresia and thereby help in planning reconstructive surgery. Ultrasonography after drainage of the bladder with a catheter may help in the diagnosis of hydrometrocolpos.
3. Retrograde genitourethrogram (RGU) to identify the urogenital sinus and its communication with the vagina (Fig. 101.2). This may be combined with a hysterovaginogram to delineate the site of vaginal obstruction. When a bulging membrane can be visualized clearly, aspiration of some of the contained fluid and injection of a water-soluble radioopaque material will outline the distended vagina and uterus.
4. Endoscopic evaluation of vaginal, urethral (type III, IV) and rectal orifices (in type V) is needed in addition to radiological procedures to give a composite and accurate picture. Endoscopic catheterization of vaginal and urethral orifices in urogenital sinus and vaginal, urethral, and rectal orifices in cloacal anomaly is indicated in order to establish the internal anatomy by contrast studies. An invertogram may be of help to identify a rectovaginal fistula in cloacal anomaly.
5. Skiagram spine to assess vertebral anomalies and digital skiagrams in the presence of digital or syndromal anomalies.
6. Echocardiogram to rule out cardiac anomalies.
7. Chromosomal anomalies may be needed rarely in cases of ambiguous genitalia to establish the genotype.
8. Intravenous urography (IVU) and computed tomography help to delineate the anatomical details to assess the anatomy while planning corrective surgery. The urogram will demonstrate anterior and superior displacement of the bladder and, possibly, hydronephrosis and hydroureter.
9. Renogram studies confirm the function of each kidney and its clearance.

Urinary hydrometrocolpos is rarely diagnosed and is most often attributed to a persistent urogenital sinus or a cloaca.

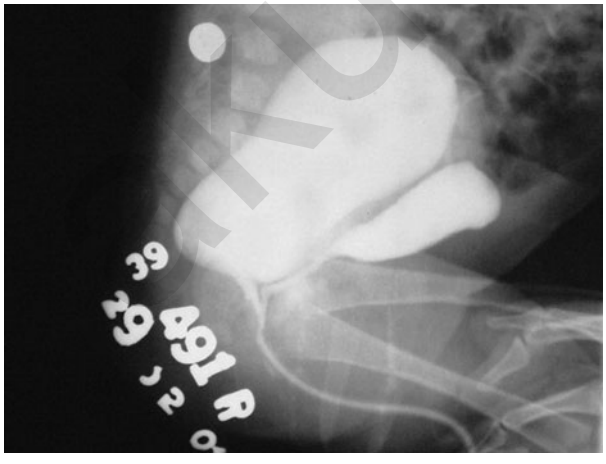

Figure 101.2 Retrograde genitourethrogram of a baby with hydrometrocolpos and anorectal malformation (pouch colon). A faint shadow of pouch colon opening in the vaginal septum (bifid vagina) can be seen. The outline of the urinary bladder with urethra anteriorly and hydrometrocolpos with bifid vagina posteriorly along with the urogenital sinus with 3 cm common channel can be appreciated.

Dynamic MRI has also been reported to accurately diagnose urinary hydrometrocolpos secondary to ectopic drainage of a small left pelvic kidney, associated with a bicornuate uterus.[32]

MANAGEMENT

The treatment of hydrometrocolpos is surgery. The kind of operative procedure and the timing of surgical intervention needed depends upon the severity of the condition and the age at presentation. Early surgery may be indicated in the neonatal period when a grossly distended hydrometrocolpos presents with bulging hymen or is associated with complications. Laparotomy is indicated for high vaginal obstruction, treatment of abdominal complications, or associated anomalies.

Timing of surgery

The management depends on the age at presentation, severity of the symptoms, and the type of the anomaly. The timing of the definitive surgery is a controversial issue.

In the authors' experience, during an acute stage with fluid infection, the baby needs resuscitation and stabilization. A temporizing procedure, such as aspiration of the turbid infected fluid or a vaginostomy in the neonatal period, will help tide over the crisis, enable definitive diagnosis with appropriate investigations, and plan the definitive management in future. Also, it is not feasible to proceed with a raft of investigations in a sick child in order to define the anatomy and withhold the urgent decompression needed. A percutaneous nephrostomy may be needed in patients with bilateral hydroureteronephrosis and uremia.

A definite protocol, awareness, and appropriate investigations with urgency before surgery are necessary and can avoid fatal complications (Fig. 101.3).

Some authors have suggested postponing the definite procedure to the age of menarche, when hematocolpos (accumulation of blood in the vagina) will develop, but before the further development of hematometra (accumulation of blood in the uterine cavity).[33] This will cause stretching of the obstructed segment, will enable correct diagnosis, facilitate the procedure, and eventually minimize the complications. However, they have suggested that if the vaginal obstruction in neonates or in childhood is symptomatic, aspiration of the fluid and temporary release of the symptoms should be the optimal choice, followed by a final surgical correction latter in life.[33]

PREOPERATIVE RESUSCITATION

Patients presenting with complications should be given incubator care with head-end elevated, systemic antibiotics, and i.v. fluid. In the case of respiratory distress, prompt decompression of the gastrointestinal tract by nasogastric aspiration and administration of oxygen and humidity is indicated. If vomiting is present with or without constipation, in addition to nasogastric decompression, fluid and electrolyte imbalance should be assessed and corrected. When

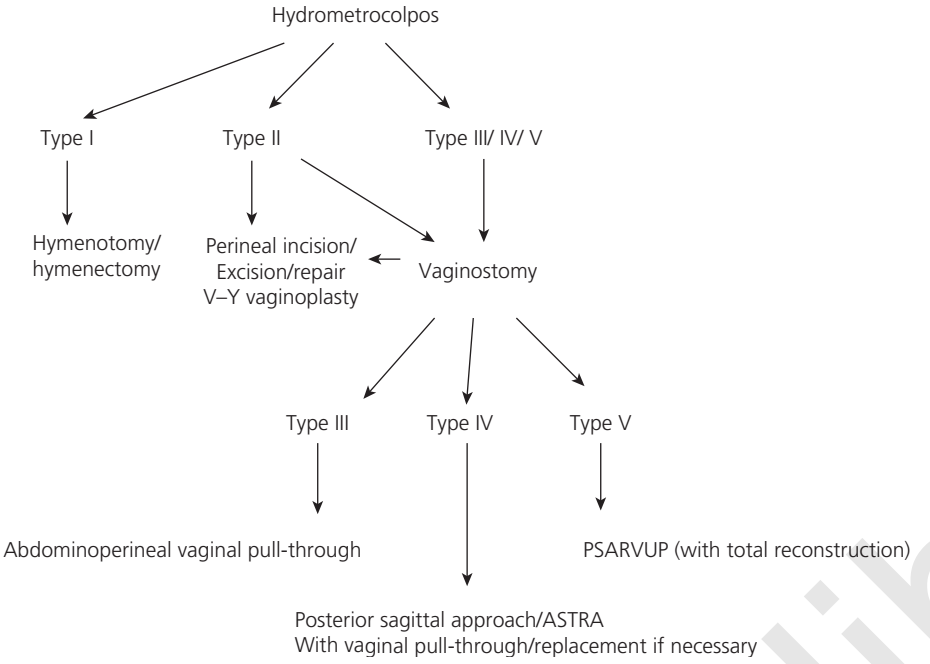

Figure 101.3 Algorithm for management of hydrometrocolpos. Vaginostomy is indicated for all cases with pyometrocolpos to drain out the pus (from the perineal or abdominal route) and improve the general condition of the baby.

dribbling or retention of urine is present, a Foley catheter should be inserted into the bladder for better drainage of urine. When huge distended abdominal mass is present in the actually ill neonate, a preliminary drainage by puncturing the vagina under ultrasonographic guidance may be performed for 24–28 hours prior to corrective surgery. Where experience is available, vaginal septum (type II anomaly) can be incised safely under ultrasonic guidance and x-ray imaging.

SURGICAL MANAGEMENT

The management options may be divided into emergency management and definitive management.

Emergency management

The management is simple with low anomalies (type I and II). However, the patients with type III, IV, and V are usually obstructed and infected. In complicated cases, the attempt should be to drain the infected material through the suprapubic vaginostomy and allow the dilated vagina to shrink. This is followed by a definitive procedure years later (staged procedure). All previous attempts to drain and simultaneously reconstruct the vaginal tract in the newborn stage carried very high mortality and it is not currently recommended.

In the presence of fused labia or adhesion, separation of adhesion followed by vaginal drainage is adequate. In others, it is a temporizing procedure and can be achieved by drainage into the perineum.

DRAINAGE PROCEDURE

Indications for early drainage in neonates

- To drain the infected material and reduce the chance of sepsis;
- To disconnect the communication and retrograde flow of urine to the vagina;
- To allow the inflamed vagina and uterus to shrink and occupy near normal anatomical positions and size to allow planning of definitive surgery.

Indications for early drainage in prepubertal age

- To allow natural passage for menstrual flow;
- To allow creation of passage for future sexual activity and fertility;
- Psychosocial reasons.

The drainage procedure through the perineum may be the only definitive treatment required in type I and II, while drainage provided through the abdominal route (extraperitoneal) will be a temporizing procedure in the other types. The majority of type I and II patients may be managed by vaginal drainage on to the perineum. Sometimes, however, in type II anomaly, due to secondary infection or complex anomalies, a perineal procedure may be deferred and these babies may need suprapubic drainage by catheter or a vaginostomy. The proximal diversion stoma helps not only in decompressing the vagina, but also provides a portal for detailed radiographic studies to delineate the anatomy. If the atretic lower portion of the vagina has been retracted up into the pelvis, it may be desirable to open the vagina through a laparotomy incision to avoid damage to the urethra, bladder, and rectum.

HYMENOTOMY/HYMENECTOMY

A bulging membrane in an infant with imperforate hymen or transverse septum of the vagina may be incised without anesthesia. If the hymen is thickened, the obstruction recurrent, or the patient an adolescent, excision is probably preferable. Hymenotomy may resolve the laboratory and

clinical abnormalities of a patient with hydrometrocolpos due to imperforate hymen presenting as acute renal failure.[34] In all cases, it is desirable to maintain patency of the opening by use of a drain and/or repeated dilatation.

In the lithotomy position, the bulging hymen becomes visible as a grayish membrane. If necessary, the abdomen may be compressed to make the hymen more prominent. A No. 8 Foley catheter is inserted into the bladder to decompress it, as well as for the identification of the urethra during surgery. A stay suture is placed at the center of the hymen and, with a No. 18 needle, an amount of fluid is aspirated and sent for microscopic examination and culture. A circular hymenal segment is excised using a No. 11 blade (Fig. 101.4). The cut margin is oversewn with vertical mattress sutures, and a soft silastic catheter is inserted into the vagina. A skiagram is taken while injecting contrast in order to delineate the internal anatomy. The vagina should be drained for a couple of days. This procedure is simple and can be performed at the bedside in a sick baby in the intensive care unit after assessing the depth with a needle puncture and ultrasonography. In case of doubt, the procedure may be safely performed in the operating room through the abdominal route after performing a dye study. A finger may be put through the vaginostomy as a guide to remove a disk of the septum which may be thick. The edges are then oversewn and a drain placed. In the postoperative period, suitable parenteral antibiotics should be given for 1 week to 10 days.

Vaginostomy

A vaginostomy may serve as a temporizing drainage procedure for cases with infected fluid:

- **Perineal vaginostomy** may be done through the perineal route in type II after needle aspiration. When a low transverse, vaginal septum is present, it presents as a bulging membrane allowing excision and drainage by the perineal route (Fig. 101.5a).
- **Abdominal vaginostomy**. In some patients with type II anomaly, the patients may have a minute opening at the site of the vaginal orifice in the septum (Fig. 101.5b). In a case with well-formed septum, it may be prudent to drain the vagina by a laparotomy approach. If the septum is 1 cm thick, it is wiser to drain the vagina from above by laparotomy and then incise the septum under direct vision after defining the anatomy, in order to prevent injury to the urethra and rectum during dissection.

For the high types (type III, IV, and V), an abdominal route is used for the vaginostomy. Abdominal vaginostomy may be of two types:

1. **Vaginostomy with indwelling catheter**: It is easy to perform. However, the disadvantages include infection, encrustation, need to keep the tube *in situ* causing social nuisance, inconvenience, and requiring frequent changings.

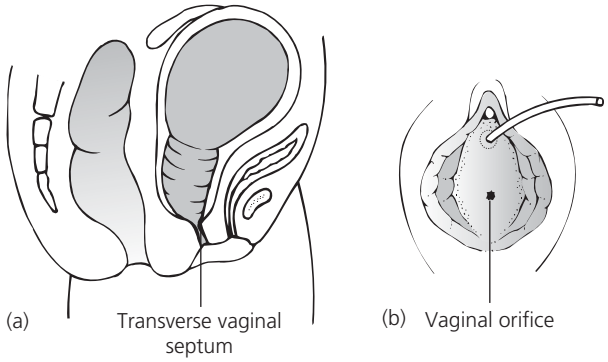

Figure 101.5 Type II hydrometrocolpos. (a) Transverse vaginal septum; (b) minute vaginal orifice.

2. **Tubed vaginostomy**: In this procedure, a U-shaped flap of the vagina is used to make a tube that provides a natural tract for effective drainage for long as necessary, until the time of definitive surgery (Fig. 101.6). A tubed vaginostomy avoids the use of any indwelling catheter and, at the same time, provides easy access for performing dye studies to outline the pathological anatomy of the cavity.[35]

COLOSTOMY

Cases of type V with associated common cloaca always require a diverting 'transverse' colostomy in the newborn stage. This is to be performed in a manner so as to preserve the sigmoid bowel for future use for vaginal replacement. Thus, a transverse colostomy is recommended in babies born with common cloaca.

Definitive management

In types III, IV, and V, the initial vaginostomy is followed by the definitive procedure. An early definitive surgery, around

Figure 101.6 *Continued*

one to two years of age, is indicated in cases with type IV and V as division of the fistulous communication is essential to decrease the morbidity associated with repeated infections. Cases of type III may be tackled at puberty.

After vaginostomy, the dilated vagina with infected material is flooded with urine making it very friable and adherent to the surrounding structures. Any attempt to mobilize and bring the vagina to the perineum may not be successful especially if the gap is >3 cm. Vaginal replacement will be the only option in such cases.

In type III, following initial vaginostomy and drainage, during the definitive procedure, the vagina is exteriorized on to the perineum by an abdominoperineal pull-through (Fig. 101.7).

In type IV, during the definitive procedure, the vagina is exteriorized on to the perineum and the urogenital sinus is left behind to function as the urethra. If the length of the common channel is less than 3 cm, posterior sagittal anorectovaginourethroplasty (PSARVUP) with disconnection of the fistula is performed, followed by mobilization and vaginal pull-through.

If the length of the urogenital sinus in type IV is more than 3 cm, then vaginal replacement would be required in most cases. The common channel in type V is usually more than 3 cm mandating a vaginal replacement.

An anterior sagittal transanorectal approach (ASTRA) in cases of neonatal urinary hydrometrocolpos associated with a persistent urogenital sinus (type IV) has also been described, although not widely practiced.[36]

In the cloacal anomaly (type V), the hydrometrocolpos may be secretory or urinary. In this condition, it is more

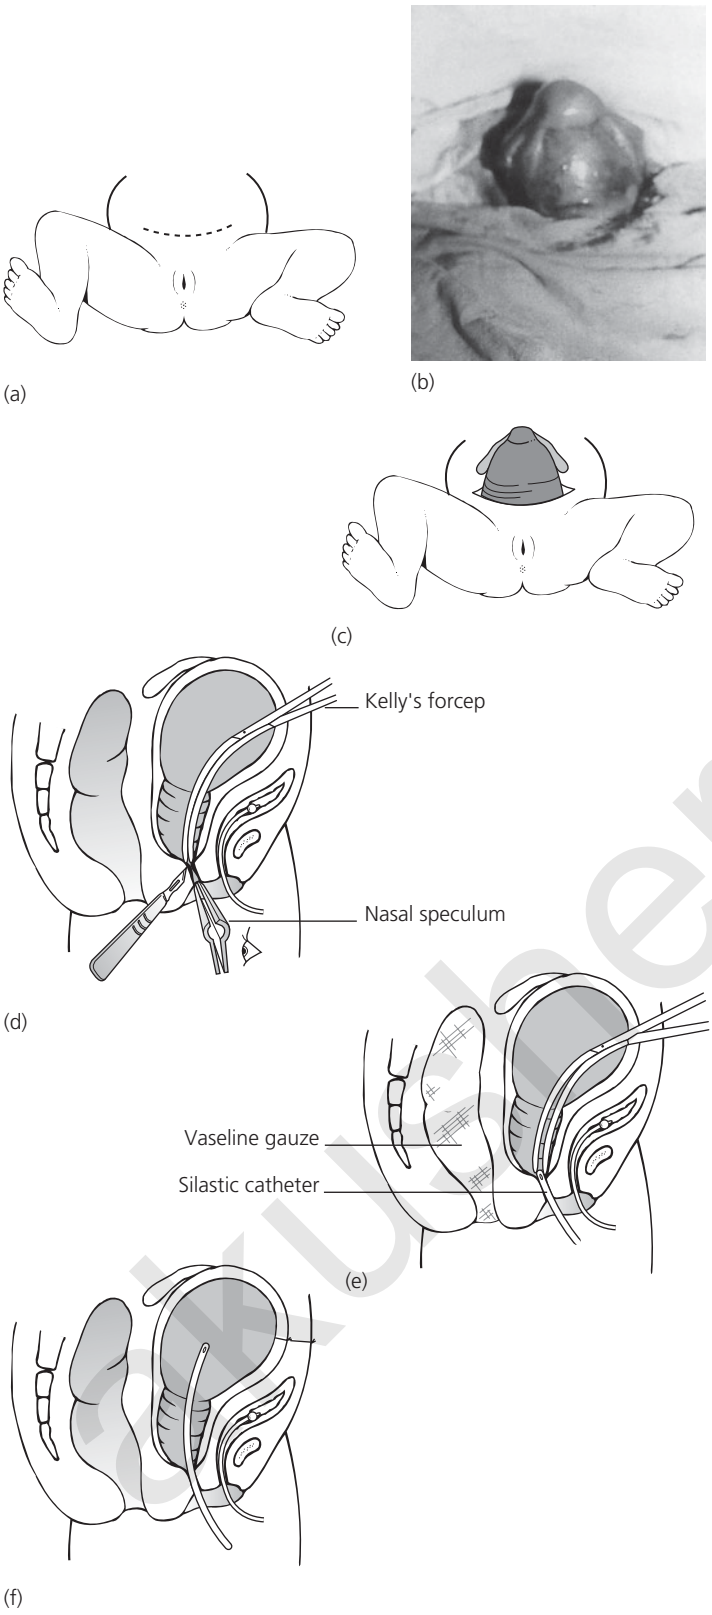

Figure 101.7 Abdominoperineal repair of type II hydrometrocolpos. (a) Low transverse abdominal incision; (b) hydrometrocolpos delivered from abdominal wound; (c) purse-string suture on vaginal wall; (d) Kelly's forcep introduced through the hysterotomy and tip advanced to the most dependent part of the dilated vagina; (e) vaginal septum is being incised while the vaginal orifice is spread open by the nasal speculum and the septum is pushed downwards by Kelly's forcep – the septum is incised and Kelly's forcep pushed down and out, grasping the tip of the Silastic catheter; (f) vagina being drained by an indwelling perineal catheter.

acceptable to perform a temporizing drainage procedure and then do the pull-through via the posterior sagittal route.[37] This route is also preferable for all cases with associated anorectal malformation, after the initial vaginostomy and colostomy (Fig. 101.2b). The vagina may occasionally open to the bladder with a small orifice.[38] Vaginal pull-through surgery and closure of the communication may be required for a vagina occasionally opening into the bladder.[38] The posterior sagittal route is the only option to reach the fistulous communication in such cases.

VAGINAL REPLACEMENT

In cases with type III, IV, and V especially with pyometrocolpos, due to severe inflammation, it may be difficult to separate it from the surrounding structures due to dense adhesions. Despite attempted mobilization, the vaginal length is just not achieved. In such situations, it would be better to replace the vagina using a segment of the bowel.

- **Bowel vaginoplasty**. A loop of sigmoid colon is usually used. Another option is an ileal loop.
- **Skin flap**. Flaps of perineal skin may be used to form the distal vaginal segment.
- **Prosthesis with skin graft**. A skin graft may be put on a prosthetic patch in a cylindrical form to form the vagina. Expertise is needed to perform such surgery. This kind of a replacement is better performed at puberty or before marriage as these are prone to shrinkage unless kept under reglar dilatation.
- **Buccal mucosa graft**. A buccal mucosa graft can be made in a mesh and used for vaginal replacement. However, it shrinks over the course of time and results in fibrosis in almost 60% of cases unless kept under regular dilatation.

MORTALITY

The main causes of mortality are associated anomalies and sepsis. As hydrometrocolpos is associated with serious anomalies, about 50% cases are stillborn. Associated genitourinary anomalies in more than half the cases with hydrometrocolpos are responsible for high morbidity and mortality in this entity. Other causes of mortality include inadequate drainage, urinary infection, spontaneous rupture, generalized peritonitis, and obstructive uropathy due to the large pelvic mass resulting in obstruction to ureters.

FOLLOW UP

If methods like skin flaps, skin grafts, or meshes have been used for vaginal replacement, vaginal calibration and dilatation is required as the chances of stenosis are high, especially if performed at an early age. On follow up (range 1–15 years; mean 7 years), more than 60% of patients have menstrual irregularity, endometriosis, and infertility. A comprehensive management is imperative to preserve the reproductive potentials, as a significant proportion of patients may experience sexual difficulties following vaginal reconstruction.[30]

Intersex disorders

MARIA MARCELA BAILEZ AND ESTELA CUENCA

INTRODUCTION

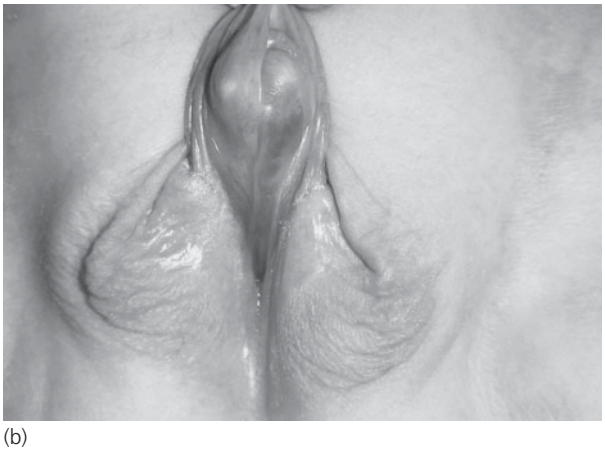
Patients with ambiguous genitalia mostly present in the newborn period and require a multidisciplinary team, including a pediatric surgeon/urologist, to assign the sex of rearing as soon as possible after a thorough genetic, anatomic, functional, and socioeconomic workup.

The diagnosis of 'ambiguous genitalia' is based on a meticulous perineal exam and gonadal palpation. Feminine phenotype presents a normal looking clitoris and no palpable gonads, while masculine phenotype presents a normal looking penis and two scrotal testicles.

Although exceptions to this pattern occur (for example, a female with an inguinal hernia or a male with a mild hypospadias or an undescended testicle), if a combined abnormal gonadal palpation and external genitalia appearance are detected, sexual ambiguity should be studied. Isolated severe defects, such as a perineal hypospadias or bilateral non-palpable gonads in a patient with a normal-looking phallus, should also be investigated (Fig. 102.1a, b and Fig. 102.2).

Occasionally, patients with previously unrecognized disorders of sex development (DSD) present later in infancy or puberty.

(a)



(b)

Figure 102.1 (a) A newborn with bilateral non-palpable gonads, but a normal looking phallus. Classic hyperpigmentation seen in congenital adrenal hyperplasia patients before treatment (b), with severe defects like a perineal hypospadias and bilateral non-palpable gonads.

ETIOLOGY

Sex differentiation refers to the anatomic development of the internal and external genitalia as male or female, dependent on the presence or absence of functioning androgens. Prenatally, genital development is constitutively female and non-dependent on estrogens. In contrast, male sex differentiation is androgen-dependent and requires optimal ligand activation of the androgen receptor.

Gonad development

Nineteen years have passed since the discovery of *Sry* as the primary testis-determining gene in Koopman *et al.*'s classic experiment showing that transgenic expression of *Sry* in XX mice results in testis development and male phenotype.[1] Studies in mice are continuing to provide exciting information about differential structural changes and gene expression

Figure 102.2 Sexual ambiguity should be studied in a patient with combined abnormal gonadal palpation and external genitalia appearance.

in normal gonad development (testis versus ovary), as well as the effect of targeted deletion of key genes involved in this process. WT1, SF1, SOX9, DHH, DMRT, SIDDT, and ARX are some of the genetic determinants of normal gonad development and gonadal dysgenesis.

Androgens

The production of androgens by fetal Leydig cells is initially gonadotrophin independent. During the first half of gestation, placental human chorionic gonadotropin (hCG) ensures that high concentrations of androgens stabilize Wolffian duct development and differentiation of the external genital anlage. Wolffian duct stabilization is dependent on high local concentrations of testosterone diffusing in a gradient along the duct from the adjacent ipsilateral gonad. This accounts for the asymmetric development of Wolffian ducts in some DSD.

The androgen receptor (AR) is a transcription factor that mediates male sexual differentiation *in utero* and is responsible for the development and maintenance of male sexual characteristics. The AR gene is located on the X-chromosome. Mutations in the AR gene may lead to diseases such as androgen insensitivity syndrome (AIS). In AIS, gonadal males had a spectrum of abnormalities ranging from individuals with a female phenotype (complete androgen insensitivity syndrome (CAIS)) through genital ambiguities in the partial form (partial androgen insensitivity syndrome (PAIS)) to men with fertility disturbances in minimal AIS (minimal androgen insensitivity syndrome (MAIS)). More than 500 mutations have now been documented in AIS.

In summary, circulating testosterone is responsible for virilization and is dependent upon 5-alpha-reductase (transforms testosterone into dihydrotestosterone) and the presence of appropriate receptors.

Anti-Müllerian hormone

The pre-Sertoli cells secrete a glycoprotein hormone – the anti-Müllerian hormone (AMH). It causes involution of the Müllerian ducts and stimulates the Leydig cells to produce testosterone. It is also responsible for the first stage of testicular descent. The AMH receptor is different from the AR. Persistent Müllerian structures in 46,XY DSD patients may be due to failure of the production of the hormone from the testes (50%) or to receptor deficiency.

Steroids

Problems in the early stages of steroid genesis can result in abnormalities of adrenal steroid synthesis, which may result in external virilization of a gonadal female-like congenital adrenal hyperplasia (CAH) or under-androgenization of the 46,XY fetus.

The 21-hydroxylase is encoded by a gene on chromosome 6. Its deficiency is inherited in an autosomal recessive fashion. Tremendous progress has been made in the past 15 years in understanding the role of mutation of factors involved in the steroid genesis process (e.g. STAR, CYP11A, HSD3B2, CYP17).

Considerably more research is needed to be able to translate this new knowledge into effective patient care and to understand the long-term outcome in specific conditions.

HISTORY

The term 'hermaphrodite' describes a person who has simultaneous male and female attributes. The term has its origin in Greek mythology: son of Hermes and Afrodita, *Hermafrodito*. The nymph Salmacis was rebuffed by him and she pleaded to the gods to unite him in one body. The gods complied, and from that time on Hermaphrodito had both male and female sex organs.

Oriental and Greek civilizations thought of hermaphrodites as superhuman and included them in much of their art. Plato, Aristotle, Galen, and Hippocrates were among many early physicians and philosophers whose hypotheses on the origin of the intersex child were based on natural phenomena**.** This is in marked contrast to the Romans, who saw the birth of such children as an evil omen, and promptly destroyed them by drowning or abandoning them in an open field to die.

Advances in identification of the molecular genetic causes of abnormal sex with a heightened awareness of ethical issues and patient advocacy concerns necessitate a re-examination of nomenclature. Terms such as 'intersex', 'pseudohermaphroditism', 'hermaphroditism', 'sex reversal', and gender-based diagnostic labels are particularly controversial. These terms are perceived as potentially pejorative by patients and can be confusing to practitioners and parents alike. The consensus

statement on management of intersex disorders proposes the term 'disorders of sex development', as defined by congenital conditions in which development of chromosomal, gonadal, or anatomic sex is atypical.

PHYSICAL EXAMINATION

External genitalia examination includes gonadal palpation and perineal exam; both are the key to choose the sequence of diagnostic procedures to reach an etiologic diagnosis. Visualization of both faces of the phallus is important, looking for the urethral orifice, defining its localization and aspect. The other diagnostic key is inguinal and perineal palpation looking for gonads. Each patient needs to be considered on an individual basis.

PRESENTATION

Traditionally, DSD patients were classified into three groups based on gonadal structure:

1. The presence of two well-defined ovaries with ambiguous or male external genitalia (female pseudohermaphroditism; now called overvirilized XX female). These patients have a 46,XX karyotype and virilization of the external genitalia which results from exposure to a high level of androgens *in utero*, while they have female internal genitalia. CAH is the most common disease in this group and accounts for 50–80% of all the cases of ambiguity, depending on the population analyzed. The most common enzymatic defect is 21-hydroxylase deficiency. The incidence of 21-hydroxylase deficiency is 1 in 15000 to 40000 newborns. Other defects are 11-hydroxylase (hypertension) and 3(β)-ol dehydrogenase or aromatase.
2. The presence of two well-defined testicles with ambiguous or female external genitalia (male pseudohermaphroditism, now called undervirilized XY male). These patients have a 46,XY karyotype and ambiguity of the external genitalia results from a failure of the masculinization androgenic action of the male fetus. This can be due to a failure in androgenic synthesis or in the biological response. This group includes rare defects of the biosynthesis of testosterone, defect of the 5-alpha-reductase (the enzyme that converts testosterone to dihydrotestosterone) and partial androgen insensitivity syndrome (partial defect of androgenic receptors). It is important to recognize that patients with a 46,XY karyotype and dysgenetic testicles are sometimes included in this group in the literature.
3. The presence of incomplete differentiated gonads or coexisting ovarian and testicular tissue with ambiguous or female external genitalia. This is a heterogeneous group with one common factor which is a structural defect in gonadal differentiation with or without a chromosome alteration. Patients with mixed gonadal dysgenesis, testicular dysgenesis, and true hermaphroditism (now called 'ovotesticular disorder of sexual development') are included in this group.

For the purpose of investigation they are divided into:

1. Disorders of chromosomes (chromosomal DSD)
2. Disorders of gonad development (gonadal DSD, sex determination)
3. Disorders of sex steroid synthesis and action (phenotypic/anatomic DSD, sex differentiation).

DIAGNOSIS

According to the Consensus Statement on Management of Intersex Disorders,[2] optimal clinical management of individuals with DSD should comprise the following:

1. Gender assignment must be avoided before expert evaluation in newborns.
2. Evaluation and long-term management must be performed at a center with an experienced multidisciplinary team.
3. All individuals should receive a gender assignment.
4. Open communication with patients and families is essential, and participation in decision-making is encouraged.
5. Patient and family concerns should be respected and addressed in strict confidence.

The initial contact with the parents of a child with a DSD is important, because first impressions from these encounters often persist. A key point to emphasize is that the child with a DSD has the potential to become a well-adjusted, functional member of society. Although privacy needs to be respected, a DSD is not shameful. It should be explained to the parents that the best course of action may not be clear initially, but the health-care team will work with the family to reach the best possible set of decisions in the circumstances. The health-care team should discuss with the parents what information to share in the early stages with family members and friends. Parents need to be informed about sexual development.

A detailed personal and familiar anamnesis can give important information. Some of these pathologies recognize a sex-linked transmission (X-link) and the mother will be able to transmit the defect to 50% of her sons (complete or partial androgen insensibility). Many have an autosomal recessive transmission (CAH, deficit of the testosterone synthesis, deficit of 5-alpha-reductase, deficit of the LH receptor). Neonatal death in the first days of life of male babies may be due to an unrecognized congenital adrenogenital syndrome. Diagnostic algorithms are useful as guidelines to simplify the study of these complex patients.[3]

Figure 102.3 resumes the sequence of investigations used in a newborn with a suspected DSD, according to gonadal palpation. A karyotype is mandatory, but this always requires several days to complete. In the absence of palpable gonads, the first blood tests are those to exclude problems that can

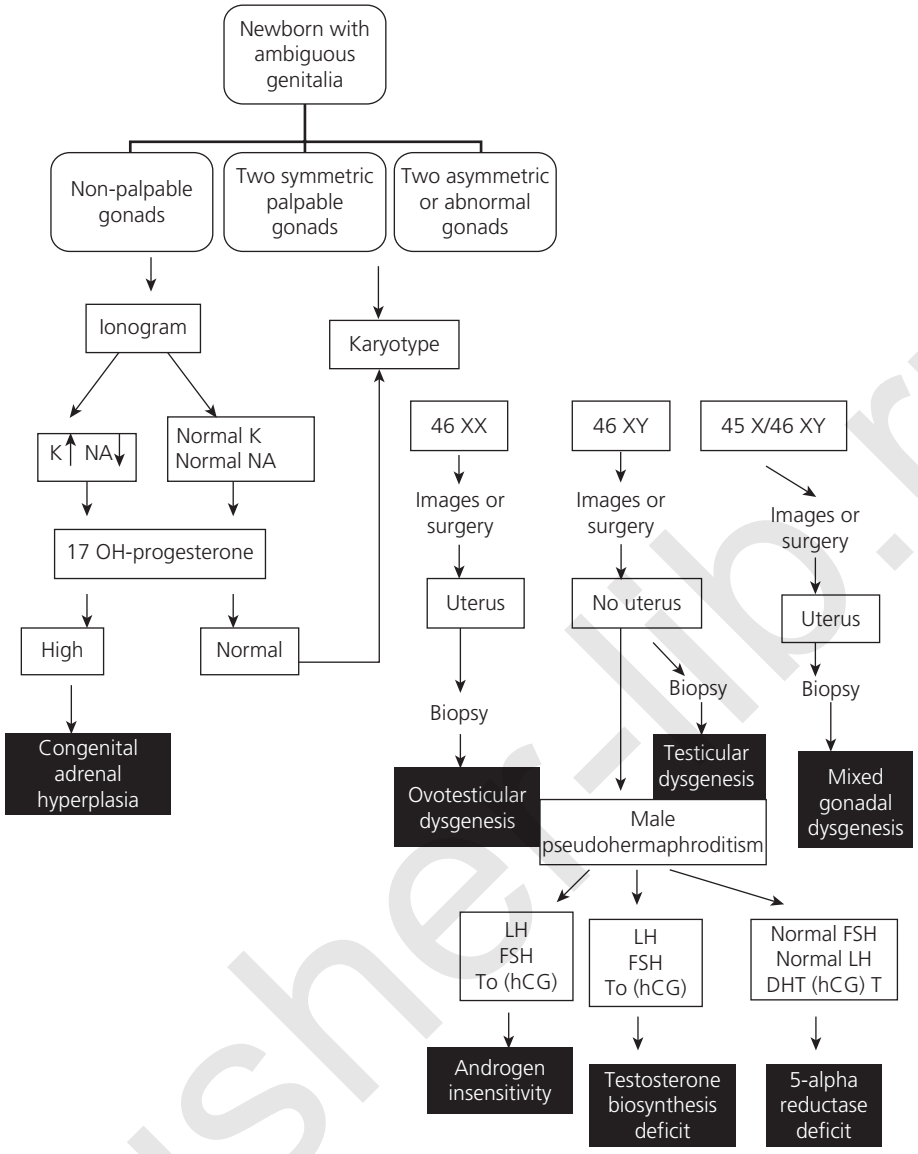


Figure 102.3 Sequence of investigations used in a newborn with a suspected disorder of sex development.

put the baby's life at risk (blood electrolytes) commonly found in the event of salt-losing CAH. The blood sexual steroids must be determined and among them the level of 17-OH-progesterone that, if elevated, will enable the diagnosis of the most common cause of DSD.[3]

The level of other steroids (testosterone, dihydrotestosterone, delta-4-androstenedione, DHEA, 17-OH-progesterone), ACTH, cortisol, and renin will allow a precise picture of the gonadal and adrenal steroidogenesis. For example, the ratio of testosterone to dihydrotestosterone (DHT) greater than 10 is suspicious of a deficit of 5-alpha-reductase enzyme.

The most valuable stimulation tests for evaluating steroid genesis are:

- hCG test for the study of testicular functionality.
- ACTH test for the study of adrenal steroid genesis.
- Low values of testosterone can be the sign of testicular dysgenesis if associated with low levels of all the other testicular steroids or of an enzyme defect of the steroid genesis path, if they are associated with high levels of their precursors.
- Normal or elevated levels of testosterone and dihydrotestosterone may be suggestive of receptor resistance to androgens.

The possibility of the ambiguous genitalia to virilize can be estimated after an hCG test or an appropriate stimulation trial with testosterone or topical DHT. This can be estimated by demonstrating the increment of the penile dimensions or indirectly by the dosage of androgen-sensitive circulating substances (SHBG). Its values are reduced if the patient tissues present sensitivity for the virilizing effect of androgens.[3]

Molecular biology techniques are more sensitive and specific tests for assessment of the tissue sensibility to androgens, but are not always available.

Histology is only required for diagnosis in patients with abnormal gonads (group 3).

Imaging tests

The primary objective of this test is the study of the internal genitalia anatomy. The pelvic ultrasound for the demonstration of the presence of Müllerian structures is an important diagnostic element.

Genitography is very useful for the study of vaginal morphology, dimension, and relation to the urethra (Fig. 102.4a–c). We look for the onset of the vaginal outlet in the urogenital sinus (UGS) with special attention to the proximal urethra to plan the urogenital reconstruction (see below under Management).

Sex of rearing

Factors that influence gender assignment include diagnosis, genital appearance, surgical options, need for lifelong replacement therapy, potential for fertility, views of the family, and, sometimes, circumstances relating to cultural practices.

More than 90% of patients with 46,XX CAH and all patients with 46,XY CAIS assigned female in infancy identify as females. Evidence supports the current recommendation to raise markedly virilized 46,XX infants with CAH as female.

Consistent penile development constitutes a basic element for the choice of male rearing, even though the criteria that must guide this choice are currently the object of debate. A good response in testosterone levels after the hCG test and an increase in penile length after administration of testosterone in the neonate will be useful to decide the choice in favor of a male.

In some patients, the possibility of future virilization at puberty has to be taken into account (deficit of 5-alpha-reductase and the defect of synthesis of testosterone from deficit of 17-βHSD). Nowadays, however, diagnosis is simpler due to the advent of molecular genetics.

Approximately 60% of 5-alpha-reductase-deficient patients assigned as female in infancy and virilizing at puberty (and all assigned male) live as males. In 5-alpha-reductase and possibly 17-hydroxysteroid dehydrogenase deficiencies, for which the diagnosis is made in infancy, the combination of a male gender identity in the majority and the potential for fertility (documented in 5-alpha-reductase-deficient patients, but unknown in 17-hydroxysteroid dehydrogenase deficiencies) should be discussed when providing evidence for gender assignment.

Among patients with partial androgen insensitivity syndrome, androgen biosynthetic defects, and incomplete gonadal dysgenesis, there is dissatisfaction with the sex of rearing in 25% of individuals, whether raised male or female.

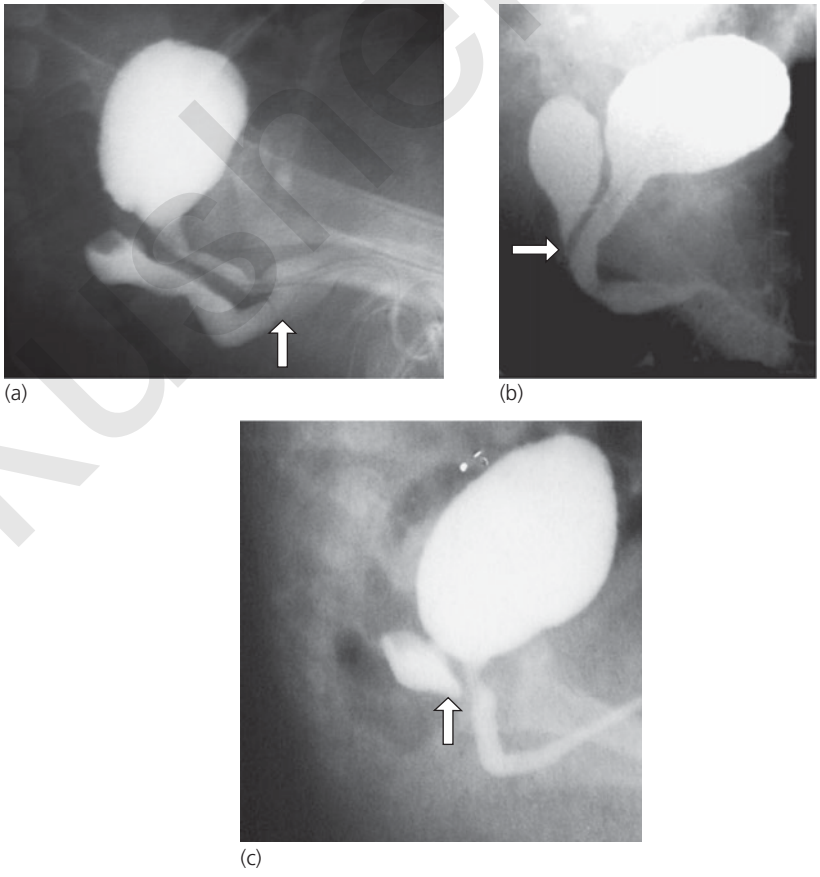

Figure 102.4 Genitography is very useful for the study of vaginal morphology, dimension, and relation to the urethra. Depending on vaginal confluence in the urogenital sinus, the vagina was classified as (a) low, (b) intermediate, and (c) high variant. The white arrows show the confluence of the vagina in the urogenital sinus.

Available data support male rearing in all patients with micropenis, taking into account equal satisfaction with assigned gender in those raised as male or female, but no need for surgery and the potential for fertility in patients reared as male.

Those making the decision on sex of rearing for those with ovotesticular DSD should consider the potential for fertility on the basis of gonadal differentiation and genital development, assuming that the genitalia are, or can be, made consistent with the chosen sex.

In the case of mixed gonadal dysgenesis (MGD), factors to consider include prenatal androgen exposure, testicular function at and after puberty, phallic development, and gonadal location.

MANAGEMENT

Except for gonadal biopsy or resection, no other surgery is performed in the neonatal period. Most of the reconstructive procedures, although performed early are not recommended in the first month of life.

However, the surgeon plays an important initial role in the interdisciplinary team that an institution is obliged to have in place to take care of these complex patients. He not only needs to take care of the best operative techniques for better functional results, but also manage the proper information (after consulting widely with the team) to be given to parents and family. The use of improper words and misinformation may result in irreversible sequela. In our opinion, the surgeon has to be fully informed and participate actively in the preoperative workup before making contact with the family.

Preoperative

A stable endocrine status, especially in CAH patients, is extremely important for a well-tolerated surgical procedure with the best postoperative results. A psychosocial analysis of the family is also recommended. Once again, the authors emphasize the interaction with clinical colleagues within the interdisciplinary team in charge of the case.

When reconstructing the urogenital sinus, a preoperative enema is indicated. Preoperative antibiotics are used according to the protocol of each institution.

Operative

The role of surgery consists of: (1) gonadal treatment, (2) feminizing genitoplasty, and (3) urethral/penile reconstruction in the undervirilized child.

GONADAL TREATMENT

Gonadal histology is required for diagnosis in intersex patients with abnormal gonadal development, such as mixed gonadal dysgenesis (MGD) and true hermaphroditism (TH), recently called ovotesticular DSD. Although sex may be assigned before the biopsy is taken, histology in these patients is required for a definitive diagnosis.

Gonadal biopsies must be taken along the longitudinal axis of the gonad as both ovarian and testicular tissue may be found at the polar ends of the gonad (Fig. 102.5). Depending on the result of the frozen section biopsy and the previous investigations, the gonad is removed. Patients with TH may have an ovary (O) and testicle (T), bilateral ovotestes (OT), and an ovary and ovotestes.[4]

Surgical management in DSD should also consider options that will facilitate the chances of fertility. The ovarian component of an ovotestes may be separated and the testicular tissue removed, using a zoom lens, although it must be borne in mind that these gonads need to be followed closely.

If a streak gonad is recognized as in most patients with MGD, it is removed without prior biopsy together with the surrounding peritoneum and the ipsilateral gonaduct (Fig. 102.6). This gonad has to be removed, avoiding previous biopsy, as it has a 25–50% chance of developing a gonadoblastoma and/or dysgerminoma and as there is the possibility of an *in situ* tumor at the time of the procedure. It is usually associated with an intra-abdominal or inguinal dysgenetic testicle, which is removed at the same time in patients with female sex assignment. Although there is the same risk of malignancy in the contralateral gonad (dysgenetic testicle), it may be biopsied and preserved in the scrotum of patients with male sex assignment because this gonad is functional.

The highest tumor risk is found in TSPY (testis-specific protein Y encoded)-positive gonadal dysgenesis and partial androgen insensitivity with intra-abdominal gonads, whereas the lowest risk (5%) is found in ovotestis and complete androgen insensitivity.

Better laparoscopic visualization and quicker access to intraperitoneal gonads encouraged the scheduling of simultaneous gonadal and genitalia procedures with good results. Nowadays, following a preoperative workup by an experienced multidisciplinary team, laparoscopic biopsies are performed followed by gonadal resection if required at the

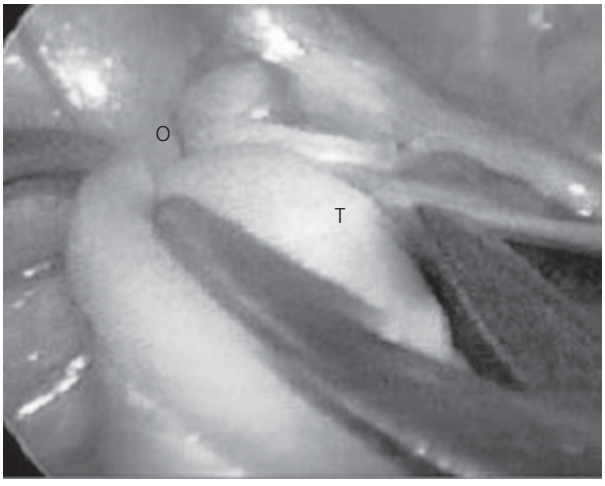

Figure 102.5 A laparoscopic view of ovotestes. This is the technique for gonadal biopsy along the longitudinal axis of the gonad. O, ovarian portion; T, testicular component.

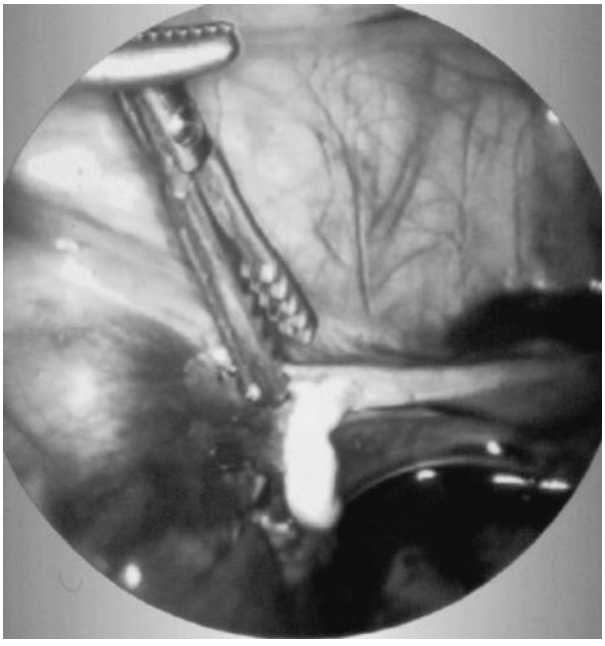

Figure 102.6 A laparoscopic view of streak gonad. Bipolar coagulation of the gonadal pedicle. These gonads are resected in block with the surrounding peritoneum.

same time of feminizing genitoplasty in female sex reassignment patients in a single stage initial approach.[4]

Sex may be assigned prior to laparoscopy in patients with 45,XO/46,XY gonadal dysgenesis. This is based on a functional and psychosocial basis in combination with the results of the karyotyping, hCG testing, and interview with the parents.

The authors have never found functional ovarian tissue in these patients, but always await the result of frozen section biopsy before removing any other gonad than a classical streak.

True hermaphroditism patients do not have such a classical pattern and definitive histology is often necessary for sex assignment. Although the most common karyotype is 46,XX and the most common gonadal combination is ovary/ovotestes, each case is unique and should be treated on an individual basis. Sometimes, the macroscopic aspect of the gonad and gonaduct, as well as the result of a frozen section biopsy strongly favors gonadectomy in patients with previous sex assignment. There is an advantage of a laparoscopic approach in these patients requiring secondary pelvic exploration, especially because many of them are potentially fertile.

An additional role of laparoscopy is excision of Müllerian structures, prostatic utricle, and orchidopexy in patients raised as males. In patients with a symptomatic utriculus, removal is best performed laparoscopically to increase the chance of preserving continuity of the vas deferens.[4]

An inguinal approach may be indicated in patients with palpable gonads (Fig. 102.7). However, a laparoscopic approach is preferred in most of them as it enables not only better visualization of potential Müllerian structures, but also allows for treatment of a patent peritoneal sac, when removing the gonads, with better cosmetic results. In addition, most of these patients have asymmetric gonads

Figure 102.7 An inguinal approach for gonadectomy in a CAIS patient with palpable gonads.

with one of them being intra-abdominal. The inguinal approach is reserved for XY patients with symmetric palpable gonads introducing the telescope through the associated hernia sac in order to rule out the presence of Müllerian structures.[5]

FEMINIZING GENITOPLASTY

Fortunately, there have been many advances in ambiguous genitalia reconstruction with many surgeons contributing. Cosmetically, a near-normal appearance can now be achieved, but long-term functional results with newer techniques are still unknown.

Timing for this type of surgery is controversial. It is now the general belief that one-stage total reconstruction can be performed in most patients in the early months of life. Regardless of the timing or the procedure elected, the surgery must be performed meticulously with a clear understanding of the anatomy and only be undertaken in centers with great experience and after all aspects of controversy have been explained in detail to the parents. Surgery consists of: (1) management of clitoral enlargement, (2) reconstruction of the urogenital sinus, and (3) labioplasty.

Management of clitoral enlargement

Management of clitoral enlargement remains controversial because of the ablative nature of the structure so vital to psychological body image and gender. Initial techniques consist of total clitorectomy based on the belief that it was necessary to prevent gender dysphoria. However, new understanding that an intact clitoris plays a crucial role in the development of female sexuality has stimulated a more conservative surgical approach, but recession of the clitoris, keeping the corpora, may lead to painful erections during sexual arousal. The most used technique has been that based on Kogan's reduction clitoroplasty, including removal of the corporal erectile tissue with preservation of the neurovascular bundle to the glans (Fig. 102.8a–c). Glans reduction is accomplished by superficial excise of the epithelium of the glandular groove, avoiding a scar in the glans tissue which is fixed to the pubis attachment.

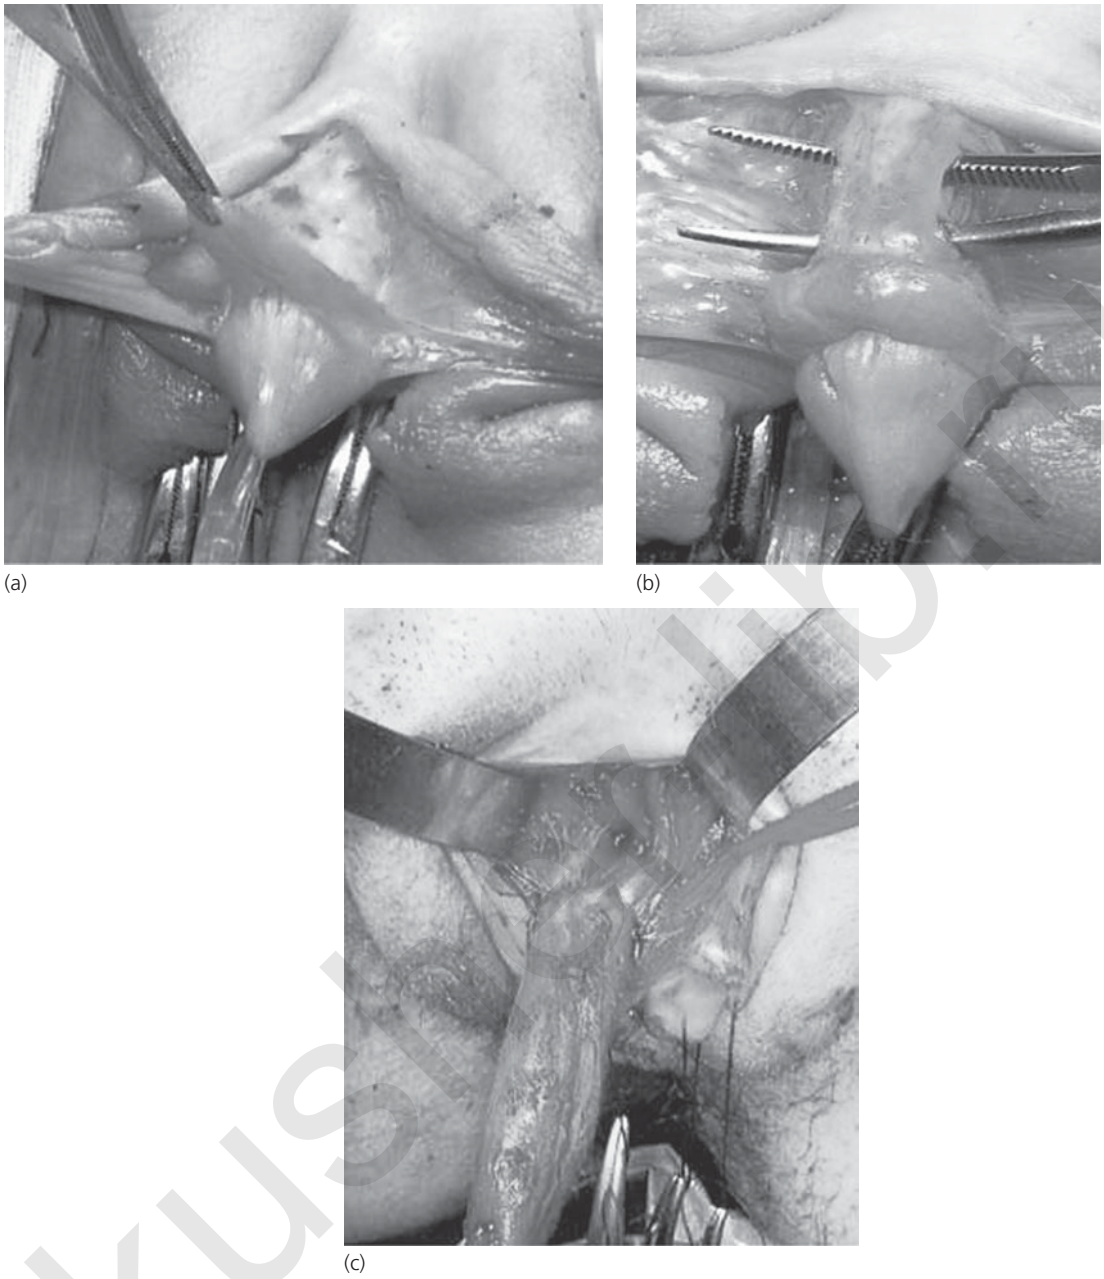

Figure 102.8 Reduction clitoridoplasty. (a) Dorsal incision of skin; (b) isolated neurovascular bundles; (c) corporal erectile tissue is ready to resect.

There is evidence that innervation of the glans comes from the surrounding skin and plays an important role in sexual arousal. Recently, surgeons have been careful in preserving most of the glands, trying to avoid its unnecessary section. The dorsal pedicle, as well as the ventral skin and mucosal surface, should be kept and it is preferable not to excise the glans in any surface, but rather hide it.

Recently, a non-ablative and potentially reversible technique that dismembers the corporal bodies keeping them in the labia major has been described by Pippi Salle *et al.*[6] in response to new understandings that an intact clitoris plays a crucial role in the development of female sexuality, but no long-term follow up is available.

Reconstruction of the urogenital sinus

UGS abnormalities present as a spectrum that goes from a labial fusion to an absent vagina, depending on the location of the vaginal confluence in the UGS. Powell *et al.*[7] described four types: (1) labial fusion, (2) distal confluence, (3) proximal confluence, and (4) absent vagina. In 1969, Hendren and Donahoe[8] described different procedures required for reconstruction depending on the location of the vaginal confluence in the UGS related to the external sphincter (low when distal and high when proximal to the sphincter). This has been very helpful for reconstructive understanding, but the vagina is not always high or low and the sphincter not well seen. Vaginas have been found to be

located in a wide spectrum of position from a normal position, to the entrance of the bladder. The low confluence was classically repaired by a 'flap vaginoplasty' and the mid to high by a 'pull-through vaginoplasty'.

Even in the low type, a very aggressive dissection of the posterior vaginal wall, separating it from the rectal wall is recommended. The vagina is then cut in the midline well back into its normal caliber and at this point a wide cutaneous flap can be sewn using delicate sutures. A rectal finger is very useful to facilitate vaginal exposure (Fig. 102.9a, b). This maneuver of bringing the vagina out (rather than skin in) prevents the known complications of the Fortunoff flap (growing of hair and stenosis).

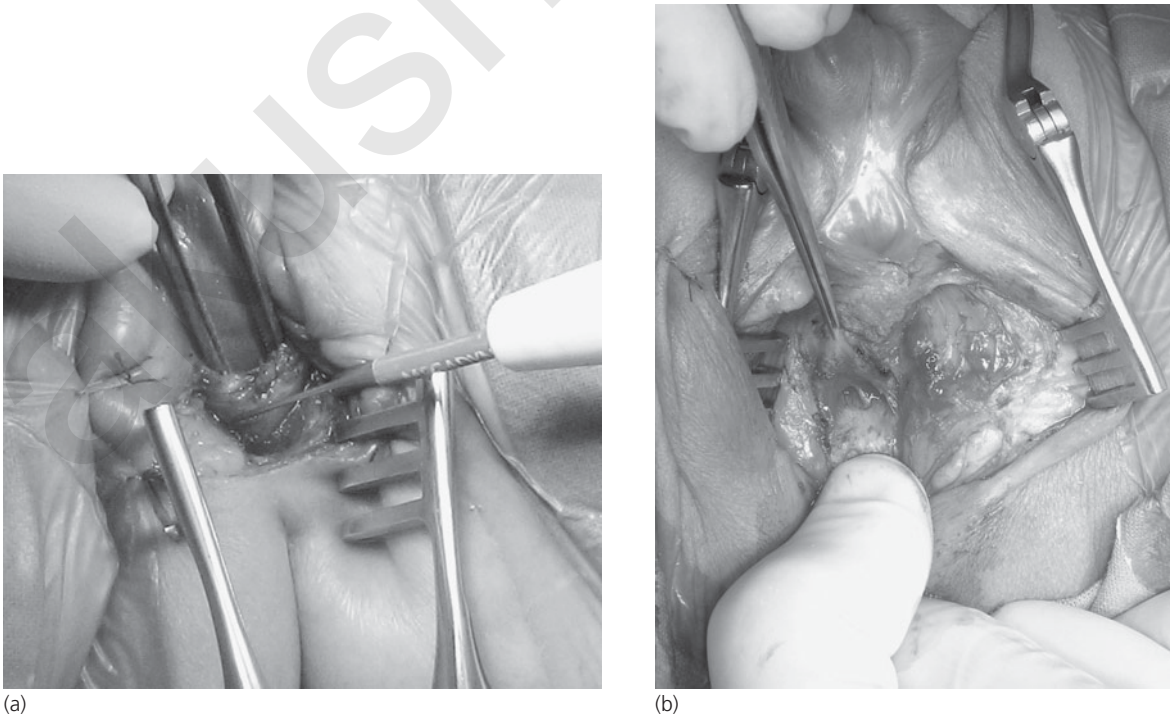
Exteriorization of the high vagina in the severely masculinized female is a surgical challenge. The vagina must be detached from the UGS and then connected to the perineum. The pull-through principle consists of placing a Fogarty balloon catheter into the vagina cystoscopically to locate it by palpation deep in the perineum later (Fig. 102.10a, b). The UGS is approached like a bulbous urethra. In severe cases, perineal anatomy is like that of a normal male. The vagina is incised over the balloon, detached from its entry point in the UGS and the anterior wall carefully dissected off the overlying urinary tract. The walls from the vagina to the perineum may be constructed using a combination of inverted U cutaneous flap (Fortunoff flap), prepucial flap (Gonzalez and Fernandez),[9] and redundant tissue from the UGS (Passerini flap). The anterior sagittal transrectal approach (ASTRA) in a prone position is another method of exposure using the perineal approach.[10]

In the middle of these two points, the authors found what is termed 'intermediate UGS'. Although the vaginal opening is distant from the UGS opening, there is enough proximal urethra to avoid urethra–vaginal dissection and separation. After Alberto Peña's description of 'total urogenital mobilization' (TUM) for the treatment of cloacas in 1997,[9] this maneuver was used to treat intermediate UGS abnormalities. The UGS is mobilized in block to the perineum (Fig. 102.11a, b). It is used in the lithotomy position, mobilized without previous opening to prevent bleeding and the sinus tissue is never amputated until the end, as it may be used in the repair. Each patient must be individualized and this technique can be combined with a pull-through if required.[11,12]

Recently, Rink *et al.*[13] has described a variant that he calls 'partial urogenital mobilization' (PUM), stopping dissection at the level of the pubo-urethral ligament. Currently, regardless of the level of the confluence, he starts with PUM, allowing a unified approach to all repairs.

A posterior sagittal approach has also been described to correct intermediate and high UGS.[10]

In the authors' opinion, the best way to treat the high UGS is a combination of several techniques. A balloon catheter (most often a Foley one using a catheter as a guide) with a cystoscope is inserted. The UGS is mobilized in the lithotomy position without opening it (Fig. 102.12a). The patient is then turned to the prone position, the rectum retracted and sometimes the anterior wall opened (Fig. 102.12b). The vagina is opened over the balloon, the Foley catheter repositioned in the proximal urethra, and the uretrovaginal fistula closed, taking care not to denervate the bladder neck (Fig. 102.12c, d). The short vagina (which is usually the case in these patients) needs to be exteriorized.



(a) (b)

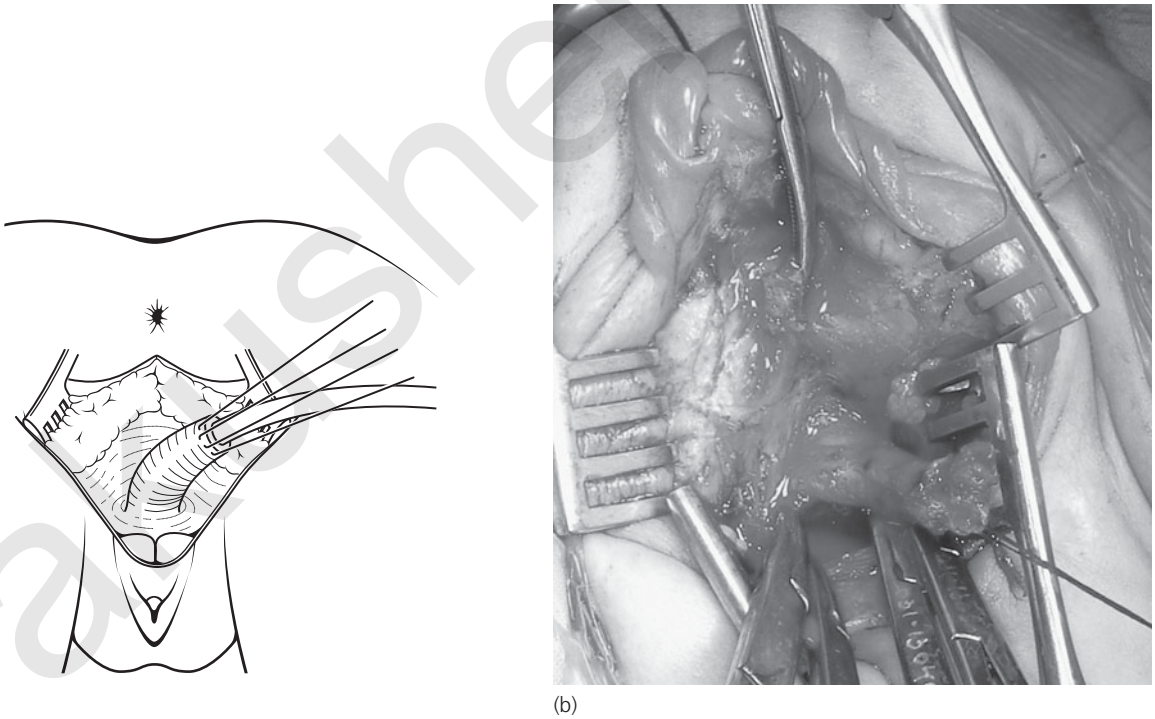
(a) (b)

Figure 102.10 (a) Illustration showing the pull-through technique. The principle consists of placing a Fogarty balloon catheter into the vagina cystoscopically to locate it by palpation deep in the perineum later. (b) Cosmetic appearance after pull-through technique.



(a) (b)

Figure 102.11 Total urogenital mobilization (TUM). The urogenital sinus is mobilized in block to the perineum, after it is incised in the ventral wall. (a) Illustration of TUM. (b) Operative TUM technique.

The transected perineal skin between the vagina and rectum is used to reconstruct the dorsal wall and the previously dissected UGS is used for the ventral wall. For that purpose, it is transected ventrally and everted to reach the vagina and, in this way, the proximal part of it remains as the urethra (Fig. 102.13a–c). In this way, three principles were combined (pull-through, TUM, and ASTRA), not just a single technique.[14]

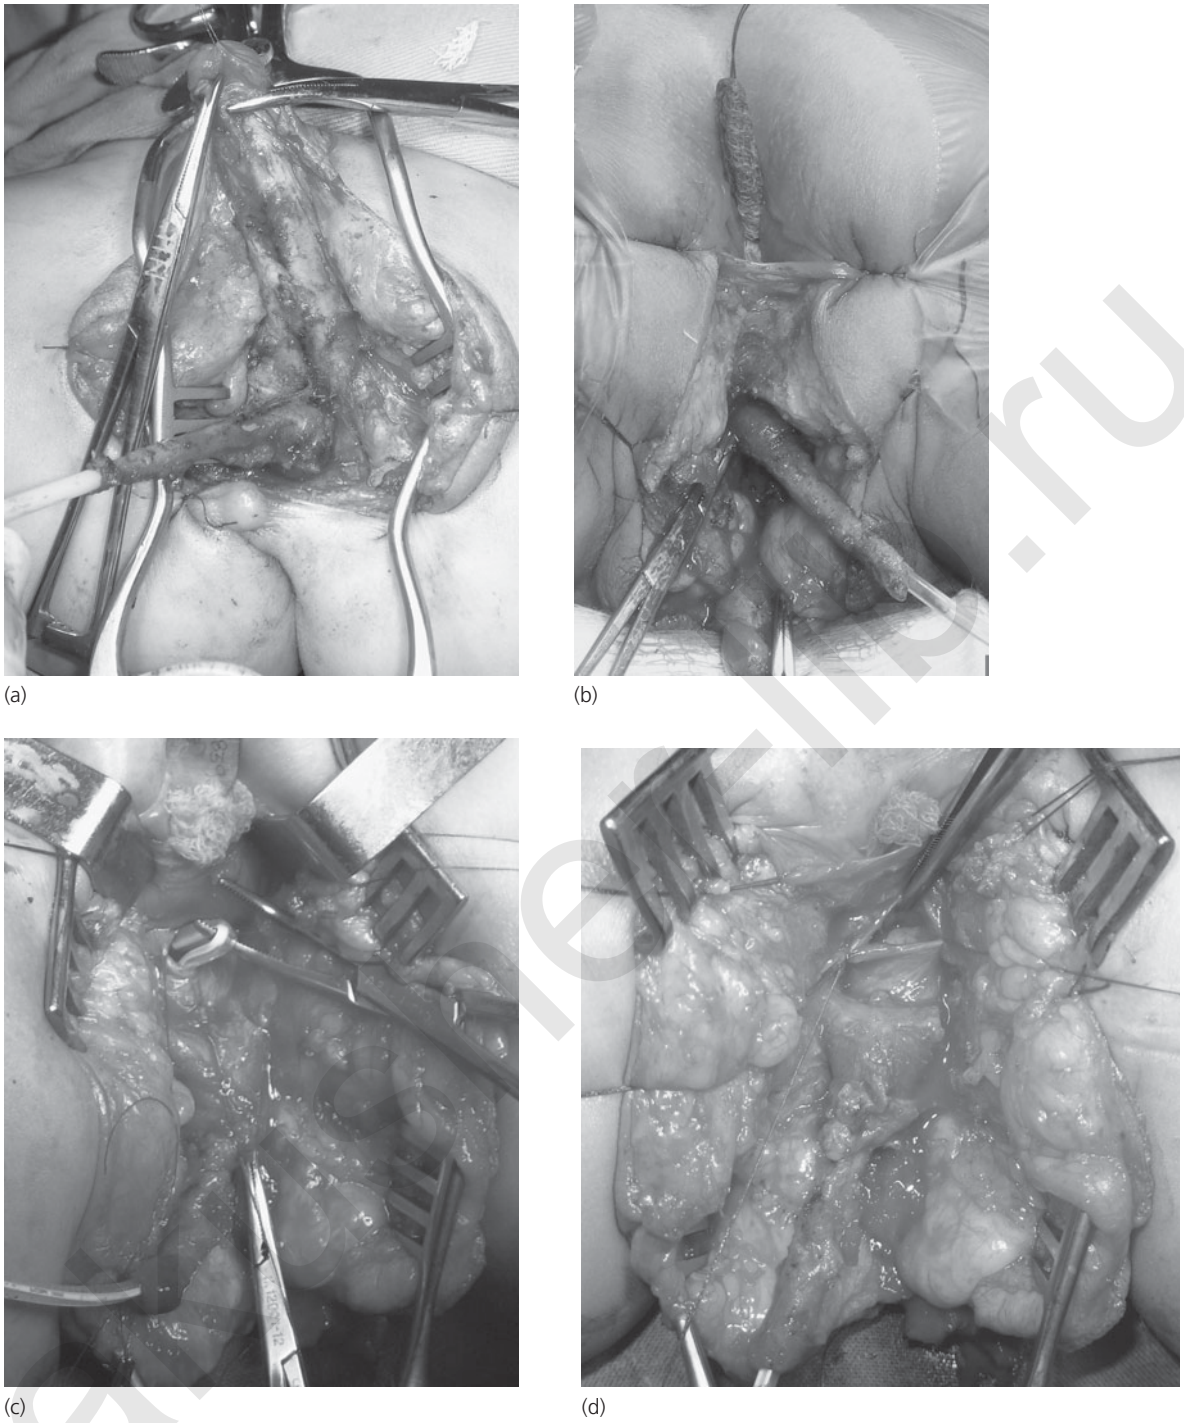


Figure 102.12 (a) Mobilization of the urogenital sinus in the lithotomy position without opening it. (b) The anterior sagittal transrectal approach. A midline sagittal incision was made through the anterior anorectal wall and provided an excellent view of the complete urethra and vagina without the need for complex preparation to gain exposure. In this patient, a previous placing of a balloon catheter in the vagina and a total urogenital mobilization were performed in the lithotomy position and the patient was then turned to prone. She had a very high urogenital sinus. (c) The vagina opened over the balloon, the Foley catheter repositioned in the proximal urethra. (d) The vagina is completed open.

Those patients with absent vagina (type IV) should undergo vaginal replacement. Most of these are undervirilized males and a bowel vagina (colon, if possible) is preferred. The authors have performed this laparoscopically since 1999 (Fig. 102.14).[15]

Labioplasty

Labioplasty is performed by dividing the clitoral hood skin in the midline (Byers flaps), sewing the flaps around the clitoris and along the central mucosal strip down to the lateral vaginal walls (Fig. 102.15a–c).

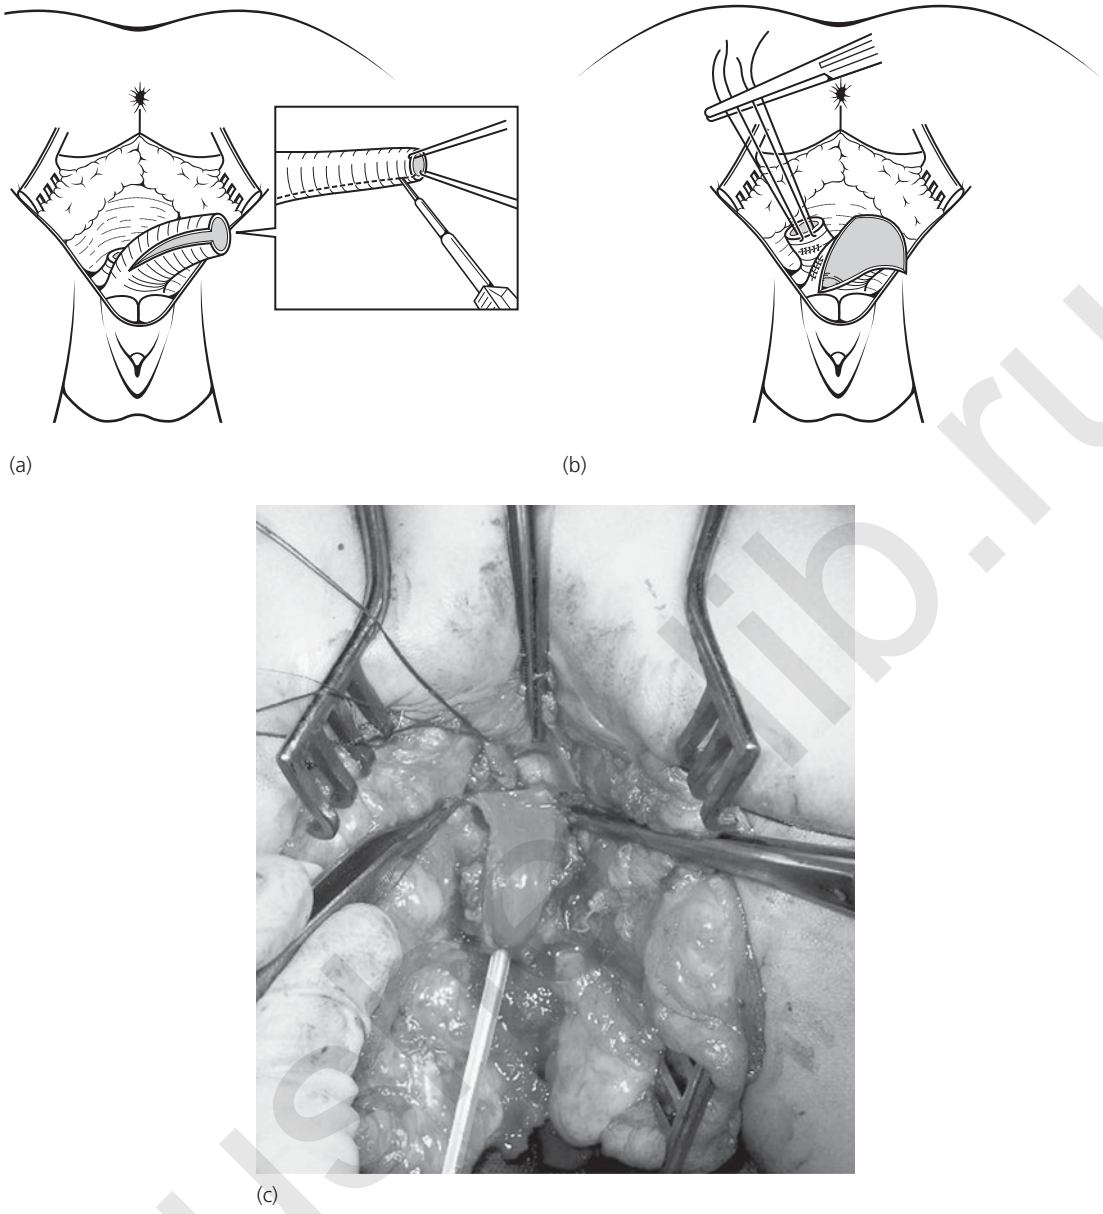

Figure 102.13 The UGS is transected dorsally (patient is in prone position) and everted to reach the anterior wall of the vagina. In this way the proximal part of it stays as urethra.

URETHRAL/PENILE RECONSTRUCTION

Urethral/penile reconstruction is addressed in Chapter 103, Male genital anomalies (hypospadias reconstruction chapter) and is not discussed here.

Postoperative

The perineum needs to be kept dry and clean for the first week to prevent dehiscence. The urethral catheter is left *in situ*, depending on the technique used. It is only left for the first postoperative day in the low or intermediate UGS and for at least 3 days in the high ones. Most of the patients only require non-steroidal anti-inflammatory drug (NSAID) for pain treatment.

COMPLICATIONS

Techniques for vaginoplasty carry the potential for scarring at the introitus, necessitating repeated modification before sexual function.

Figure 102.14 Laparoscopic aspect of an isolated piece of sigmoid colon to vaginal replacement.

The risks from vaginoplasty are different for high and low confluence of the urethra and vagina. The risk of urinary incontinence is decreased by recognizing the location of the vaginal confluence for the selection of the surgical approach and avoiding unnecessary mobilization or dissection in the urethrovaginal septum.

LONG-TERM RESULTS

The pattern of surgical practice in DSD is changing with respect to the timing of surgery and the techniques used. It is essential to evaluate the effects of early versus later surgery in a holistic manner, recognizing the difficulties posed by an ever-evolving clinical practice.

Some studies suggest satisfactory outcomes from early surgery. Nevertheless, outcomes from clitoroplasty identify problems related to decreased sexual sensitivity, loss of clitoral tissue, and cosmetic issues.

The analysis of long-term outcomes is complicated by a mixture of surgical techniques.

The outcome in undermasculinized males with a phallus depends on the degree of hypospadias and the amount of erectile tissue (Fig. 102.16). Feminizing genitoplasty as opposed to masculinizing genitoplasty requires less surgery to achieve an acceptable outcome and results in fewer urologic difficulties. Long-term data regarding sexual function and quality of life among those assigned female, as well as male, show great variability. There are no controlled clinical trials of the efficacy of early (12 months of age) versus late (in adolescence and adulthood) surgery or of the efficacy of different techniques.

Gender-role change occurs at different rates in different societies, suggesting that social factors may also be important modifiers of gender-role change.

Male genital anomalies

JOHN M HUTSON

INTRODUCTION

Development of the external genitalia is a complex process in the male, which predisposes to many congenital anomalies. Understanding these anomalies requires a detailed knowledge of the embryology, and particularly the central roles of androgens (in coordinating the masculinization of the anatomy) and the processus vaginalis (which allows descent of the intra-abdominal fetal testis into the scrotum).

EMBRYOLOGY

Masculinization of the external genitalia occurs in normal human embryos between 8 and 12 weeks of gestation. The inner genital folds fuse to create the male anterior urethra, while the outer genital folds fuse to make the scrotum. The genital tubercle enlarges to form the phallus. All these processes are mediated by secretion of testosterone from the embryonic testis. An enzyme in the target tissues, 5-alpha-reductase, converts the small amount of circulating testosterone into dihydrotestosterone, which binds five to ten times more tightly to the androgen receptor than testosterone itself. Although the genitalia appear 'male' by 12 weeks of gestation, the phallus is still tiny, but it continues to grow throughout pregnancy, in response to testosterone, to reach its newborn size (3–4 cm stretched length).

The normal process of testicular descent is multistaged. The first phase involves enlargement of the genitoinguinal ligament (or 'gubernaculum') and regression of the cranial suspensory ligament. The swollen distal gubernaculum anchors the embryonic testis near the groin during enlargement of the abdominal cavity. The hormonal regulation of this enlargement is by Leydig insulin-like hormone-3 (insulin-3, Insl3, or relaxin-like factor), as mutant mice with this gene deactivated have high intra-abdominal testes.[1,2]

The second phase involves development of a peritoneal diverticulum (processus vaginalis) inside the gubernaculum. Migration of the gubernaculum (with elongation of the processus) to the scrotum is likely to be controlled by the genitofemoral nerve releasing calcitonin gene-related peptide (CGRP), under stimulation of androgen.[3] During migration, the distal end of the gubernaculum is not anchored to the scrotum, which could predispose to extravaginal torsion in the perinatal period. After migration is complete, the gubernaculum involutes and the tunica vaginalis becomes adherent to the inside of the scrotum, preventing any further risk of extravaginal torsion.

Following testicular descent, the processus vaginalis obliterates between the internal inguinal ring and the top of the scrotum, leaving the testis within the tunica vaginalis. Failure of closure leads to inguinal hernia, hydrocele, or encysted hydrocele of the cord. In addition, failure of the fibrous tissue around the processus to disappear completely predisposes to acquired undescended testis (the 'ascending' testis) later in childhood.

PENIS

The penis of neonatal males is a focus of considerable parental anxiety and attention. The normal foreskin in a premature infant may appear relatively deficient, but by term it protrudes beyond the glans. The inner prepuce is attached to the glans and the distal opening is narrow, sometimes making catheterization difficult. Anomalies of the foreskin, such as phimosis or balanitis are rare in the neonatal period, although phimosis can occur secondary to neonatal cystoscopy in babies with urethral valves.

Circumcision

Neonatal circumcision is one of the most common operations in the United States and Israel, although in other Western countries the frequency is much lower.[4,5]

The procedure was known in the ancient societies of the Middle East and may have arisen as a way of preventing balanitis and phimosis in an arid, sandy region. Circumcision

is part of the ritual for such religions as Judaism, Christianity, and Islam, which all arose in the same geographic area.

In our own time, there is controversy over the advantages versus the risks of routine neonatal circumcision.[6–8] The American Academy of Pediatrics (AAP) first issued guidelines about neonatal circumcision in 1971, concluding that there was no absolute medical indication for routine circumcision.[9] By 1998, new evidence showed a potential benefit of circumcision in preventing neonatal urinary tract infection and sexually transmitted diseases, including HIV; this led to a revision of the guidelines to balance the risks against the advantages.[10] The current position of the AAP is to provide parents with an informed choice with accurate and unbiased information. Where circumcision is requested, the AAP now recommend procedural analgesia be provided.[9]

Circumcision should prevent phimosis, paraphimosis, and balanitis, although good clinical studies proving this at a population level are hard to find. Learman[5] concluded that the evidence supporting circumcision was too weak to recommend routine operation. Urinary tract infection in neonatal males can be reduced by circumcision from 7/1000 to 1.9/1000,[11] but whether improved penile hygiene would have the same effect is unknown. Sexually transmitted disease (STD) rates in circumcised men are 10% lower than without circumcision, when comparing men presenting to an STD clinic in a Western country.[12] In sub-Saharan Africa, the benefits of circumcision in reducing HIV risk may be much greater,[13] although meta-analysis has not confirmed a benefit.[14,15] Circumcision is linked with a three-fold reduction in penile cancer, although the low frequency of the condition does not justify routine neonatal operation. Learman[5] estimated that over 300 000 circumcisions were required to prevent one penile cancer per year. In Denmark, the incidence of penile cancer is falling, despite no increase in the number of circumcisions, suggesting that other factors, such as hygiene, are important.[16]

The complications of circumcision may be extreme, including amputation or diathermy necrosis,[17] although most complications are minor (e.g. minor bleeding or infection) and uncommon (<1%) (Fig. 103.1).[9] The Plastibell device or the Gomco clamp both have a low (0.2%) complication rate in neonates, and are equally safe techniques.[5]

Figure 103.1 Postoperative penile hemorrhage after circumcision.

Neonatal circumcision should only be performed with adequate analgesia, using a ring penile block, local anesthetic cream, or a dorsal penile nerve block. If a Plastibell device is used, it is important to select the right size to avoid the ring slipping down the shaft and causing a form of paraphimosis.[18] The key to circumcision in the neonate is complete mobilization of the foreskin by separation from the glans with a lacrimal probe, and then inspection of the glans and urethral meatus to exclude hypospadias or other anomalies. Marking the level of the coronal groove through the base of the foreskin ensures that the skin of the shaft is not pulled up into the device.

Hypospadias

Failure of fusion of the urethral or inner genital folds leads to hypospadias (Greek for 'hole underneath'). Secondary anomalies include deficiency of the ventral prepuce (leading to a 'dorsal hood'), and relative deficiency in growth of the periurethral tissues compared with dorsal structures, such as the corpora cavernosa. The latter causes 'chordee', or relative curvature of the penis, particularly on erection.[19]

Depending on diagnostic criteria, the incidence of hypospadias is 1/100 to 1/300.[20] Siblings or the father are affected in about 10% of patients, suggesting polygenic inheritance. Hypospadias is an anomaly with a wide variation in severity, from a minor degree of meatal ectopia on the ventral glans to a severe abnormality with a perineal opening.

'Hypospadias' can be confused with more serious genital anomalies, and the most important initial aim is to exclude a disorder of sex development (DSD) (Fig. 103.2). Since hypospadias is an anatomical anomaly of anterior urethral development, the rest of the external (and internal) genitalia should be normal. By contrast, patients with DSD, have extensive genital abnormalities secondary to failure of all aspects of androgen-dependent development. A DSD can be

Figure 103.2 Apparent 'hypospadias and bifid scrotum', in a child with a severe genital anomaly. This child needs urgent investigation for disorder of sex development.

excluded if the scrotum is completely fused and both testes are descended. Babies with possible ambiguity need immediate referral, while those with hypospadias alone can be managed after the neonatal period.

Surgical treatment can be offered at three to six months of age, often as day surgery or overnight stay. Admission may be needed for urinary diversion, depending on severity of the anomaly and the surgeon's preference. A wide range of techniques are available,[21–24] which are not the main subject of this volume. Readers should consult the references for specific details.

Epispadias is a more severe and distantly related condition, which is more related to exstrophy of the bladder, and is included in Chapter 73, Bladder exstrophy: considerations and management of the newborn patient.

Micropenis/buried penis

A small penis may be caused by inadequate hormonal stimulation during pregnancy (hypothalmic, pituitary, or placental deficiency), although in some cases there is an anatomical deficiency. The buried penis occurs where the erectile tissue is adequate but the shaft skin is deficient.

Micropenis can be treated by androgen treatment, although whether postnatal hormone therapy is beneficial is controversial.[25,26] A number of operations have been proposed for buried penis, most of which use the foreskin.[27]

Penoscrotal web is a variant of buried penis where there is inadequate ventral shaft skin. This can be repaired later in infancy by Z-plasty.

Rare penile anomalies

Rare anomalies of the penis may be obvious at birth, including urethral duplication (Fig. 103.3) and megalourethra, which may be associated with prune belly syndrome[19,28] Partial duplication of the caudal embryo may lead to duplication of the penis, while penile 'agenesis' is usually a form of posterior ectopia, with the erectile tissue and urethra buried in the perineal body and the meatus on the anterior lip of the anal canal.[29,30] The latter anatomy is similar to the normal situation in marsupials, where the scrotum is inguinal in position and the phallus is in the perineum. Minor variants of penoscrotal transposition are common in DSD patients.[31,32]

Undescended testis

Any anomaly in the anatomical structures involved in testicular descent, or their hormonal regulation, will lead to congenital maldescent.[33] Failure of the transabdominal phase causes intra-abdominal testes that are truly 'cryptorchid' or hidden. Impalpable testes within the abdomen or canal are relatively uncommon (<5–10% of patients, depending on different authors).[34]

Intra-abdominal testes are associated with hypoplasia of the ipsilateral scrotum and often with absence of the external inguinal ring. The latter is a useful clinical feature to confirm absence of any inguinoscrotal migration. When the testis is inside the canal, the external ring may be open, consistent with intermittent emergence of the canalicular gonad.

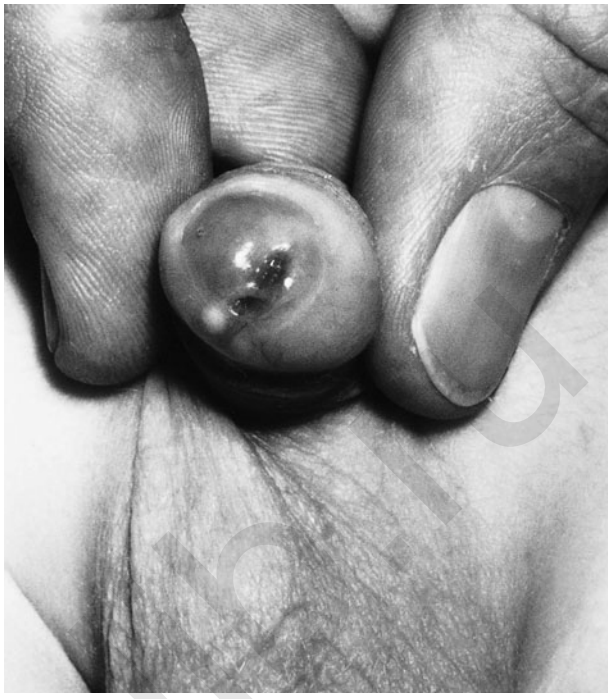

Figure 103.3 Urethral duplication in an infant.

The common site for undescended testes is just outside the external ring. Denis Browne described this as the 'superficial pouch', which is the name given to the tunica vaginalis when it is located in the groin, superficial to the abdominal wall, and deep to the superficial abdominal wall fascia (Scarpa).[35]

Maldescent is likely to have multiple causes, the most common being failure of gubernacular migration for various mechanical reasons.[34,36] Transient deficiency of gonadal androgens related to hypothalmic or pituitary anomalies or defects in placental function also may be important.[37] A number of less common and rare causes for cryptorchidism have been proposed (Box 103.1, Fig. 103.4).

In premature infants, as well as many term babies, cryptorchidism may be transitory, with further descent into the scrotum in the first 12 weeks postnatally.[38] These so-called 'late descenders' are at a high risk of developing acquired 'ascending' testes later in childhood.[39] The etiology of the latter is controversial, but has been proposed to be failure of the processus vaginalis to obliterate fully postnatally, leaving a fibrous remnant that prevents the normal elongation of the spermatic cord with growth.[40,41]

DIAGNOSIS

The aim of the physical examination is to locate the testis and determine its lowest position without undue tension. The latter corresponds with the caudal limit of the undescended tunica vaginalis.[42] In neonates, the examination may be hampered by vigorous leg movements, small size of all structures (including

Box 103.1 Proposed causes of cryptorchidism in rare cases

1. Aberrant location of genitofemoral nerve (perineal testis)
2. Persistent Müllerian duct syndrome (transverse ectopia with uterus and elongated gubernaculum)
3. Prune belly syndrome (massive bladder enlargement precluding entrance into inguinal canal)
4. Posterior urethral valves (same proposed mechanism as 3, above)
5. Anterior abdominal wall defects (ruptured gubernaculum)
6. Connective tissue disorders (deficient gubernacular migration)
7. Neural tube defects (genitofemoral nerve anomalies)

Figure 103.4 Ectopic undescended testis. In this case of perineal testis, it has been suggested that the cause is aberrant migration of the gubernaculum secondary to abnormal location of the genitofemoral nerve.

the testis, which is only 1–2 mL in volume), and motility of the testis within the tunica vaginalis. The scrotum is hypoplastic if the testis has never reached it, and the inguinal canal is shut in intra-abdominal testes. Palpation of a triangular defect at the pubic tubercle confirms the external ring is open and suggests that the testis is inside the canal. Conversely, hypertrophy of the contralateral testis (2–3 mL) suggests atrophy of the ipsilateral organ ('the vanishing testis').

TREATMENT

The aim of surgical treatment of undescended testis is to relocate the gonad into the scrotum before secondary dysfunction and degeneration occur (from high temperature). It is based on a premise, currently not proven in humans, that early placement of the testis in the scrotum will allow normal postnatal maturation of the germ cells to proceed. Careful study of testicular biopsies now suggests that the germ cells undergo transformation, from gonocytes to type A-spermatogonia, within 6–12 months after birth,[43] and that this maturation is deficient or arrested in cryptorchid testes. In addition, adult dark (AD) spermatogonia are now thought to be the stem cells for subsequent spermatogenesis. Animal models support the premise that early intervention can prevent germ cell loss[44] but this has not been confirmed in humans yet because of the inordinate lag time between treatment and end result (adult fertility).

The recommended age of orchidopexy has changed over the years, reflecting the accumulating knowledge about testicular function in infants. In our own department, orchidopexy is performed after about six months, as long as the anesthetic support is adequate. Since 4–5% of the males have undescended testes at birth, but about half of these show postnatal descent by 12 weeks, the baby should be re-examined then to confirm persisting cryptorchidism prior to referral for surgery. At this age, the operation is best performed by a trained pediatric surgeon, who is familiar with the handling of delicate tissues. Recent prospective trials confirm that surgery before one year (at approximately nine months) leads to better testicular growth (measured by ultrasonography) than when operation is delayed until three years of age.[45]

Rare anomalies of the testis

Tumors of the testis are rare at birth, but teratomas have been reported (Fig. 103.5). In a review of 68 patients with testicular

Figure 103.5 Neonate with a teratoma of the left testis.

(b) Folding of legs confirmed that the right heel fitted exactly over the pressure area in the anterior urethra.

tumors over 30 years, one baby was found with a genital anomaly and a gonadoblastoma.[46] A neonatal teratoma may need to be distinguished from a hydrocele or testicular torsion. If the hydrocele is too tense to palpate a normal testis, an ultrasound examination would be useful. Most teratomas can be shelled out of the testis, thereby avoiding orchidectomy.

Exstrophy of the testis has been reported, presumed to be secondary to pressure necrosis of the scrotal skin from the baby's heel, and prolapse of the scrotal contents.[47] A similar defect has been reported in the proximal penile urethra from probable pressure atrophy, leading to a congenital urethral fistula (Fig. 103.6).[48]

Duplication of the gonadal primordium can cause polyorchidism. The presentation is of three scrotal masses, all of which feel like normal testis.[49] The differential diagnosis includes complete inguinoscrotal hernia, encysted hydrocele of the cord, and transverse testicular ectopia, where both testes are on the same side. In the latter situation, the contralateral hemiscrotum is empty. No treatment may be required, although one gonad can be removed if the vas deferens is deficient.

Transverse testicular ectopia is a rare anomaly, which may be associated with prenatal rupture of the ipsilateral gubernaculum, allowing the testis to prolapse into the contralateral processus vaginalis. In most cases, the ectopic testis has no gubernacular attachments; the diagnosis can be confirmed on scrotal ultrasound.[50] Transverse ectopia of the testis is also seen in a rare form of DSD known as persistent Müllerian duct syndrome.[51] Transverse ectopia is treated by trans-septal scrotal orchidopexy (i.e. both testes are brought through the same inguinal canal into the scrotum and one is placed in the contralateral hemiscrotum).

The vas deferens may be absent in the Rokitansky syndrome or in babies with cystic fibrosis. In the Rokitansky anomaly, the caudal growth of the distal Wolffian duct is arrested, leading to subsequent absence of the ipsilateral vas deferens, seminal vesicle, and ureteric bud (and hence ipsilateral renal agenesis)[52] The etiology of absent vas deferens is different in cystic fibrosis, where the Wolffian ducts undergo involution/atresia in mid-gestation. At birth, only the head of the epididymis is palpable, and the epididymal tail and vas deferens are absent bilaterally: this finding can be used to diagnose cystic fibrosis in neonates with possible meconium ileus.[53–55]

Apart from DSD anomalies with separate labioscrotal folds or bifid scrotum, scrotal anomalies are rare. There are case reports of ectopic hemiscrotum and duplication, which are a local manifestation of partial twinning of the caudal embryo or compression of the perineum by the feet of the fetus.[56]

Neonatal testicular torsion

DAVID M BURGE

INTRODUCTION

Torsion of the neonatal testis is a well-recognized clinical entity which accounts for about 10% of all cases of testicular torsion admitted to pediatric surgical centers.[1] Torsion usually occurs extravaginally, i.e. in the spermatic cord above the insertion of the tunica vaginalis (Fig. 104.1), but both intravaginal and mesorchial torsion are reported.[2,3] Either testis may be involved. Bilateral torsion occurs and may be synchronous or metachronous.[4,5] Asynchronous torsion may occur in as many as 33% of cases.[6] Apparent primary infarction of the neonatal testis in the absence of torsion occurs less commonly,[7] and while it has been postulated that this represents previous torsion that has untwisted, good evidence exists to suggest that the initial event in neonatal torsion is a vascular one and that torsion may occur secondarily.[2] The neonatal testis may be prone to extravaginal torsion because of its extreme mobility within the scrotum.[8]

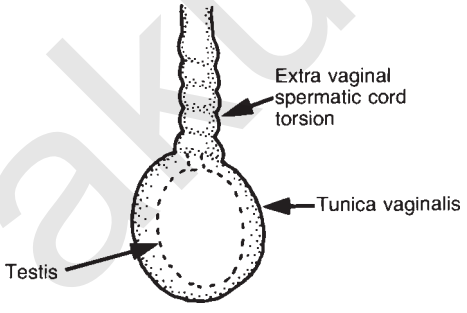

Figure 104.1 Anatomy of extravaginal torsion.

CLINICAL FEATURES

Neonatal torsion appears to be a condition of large term babies[2] and it rarely, if ever, affects the preterm infant. Previously, breech delivery was suspected as being a causative factor. Recent reports, however, fail to confirm this.[2] Affected babies are usually totally asymptomatic. The typical physical features are of a hard, edematous hemiscrotum with a noticeable blue or black discoloration.

The testis feels firmly adherent to the scrotal wall and is apparently non-tender. While there may be some enlargement of the hemiscrotum, this is not usually marked. These features are usually present from birth, supporting the contention that neonatal torsion is often an antenatal event. However, the clinical features are not always noted at delivery and in many cases are not detected until the second or third day of age. Occasionally, features consistent with acute torsion (sudden onset of swelling, erythema, and pain) may develop some days or weeks after delivery, and it appears that in these cases the torsion is more likely to be intravaginal. Torsion of an undescended testis may present in this way.[2]

Diagnosis can usually be made on the clinical features alone. The differential diagnosis includes hydrocele, testicular tumor, trauma, adrenal hemorrhage, and meconium peritonitis with tracking down a patent processus. Distinction from a simple hydrocele is usually easy by transillumination. Testicular neoplasia can be excluded by the presence of bluish discoloration and scrotal edema. Torsion can only be differentiated from spontaneous infarction at surgery. Some bruising of the scrotum may occur after breech delivery,[9] but this is usually in the presence of a testis that feels normal to palpation. Intraperitoneal injury from birth trauma may result in hematocele formation, but the fluctuation of this lesion will usually distinguish it from torsion. Adrenal hemorrhage may present with features indistinguishable for torsion, but adrenal ultrasound would be diagnostic.[10] While color Doppler studies of testicular artery flow and radionuclide scanning of the scrotum might support the diagnosis, they are not required.

A clinical diagnosis of neonatal torsion is sufficient indication for scrotal exploration. While it might seem mandatory that this be conducted urgently, reports of successful testicular salvage are rare.[3,11–13] The classical clinical features seem to be due to the presence of established testicular infarction and it can be argued that the only reason for surgery is to fix the contralateral testis. Because delayed

torsion of the contralateral testis does occur and may be at extravaginal, intravaginal, or mesorchial level, early surgery to assess the affected testis, excise it if necessary and securely fix the contralateral testis is recommended. No specific preoperative preparation is required.

OPERATIVE TECHNIQUE

Under general anesthesia, the scrotum is incised in the midline and dissection continued into the affected hemiscrotum (Fig. 104.2). Both testes are easily approached through this single incision (Fig. 104.3). In most cases, established infarction will have resulted in edema and fixation of the testis to the subcutaneous tissues. It is usual, however, to find a plane of cleavage outside the tunica vaginalis, resulting in a clear demonstration of the site of torsion. In some instances, necrosis is well established and the exact origin of the pathology cannot be identified. If, as is usually the case, the testis is clearly beyond salvage, it is wise to excise it, having transfixed the spermatic cord above the site of torsion. Retention of a necrotic testis is inadvisable as it invites sepsis which may put the contralateral testis at risk. While there is a theoretical possibility that retention of the infarcted testis may result in some hormonal production,[8] in the majority of cases in which the affected testis is not removed, involution occurs.[2] Following excision of the affected testis, the contralateral testis is exposed through the same excision. The tunica vaginalis is opened to allow accurate inspection of the anatomy and permit effective fixation. This may be performed by placement of the testis in a subdartos pouch, as used in orchidopexy, or by suture fixation, which is now described. The tunica vaginalis is sutured to the tunica albuginea of the testis at four points, using a fine non-absorbable monofilament material, thus preventing intravaginal torsion. It is wise to incorporate the scrotal septum in the two medial sutures, thus fixing the tunica vaginalis to the scrotum and preventing extravaginal torsion (Fig. 104.4). Care should be taken to site these two sutures fairly deep in the wound or else the testis will lie too superficially and skin closure made more difficult. The scrotal incision is then closed with a fine continuous absorbable suture. No specific postoperative care is required.

Long-term outcomes in newborn surgery

CASEY M CALKINS AND KEITH T OLDHAM

INTRODUCTION

Ongoing advancements in the pre- and postoperative care of the neonate with a surgical condition have enabled the survival of an increasing number of infants with congenital malformations. For decades, surgeons have insisted on a regular self-examination of outcomes in order to ensure the optimal treatment of our patients. Outcome analysis traditionally relates to the rudimentary end result of an operation – utilizing variables such as mortality, operative time, specific complication rates (i.e. incidence of esophageal stricture following esophageal atresia repair), and hospital length of stay, to name a few. Recently, outcomes research has become a more complex endeavor. Measures of long-term outcomes, including 'functional outcome' and 'health-related quality of life' are equally important to the morbidity sustained as a result of a congenital malformation and its attendant surgical correction. The methods by which subjective assessments are expressed as a quantitative measure are therefore important for the surgeon to understand. These data serve as an important adjunct to prenatal counseling, offer information about future health expectations for families, assist the surgeon in identifying potential improvements in perioperative management, and will likely be utilized by public agencies charged with implementing health policy, especially in an era of diminishing resources. Therefore, long-term outcomes are of specific import to the neonates we care for, the families we answer to, and our colleagues charged with the continued efforts to improve the surgical care of our youngest patients. This chapter will begin by focusing on the specific language and methodology of modern long-term outcomes research as a prelude to the current status of long-term outcomes assessment in newborn surgical conditions commonly treated by the pediatric surgeon.

WHAT IS AN 'OUTCOME'?

In 1934, Ernest A Codman, an orthopedic surgeon, espoused the 'end result idea'. In his book *The shoulder*, Dr Codman introduced this 'common sense notion that every hospital should follow every patient it treats long enough to determine whether or not the treatment has been successful, and to inquire "if not, why not?"'.[1] Today, this 'end result idea' represents the very basis for conducting outcomes research, which examines how interventions delivered in the treatment of medical and surgical disease affect patient populations over time. It is one of many areas of investigation within the broad field of health services research.[2] Although, one can formally define a 'health service',[3] it seems intuitive to say that it is any organized effort to improve the health of a patient. The measurements and assessments utilized in outcomes research have changed considerably over the course of the last two decades. Regular assessment of our operative outcomes in the form of 'morbidity and mortality' conferences is, and continues to be an essential endeavor to ensure that we continue to improve the surgical care delivered to infants and children. It is an indispensable form of self-assessment and allows us to learn from one of the realities of human nature – error. However, assessment of individual and system failure represents only one part of how we improve the practice of pediatric surgery. Individual quality improvement depends on refining surgical technique, learning at regional and national society meetings, remaining knowledgeable by reading relevant peer-reviewed literature, and incorporating successful strategies and techniques into practice.

Assessment of patient outcomes (bad and good) helps us to understand what works and what does not. In this sense, an outcome can be any measure that affects the health, perceived health, physiologic function, financial status, or experience of a patient. Modern outcome measures have developed as a result of three general trends. First, traditional clinical outcomes are supplemented by measurements that take patient experience and concerns into account, particularly with regard to chronic illness, where the intent is typically to treat or offer palliation, rather than provide a definitive cure. Second, when making decisions regarding healthcare, patient preference is critically important, and information on health-related quality of life or functional results of one treatment versus another may ultimately influence decision-making in this regard. Finally,

health care policy-makers remain under pressure to effectively allocate resources. Benefits and quality of life perceived by patients and society as a whole may allow appropriate governmental bodies to do so with a sense of what is best for the collective good when resources may be limited. A common feature of health-related outcome measures today is measurement of well-being from the subjective viewpoint of the individual patient (or parent – the 'proxy') concerned. The three items crucial to understanding of modern-day outcomes research are: health-related quality of life, functional outcome, and utility (cost-effectiveness).

HEALTH-RELATED QUALITY OF LIFE

Where health and quality of life clearly intersect – the concept of health-related quality of life (HRQoL) assessment is born. In contrast to objective data obtained by laboratory, radiographic, or purely functional assessments, the measurement of HRQoL provides additional information about the subjective impact of a condition, or, for our purposes, the ramifications of an operation utilized to treat that condition. Transformation of qualitative assessments into quantitative data requires identification of measurable elements related to an individual's existence and assessment by way of an instrument.[4] Five general concepts define the scope of such an instrument: (1) impairment, (2) functional state, (3) health perception, (4) social opportunity, and (5) duration of life.[5] Distinct domains have been subsequently operationalized in order to translate these five concepts into quantifiable data. Although there is no consensus regarding a universal and inclusive set of domains, most researchers will agree that 'quality of life' differs greatly from person to person. A survey respondent may weigh various domains differently, and one must decide how to assess for these differences when interpreting the results from a cohort of respondents. The seven general domains of health in most HRQoL surveys include physical functioning, social functioning, emotional functioning, cognitive functioning, pain/discomfort, vitality, and overall well-being.

Instrument standards

A HRQoL instrument is developed utilizing psychometric testing principles and, once constructed, is reviewed against standards outlined by the Scientific Advisory Committee of the Medical Outcomes Trust.[6] Evaluation criteria include: appropriateness, validity, reliability, responsiveness, precision, acceptability, interpretability, and feasibility. **Appropriateness** is the first and most fundamental criterion to assess and asks whether the instrument measures what have been identified as the most important outcome(s) for the purposes of evaluation. Specifically, is the instrument relevant, and are the methods of evaluation and administration appropriate? **Validity** concerns whether an instrument measures what is intended. Face and content validity are matters of qualitative judgment – for instance, were the patient types targeted for assessment included in the creation of the instruments' content? Construct validation refers to comparisons with other instruments, relating the scores to sociodemographic variables, and comparing domain scores within the instrument itself. **Reliability** assesses whether or not an instrument is consistent in its measurements, both internally and over time. **Responsiveness** refers to the ability of an instrument to measure significant changes in health and is assessed by looking at changes in instrument scores for groups whose health is known to have changed. The **precision** of an instrument is measured by the range of response options and the existence of ceiling (maximum score) or floor (minimum score) effects. An instrument is likely to be **acceptable** to a patient or population group if it measures what they consider to be important aspects of quality of life. The optimal instrument is **interpretable** – and is able to translate a quantitative score into an external measure that has a familiar meaning. This aspect of an instrument is easily assessed when there are normative data from a representative sample of the general populous and/or patients with similar conditions for whom the instrument is intended. Finally, **feasibility** refers to the time and effort needed to complete the instrument, and whether such issues are prohibitive to completion of the instrument, or affect the manner in which it is completed. The United States Centers for Disease Control has established a comprehensive website that may aid the clinician when faced with the possibility of instrument evaluation or utilization (www.cdc.gov/hrqol).

Unique issues in health services research for the newborn population

As the goal of adult functioning is to be self-sufficient and economically productive, adult-based measures of functioning and quality of life are not likely to be relevant to children.[7] Furthermore, children often view health and illness as separate entities, whereas adults see these two items as part of a continuum.[8] Lack of a consensus upon a theoretical framework as to the nature of HRQoL in children means that there is lack of agreement regarding the optimal domains in a pediatric HRQoL assessment tool. Even within domains, there are often variations of emphasis. For example, within the physical functioning domain, an instrument may place varied emphasis on physical symptoms, self-care, participation in physical activities, or distress caused by limitations. As a result, different instruments may yield different results depending on the age of the child, the medical or surgical condition, the emphasis of the questions within a domain, and a variety of other factors unique to pediatric healthcare.

Although adult HRQoL measures suffer from some of the same issues of validity, the common feature of most adult instruments is that they measure health from the subjective viewpoint of the individual concerned. In children, this information is not always easily obtained from the subject. Although many children are able to provide self-reports of HRQoL if an instrument is chosen that is appropriate to his/her abilities, this assertion has not been well evaluated. Furthermore, different domains within an instrument may pose unique challenges to different age groups. Children as young as five years may be able to provide accurate

self-reports of pain, whereas subjective concepts such as behavior or self-esteem may not be able to be accurately assessed until ten years of age.[9] Several self-reporting biases are also more problematic in pediatric populations. Position bias (tendency to select the first answer), acquiescent response bias (tendency to agree with questions regardless of content), failure to accurately perceive time periods, boredom with having to answer written questions, and difficulty in understanding negatively worded items makes construction of pediatric outcome tools difficult. Given that self-reports suffer from such bias and many children are truly unable to fill out a self-assessment, other individuals – 'proxies' – have served to provide data on the child's behalf. Parents or caregivers who have a longstanding relationship with the patient commonly complete such proxy reports. However, the choice of proxy may add further bias to the instrument. For example, fathers generally rate children as having fewer behavioral and psychological problems than do their mothers.[10] In another study, children aged 8–11 years with a chronic health condition reported significantly lower HRQoL than their parent proxies.[11] In one review, nearly 90% of pediatric HRQoL assessments were completed by a proxy.[12] However, most modern pediatric-specific instruments can be utilized in a self-reporting mode, and proxy assessments may be applicable to only the youngest of children. When possible, self-reports should always be sought over proxy-generated data.

As the development of a child is not always linear, how does one separate development from outcome? This is one of several questions that remain unanswered regarding the instruments currently utilized for pediatric HRQoL. Outcome measures that not only are sensitive to changes in development and health, but also make allowances for different cognitive abilities of children at various ages with regard to reporting and valuing health status are required.[13] When selecting an instrument, the clinician should consider whether the concepts inherent in the tool are developmentally appropriate for age, gender, and culture. In addition, if one is interested in measuring longitudinal HRQoL in a patient cohort, selection of an instrument with items that are not overly age related may be optimal so that children of different ages may complete the same instrument.

To get around the problematic issue of 'child-friendly' tools and feasibility, some instruments have employed unique methods to entice children to complete the surveys. For example, the KINDL® instrument employs a computerized program to measure pediatric HRQoL by means of a touch-screen monitor or a mouse. It is a child-friendly (independent of reading and writing skills, in a playful format), economical, and developmentally appropriate program that is valid, reliable, and available in two languages (German and English). Other methods to entice and facilitate child participation include third-party interviewing and age-appropriate storybook formats.

Multidimensional generic measures of HRQoL

Generic quality-of-life measures are designed to assess physical, psychological, and social aspects of health without attention to a specific ailment or disability. These instruments emphasize breadth over specificity by focusing on the common elements of health that transcend all diseases. In practice, these instruments may also augment subjective and objective clinical data that focus on signs, symptoms, and effects of a specific disease.[14] The following list of instruments (Table 105.1) is not, by any means comprehensive, but serves to highlight the most common instruments available for the assessment of generic HRQoL in infants and children.

Table 105.1 Health-related quality of life instruments.

Instrument	Applicable age	Time to complete (mins)
PedsQL	5–18 years (self) 2–18 (proxy)	<5 (self or proxy)
CHIP	'CE' 6–11 years (proxy) 'AE' 6–18 years (self)	20 (self or proxy)
CHQ	5–15 years (proxy) 10–18 years (self)	7–30 (proxy) 15–30 (self)
KINDL	4–16 years (self) 4–16 years (proxy)	10–15 (self) 10 (parent)
KIDSCREEN	8–18 years (self) 8–18 years (proxy)	20 (52 items) 15 (27 items) 5 (10 items)
DISABKIDS	4–7 years (self or proxy) 8–16 (self or proxy)	20 (37 items)

CHQ, Child Health Questionnaire; PedsQL, Pediatric Quality of Life Inventory.

PEDIATRIC QUALITY OF LIFE

The Pediatric Quality of Life (PedsQL™) measurement model is a modular approach to measuring HRQoL in children and adolescents who are healthy, as well as those with acute and chronic health conditions. The model has the added ability to integrate both generic core scales and disease-specific modules into one measurement system. The PedsQL generic core scales include: brief (23 items), practical (less than 4 minutes to complete), and flexible (designed for use with community, school, and clinical pediatric populations). Its permutations are meant to be developmentally appropriate (different modules for ages – child self-report ages 5–7, 8–12, 13–18; parent proxy-report ages 2–4, 5–7, 8–12, 13–18). It is one of the most interpretable tools due to its widespread use. Additionally, it is translated into multiple languages including Spanish.[15–18] The 23-item PedsQL generic core scales were designed to measure the principal dimensions of health as delineated by the World Health Organization, as well as role (school) functioning. PedsQL condition-specific modules complement the generic core scales and are used in designated clinical populations. These are designed to provide greater measurement sensitivity for circumscribed populations (currently available for asthma, rheumatology, diabetes, cancer, and cardiac conditions, with additional modules in the development and planning stages). For the pediatric surgeon, the PedsQL is an attractive option as it is brief, practical, developmentally appropriate, multidimensional, reliable, valid,

and responsive. It has been cited in numerous peer-reviewed publications. The instrument has the ability to measure HRQoL over time with instruments that are age-appropriate and available in both patient and proxy forms.

CHILD HEALTH AND ILLNESS PROFILE

The Child Health and Illness Profile (CHIP) instruments were developed by Dr Starfield and colleagues at the Johns Hopkins School of Public Health.[19] Development of the child and adolescent editions occurred over 12 years and involved more than 5000 children and adolescents from ethnically and socioeconomically diverse families. The CHIP-CE (child evaluation, CE) instruments provide a comprehensive assessment of health status that can be completed by children 6–11 years old or by their parents. It describes aspects of health that can be influenced by health systems, school health systems, and health promotion efforts. The CHIP-AE (adolescent evaluation, AE) was developed to document the state of health in adolescent age populations, identify differences in the health of subpopulations, and assess the impact of medical and surgical interventions on health.

CHILD HEALTH QUESTIONNAIRE

Perhaps the most commonly used outcome assessment tool in contemporary health services research is the SF-36 ('short-form 36').[20] The Child Health Questionnaire (CHQ) is a byproduct of the SF-36 and a more appropriate choice for use in children and adolescents. A product of the RAND-sponsored Medical Outcomes Study (MOS), the SF-36 is a 36-item general health status assessment questionnaire. It has nine separate scales, although recent work has identified two dimensions that underlie the nine subscales: physical and mental health. There is substantial reliability and validity data for the SF-36 in a wide variety of adult populations.[21] However, the 28-item and 50-item CHQ short-forms (which cover the same 12 concepts as the full-length CHQ) are more efficient measures than the SF-36 and are valid for use in children aged 5–18 years.[22] In the United States, normative values and benchmarks for the parent-reported versions of the CHQ are available for some specific health conditions. The youth self-report version is 87 items, and was developed for use in individuals aged ten years and older. Authorized translations and internet-administered versions are also available.[23]

KINDL

Initially developed in Germany, the KINDL is a 24-item, methodologically suitable, psychometrically sound, and flexible instrument. The questionnaire can be completed by children and adolescents (aged 4–16), or by way of a parent proxy. The questionnaire is available for different age groups. The computer-assisted version (CAT-SCREEN) is a unique method of instrument administration that may be especially suitable for toddlers. Disease-specific modules exist for obesity, asthma, atopic dermatitis, cancer, and diabetes. The KINDL has been validated and is especially effective in the assessment of psychological well-being, social relationships, physical function, and everyday life activities.[24]

OTHER PEDIATRIC GENERIC INSTRUMENTS

The Infant Toddler Quality of Life Questionnaire™ (ITQOL) was developed for use in infants and toddlers from at least two months of age up to five years. The ITQOL adopts the World Health Organization's definition of health, as a state of complete physical, mental, and social well-being and not merely the absence of disease. The survey was developed following a thorough review of the infant health literature and a review of developmental guidelines used by pediatricians. Its child equivalent is the aforementioned CHQ. The Dartmouth COOP child-report charts were developed as a survey to evaluate treatment outcomes and as a tool for the detection of important health problems. It consists of six charts addressing physical fitness, emotional feelings, schoolwork, social support, family communications, and health habits.[25] The instrument was developed from literature review and a focus group of physicians and adolescents. The tool is completed by the subject and is reasonably feasible in that it contains only six items. The Exeter Quality Of Life Measure (Exqol) is another generic self-report HRQoL measure for children aged 6–12 years based on the authors' experience with chronically ill children. Like the KINDL CAT-SCREEN, it is computer administered and consists of 12 gender-specific pictures – each of which is rated twice: the first in terms of 'like me' and the second in terms of 'as I would like to be'. The DISABKIDS and KIDSSCREEN instruments were developed and validated in European countries to measure HRQoL in children from 4 to 18 years of age. These instruments are available in a variety of lengths and languages. Several disease-specific modules have been developed for both instruments (i.e. cerebral palsy, cystic fibrosis, and diabetes). Both instruments can be administered by a standard questionnaire or computer; and a child-friendly version of DISABKIDS is available for individuals from four to seven years of age.

CONDITION-SPECIFIC MEASURES OF HRQOL

Condition-specific measures aim to assess quality of life following a specific intervention or for individuals with a specific diagnosis. When condition-specific instruments are developed to assess quality of life following treatment of a specific anomaly, such measures are designed to be more sensitive to the detection of small treatment effects when compared to generic measures. In this regard, a condition-specific measure is designed to tap the domain(s) of greatest interest for the condition in question. At present, none of the generic HRQoL instruments have been specifically designed to evaluate patients who suffer from the conditions that are principally cared for by neonatal surgeons. However, a variety of studies have been performed with the intent of validating generic HRQoL instruments in patients with neonatal surgical disease. Furthermore, a select number of disease-specific outcome measures have been developed to assess quality of life after the treatment of pediatric surgical conditions. For example, in Europe, a proxy version of

EuroQOL (see below) was found to be feasible and valid in a population of children with anorectal malformations.[26] Similar studies have utilized generic quality-of-life measures in children with Hirschsprung's disease (HD),[27] anorectal malformations,[28] congenital diaphragmatic hernia,[29] and neurological impairment requiring gastrostomy or surgical treatment of gastro-esophageal reflux,[30,31] to name a few. Unvalidated questionnaires have also been utilized to assess health-related quality of life in many conditions treated by pediatric surgeons.[32,33] Condition-specific HRQoL measures have also been described for children with anorectal malformations and HD.[34] Ultimately, very few HRQoL measures to date have been specifically validated or developed for use in the neonatal surgical population.

FUNCTIONAL OUTCOMES

Functional outcomes can be measured in a variety of formats. It is a difficult area of health services research to clearly define. In one sense, these outcomes can be measured within the context of a specific disease state and the procedure that is designed to treat that disease. However, for neonatal surgery the impact of functional outcomes may be inherently distinct from adult conditions. Take, for example, a professional football (soccer in the United States) goalie who is able to consistently punt the ball to the opposite penalty box. He suffers a knee injury in the prime of his career and must undergo reconstructive knee surgery. A 'disease-specific' functional outcome measure following repair could be as simple as assessing his ability to kick the ball that same distance following surgery and physical rehabilitation. From the player's point of view, he is 100% functional if he is able to kick that same distance without any pain after treatment. However, how do we measure function in this case if he is only able to punt the same distance inconsistently? Also, what if he is able to punt the same distance, but suffers incredible pain in doing so – is this a issue of quality of life, function, or both? Thus, the assessment of 'functional outcome' is complex. However, since the sample of premier league goalies who consistently punt a soccer ball nearly the entire length of the football field is relatively small, most generic functional outcome instruments focus on the assessment of individuals with chronic health problems and their ability to 'function' in everyday life. These same issues confront the newborn surgeon attempting to study functional outcomes in populations where the congenital malformations are relatively rare. Furthermore, for such measures to have a meaningful individual and societal impact, they must be measured in adult life, where independent functioning is the expectation. The ability to function is distinct from the quality of function, or life. As it relates to health services research, functional outcomes are not necessarily meant to be condition specific, but are related to any of the general domains of functional health in a survey introduced earlier: physical, social, emotional, or cognitive functioning. The following instruments are the three most common tools utilized to measure general functional outcomes in children (Table 105.2).

Table 105.2 Functional outcomes tools.

Instrument	Applicable age	Time to complete (mins)
FIM[SM]/WeeFIMII[SM]	0–18 (proxy)	15–20 (18 items)
FSIIR	0–16 (proxy)	15 (short), 30 (long)
PEDI™	0–7 (proxy)	45–60 (237 items)

FIM[SM]/WeeFIMII[SM], Functional Independence Measure; FSIIR, Functional Status II; PEDI, Pediatric Evaluation of Disability Inventory.

Functional Status II

The Functional Status II (FSIIR) is able to distinguish between children with and without chronic health conditions, has acceptable internal consistency, reliability, and correlates with other indicators of illness, such as utilization of medical services and illness-related absenteeism.[35] The FSIIR is a 14-item instrument administered to parents to measure their child's capacity to perform age-appropriate roles and tasks in a variety of areas, such as communication, mobility, mood, energy, sleeping, and eating. Parents use a three-point categorical scale to indicate the observed frequency of specific behaviors. When impairment in child functioning is described, parents are asked to report whether each specific impairment is due to the child's illness. The **total** score is the sum of the scores, thus indicating the child's functional status without regard to whether or not observed impairment is due to the child's illness. The **illness** score is the sum of the scores indicating the child's functional status with deduction of points only for impairment related to the child's illness, thus often resulting in a score higher than the total score. The higher the score, the better the functional status.[36]

Pediatric Evaluation of Disability Inventory

The Pediatric Evaluation of Disability Inventory (PEDI) was developed to provide a comprehensive clinical assessment of key functional capabilities and performance in children between the ages of six months and seven years. The PEDI was designed primarily for the functional evaluation of young children; however, it can also be used for the evaluation of older children if their functional abilities fall below that expected of a seven-year-old child. The assessment is designed to serve as a descriptive measure of the child's current functional performance, as well as a method for tracking change over time. The PEDI measures both capability and performance of functional activities in three content domains: (1) self-care, (2) mobility, and (3) social function. It has been primarily utilized in the functional evaluation following neurologic insults (i.e. traumatic brain injury or stroke).[37–40]

Functional Independence Measure

The Functional Independence Measure (FIM[SM]) and its pediatric counterpart (WeeFIMII[SM]) are standardized instruments initially designed to allow clinicians to document

functional performance in children and adolescents with acquired or congenital disabilities.[41] These measures have been approved by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) to provide information for the ORYX initiative (a standardized initiative to allow JCAHO to measure performance standards across accredited organizations), as well as to meet accreditation standards for the Commission on Accreditation of Rehabilitation Facilities (CARF).[42]

Other assessments of functional outcome

The aforementioned scoring systems provide generic assessments of child functioning in daily life. However, a pediatric surgeon is often most interested in how a patient compares to his or her age-related peers following a specific intervention performed in the neonatal period. In this regard, disease-specific functional outcome measures have been utilized for a variety of different pediatric surgical conditions. However, 'function' can be measured by different instruments and/or objective assessments pertinent to the condition in question. The literature regarding the long-term functional results of congenital diaphragmatic hernia (CDH) illustrates this point.

The collaborative UK ECMO (Extracorporeal Membrane Oxygenation) trial concluded that a policy of ECMO support reduces the risk of death without a concomitant rise in severe disability, defined as an overall developmental quotient of <50 using the Griffiths Mental Development Scales.[43] In another study of infants with severe CDH (those who required ECMO support), survivors displayed mild neuromotor and cognitive delay in development at 24 months of age as measured by impairments in mean Bayley Mental Developmental Index and Psychomotor Developmental Index scores.[44] Both of these studies utilized cognitive functioning scores to report on the functional outcomes of infants with CDH.

Other assessments of functional outcome may be related to objective physiologic measurements. In a study of 23 adult survivors of CDH, pulmonary function tests, diffusion capacity, and a cardiopulmonary exercise test (CPET) were performed. The FEV_1 and FEF25–75% were found to be lower in CDH survivors. Despite these abnormalities, during CPET, percent predicted work load and percent predicted maximal oxygen uptake were normal in most of the patients.[45] In another study of functional respiratory outcomes of CDH patients treated in the perinatal period, 26 adolescent survivors and age- and gender-matched controls were subjected to pulmonary function testing. Significant differences were found in nearly every spirometric measurement.[46] Thus, as function relates to pulmonary mechanics in the CDH population, functional outcomes can be construed as favorable or unfavorable depending on the measure utilized.

In general, functional outcomes refer to things that are meaningful to the patient in the context of everyday living. However, for pediatric surgeons, function may be best related to how well the operation is able to recapitulate the 'normal'. In that regard, condition-specific functional outcomes are also worthy to gauge the 'success' of a neonatal operation. For example, it would be helpful for the pediatric surgeon to know what percentage of patients with a type C esophageal atresia are able to eat any food without dysphagia in adult life. Similarly, anorectal function (fecal continence) after the period where toilet training is typically achieved is an especially salient outcome measure for patients with anorectal malformations and HD. These types of disease-specific measures are helpful for patients and their families as they consider the long-term functional issues related to the congenital malformations we are charged with treating. In the final analysis, both disease-specific and generic functional outcomes have merit in the long-term assessment of patients with neonatal surgical conditions.

COST-EFFECTIVENESS AND UTILITY MEASURES

A panel convened in 1993 by the US Department of Health and Human Services suggested that standardized outcomes analyses be conducted to evaluate the cost-effectiveness of medical care.[47] One way to directly compare relative treatment effectiveness is to examine the impact of interventions on the utility gained. Cost-utility analysis fulfills this requirement.[48] In this type of analysis, health treatment effects are most commonly measured in terms of quality-adjusted life-years (QALYs) gained. Preference-based instruments allow one to compare interventions and treatment regimens for a given condition in this manner. Such analyses have become popular for examining the economic consequences of disease and the medical and surgical interventions aimed at treating such problems. A QALY takes into account both quantity and quality of life generated by health-care interventions. It is the arithmetic product of life expectancy and a measure of the quality of remaining life-years. A QALY places weight on time during different health states such that a year of perfect health is worth a score of 1, whereas death receives a score of 0. Health states considered to be worse than death receive a score below zero. The strength of QALY analysis is the fact that it provides a common currency to assess the extent of benefit gained from interventions to improve the quality of life. A cost-utility ratio can be calculated from a QALY assessment combined with the cost of treatment for the condition. For example, a disease that reduces the quality of life by one-half will take away 0.5 QALYs over the course of one year. If it affects two people, it will take away 1.0 QALY (equal to 2×0.5) over a one-year period. A medical treatment that improves the quality of life by 0.2 for each of five individuals will result in a score of 1 QALY if the benefit is maintained over a one-year period. Using this system, it is possible to express the benefits of various interventions by showing how many QALYs they produce versus the total economic cost of the intervention.[49]

Utility and cost ultimately are important components of health-care policy formulation (Table 105.3). Using the common metric of QALYs also allows one to introduce quality of life into the direct cost comparison of programs. This approach provides a framework within which to make policy decisions that require selection between competing

Table 105.3 Utility instruments.

Instrument	Applicable age	Time to complete (mins)
QWB	5–18 (self and proxy)	10
HUI:2	6–18 (self and proxy)	3–10
EQ-5D	5–18 (self and proxy)	1–2

EQ-5D, Euro Quality of Life; HUI:2: Health Utilities Index; QWB, Quality of Well-being scale.

alternatives. Importantly, these types of analyses are potentially influential in determining the extent of funding for particular pediatric interventions.[13] The Quality of Well-Being scale (QWB), the Health Utility Index (HUI), and the EQ-5D are three examples of utility-based measures developed for and validated in pediatric populations.

Quality of Well-Being Scale

Developed by researchers at The University of California, San Diego, the QWB assesses a patient's objective level of functioning in three areas: mobility, physical activity, and social activity.[50] An important distinction is made between 'functional ability' and 'functional performance' – whereby a patient is asked to report activity performed rather than what can possibly be performed. The scoring of the instrument utilizes population-derived preference weights. Current studies are addressing the validity of the QWB-SA translated into Spanish, German, Italian, Swedish, French-Canadian, and Dutch.

Health Utilities Index

The HUI (HUI2, version 2; HUI3, version 3) is a family of health status and preference-based health-related quality of life measures suitable for use in clinical and population studies.[51] Both HUI2 and HUI3 focus on capacity rather than performance. Each includes a health status classification system, a preference-based multi-attribute utility function, data collection questionnaires, and algorithms for deriving HUI variables from questionnaire responses. The attributes of health status included in HUI were chosen on the basis of their importance to people. HUI utility scores are based on the preferences of the community. HUI2 consists of seven attributes: sensation (vision, hearing, speech), mobility, emotion, cognition, self-care, pain, and fertility.[52] Similarly, HUI3 consists of eight attributes: vision, hearing, speech, ambulation, dexterity, emotion, cognition, and pain.

EQ-5D

Established in 1987, the EuroQOL Group initially comprised a network of international, multilingual, and multidisciplinary researchers from seven centers in Finland, the Netherlands, Norway, Sweden, and the UK. Currently, the group has expanded to researchers from Canada, Denmark, Germany, Greece, Japan, New Zealand, Slovenia, Spain, the United States, and Zimbabwe. The EQ-5D is a generic measure of health status that provides a simple descriptive profile and a single index value that can be used in the clinical and economic evaluation of healthcare and in population health surveys. The EQ-5D system consists of five dimensions: mobility, self-care, usual activity, pain/discomfort, and anxiety/depression. Each dimension has three levels designated simply as no problem, some problem, or extreme problem, and subjects are asked to check the level most descriptive of their current level of function or experience in each dimension. These five dimensions, yield 243 possible distinct 'health states' comprising the classification system. The classification system has been assigned standardized scores derived through population-based samples of respondents asked to assign values to subsets of the 243 states. A set of valuation weights has been derived from a US sample.[53]

Although several measurement instruments have been developed to measure utility in children, measurement methods are seemingly fraught with inconsistencies and biases.[54] Indeed, a study of cost-utility analyses in the medical literature between 1976 and 1997, recommended the need for more consistency and clarity in reporting.[55] In response to such criticisms, the Paediatric Economic Database Evaluation (PEDE) project was conceived to promote research into pediatric health economic methods. In recent years, standard methods for the conduct of economic evaluations have evolved to improve allocation decisions that are unique to the pediatric population. The database contains over 1500 citations from January 1, 1980 to December 31, 2005 and continues to be updated. Consistent with use in allocation decision-making, only full economic evaluations are accepted for inclusion.[56]

Long-term outcomes in specific neonatal surgical disease

Assessment of outcome is an important part of the practice of neonatal surgery. The current tools available to quantify quality of life, function, and cost-utility have changed dramatically over the last decade. However, this area of health research remains in its infancy where patients with neonatal surgical conditions are concerned. Unfortunately, there are few studies in pediatric surgery that address long-term outcome. This offers an opportunity for further research, yet represents a host of difficulties. Information on long-term outcomes is difficult to obtain as studies require the meticulous collection of data over many years, are hampered by lack of long-term follow up (especially for those children who do well!), and attempts to corral a mobile patient population require efforts beyond the willingness or resources of most pediatric surgeons. Furthermore, relatively few clinical interventions and treatments in pediatric surgery are supported by adequately powered randomized controlled trials – which may undermine the subsequent analysis of long-term outcome. In many cases, the specific short- and long-term morbidities of each congenital malformation and its respective operative treatment have been previously addressed in the specific chapters of this text. However, we will cover some of the salient long-term standard and

modern outcome measures of the most common neonatal thoracic and abdominal surgical conditions and propose future opportunities to further our understanding of the ramifications of these malformations and the operations utilized to treat them.

LONG-TERM OUTCOMES FOR SURGERY IN THE NEWBORN PERIOD

General considerations: prematurity and low birth weight

The neonatal period is defined as the period after birth within the first 28 days of life. Indeed, no other patient demographic in medicine has achieved such a dramatic improvement in survival over the last 30 years as that of the premature neonate. Today, the survival for very low birth weight (VLBW) infants (birth weight less than 1500 g) has increased to over 80%. Furthermore, patients weighing less than 1 kg (extremely low birth weight, ELBW) have realized survival in as many as 70%. These increases have occurred as a result of many substantive improvements in perinatal care and the expertise and methods by which that care is delivered. However, as the number of deaths from sepsis and the sequelae of group B streptococcal infection and chorioamnioitis have declined, the proportion of mortality due to congenital anomalies has increased in both the United States and the United Kingdom. In 1998, some 28% of infant deaths in the United Kingdom were due to a congenital anomaly. In the most recent national vital statistics report released by the United States Centers for Disease Control in 2007, only 0.8% of infants died prior to 28 days of postnatal life, but the leading cause of death in this group is attributed to congenital malformations. In the United Kingdom, approximately 114 out of every 10 000 live births is complicated by a congenital malformation. In the United States, it is estimated that some 2–3% of infants are born with a major congenital malformation. For appropriately grown infants (not suffering from intrauterine growth restriction (IUGR)) between a birth weight of 1500 and 2500 g the mortality rate remains less than 10%. Below this weight, mortality rates incrementally increase and survival below 500 g is uncommon. Today, the gestational age at which there is a 50% chance of survival has declined to 25 weeks.[57]

Perhaps the most salient long-term outcome as it relates to prematurity and low birth weight is the incidence of impairment, disability, and handicap. According to the World Health Organization, 'long-term impairment' includes any loss or abnormality of psychological, physiological, anatomic structure, or function. 'Disability' is defined as any restriction of ability to perform an activity within the range considered normal for a human being. A disability reflects the consequence of an impairment in terms of functional performance and activity. Finally, a 'handicap' is a disadvantage for a given individual resulting from an impairment or disability that limits fulfillment of the role that is normal based on age, sex, and social and cultural factors.[58] The most significant major disability affecting premature infants is cerebral palsy (CP). CP is defined as a permanent impairment of voluntary movement or posture due to damage to the developing brain. It may involve one limb (monoplegia), both lower limbs (diplegia), or all four (quadriplegia). In patients weighing less than 2 kg at birth, the incidence of cerebral palsy at the age of two years was 8% in a geographical study of 1000 children.[59] Very and extremely low birth weight survivors are also at an increased risk for long-term visual impairment, such that approximately 5% of infants in this category are 'blind'. Retinopathy of prematurity is the most common cause of poor visual outcome, however cortical blindness can occur from damage to the occipital cortex due to periventricular leukomalacia or optic atrophy as a result of hydrocephalus. Cryotherapy for retinopathy of prematurity is an effective treatment, reducing the chance of severe visual loss by 50%, and this treatment has resulted in an improvement in long-term visual handicaps associated with prematurity.[60] Sensorineural hearing loss is also a problem in survivors of premature birth. This is most frequently seen in survivors with persistent pulmonary hypertension (PPHN) and high incidences are widely reported in survivors of extracorporeal life support (ECLS). In modern intensive care units, all infants are screened for hearing loss. Early diagnosis guides appropriate support and improves language development later in life. Whereas cerebral palsy is clearly one of the most devastating long-term consequences of prematurity, cognitive impairment is a more common adverse outcome.[61] The intelligence quotient (IQ) in long-term survivors of VLBW gestations is shifted one standard deviation lower when compared to normal birth weight controls, and a significant number of these children suffer from attention deficit or hyperactivity disorders when compared with controls. However, even with an IQ in a normal range, the VLBW survivor is more likely to require special educational provisions. In addition, small for gestational age infants suffer from a negative impact on school performance; 25% of such infants in 1985 were failing at school at age ten years compared to 14% of children who had been weight appropriate for gestational age.[62] Nevertheless, small for gestational age survivors report 'adequate' satisfaction with life, despite the fact that these individuals are less likely to secure professional or managerial employment.[63] Finally, poor motor coordination, altered manual dexterity and balance, short attention span and visual impairment are generally coexistent and together significantly impair the child's ability to function in school. The highest proportion of these adverse neurodevelopmental outcomes are seen in those treated with the highest acuity of care (i.e. ECLS).[64–67]

General considerations: psychological effects of neonatal surgery

In addition to the consequences of prematurity and low birth weight, the psychological consequences of surgery performed within the first 28 days of life should not be overlooked. Studies on the effects of hospitalization on young children show that between six months and four years of age, children will most likely demonstrate short-term emotional and

behavioral problems during that admission, and later psychological disturbances were associated with repeat hospital admission, as well as those hospitalizations lasting for more than a week. Based on these observations, Dr Loraine Ludman and colleagues at the Great Ormond Street Hospital for Children in London began a prospective longitudinal study to examine the psychological effects of major neonatal surgery on infants and their families. The infants studied were born at term and required major surgery within the first 28 days of life. These infants were compared to a carefully matched group of healthy newborns not requiring neonatal surgery. Interestingly, very early hospitalization and periods of separation did not differentiate between the case-control pairs at 12 months of age. However, by three years of age, the rate of behavioral disturbance was approximately 2.5 times greater among the patients undergoing surgery in the first 28 days of life compared to the control group (30% versus 11.5%). The two predominant factors associated with difficulty in the mother–child relationship were a lengthy first admission (more than 25 days) and/or repeat hospital admissions. In longer-term follow up between 11 and 13 years of age, emotional and behavioral problems were more frequent among the surgical group than among the controls based on parent and teacher reports. These data suggest that surgery and repeated admissions in early childhood have long-term effects on emotional behavior adjustment. However, although a third of children were affected by the chronic nature of their condition in their preschool years, at early adolescence only a small proportion of those included in the dataset were regarded as having a 'chronic condition'. In addition, the youngsters all rated themselves as 'well adjusted' and there were no differences between the two groups in terms of self-esteem and depression self-report scales. These data raise the need for long-term focused psychological support for children and their families who care for children with major congenital anomalies requiring surgery in the neonatal period.[68–70]

Thoracic surgery: general considerations

A number of conditions diagnosed within the first 28 days of life require access to the thoracic cavity by way of thoracotomy or thoracoscopy. Neonatal thoracotomy is typically well tolerated in the short term. The recovery and return to normal physiologic function following neonatal thoracotomy is in contrast with that observed in adults – in which long-term pain and disability is more often realized in older patients. However, rapid neonatal 'recovery' must be tempered by the potential for long-term chest wall growth abnormalities resulting from thoracotomy. Several types of orthopedic deformities have been described following neonatal thoracotomy, including scoliosis, rib deformities and synostosis, and shoulder deformities. Jaureguizar *et al.*[71] reported on 89 patients operated for esophageal atresia via standard right posterolateral thoracotomy with a follow up of 3–16 years. Of these, 32% had significant musculoskeletal deformities including 'winged scapula', marked asymmetry of the thoracic cage from atrophy of the serratus anterior, rib fusion, and severe thoracic scoliosis. Chetcuti and colleagues[72] reported on a similar experience in the study of 232 patients with esophageal congenital anomalies without pre-existent congenital vertebral anomalies who underwent neonatal thoracotomy. In this series, 33% of patients later developed chest wall deformities and 8% were reported to have scoliosis. One of the purported benefits of minimally invasive access to the chest (thoracoscopy) for lung resection and repair of esophageal atresia is the potential benefit of limiting this chest wall morbidity. The long-term outcome from minimally invasive access to the thorax requires assessment of this possible benefit. Because of the above concerns, many pediatric surgeons today utilize a muscle-sparing thoracotomy through the ausculatory triangle, while preserving the latissimus dorsi and serratus anterior musculature. The long-term benefits of this type of approach also have not been reliably compared to that of a standard muscle-splitting thoracotomy. Both of these newer approaches to thoracic access offer opportunities for the pediatric surgeon to assess the potential benefits of modern surgical technique to the long-term outcomes of neonatal thoracic surgery.

MALFORMATIONS OF THE TRACHEOBRONCHIAL TREE

Subglottic stenosis did not become an issue until prolonged endotracheal intubation and ventilation of neonates became commonplace in the mid-1960s. As survival of low birth weight infants increased, so too did the number of patients with acquired laryngotracheal stenosis. Today, advances in the equipment utilized for neonatal endotracheal intubation, tube stabilization, and the recognition of the deleterious effects of prolonged transglottic instrumentation have decreased the incidence of laryngotracheal stenosis to less than 10%. In patients suffering significant laryngotracheal stenosis, the surgical options largely depend on the grade of stenosis realized. The functional outcomes of laryngotracheal reconstructive (LTR) surgery are clearly critical in the determination of long-term success. Studies evaluating exercise tolerance, speech, swallowing, and voice are at this point limited, owing to the relatively recent advances in the surgical correction of these disorders. Early studies of voice function after LTR surgery were entirely subjective assessments; however, recent studies in children have paired subjective observations with objective measurements.[73]

PULMONARY RESECTION

Pulmonary resection in the neonatal period may be undertaken for a congenital pulmonary airway malformation (formerly 'CCAM'), pulmonary sequestration, or congenital lobar emphysema. The most significant long-term outcome facing patients undergoing neonatal pulmonary resection is that of respiratory function. Ayed and Owayed[74] reported on the safety of lung resection in the neonatal period for congenital malformations and found that none of the patients had physical limitations at a mean follow up of four years. In addition, Caussade and co-authors[75] reported normal spirometry values for vital capacity in 27 patients who underwent neonatal pulmonary lobectomy. Neonates

undergoing lung resection can expect to have normal vital capacity due to the compensatory growth of the remaining lung and most studies indicate that few children are functionally impaired by lung resection performed in the neonatal period. In addition, in patients who undergo pneumonectomy prior to the age of five years, ventilatory capacity is only minimally reduced when compared to that predicted for an individual with a complement of two normal lungs suggesting that 'lung growth' occurs well beyond the neonatal period as a result of compensatory pulmonary hyperplasia.[76] It appears that normal postnatal growth of lung parenchyma at the gas exchange (alveolar) level up to about seven to eight years of age contributes most of this additional reserve, as there is not regeneration of conducting airways. Whereas functional outcome studies have been limited in patients undergoing pulmonary resection in the neonatal period, reports of health-related quality of life are noticeably absent in this patient cohort. To date, there is no literature classifying the health-related quality of life of infants undergoing neonatal pulmonary resection.

MALFORMATIONS OF THE ESOPHAGUS

One of the most commonly performed operations undertaken by the pediatric surgeon in the neonatal period is the repair of esophageal atresia and/or tracheo-esophageal fistula. Mortality rates in patients with Waterson risk groups A and B esophageal atresia is well below 5% overall. Today, the nature of coexisting anomalies that determine survival is best described by a newer risk stratification taking into account birth weight and the presence of cyanotic congenital heart disease.[77] Early surgical complications, such as anastomotic leak, disruption, or stenosis, are often associated with a favorable short-term outcome when adequately treated. In the long term, dysphagia and food impaction are the most common foregut issues facing the child with repaired esophageal atresia. The motility of the esophagus is inherently abnormal to some degree in all patients despite 'adequately' repaired esophageal atresia.[78] Although symptoms of 'choking with feeding', odynophagia, and 'food impaction' are relatively common during childhood following esophageal atresia repair, these problems tend to decline with age. Those who have persistent difficulties with swallowing are more likely to have or have had an esophageal stricture or significant gastro-esophageal reflux. Today, radial balloon dilation of the esophagus under fluoroscopic control and medical and/or surgical control of reflux disease are useful adjuncts in the prevention of these long-term sequelae. Indeed, most adult survivors with repaired esophageal atresia have minor persistent gastrointestinal symptoms such that less than 10% report dysphagia that occurs once a day, and the majority report no symptoms of gastro-esophageal reflux.[79] While it is generally believed that persistent gastro-esophageal reflux in patients undergoing esophageal atresia repair contributes to dysphagia, there is little objective evidence of this. The majority of neonatal gastro-esophageal reflux disease (GERD) is a transient problem that abates by childhood. Although adults with repaired esophageal atresia may be at increased risk for developing esophageal malignancy, it is too early to tell whether or not the history of esophageal atresia affects the incidence of esophageal carcinoma later in life. Although there are sporadic reports of early development of esophageal adenocarcinoma following esophageal atresia repair, there is no clear-cut evidence that the anomaly itself or its correction contributes to the development of esophageal malignancy.[80] The concern is that esophageal dysmotility, poor esophageal clearance, and reduced lower esophageal sphincter pressure, even in the absence of symptoms may lead to the development of Barrett's esophagus, which is associated with an increased risk of adenocarcinoma of the distal esophagus. To date, there is no specific recommendation with regard to long-term surveillance for patients with esophageal atresia; however, as more survivors make their way into adult and elderly life, this certainly should be a consideration for pediatric and adult surgeons caring for patients who have undergone esophageal atresia repair. Follow up should be vigilant and lifelong until the risk of malignant degeneration in these patients is better delineated.

Few studies to date have examined the health-related quality of life in children and adolescents after repair of esophageal atresia. In a recent study by Peetsold and colleagues,[81] 24 patients with esophageal atresia (and their parents) completed a health-related quality of life instrument. In addition, functional outcome was assessed by a validated standardized gastro-esophageal reflux questionnaire and data compared to a healthy reference population. Parents, as well as patients themselves, scored significantly lower on the general health domain perception. In addition, patients reported that GERD symptoms reduced their general health perception. In another study examining psychosocial functioning in adolescents with neonatally repaired esophageal atresia, Faugli *et al.*[82] reported on a group of 21 adolescents with esophageal atresia and compared them to 36 adolescents from a general population. Overall, adolescents with esophageal atresia have normal mental health and psychosocial functioning compared to their peers. However, the need for postoperative dilatation of the esophagus and low birth weight were significant predictors of impaired mental health and psychosocial functioning. In another assessment of long-term, health-related quality of life in adult survivors following correction of esophageal atresia, Deurloo *et al.*[83] found no differences in overall physical and mental health compared to a control group. Interestingly, the presence of concomitant congenital anomalies did not negatively influence health-related quality of life. Only a third of the patients reported that esophageal atresia had negative effects on their daily lives and gastrointestinal (GI) symptoms, such as dysphagia, were the most often mentioned contributing to such.

There are fewer problems more technically challenging for the pediatric surgeon than the patient with long gap esophageal atresia. In the short term, the surgeon must decide on the appropriate management strategy for reconstruction of the esophageal conduit. The techniques by which this is accomplished are varied and each technique has its advantages and disadvantages. Although it is widely accepted that the optimal esophageal conduit is the native esophagus, a number of surgeons use either colon, native stomach, or jejunal grafts to bridge abbreviated esophageal segments. Techniques for

sequential and gradual elongation of the native esophagus, such as those popularized by Foker *et al.*[84] and Kimura *et al.*[85] appear to offer favorable short-term surgical outcomes in the institutions where they are employed. Nevertheless, the adverse long-term sequelae of either esophageal replacement or native esophageal lengthening are significant. In a recent study from the Great Ormond Street Hospital, the large majority of patients undergoing long gap esophageal atresia repair had long-term issues with gastro-esophageal reflux.[86] A report from the Children's Hospital of Los Angeles concluded that patients with a gastric conduit had a lower overall complication rate without evidence of conduit ischemia when compared to those with a colonic interposition; however, the incidence of long-term adverse physiologic sequelae were significant. In a review of published studies for esophageal replacement in children by Arul and Parikh,[87] there was no significant difference in either early or late complications associated with the different type of conduits utilized for interposition. However, the authors did note that larger series tended to have lower complication rates than those of small series likely reflecting the association between clinical expertise and experience and outcomes in larger surgical centers.

To date, the short- and long-term physiologic outcome of esophageal atresia and tracheo-esophageal fistula could be considered favorable. However few data exist with regard to health-related quality of life in this cohort of patients. Furthermore, the long-term follow up of patients with esophageal atresia and the impact of Barrett's esophagitis and later development of adenocarcinoma is yet to be fully realized and mandates vigilant postoperative follow up and a surveillance program that should be overseen by a practicing pediatric surgeon.

CONGENITAL DIAPHRAGMATIC HERNIA

Congenital diaphragmatic hernia has been widely studied. The mortality rate and adverse sequelae in survivors of CDH remain significant compared to the other commonly treated newborn surgical conditions addressed by the pediatric surgeon. Historically, the long-term follow up of patients with congenital diaphragmatic hernia was sporadic and uncoordinated. This likely led to an underestimation of the number and severity of problems affecting survivors of CDH repair. Data from long-term follow-up studies identifies several potential morbidities involving a number of different organ systems including pulmonary, cardiac, neurologic, gastrointestinal, urogenital, and musculoskeletal. Today, it is recognized that these patients are best cared for in a multidisciplinary setting where coordinated follow-up care involving multiple specialties is possible.[88,89] Although this is not a widespread practice among pediatric surgeons, large pediatric centers are encouraged to develop these types of outcome clinics to coordinate follow up and address ongoing physiologic concerns among survivors of CDH.[90] Indeed, the most remarkable accomplishment in caring for a patient with CDH is the improved survival to hospital discharge during the past decade.[91,92] However, while some authors have reported survival figures approaching 90%,[93] the current overall survival in the Unites States is 70% among 2676 live born infants from 50 tertiary centers.[94] For those patients who do survive to hospital discharge, long-term morbidity is a function of the severity and laterality of the defect, as well as the need for extracorporal life support (ECLS).[66,89,95]

Pulmonary morbidity is perhaps the most significant problem during early childhood in survivors of CDH.[96–100] Ventilatory barotrauma, bronchopulmonary dysplasia, and chronic lung disease play a larger role than previously suspected in both mortality and morbidity of those patients with CDH.[91,101,102] Nearly 60% of survivors require some form of medical therapy for reactive airway disease and long-term obstructive airway disease is demonstrable in approximately 25% of patients at five years of follow up.[103,104] The long-term sequelae of ventilation perfusion mismatch may also result in significant limitations in exercise tolerance in the adolescent years.[99] Mild airway obstruction and a slightly reduced diffusion capacity for carbon monoxide are observed in most survivors of CDH. Furthermore, pulmonary hypertension and subsequent right ventricular hypertrophy has been reported in as many as 50% of survivors of CDH treated with ECLS.[105] Nutritional morbidity and growth failure is also unfortunately common in patients surviving CDH. In a retrospective analysis of 121 survivors of CDH, over half of the patients were below the 25% for height and weight during the first year of life.[106] Approximately one-third of this population had issues severe enough to require a gastrostomy to provide adequate caloric intake. The need for ECLS and an oxygen requirement at discharge are predictive of growth failure within the first year of life. Others have reported similar trends in growth failure and nutritional morbidity.[107–110] Oral aversion, foregut dysmotility, and persistent GERD all contribute to the nutritional morbidity of CDH survivors.[99,111] Neurocognitive deficits play a significant role in the long-term functional outcome of CDH patients surviving to discharge. Mild-to-moderate development delay has been reported in more than one-third of CDH survivors followed in a multidisciplinary clinic.[90,112] Although the neurologic deficits in CDH survivors are the result of the critical nature of the postnatal disease process and its treatment, the contribution of ECLS on neurologic morbidity is of significant concern. The incidence of neurologic abnormalities among all neonatal survivors of ECLS ranges from 10 to 15% and includes cerebral palsy, hearing loss, seizure disorder, cognitive delay, and vision impairment. However, the use of ECLS in CDH patients confers an increased risk for long-term neurocognitive impairment such that up to 70% of survivors demonstrate some type of neurocognitive deficit. Furthermore, the incidence of sensorineural hearing loss in survivors of CDH ranges from 25 to 37% in reported studies.[99,102,113–116] The orthopedic deformities associated with CDH are also of significance in that CDH survivors are prone to scoliosis and chest wall deformities. Nobuhara *et al.*[90] reported a 21% incidence of pectus deformities and a 10% incidence of mild-to-moderate scoliosis in long-term follow up. These chest wall deformities are more common among patients with an initial severe ventilatory impairment and a diaphragmatic defect requiring the need for a prosthetic patch. It has been observed that these complex long-term issues appear more

prevalent as newer support strategies have allowed infants with severe disease to survive.

In terms of health-related quality of life of CDH survivors, Peetsold and co-authors have described a significant reduction and perception of general health in survivors of CDH compared to a reference population.[81] Lower functional status has also been described in CDH survivors in a recent study using the FSIIR tool.[117] Furthermore, in a study from the Children's Hospital of Boston, family impact was found to be profound and longstanding at a median of eight years after surgery for a subset of CDH survivors with comorbidities and current clinical problems.[118]

ABDOMINAL CONDITIONS

General considerations

Apart from the repair of inguinal hernia, abdominal conditions in the neonate comprise the majority of work performed by the practicing pediatric surgeon. The long-term outcome of a variety of these conditions is dependent on the method of peritoneal access. The two most important potential adverse outcomes of laparotomy include adhesive bowel obstruction and incisional hernia. In a study from the Great Ormond Street Hospital, the authors described only four documented cases of incisional hernia in 507 pediatric laparotomies.[119] More salient to the intra-abdominal conditions of the neonate is the potential for adhesive bowel obstruction following laparotomy or laparoscopy. In a study of 649 neonates undergoing laparotomy over ten years, 8.3% developed adhesive intestinal obstruction requiring surgical intervention.[120] In a similar study from the Netherlands of 304 neonates undergoing laparotomy, adhesive intestinal obstruction occurred in 3.3% of cases.[121] The indication for laparotomy clearly plays a role in the incidence of postoperative adhesive bowel obstruction. For example, in patients undergoing gastroschisis repair, up to 15% of patients may experience adhesive bowel obstruction, which can occur years following primary repair.[122,123] In patients undergoing a Ladd's procedure, 8–15% of patients experience one episode of postoperative adhesive bowel obstruction.[120] Techniques to prevent intestinal adhesions emphasize minimizing peritoneal trauma and the separation of potentially involved surfaces. Clearly, one of the benefits of minimal access surgery or laparoscopic surgery is in the potential decrease in the incidence of adhesive bowel obstruction, although persuasive long-term data are yet to be realized in supporting this contention. In addition, minimally invasive access to the abdominal cavity does result in a postoperative cosmetic result that is preferred by many patients after they grow into adulthood.[124] Indeed, a noticeable scar can have physical, esthetic, and psychologic consequences in children.[125] Cosmetic concerns with regards to abdominal wall scarring are likely to be more important for neonates as they grow into the teenage years. Minimizing these concerns is probably a unique benefit of minimal access neonatal surgery. Other purported benefits of minimal access laparoscopic surgery are that of a decreased inflammatory response, less postoperative pain with a subsequent decrease in the need for postoperative analgesia, and a shorter time to hospital discharge.[126–128]

Malformations of the midgut

The most profound sequela of neonatal surgical conditions involving the midgut involves massive small bowel resection or malabsorption and altered motility. Thankfully, the outcomes of intestinal failure due to short bowel syndrome have changed dramatically over the last 30 years. The development of total parenteral nutrition introduced a new era in the management of children with short bowel syndrome.[129] Although the functional impairment in short bowel patients typically results from an anatomic loss or deficiency of intestinal surface area, it may also occur in the setting of a normal intestinal mucosal surface with perturbations in intestinal absorption, motility, or both. The length of small bowel is clearly an important predictor of the development of short bowel syndrome, however the absolute length of 'viable' small intestine in the neonatal population may not be an adequate predictor of short bowel syndrome and intestinal failure. Today, the consensus definition for short bowel syndrome is 'intestinal failure as a result of surgical resection or congenital defect or disease which is associated and characterized by the inability to maintain protein energy fluid and electrolyte or micronutrient balances on a generally accepted normal diet'.[130] Although the amount of bowel that must be lost to produce malabsorption in short bowel syndrome is variable and depends on segments lost and whether the ileocecal valve is preserved, loss of greater than 80% of the small bowel is associated with an increased requirement for enteral nutritional support, decreased overall survival, and the need for further surgical intervention or small bowel transplantation. The neonatal surgical population at risk for developing short bowel syndrome includes patients with necrotizing enterocolitis, small intestinal atresia, malrotation and midgut volvulus, and gastroschisis. The complications encountered in short bowel syndrome are varied in complexity and dependent on a variety of factors. Survival rates reported for short bowel syndrome are influenced by the variable severity of the condition, underlying disorders and comorbidities. Potential complications are myriad and can include diarrhea and electrolyte disturbances, osteopenia, urinary oxalate stone formation, and total parenteral nutrition (TPN)-associated liver disease. In addition, the achievement of normal somatic growth is a challenge for the patient with short bowel syndrome. The most common causes of mortality following massive small intestinal resection in the neonate include liver failure and sepsis in patients requiring TPN for the majority of their nutritional support. In addition, the care of the patient with short bowel syndrome entails substantial economic expense. In 1992, the annual direct cost per home for patients requiring TPN averaged approximately US$100 000.[131] In addition, the complex medical needs and potential complications of short bowel syndrome have a clear and obvious impact on health-related quality of life. Although the development of home parenteral nutrition programs has

provided greater independence from the hospital for these patients, the responsibility has been shifted to caretakers, which has a profound impact on the family.[132] Unfortunately, there are few rigorous assessments of the obvious psychosocial impact of this chronic illness on both patients and their families. In adults requiring home TPN, social and emotional function as well as quality of life were lower in patients requiring home parenteral nutrition compared to those with short bowel syndrome not on TPN.[133] Although it is intuitive that the quality of life for both patients and their parents suffering from short bowel syndrome resulting from neonatal surgical conditions is likely to be low relative to normal, the real question is whether or not subsequent surgical interventions may improve the quality of life for these patients. Surgical treatment beyond the neonatal period (i.e. Bianchi procedure, longitudinal intestinal lengthening and tailoring, and the STEP procedure) may offer hope for improving the quality of life for these patients.[134] In addition, developing non-surgical enteral support strategies beyond the scope of this review offer some promise.

In those patients surviving to small intestinal transplantation, important outcome measures include graft and patient survival. In a study from the University of Pittsburgh, the overall patient survival at five years following small bowel and intestinal transplantation was 56%.[135] At the University of Miami, the two-year survival rate following small intestinal transplantation between 1997 and 2000 was 46%, although the current one-year survival is approximately 85% due to improvements in surgical technique and immunosuppressive care.[136] Furthermore, combined transplantation of the intestine and liver is associated with a 40% graft survival at five years,[137] although patient survival is best with isolated intestinal grafts. Both graft and patient survival will likely continue to improve with time. Also encouraging is that health-rated quality of life is improved with intestinal transplantation in patients with short bowel syndrome. Sudan and colleagues[138] obtained quality of life data from 29 successful pediatric transplant patients, and found that patients had comparable CHQ assessments to norms in physical function role, social limitation, general health, bodily pain, role limitations, self-esteem, health, and behavior. However, the parental assessment was generally lower than the child's in general health perception and role imitation. From a public health standpoint, the financial and emotional costs for caregivers must impact decisions regarding the allocation of medical resources. Long-term outcomes of the surgical treatment of intestinal failure including intestinal transplantation must include assessments of health-related quality of life, functional outcome, and utility, such that families can make appropriate decisions in the neonatal period when faced with the potential for short bowel syndrome.

Malformations of the hindgut

In patients with malformations of the hindgut, the importance of health-related quality of life and functional outcome cannot be ignored. As patients with anorectal malformations (ARM) and HD now frequently survive into adulthood, the quality of life, and functional outcomes related to these congenital malformations and their attendant surgeries must be examined with care. Perhaps one of the most salient contributions to the technical practice of pediatric surgery over the last several decades is that of the posterior sagittal approach to the repair of anorectal malformations popularized by Dr Alberto Pena.[139] However, as advances in surgical technique have allowed us to recreate the anatomic relationships in the perineum with greater short-term 'success', the long-term functional outcomes are less clear, and appear most dependent on the type of malformation encountered.[140] In addition, although few patients today die of Hirschsprung's-related enterocolitis in the neonatal period, the long-term functional results of the surgical treatment of HD are also variable as our patients proceed into childhood and adult life. The common relevant 'functional' outcome measure for both of these patient groups is that of bowel control. We are most interested in the ability for a child to defecate normally commensurate with his or her peers. However, the implications of constipation and incontinence also have significant impact on health-related quality of life.

In patients with anorectal malformations, associated anatomic malformations of the genitourinary tract and spinal cord not only affect the surgical complexity, but also impact the functional outcome and quality of life. Continued evaluation after the neonatal period must address the functional sequelae of anorectal malformations. Simply put, two parameters of bowel control are especially salient for the child with an anorectal malformation. The first is the capacity for voluntary bowel movements. The second is the incidence of soiling or defecation between bowel movements, that is uncontrolled and unwanted. The patient who can verbalize a desire to pass stool and uses the commode to pass voluntary bowel movements, has a significant advantage over the individual who has never had voluntary bowel movements following the repair of an anorectal malformation. The latter patients are physiologically incontinent, that is with either sensory or muscular failure (or both), and represent a specific category. In terms of soiling, Levitt and Pena[141] have categorized patients with soiling into two grades. Grade 1 patients soil once or twice a week where there is a spot or smear of stool in the underwear. The patient who soils every day is considered to have grade 2 soiling. Clinically, this is a simple and practical way to categorize patients in long-term follow up. However, for long-term functional outcome studies, disease-specific scores to assess and quantify bowel control in these patients may be useful for academic purposes. Brandt and colleagues[142] have developed and validated a continence scale in children with anorectal malformations termed the Baylor Continence Scale (BCS). This disease-specific functional outcome measure is administered by recording the responses to 23 questions using a psychometric response analog scale, and the higher the score the more significant the impact on continence. Higher scores were noted in their population of patients with ARM compared with both enuresis and normal control groups. This type of scoring system may allow pediatric surgeons and physicians to be able to quantitate qualitative data as they relate to the postoperative function following the repair of anorectal malformations. Overall, the most salient predictor of bowel control is related to the type of anorectal

malformation. The terms, 'low' or 'high' imperforate anus should be abandoned such that clinicians can adequately report and address the specific functional outcomes for each of the anatomic abnormalities.[143] Indeed, children with a perineal fistula are likely to be continent, but have a higher likelihood of constipation. Similarly, male patients with a recto-bladder neck fistula are more likely to be incontinent of stool compared to their anatomically normal peers.[140]

Assessment of generic health-related quality of life in patients with ARM has been undertaken in a number of studies. The EuroQOL score has been validated in children with a history of an anorectal malformation and repair.[26] In addition, disease-specific quality of life questionnaires have been developed.[34,144,145] In the Brandt study from 2007, patients with anorectal malformations in general had a lower HRQoL score (CHQ) compared to both enuresis patients and a normal control group. Utilizing a disease-specific quality of life questionnaire, Grano and colleagues[146] found that adults with previously repaired ARMs reported significantly lower emotional functioning and problems in the area of body image and physical symptoms when compared to those patients in the control group. In Hartman *et al.*'s study,[144] HRQoL is directly related to the nature and severity of the anorectal malformation. However, children and adolescents with anorectal malformations reported better quality of life over time. This could be attributed to coping mechanisms, utilization of a bowel management program, or more specific attention by the medical community to addressing the psychological and physiological needs of these patients in their societal context. Although psychological functioning is typically an attribute of HRQoL, specific psychological effects of anorectal malformations and their repair is also clinically important. A high proportion of children with previously repaired ARMs have clinically significant emotional problems based on psychiatric diagnostic interviews. Approximately 29% of children were found to have a psychiatric disorder with 19% having disorders severe enough to influence their daily lives.[147,148] This was significantly higher than the general child population in the United Kingdom where the rate of a significant psychiatric disorder is 10%. Other studies have delineated similar findings.[149,150]

For patients with HD, the recognition of enterocolitis and its prompt treatment have decreased the short-term morbidity and mortality associated with this disorder. Early recognition of the disease, improvements in neonatal and anesthetic care, and surgical technical advancement have allowed for successful and prompt surgical treatment in the neonatal period. Single stage laparoscopic or transanal pull-throughs are relatively new additions to the armamentarium that await long-term functional assessment. For long-term outcomes, the issues of bowel function and continence again become the most salient issues. All of the operations utilized in the treatment of HD carry some risk of constipation. In most series, the severity of constipation following repair improves with time or resolves. However, it is important to recognize and treat constipation in the postoperative period so as to prevent the long-term functional impairment of the pull-through segment. The occurrence of fecal soiling in patients who have undergone repair of HD can also affect quality of life. Indeed, the complete or partial loss of the rectal reservoir is an inevitable result of pull-through operations for HD owing to high amplitude peristaltic contractions. The incidence of true fecal incontinence is low regardless of the operative technique utilized to address HD. However, when postoperative fecal soiling is critically assessed in childhood, the proportion of patients with some degree of fecal incontinence or soiling is approximately 50%.[27,151–153] In a study by Mills and colleagues,[154] functional outcome and HRQoL were evaluated in 51 patients who had undergone surgical treatment for HD.[154] Overall, the mean continence score as assessed by this instrument was 3.34 and categorized as 'fair', however, there was statistically significant improvement in fecal continence scores with age, confirming the previous speculation of improvement of this particular entity with time. Only 7% reported poor fecal continence in the teenage years. Good fecal continence was reported in 80% of teenagers. Utilizing the PedsQL score for HRQoL assessment, these authors found that there was no statistically significant difference between patients with HD and healthy children, either by overall or age group. Interestingly, females had noticeably higher quality of life compared to their male cohorts, which also corroborates the long-held view that females with HD may fare better than their male counterparts. Despite the significant advances in the management of HD, the long-term functional outcome remains far from perfect for some patients. Furthermore, no individual surgical procedure is demonstrably superior with regard to long-term results, either as it relates to constipation or continence.

CONCLUSION

Today, the pediatric surgeon interested in the study of long-term outcomes must be cognizant of the tools available for outcome assessment and choose the instrument most appropriate for the patient population in question. Selection of the appropriate tool to measure an outcome is as important as the act of measuring it. Furthermore, although it is important to give emphasis to development and appropriate use of outcomes instruments, it is imperative that we think of ways in which to improve the quality of life or physical, cognitive, or social functioning of our patients. Interventions aimed at improving quality of life may play an important adjunct in positively affecting the health of infants and children as they make the transition into adult life (i.e. counseling to teach children better coping skills, support groups, or psychological therapy). Excellent instruments already exist in the realm of generic health-related quality of life and functional outcomes. Choosing the appropriate instrument is dependent on knowing what the instrument is capable of measuring. National and international organizations dedicated to the surgical care of infants and children would do well to recommend specific generic, or disease-specific instruments such that clinicians can utilize equalities of scale when comparing HRQoL or functional outcomes following the surgical correction of congenital or acquired disease. We owe it to our pediatric surgical patients to utilize these instruments, validate them in pediatric surgical populations, and employ strategies to ultimately improve outcomes.
