Preface to the third edition

It has been eight years since the second edition of the book was published in 2003. Over the last decade, major advances have occurred in the understanding and treatment of neonatal surgical conditions. Advances in prenatal diagnosis, imaging, intensive care, and minimally invasive surgery have transformed the practice of surgery in the newborn. The third edition of Newborn Surgery has been extensively revised and contains 105 chapters by 160 contributors from all five continents of the world. This edition contains many new chapters taking account of the recent advances in neonatal surgery. The new chapters include: Perinatal physiology; Clinical anatomy of the newborn; Epidemiology of birth defects; Fetal counselling for surgical malformations; Neonatal sepsis; Liver transplantation; Congenital pouch colon; Megacystis microcolon intestinal hypoperistalsis syndrome; and Urinary tract infections. Each chapter has been written by world class experts in their respective fields, along with their co-authors.

This textbook provides an authoritative, comprehensive and complete account of the pathophysiology and treatment of various surgical conditions in the newborn. This book should be of interest to all those who have a clinical responsibility for newborn babies. It is particularly intended for trainees in pediatric surgery, established pediatric surgeons, general surgeons with an interest in pediatric surgery as well as neonatologists and pediatricians seeking more detailed information on newborn surgical conditions.

I wish to thank most sincerely all the contributors for their outstanding work in producing this innovative text-book. I also wish to express my gratitude to Ms Vanessa Woods and Ms Lisa Kelly for their skilful secretarial help. I am grateful to Dr G.P. Seth for reading each and every word of the galley proofs of the entire book. I wish to thank the editorial staff of Hodder Arnold, particularly Mr Stephen Clausard, for their help during preparation and publication of this book. I am thankful to the Children's Medical & Research Foundation, Our Lady's Children's Hospital, Dublin for their support.

Prem Puri
2011

Preface to the second edition

The 2nd edition of *Newborn Surgery* has been extensively revised. Many new chapters have been added to take account of the recent developments in the care of the newborn with congenital malformations. This edition, which comprises 97 chapters by 121 contributors from all five continents of the world, provides an authoritative, comprehensive, and complete account of the various surgical conditions in the newborn. Each chapter is written by the current leading expert(s) in their respective fields.

Newborn surgery in the twenty-first century demands of its practitioners detailed knowledge and understanding of the complexities of congenital anomalies, as well as the highest standards of operative techniques. In this textbook, great emphasis continues to be placed on providing a comprehensive description of operative techniques of each individual congenital condition in the newborn. The book is intended for trainees in pediatric surgery, established pediatric surgeons, general surgeons with an interest in pediatric surgery, as well as neonatologists and pediatricians seeking more detailed information on newborn surgical conditions.

I wish to thank most sincerely all the contributors for the outstanding work they have done for the production of this innovative textbook. I also wish to express my gratitude to Mrs Karen Alfred and Ms Ann Brennan for their secretarial help and to the staff of Hodder Arnold for their help during the preparation and publication of this book. I am grateful to the Children's Medical & Research Foundation, Our Lady's Hospital for Sick Children, Dublin for their support.

Prem Puri
2003

Preface to the first edition

During the last three decades, newborn surgery has developed from an obscure subspecialty to an essential component of every major academic pediatric surgical department throughout both the developed and the developing world. Major advances in perinatal diagnosis, imaging, neonatal resuscitation, intensive care, and operative techniques have radically altered the management of newborns with congenital malformations. Embryological studies have provided new valuable insights into the development of malformations, while improvements in prenatal diagnosis are having a significant impact on approaches to management. Monitoring techniques for the sick neonate pre- and postoperatively have become more sophisticated and there is now greater emphasis on physiological aspects of the surgical newborn, as well as their nutritional and immune status. This book provides a comprehensive compendium of all these aspects as a prelude to an extensive description of surgical conditions in the newborn. Modern-day newborn surgery demands detailed knowledge of the complexities of newborn problems. Research developments, laboratory diagnosis, imaging, and innovative surgical techniques are all part of the challenge facing surgeons dealing with congenital conditions in the newborn. In this book, a comprehensive description of operative techniques of each individual condition is presented. Each contributor was selected to provide an authoritative, comprehensive, and complete account of their respective topics. The book, comprising 90 chapters, is intended primarily for trainees in pediatric surgery, established pediatric surgeons, general surgeons with an interest in pediatric surgery, and neonatologists.

I am most grateful to all contributors for their willingness to contribute chapters at considerable cost of time and effort. I am indebted to Mr Maurice De Cogan for artwork, Mr Dave Cullen for photography, and Ms Ann Brennan and Ms Deirdre O'Driscoll for skilful secretarial help. I am grateful to the Children's Research Centre, Our Lady's Hospital for Sick Children, for their support. Finally, I wish to thank the editorial staff, particularly Ms Susan Devlin, of Butterworth-Heinemann for their help during the preparation and publication of this book.

Embryology of malformations

DIETRICH KLUTH, WOLFGANG LAMBRECHT, CHRISTOPH BÜHRER, AND HOLGER TILL

INTRODUCTION

Approximately 3% of human newborns present with congenital malformations.[1] Without surgical intervention, one-third of these infants would die since their malformations are not compatible with sustained life outside the uterus.[1,2] In figures, this means that in a country such as Germany, nearly 6000 children are born every year with a life-threatening malformation.

Due to the development of prenatal diagnostic procedures, advanced surgical techniques, and intensive post-operative care, most infants with otherwise fatal malformations can be rescued by an operation in the neonatal period. However, morbidity remains high in some of these children[2] with the necessity of repeated operations and hospitalizations despite a successful primary operation. This may also be the fate of many children with non-life-threatening malformations such as hypospadias or cleft palate.

Mortality is still high in newborns with certain malformations such as congenital diaphragmatic hernias or severe combined defects. As a consequence, congenital malformations today are the main cause of death in the neonatal period. In the United States, 21% of neonatal mortality can be related to congenital malformations.[3]

These figures probably do not reflect a real increase of the actual incidence of congenital malformation. The observed mortality shift might rather be due to improved intensive care medicine in today's Western world countries where neonates (even those with birth defects) have a better chance of survival. On the other hand, this statistical shift indicates that knowledge about congenital malformations lags behind the progress clinical research has made in the surrounding fields. Efforts are needed to close the gap and learn more about baby killer No. 1. Identification of teratogens will help to reduce the incidence of malformations when exposure can be avoided, and pathogenetic studies might aid in designing therapeutic measures. Both treatment and prevention critically depend on basic embryological research.

GENERAL REMARKS ON EMBRYOLOGY AND THE EMBRYOLOGY OF MALFORMATIONS

Despite many efforts, the embryology of numerous congenital anomalies in humans is still a matter of speculation. This is due to the following reasons:

- a shortage of study material (both normal and abnormal embryos);
- various technical problems (difficulties in the interpretation of serial sections, shortage of explanatory three-dimensional reconstructions);
- misconceptions and/or outdated theories concerning normal and abnormal embryology.

Fortunately, a number of animal models are known today which allow advanced embryological studies in various embryological fields. Especially for the studies of anorectal malformations, a number of animal models is at hand. In addition, a Scanning Electron-Microscopic Atlas of human embryos has been published recently which provides detailed insights into normal human embryology.[4]

Appropriate and illustrative findings in various fields of embryology are still lacking. This explains why today many typical malformations are still not explained satisfactorily. Pediatric surgeons are still confused when they are confronted with the embryological background of normal and abnormal development.

For the described misconceptions and/or outdated theories, Haeckel's 'biogenetic law'[5] is one example. According to this theory, a human embryo recapitulates in its individual development (ontogeny) the morphology observed in all life-forms (phylogeny). This means that during its development an advanced species is seen to pass through stages represented by adult organisms of more primitive species. This theory still has an impact on the nomenclature of embryonic organs and explains why human embryos have 'cloacas' like adult birds and 'branchial' clefts like adult fish.

Another very popular misconception is the theory that malformations actually represent 'frozen' stages of normal

embryology ('Hemmungsmißbildung').[6] As a result, our understanding of normal embryology stems more from pathological-anatomic interpretations of observed malformations than from proper embryological studies. The theory of the 'rotation of the gut' as a step in normal development is a perfect example of this misconception.

DEFINITION OF THE TERM 'MALFORMATION'

After birth, neonates can present with a broad spectrum of deviations from normal morphology. This extends from minor variations of normal morphology without any clinical significance to maximal organ defects with extreme functional deficits of the malformed organs or of the whole organism.

The degree of functional disorder is decisive when dealing with the question of whether a variation of normal morphology has to be viewed as a dangerous malformation requiring surgical correction. This means that functional disturbance is essential when using the term 'malformation'. Inborn deviations can be detrimental, neutral, or even beneficial, otherwise evolutionary progress could not take place. An example of a beneficial deviation is the longevity syndrome of people with abnormally low serum cholesterol levels. Abnormalities with little or no functional disturbance might still require surgical correction when patients are in danger of social stigmatization. Coronal or glandular hypospadias might serve as an example for this condition.

ETIOLOGY OF CONGENITAL MALFORMATIONS

In most cases, the etiology of congenital malformations remains unclear. Possible etiological factors are listed in Table 1.1.

In about 20% of cases genetic factors (gene mutation and chromosomal disorders) can be identified.[1,2,7] In 10% an environmental origin can be demonstrated.[1,2] In 70% the factors responsible remain obscure.

Table 1.1 Etiology of congenital malformations.

Etiology	%
Genetic disorders	20
Environmental factors	10
Unknown etiology	70

Environmental factors

A large number of agents are known which might interfere with the normal development of organ systems during embryogenesis.[1,7] The underlying mechanisms of this interference is poorly understood in most cases. Characteristically, during organogenesis, different organs of the embryo show distinct periods of greatest sensitivity to the action of the teratogen. These phases of greatest sensitivity are called the 'teratogenetic period of determination'.[8] The typical patterns of some syndromes can be explained by an overlap of these phases during embryological development.

In 1983, Shepard[2] published a catalog of suspected teratogenic agents. Over 900 agents are known to produce congenital anomalies in experimental animals. In 30, evidence for teratogenic action in humans could be demonstrated. Teratogenic agents can be divided into four groups (Table 1.2).

The teratogenic potential of virus infections,[1] especially rubella and herpes, and that of radiation[1] has been clearly established. Maternal metabolic defects and lack of essential nutritives can be teratogenic. After a vitamin A-free diet[9] and riboflavin-free diet[10] various congenital malformations were observed in rats and mice. Among these were diaphragmatic hernias, isolated esophageal atresias, and isolated tracheoesophageal fistulas. Similarly, inappropriate administration of hormones can be associated with intrauterine dysplasias.[11]

Industrial and pharmaceutical chemicals such as tetrachlor-diphenyl-dioxin (TCDD) or thalidomide have inflicted tragedies by their teratogenic action. When thalidomide was prescribed to women in the early 1960s as a 'safe' sleeping medication, numerous children were born with dysmelic deformities.[7,12,13] In addition, atresias of the esophagus, the duodenum, and the anus were observed in some children.[12] The data collected suggest that teratogenic agents do not cause new patterns of malformations but rather mimic sporadic birth defects. This had posed problems in identifying thalidomide as the responsible agent. It appears likely that among those 70% congenital malformations with unclear etiology a considerable percentage might be precipitated by as yet unidentified environmental factors. In a rat model, the herbicide nitrofen (2.4-dichloro-phenyl-p-nitrophenyl ether) has been shown to induce congenital diaphragmatic hernias, cardiac abnormalities and hydronephrosis.[14–18] In 1978, Thompson *et al.*[19] described the teratogenicity of the anticancer drug adriamycin in rats and rabbits. More recently, Diez-Pardo *et al.*[20] re-described this model with emphasis to its potentials as a model for foregut anomalies. Today, the adriamycin model is generally described as a model for the VACTERL-association (V = vertebral, A = anorectal, C = cardiac, T = tracheal, E = esophageal, R = renal, L = limb).[21,22] Thus, classic malformations such as atresias of the esophagus and the intestinal tract, intestinal duplications and others can be mimicked by teratogens in animal models.

Table 1.2 Teratogenic agents in congenital malformations.

Teratogenic agents	
Physical agents	Radiation, heat, mechanical factors
Infectious agents	Viruses, treponemes, parasites
Chemical, drug, environmental agents	Thalidomide, nitrofen, hormones, vitamin deficiencies
Maternal, genetic factors	Chromosomal disorders, multifactorial inheritance

After Nadler.[1]

Genetic factors

Approximately 20% of congenital malformations are of genetic origin. Most surgically correctable malformations are associated with chromosomal disorders, e.g. trisomy 21, 13, or 18, or are of multifactorial inheritance[23] with a small risk of recurrence. The assumption of multifactorial inheritance results from the fact that with nearly all major anomalies familiar occurrences had been observed.[1] In animals, inheritance has also been found for some malformations.[24–27]

EMBRYOLOGY AND ANIMAL MODELS

Over the last two decades a number of animal models were developed with the potential to gain a better understanding of the morphology of not only malformed but also of normal embryos. These animal models can be divided into four subgroups.

Surgical models

In the past, the chicken was an important surgical model to study embryological processes. Due to the easy access to the embryo, its broad availability and its cheapness, the chicken is an ideal model for experimental studies. It has been widely used by embryologists, especially in the field of epithelial/mesenchymal interactions.[28–30] Pediatric surgeons used this model to study morphological processes involved in intestinal atresia formation,[31,32] gastroschisis,[33] and Hirschsprung's disease.[34]

The Czech embrologist Lemez[35] used chicken embryos in order to induce tracheal agenesis with tracheo-esophageal fistula.

Apart from these purely embryonic models, a large number of fetal models exist. However, these models were mainly used in order to demonstrate the feasibility of fetal interventions.[36]

Chemical models

A large number of chemicals can have an impact on the normal development of humans and animals alike. Most important today are: (1) the adriamycin model,[19,20] (2) etretinate,[37,38] (3) all-trans retinoic acid (ATRA),[39–41] (4) ethylenethiourea,[42–44] and (5) nitrofen.[15,16,18]

While models (1)–(4) are used to study the embryology of atresias of the esophagus, the gut, and the anorectum, model (5) was developed to study the malformations of the diaphragm, the lungs, and the heart and kidneys (hydronephrosis).

Genetic models

A number of genetic models had been developed which were used for embryological studies in the past:

- models of spontaneous origin: the SD-mouse model;[25,27]
- inheritance models: the pig model of anal atresia;[24,26]
- 'knock-out' models.[45–47]

These animals can be the product of spontaneous mutations or are the result of genetic manipulations mainly in mice (transgenic mice).

The number of transgenic animal models is growing fast. For pediatric surgeons those models which result in abnormalities of the fore- and hindgut are of major importance. Here, interference with the sonic hedgehog (Shh) pathway has proven to be very effective.[45–47] There are two ways to interfere with that pathway: (1) targeted deletion of Shh;[45,46] and (2) deletion of one of the three transcription factors, Gli1, Gli2, and Gli3.[46,47]

In the foregut, targeted deletion of Shh in homozygous Shh-null mutant mice causes esophageal atresia/stenosis, tracheo-esophageal fistulas, and tracheal/lung anomalies.[45] In the hindgut, the deletion of Shh caused the formation of 'cloacas'[46] while Gli2 mutant mice demonstrated the 'classic' form of anorectal malformations and Gli3 mutants showed minor forms such as anal stenosis.[46,47] Interestingly, the morphology of Gli2 mutant mice embryos resembles that of heterozygous SD-mice embryos while Shh-null mutant mice embryos had morphological similarities with homozygous SD-mice embryos. Interestingly, after administration of adriamycin, changes in the normal pattern of Shh distribution in the developing foregut were demonstrated.[48]

Viral models

Animal models that use virus infections to produce malformations important for pediatric surgeons are very rare. One exception is the murine model of extrahepatic biliary atresia (EHBA). In this model, newborn Balb/c mice are infected with rhesus rotavirus group A.[49] As a result the full spectrum of EHBA develops, as is seen in newborns with this disease. However, this model is not a model to mimic failed embryology, but it highlights the possibility that malformations are not caused by embryonic disorders but are caused by fetal or even postnatal catastrophes.

This part on embryology and animal models further highlights the importance of the study of normal animal embryos. Today, much information in current textbooks on human embryology stems from studies carried out in animals of varies species. Many of these are outdated. However, the wide use of transgenic mice in order to mimic congenital malformations makes morphological studies of the various organ systems in normal mice mandatory, otherwise the interpretation of the effects of the deletion of genetic information can be very difficult.[50]

EMBRYOLOGY OF MALFORMATIONS

Disturbances of normal embryological processes will result in malformations of organs. This was first shown by Spemann[51] in 1901 by experimentally producing supernumary organs in

the triton embryo after establishing close contact between excised parts of triton eggs and other parts of the same egg. Spemann and Mangold[5] coined the term 'induction' to describe this observation. They found that certain parts of the embryo obviously were able to control embryonic development of other parts. These controlling parts were called 'organizers'.[5] The process of influence itself was called 'induction'.

It was believed by many scientists in the field that 'induction' could serve as the overall principle of hierarchical control of embryonic development. Ensuing investigations, however, made modifications necessary, which finally resulted in a very complex model of organizers and inductors. The nature of inductive substances remained obscure and attempts to isolate inductive substances, meanwhile called 'morphogenes', were unsuccessful.[52] Interestingly, not only live cells could induce development in certain experiments, but also dead and denaturated material.[5]

A process essential for the formation of early embryonic organs is the invagination of epithelial sheets. This invagination is preceded by a thickening of the epithelial sheet,[53] a process known as placode formation. The thickening itself is caused by elongation of individual cells of the placode. This process can be studied in detail in epithelial morphogenesis.[54] The same sequence of developmental events has been observed in the formation of the neural plate, in the formation of the otic and lens placode and in the development of most epitheliomesenchymal organs including lung, thyroid gland, and pancreas. From these observations it can be concluded that most epithelial cells behave uniformly in the early phase of embryonic development.

Today, it is generally accepted that early embryonic organs are especially sensitive for alterations. Therefore researchers are more and more interested to understand the formation of early embryonic organs.

In 1985, Ettersohn[55] stated that most invaginations are the result of mechanical forces that are local in origin. He focused on three possible mechanisms which might lead to placode formation and subsequent invagination:

1. change of cell shape by cell adhesion;
2. microfilament-mediated change of cell shape;
3. cell growth and division.

In the following text, we will discuss some aspects of these mechanisms.

A teratological method used to determine the function of cell adhesion molecules *in vivo* during embryogenesis has been reported recently.[56] Mouse hybridoma cells producing monoclonal antibodies against the avian integrin complex were grafted into 2- or 3-day-old chick embryos. Depending on the site of engraftment, local muscle agenesis was observed. This is an example that the immunologic immaturity of the embryo can be exploited to study the contribution of cell attachment molecules to organ development in a functional fashion. A number of monoclonal antibodies directed against cell attachment molecules of various species have become available over the last years, and the structure of the binding molecules has been elucidated biochemically and by cDNA cloning. Functionally, adhesion molecules may be grouped into three families: cell adhesion molecules (CAMs), which mediate specific and mostly transient cell recognition of other cells; substrate adhesion molecules (SAMs), necessary for attachment to extracellular matrix proteins; and cell-junctional molecules (CJMs), found in tight and gap junctions. Whereas CJMs apparently play an important role for metabolic signaling within established tissues, CAMs and SAMs are necessary for the formation of histologically distinct structures and directed migration of single cells. Among CAMs and SAMs, at least three families have been identified biochemically: integrins,[57] members of the immunoglobulin superfamiliy, and LEC-CAMs.[58] Integrins are heterodimeric molecules consisting of a larger α chain, which is associated with a smaller β chain in a calcium-dependent way. Usually, one given α chain might be found in association with various chains but promiscuity of β chains has been described recently. Functionally, members of the integrin family present as SAMs (adhesion to vitronectin, collagen, fibronectin, complement components, or other intercellular matrix proteins) or CAMs (direct adhesion to other cells via corresponding cell surface target molecules). For example, cells bearing the integrin LFA-1 on their cell surface bind to cells expressing ICAM-1 or ICAM-2, both of which are members of the immunoglobulin superfamily.[59,60] Other members of the immunoglobulin superfamily which are known to be important during morphogenesis include L-CAM[61] (liver cell adhesion molecule) and N-CAM[62,63] (neural cell adhesion molecule). Both show homophilic aggregation, that is, N-CAM serves as a target structure for N-CAM, and L-CAM serves as a target structure for L-CAM, but there is no crossreactivity. In developing feather placodes in avian embryos, L-CAM and N-CAM are mutually exclusive expressed on epidermal or mesodermal cells, respectively. When the placodes are incubated with antibodies to L-CAM, primarily only epidermal cell-to-cell contact is disturbed.[64] However, the structure of the surrounding mesoderm is altered subsequently, suggesting an inductive signal loop between epidermal and mesodermal cells. A third group of adhesion molecules has been termed LEC-CAMs to indicate that their extracellular part consists of a lectin domain, an epidermal growth factor-like domain, and a complement regulatory protein repeat domain. The lectin domain is presumed to contain the active center; binding mediated by the murine homolog to the leukocyte adhesion molecule 1 (LAM-1)[65] can be blocked by mannose-6-phosphate or its polymers.[66] Lectin-dependent organ formation should be accessible experimentally by administration of the respective carbohydrates, but few if any data have been reported so far.

Cell shape is mainly maintained by microtubules forming the cellular cytoskeleton. In addition, contractile elements exist such as actin, which are essential for cell movement, the so-called microfilaments. These structures are thought to be essential for the process of placode formation and invagination.[67] Microfilament-mediated change of cell shape is based on the idea that actin filaments could alter the shape of cells by contraction. Most of these filaments are found at the apex

of epithelial cells. Contraction of these filaments in each individual cell of a cell layer would result in an increasing infolding of the whole cell layer,[67,68] finally resulting in invagination. It is a disadvantage of this model, however, that there is no apparent reason why apical constriction should be preceded by cell elongation.[55]

Cell proliferation is probably an essential factor in the morphogenesis of epithelio-mesenchymal organs. During morphogenesis of these organs repeated invagination can be observed, which might be dependent upon cell proliferation.[69] The way in which epithelial cell growth and proliferation is controlled in the embryo is not clear. However, it is believed that the surrounding mesenchyme might regulate the timing and location of invagination of the epithelial layer. Goldin and Opperman[28] proposed that epidermal growth factor (EGF) might be excreted by mesenchymal cells, which would stimulate epithelial cell proliferation and repeated invagination. When agarose pellets impregnated with EGF were cultured alongside 5-day embryonic chick tracheal epithelium, supernumerary buds were induced to form at those sites. EGF and the related peptide transforming growth factor-β (TGFβ) have been shown to lead to precocious eyelid opening when injected into newborn mice.[70] Thus, complex changes of late-stage organ development can be induced by physiological stimuli in the laboratory. Interestingly, EGF is a mitogen for many epithelial cells *in vitro* without affecting most mesenchymal cells. A large variety of cells have been demonstrated to display the receptor for EGF/TGFβ on their cell surface, which is encoded by the cellular proto-oncogene c-erbB. Structural alterations of this receptor are known to result in uncontrolled proliferation and ultimately malignant transformation. When secreted locally, EGF might provide physically associated cells with appropriate on- and off-signals required for the formation of complex organs. Other polypeptides, such as platelet-derived growth factor (PDGF) or transforming growth factor-α (TGFα) appear to function in an antagonistic way in that they stimulate rather the proliferation of mesenchymal cells.[71,72] In defined experimental situations, TGFα has been shown to be a mitogen for osteoblasts while being a potent inhibitor of the proliferation of epithelial and endothelial cells at the same time. Embryonic fibroblasts, however, are also inhibited by TGFα.[73] TGFα is a powerful chemotactic agent for fibroblasts and enhances the production of both collagen and fibronectin by these cells. There is, however, little data available concerning the involvement of these factors during normal and pathologic development of the embryo. Future investigations using such powerful approaches as *in situ* hybridization with cloned genes, preparation of transgenic animals, and direct administration of the recombinant proteins to various parts of the embryo might shed some light on signaling pathways mediated by soluble cytokines.

The surrounding mesenchyme might limit the epithelial bud to expand,[74] forcing the epithelial sheet to fold in characteristic patterns. If a growing cell layer is restricted from lateral expansion, 'mitotic pressure' by dividing cells will result in elongation of cells and then invagination of the 'crowded' cell sheet. This does not necessarily imply that cells divide more rapidly in the region of invagination than in the surrounding areas. The main effect is caused by restriction of lateral expansion.[29,30] In the early anlage of the thymus, cell proliferation counts are actually lower in the thymus anlage than in the surrounding epithelium.[75] Steding[29] and Jacob[30] have shown experimentally that restriction of lateral expansion might be responsible for thickening and subsequent invagination of epithelial sheets. In their experiments, restriction of lateral expansion was caused by a tiny silver ring placed on the epithelium of chick embryos.

EXAMPLES OF PATHOLOGICAL EMBRYOLOGY

The focus of our research has been the embryology of foregut, anorectal, and diaphragmatic malformations. We studied the normal development of all embryonic organs involved by scanning electron microscopy (SEM).[76–82] In addition, we employed two rodent animal models to study malformations of the anorectum and the diaphragm. Pathogenetic concepts concerning these malformations were controversial in the past due to lack of detailed data.

EMBRYOLOGY OF FOREGUT MALFORMATIONS

The differentiation of the primitive foregut into the ventral trachea and dorsal esophagus is thought to be the result of a process of septation.[83] It is guessed that lateral ridges appear in the lateral walls of the foregut, which fuse in midline in a caudo-cranial direction thus forming the tracheo-esophageal septum. This theory of septation has been described in detail by Rosenthal and Smith.[84,85] However, others[86,87] were not able to verify the importance of the tracheo-esophageal septum for the differentiation of the foregut. They instead proposed individually that the respiratory tract develops simply by further growth of the lung bud in a caudal direction.

Using SEM, we studied the development of the foregut in chick embryos.[76,77] In this study, we were unable to demonstrate the formation of a tracheo-esophageal septum (Fig. 1.1). A sequence of SEM photographs of staged chick embryos suggests that differentiation of the primitive foregut is best explained by a process of 'reduction of size' of a foregut region called 'tracheo-esophageal space' (Fig. 1.2). This reduction is caused by a system of folds that develops in the primitive foregut. They approach each other but do not fuse (Fig. 1.2).

Based on these observations, the development of the malformation can be explained by disorders either of the formation of the folds or of their developmental movements:

- Atresia of the esophagus with fistula (Fig. 1.3a):
  - The dorsal fold of the foregut bends too far ventrally. As a result the descent of the larynx is blocked. Therefore the tracheo-esophageal space remains partly undivided and lies in a ventral position. Due to this ventral position it differentiates into trachea.

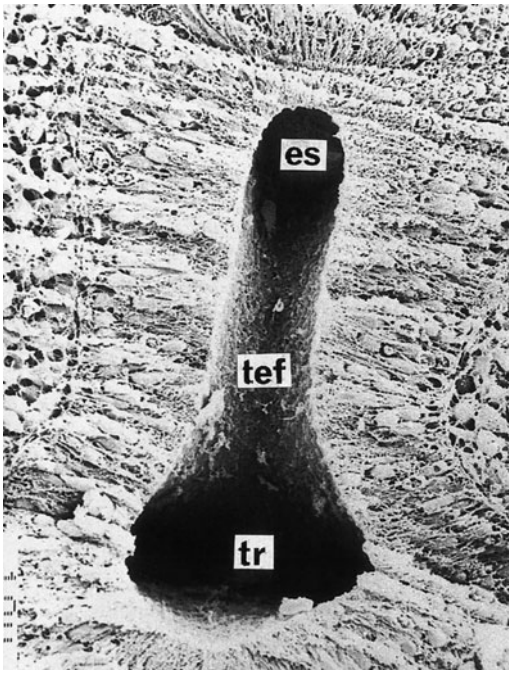

Figure 1.1 SEM photograph of the inner layer of foregut epithelium in a chick embryo (approximately 3.5 days old). View from cranial. Between trachea (tr) on bottom and esophagus (es) on top, the tip of the tracheo-esophageal fold (tef) is recognizable. Lateral ridges or signs of fusion are not found.

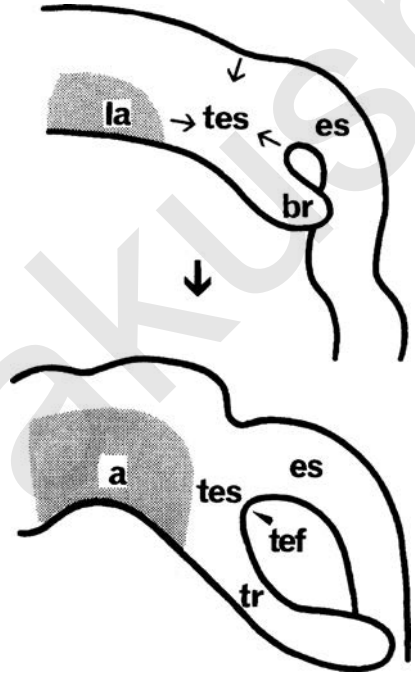

Figure 1.2 Summarizing sketch of foregut development. The tracheo-esophageal space (tes) is reduced in size by developmental movements of folds (indicated by arrows) (es, esophagus; la, anlage of larynx; br, bronchus; tr, trachea). Short arrow marks tip of tracheo-esophageal fold (tef) (compare Fig. 1.1).

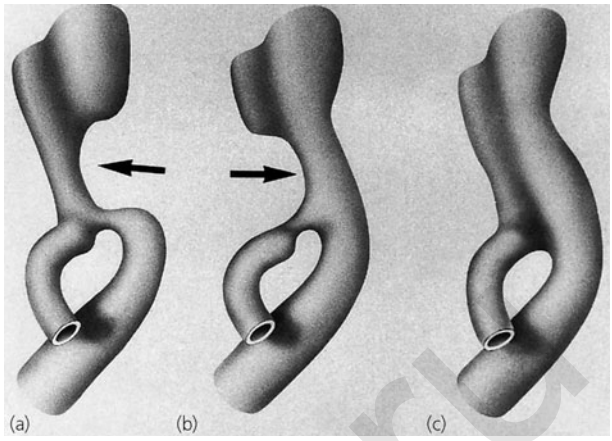

Figure 1.3 Sketch of formal pathogenesis of typical foregut malformations (see text for details): (a) atresia of esophagus with fistula; (b) atresia of trachea with fistula; (c) laryngotracheo-esophageal cleft. Arrows indicate sites of possible deformation of the developing foregut.

- Atresia of the trachea with fistula (Fig. 1.3b):
  - The foregut is deformed on its ventral side. The developmental movements of the folds are disturbed and the tracheo-esophageal space is dislocated in a dorsal direction. Therefore it differentiates into esophagus.
- Laryngotracheo-esophageal clefts (Fig. 1.3c):
  - Faulty growth of the folds results in the persistence of the primitive tracheo-esophageal space.

Recently it has been shown that esophageal atresias and tracheo-esophageal fistulas can be induced by maternal application of adriamycin into the peritoneal cavity of pregnant rats.[19,20] The dosage may vary between 1.5 and 2.0 mg/kg depending on the number of days it will be given. In most reports the most promising dosage is 1.75 mg/kg given on days 6–9 of pregnancy. The adriamycin model has been intensively studied over the last couple of years, resulting in more than 70 reports between 1997 and 2010.[88] It could be demonstrated that in this model not only foregut malformations but also atypical patterns of malformation can be observed which are usually summarized under the term 'VATER' or 'VACTERL' association.[21,22] Therefore, this model is not only promising for the studies of foregut anomalies but also for anomalies of the hind- and midgut.

DEVELOPMENT OF THE DIAPHRAGM

In the past, several theories were proposed to explain the appearance of posterolateral diaphragmatic defects:

- defects caused by improper development of the pleuro-peritoneal membrane;[89,90]
- failure of muscularization of the lumbocostal trigone and pleuro-peritoneal canal, resulting in a 'weak' part of the diaphragm;[89,91]
- pushing of intestine through posterolateral part (foramen of Bochdalek) of the diaphragm;[92]

- premature return of the intestines into the abdominal cavity with the canal still open;[89,91]
- abnormal persistence of lung in the pleuro-peritoneal canal, preventing proper closure of the canal;[93]
- abnormal development of the early lung and posthepatic mesenchyme, causing non-closure of pleuro-peritoneal canals.[18]

Of these theories, failure of the pleuro-peritoneal membrane to meet the transverse septum is the most popular hypothesis to explain diaphragmatic herniation. However, using SEM techniques,[78] we could not demonstrate the importance of the pleuro-peritoneal membrane for the closure of the so-called pleuro-peritoneal canals (Fig. 1.4).

As stated earlier, most authors assume that delayed or inhibited closure of the diaphragm will result in a diaphragmatic defect that is wide enough to allow herniation of the gut into the fetal thoracic cavity. However, this assumption is not the result of appropriate embryological observations but rather the result of interpretations of anatomical/pathological findings. In a series of normal staged embryos we measured the width of the pleuro-peritoneal openings and the transverse diameter of gut loops.[82] On the basis of these measurements we estimated that a single embryonic gut loop requires at least an opening of 450 μ size to herniate into the fetal pleural cavity. However, in none of our embryos were the observed pleuro-peritoneal openings of appropriate dimensions. This means that delayed or inhibited closure of the pleuro-peritoneal canal cannot result in a diaphragmatic defect of sufficient size. Herniation of gut through these openings is therefore impossible. Thus the proposed theory about the pathogenetic mechanisms of congenital diaphragmatic hernia (CDH) development lacks any embryological evidence. Furthermore, the proposed timing of this process is highly questionable.[79,80]

Recently, an animal model for diaphragmatic hernia has been developed[14–18] using nitrofen as noxious substance. In these experiments CDHs were produced in a reasonably high percentage of newborns.[15,16] Most diaphragmatic hernias were associated with lung hypoplasias. Using electron microscopy, our group[79–82] used this model to give a detailed description of the development of the diaphragmatic defect. Our results are discussed in the following.

Timing of diaphragmatic defect appearance

Iritani[1] was the first to notice that nitrofen-induced diaphragmatic hernias in mice are not caused by an improper closure of the pleuro-peritoneal openings but rather the result of a defective development of the so-called post-hepatic mesenchymal plate (PHMP). In our study in rats, clear evidence of disturbed development of the diaphragmatic anlage was seen on day 13 (left side) and day 14 (right side, Fig. 1.5).[79,82] In all embryos affected, the PHMP was too short. This age group is equivalent to 4–5-week-old human embryos.[79]

Location of diaphragmatic defect

In our SEM study, the observed defects were localized in the PHMP (Fig. 1.5). We identified two distinct types of defects: (1) large 'dorsal' defects and (2) small 'central' defects.[79] Large defects extended into the region of the pleuro-peritoneal openings. In these cases, the closure of the pleuro-peritoneal openings was usually impaired by the massive in-growth of liver (Figs. 1.6 and 1.7). If the defects were small, they were consistently isolated from the pleuro-peritoneal openings closing normally at the 16th or 17th day

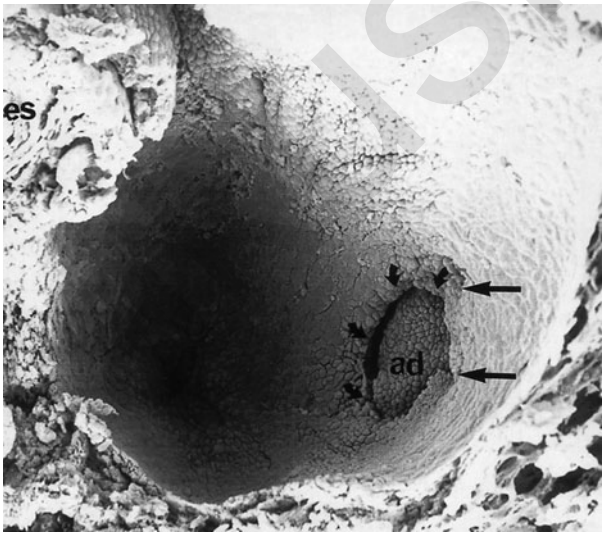

Figure 1.4 SEM photograph of right pleural sac in a rat embryo (approximately 16.5 days old). View from cranial. The so-called pleuro-peritoneal canal (PPC) is nearly closed. Small arrows point at the margin of PPC. In the depth of the abdomen the right adrenals (ad) are seen. Large arrows point at margins of the so-called pleuro-peritoneal membrane. Its contribution to the closure of the canal is minimal (es, esophagus).

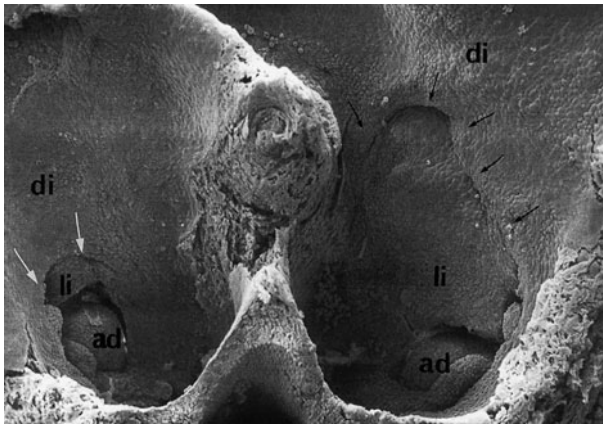

Figure 1.5 Cranial view of the pleural sacs in a rat embryo after exposition to nitrofen on day 11 of pregnancy. The embryo is approximately 15 days old. Note the big defect of the right diaphragmatic primordium. Small black arrows point at margins of the defect, which leaves parts of the liver (li) uncoated. On the left, the diaphragmatic anlage is normal. Note the low position of the cranial border of the pleuro-peritoneal opening on this side (white arrows). (ad, adrenals; di, anlage of diaphragm.)

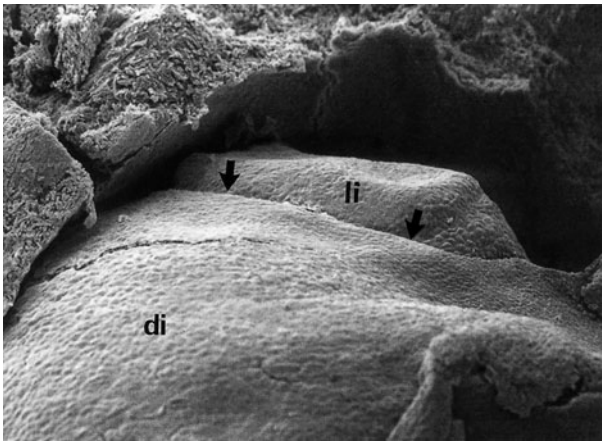

Figure 1.6 Liver (li) protrudes through diaphragmatic defect. Arrows point to the margin of the defect (di, diaphragmatic anlage). Rat embryo (approximately 16 days old), nitrofen exposition on day 11 of pregnancy.

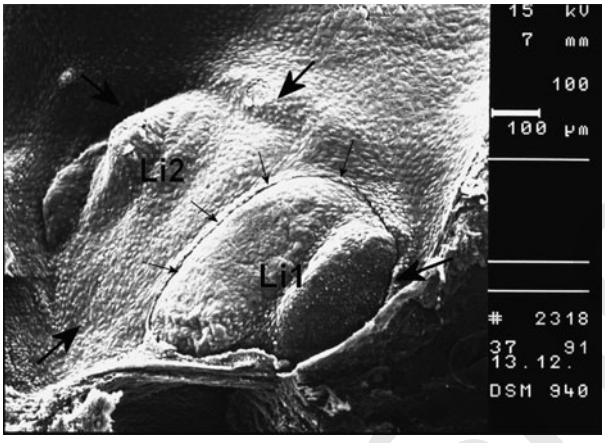

Figure 1.7 SEM photograph of a right pleural sac in a rat embryo after nitrofen exposure on day 11 of pregnancy. The embryo is approximately 15.5 days old. Note the big defect of the right dorsal diaphragm (large arrows). The closure of the pleuro-peritoneal canal (PPC) is impaired by the in-growths of liver (small arrows). Li1 = liver growing through PPC. Li1 + Li2 = liver growing through the defect of the diaphragm.

of gestation. Thus, in our embryos with CDH, the region of the diaphragmatic defect was a distinct entity and was separated from that part of the diaphragm where the pleuro-peritoneal 'canals' are localized. We conclude therefore that the pleuro-peritoneal openings are not the precursors of the diaphragmatic defect.

Why lungs are hypoplastic

Soon after the onset of the defect in the 14-day-old embryo, liver grows through the diaphragmatic defect into the thoracic cavity (Fig. 1.6). This indicates that from this time on the available thoracic space is reduced for the lung and further lung growth hampered. In the following stages, up to two-thirds of the thoracic cavity can be occupied by liver (Fig. 1.7). Herniated gut was found in our embryos and fetuses only in late stages of development (21 days and newborns). In all of these the lungs were already hypoplastic when the bowel entered the thoracic cavity.[79]

Based on these observations, we conclude that the early in-growth of the liver through the diaphragmatic defect is the crucial step in the pathogenesis of lung hypoplasia in CDH. This indicates that growth impairment is not the result of lung compression in the fetus but rather the result of growth competition in the embryo: the liver that grows faster than the lung reduces the available thoracic space. If the remaining space is too small, pulmonary hypoplasia will result.

DEVELOPMENT OF THE CLOACA

In the literature, several theories have been put forward to explain the differentiation of the cloaca into the dorsal anorectum and the ventral sinus urogenitalis. To many authors this differentiation is caused by a septum which develops cranially to caudally and thus divides the cloaca in a frontal plane. Disorders in this process of differentiation are thought to be the cause of cloacal anomalies such as persistent cloaca and anorectal malformations.

However, there is no agreement on the mechanisms of the septational process. While some authors[94,95] believe that the descent of a single fold separates the urogenital part from the rectal part by in-growth of mesenchyme from cranial, others[96] think that lateral ridges appear in the lumen of the cloaca, which progressively fuse along the midline and thus form the septum. In a recent paper[97] the process of septation had been questioned altogether.

Using SEM techniques, our group studied cloacal development in rat and SD-mice embryos. The SD-mouse is a spontaneous mutation of the house mouse characterized by having a short tail (Fig. 1.8). Homozygous or heterozygous offspring of these mice show skeletal, urogenital, and anorectal

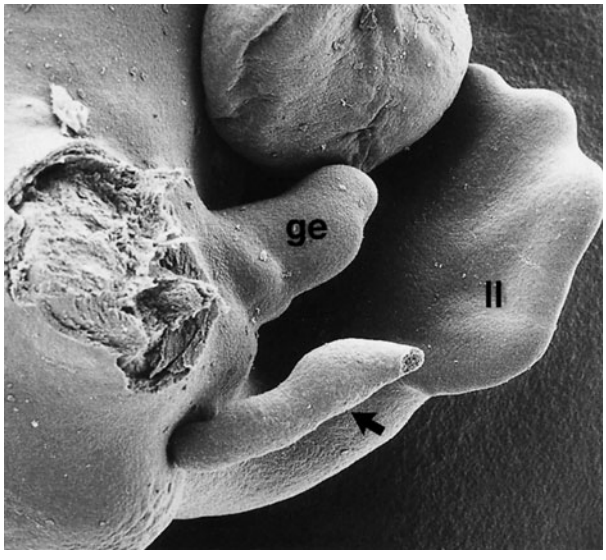

Figure 1.8 Characteristic short tail (arrow) of SD-mouse embryo (approximately 13 days old) (ll, left lower limb; ge, genital tuberculum, abnormal).

malformations.[25,28] Therefore these animals are ideal for the study of the development of anorectal malformations.

Normal cloacal embryology (rat)

As in the foregut of chick embryos, signs of median fusion of lateral cloacal parts could not be demonstrated during normal cloacal development in the rat. However, in contradiction to vdPUTTE,[97] we think that down-growth of the urorectal fold takes place, although it is probably not responsible for the formation of cloacal malformations.

Abnormal cloacal embryology (SD-mouse)

Cloacal malformations are caused by improper development of the early anlage of the cloacal membrane as demonstrated in SD-mice embryos.[98,99]

Our studies of abnormal cloacal development in SD-mice had the following results:

- the basis of the pathogenesis of anorectal malformations is too short a cloacal membrane;
- the anlage of the cloacal membrane is too short and results in a maldeveloped anlage of the cloaca, which is undeveloped in its dorsal part (Fig. 1.9);
- the caudal movement of the urorectal fold is impaired by the malformed cloaca. Thus the hindgut remains in abnormal contact with the cloaca. This opening is true ectopic and will develop into the recto-urogenital fistula (Fig. 1.10).

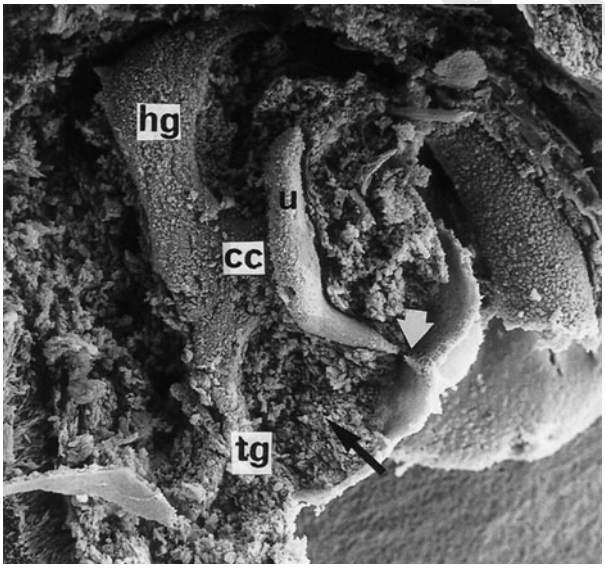

Figure 1.9 Malformed cloaca of SD-mouse embryo (approximately 11 days old). The surrounding mesenchyme is removed by microdissection. View on the basal layer of the cloacal entoderm. The cloaca has lost its contact to the ectoderm of the genitals (white arrow). The dorsal part of the cloaca is missing (black arrow). Tailgut (tg) and hindgut (hg) are hypoplastic. This malformed cloaca developed because the anlage of the cloacal membrane was too short in early embryogenesis (see text for details) (cc, rest of cloaca; u, urachus, rudimentary).

Figure 1.10 Malformed cloaca of SD-mouse, embryo (approximately 13 days old). Urachus (u) and rectum (re) nearly normal (cl, ventral part of cloaca with short cloacal membrane). The dorsal part of the cloaca is missing (long white arrows). Short white arrow points to the region of the future fistula.

It is interesting to note that the morphology of the anorectal malformations observed is very similar in all animal models used irrespective of the source of the malformed embryo (spontaneous mutation versus chemically induced versus transgenic models).

HYPOSPADIAS

Many investigators[100–103] believe that the urethra develops by fusion of the paired urethral folds following the disintegration of the urogenital membrane. Impairment of this process is thought to result in the different forms of hypospadia.[103] However, in our study of normal cloacal development,[104] we were puzzled by the fact that disintegration of the urogenital part of the cloacal membrane could not be observed in rat embryos (Fig. 1.11). This finding caused us to call into question the generally assumed concepts of hypospadia formation. Instead we found that:

- the urethra is always present as a hollow organ during embryogenesis of rats and that it is always in contact with the tip of the genitals, and that;
- an initially double urethral anlage exists. The differentiation in female and male urethra starts in rats of 18.5 days old. On the other hand, we found no evidence for:
  - the disintegration of the urogenital cloacal membrane, and;
  - a fusion of lateral portions within the perineum.

In our opinion, more than one embryological mechanism is at play in the formation of the hypospadias complex. The moderate degrees, such as the penile and glandular forms, represent a developmental arrest of the genitalia (Fig. 1.12). They take their origin from a situation comparable to the 20-day-old embryo. Consequently the penis, not the urethra, is the primary organ of the malformation.

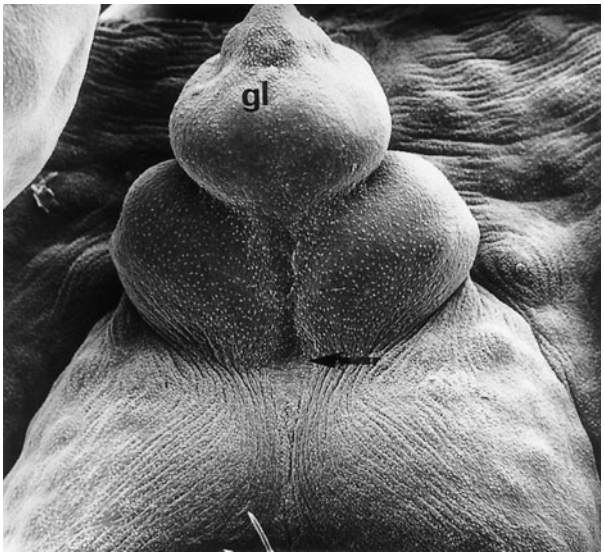

Figure 1.11 Genitals of a normal female rat embryo (approximately 18.5 days old) (gl, glans). Arrow points to future opening of the female urethra. No signs of disintegration of the cloacal membrane.

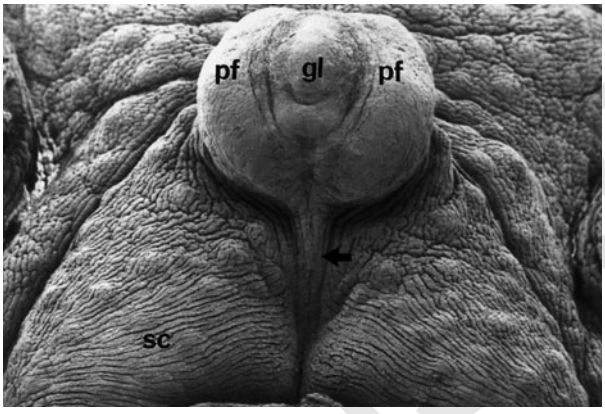

Figure 1.12 Genitals of a normal male rat embryo (approximately 20 days old) (gl, glans; pf, preputial fold; sc, scrotum). Arrow points to the raphe up to this stage; disintegration of the urogenital part of the cloacal membrane was not seen. Note similarity with clinical picture of hypospadia!

Perineal and scrotal hypospadias are different from the type discussed previously. Pronounced signs of feminization in these forms suggest that we are dealing with a female-type urethra. Origin of this malformation complex is an undifferentiated stage as may be seen in the 18.5-day-old rat embryo.[104]

CONCLUSION

Despite the long history of experimental embryology, we know very little about etiology and pathogenesis of congenital malformations. For decades, hypotheses were abundant while few data existed to support them. The tremendous progress of neighboring biological sciences is now providing powerful tools for researchers in the field, such as recombinant DNA and hybridoma technology. Future investigations will monitor closely how genes are switched on and off during embryogenesis and determine the relation of spatial and temporal disturbances to ensuing malformations. Target structures of chemical or viral teratogens within the embryonic cells await identification. Finally, improved understanding of growth coordination *in utero* will extend to related areas such as wound healing and proliferation of cancer cells.

Perinatal physiology

CARLOS E BLANCO, EDUARDO VILLAMOR, AND LUC JI ZIMMERMANN

INTRODUCTION

Perinatal physiology is a field of medicine which studies the life of an individual, human, or animal during gestation and its preparations to adapt to a new world. This world will demand from the individual to breathe air and obtain its food from the environment instead of depending on the circulatory system to perfuse an area where metabolic waste will be disposed of and nutrients and oxygen will be acquired. Successful transition at birth is dependent on establishment of the lungs as the organ of gas exchange.

The transition is very fast and it demands and depends on capable organs and systems in order to make a soft landing and provide survival and good quality of life. In order to succeed the respiratory system must be developed enough to assure a sufficient alveolar exchange area, it must have a drive to offer a continuous breathing activity and the circulatory system should start perfusing the lungs instead of the placenta.

The objective of this chapter is to provide a general overview of the mechanisms preparing the fetus to be born, the transition at birth, and the successful adaptation to the air-breathing world. We will consider two main systems: the respiratory system including lung development, maturation, and role of surfactant system, lung fluid dynamics, lung expansion at birth and its maintenance, respiratory drive and chemoreceptor role; the circulatory system including fetal circulation and its changes at birth, fetal circulatory adaptations to oxygenation challenges, role of the ductus arteriosus in the fetal circulation and mechanisms for its closure, or failure to close, after birth.

FETAL BREATHING MOVEMENTS

Periodic non-air intrauterine breathing patterns must change at birth to a continuous air-breathing pattern. This change happens after clamping the umbilical cord, full perfusion of the lungs, changes in temperature, changes in behavioral state, increase in metabolism, increase in afferent input to the central nervous system, and many other changes associated with the moment of birth.

Breathing-like activity *in utero* is present from very early in gestation and is the consequence of rhythmic activation of respiratory neurons in the brainstem,[1,2] however these breathing movements play no part in fetal gas exchange. The efferent activity of these respiratory neurons activates the respiratory motoneurons and hence the muscles, mainly the diaphragm, which generate a negative intrathoracic pressure. In fetal lambs, spasm of the diaphragm at the 38th day of gestation (term 147 days) and rhythmic movements of the diaphragm at the 40th day of gestation have been described.[3] Chronic recordings from fetal lambs *in utero* performed at approximately 50 days of gestation showed two types of diaphragmatic activity: (1) unpatterned discharge, (2) patterned, bursting discharge.[4] In the human fetus thoracic movements were observed from the 10th to the 12th week of gestation.[5] At this time in gestation there is still not a clear pattern and fetal breathing movements (FBM) appear to be more 'free-wheeling'.

Later in gestation in the fetal lamb (75–110 days), movements of the diaphragm start to become periodic. At this age they are often associated with nuchal muscle activity and rapid eye movements.[6,7] A more definitive pattern starts to appear at 108–120 days of gestation when breathing movements become organized into a more complex state, now associated with the presence of rapid eye movements and nuchal muscle activity.[6–9] At this time in gestation the electroencephalographic (ECoG) activity, commonly known as electrocortical activity, still does not show any signs of differentiation. However, by 120–125 days of gestation the ECoG shows a clear differentiation into low voltage electroencephalographic (LVECog), high frequency activity (range 13–30 Hz; LVECoG) and high voltage electroencephalographic (HVECog), low frequency activity (3–9 Hz; HVECoG).[6,10–12] At this gestational age breathing movements are rapid and irregular, with a frequency of 0.1–4 Hz and an amplitude of 3–5 mmHg and they produce small movements of tracheal fluid (<1 mL).[13] There are now two

clearly defined fetal behavioral states in the fetal lamb: there is no nuchal muscle activity during LVECoG but rapid eye movements and FBM are present. Polysynaptic spinal reflexes are also relatively inhibited during the LVECoG state.[14] During HVECoG, there are no eye movements or FBM, but nuchal muscle activity is present and polysynaptic reflexes are stronger. The link between ECoG state and FBM implies either that breathing activity is facilitated (or even stimulated) during LVECoG and/or that it is inhibited during HVECoG. During LVECoG there is more neural activity in cortical and subcortical structures, including the brainstem reticular formation. This facilitatory state could increase the sensitivity for tonic stimuli, such as the level of arterial CO_2, and generate respiratory output. This hypothesis is supported by the observation that there are no breathing movements during fetal hypocapnia even during the LVECoG state.[15] Extending this idea, the absence of FBM during HVECoG could be due to a disfacilitation, as reported during quiet sleep in the adult when slow waves appear on the EEG.[16,17] Other evidence also leads us to believe that during HVECoG there is an active inhibition of breathing activity, because in fetal sheep FBM and ECoG were dissociated after the brainstem was transected at the level of the colliculi.[18] Furthermore, FBM response to hypercapnia is limited to LVECoG activity in the intact fetus but hypercapnia can produce continuous breathing in both LV and HVECoG after small bilateral lesions are made in the lateral pons.[19] The mechanisms, origin, and location for this inhibition are not clear, but it is known that it is of central origin, and that it can be overridden *in utero* and at the time of birth when breathing becomes continuous.

Control of fetal breathing movements

The work of Barcroft[20] gave rise to the concept that inhibitory mechanisms, which descend from higher centers, are involved in producing apnoeic periods in the fetus. This inhibitory control develops during the second half of gestation. This work also showed that the inhibition of FBM by hypoxemia is not seen early in gestation, and the descending inhibitory processes develop later. While the inhibition of FBM in HVECoG and in hypoxia involves descending inhibitory processes, they do not necessarily utilize the same neural mechanisms. Barcroft employed similar brainstem transection techniques to those of Lumsden[21] to show that neural structures above the level of the pons do not exert significant control over FBM. These studies were extended by Dawes and co-workers[22] who employed the technique of transection in the chronically instrumented late gestation fetal sheep. They showed that transection at the level of upper midbrain/caudal hypothalamus resulted in FBM which were episodic but not related to the ECoG. These FBM were still inhibited by hypoxia. This makes it clear that the processes that mediate the inhibition of FBM in HVECoG are different from those that produce the inhibition in hypoxia. Transection through the rostral pons/caudal midbrain produced FBM that occurred almost continuously and were not inhibited by hypoxia. This focused attention on the upper pons in the inhibition of fetal breathing movements in hypoxia. Gluckman and Johnston[23] pursued this by making lesions in the rostrallateral pons, and compiled a diagram showing areas not needed for the inhibition to be manifest, and the location of an area in the lateral pons which, if lesioned bilaterally, prevented the inhibition.

One of the key questions which emerged from these brainstem studies was whether the descending inhibitory mechanism is capable of inhibiting the input from peripheral chemoreceptors. Once it had been established that the peripheral chemoreceptors are active *in utero* and respond to natural stimuli such as hypoxia or hypercapnia (see below), it was no longer necessary to view the effect of modest hypoxia in inhibiting FBM as a direct depression of the medulla. The results of transection and lesion studies suggested that stimulation of FBM occurred during hypoxia after the damage to the brainstem, as if a stimulatory effect of the peripheral chemoreceptors had been unmasked. Direct confirmation of this idea came from the study of Johnston and Gluckman,[24] who conducted a two-stage procedure: first, lesions were placed as before in the brainstem to prevent the inhibition of FBM in hypoxia or to give an overt stimulation; this was then prevented by chemodenervation at a second operation.

The nature (and indeed the location) of the inhibitory processes is not known. Because the inhibition occurs even in chemodenervated fetuses[25] it is clear that the neurons involved do not receive an excitatory input from the chemoreceptors. They may therefore be chemoreceptors themselves or receive input from other cells thought to be sensitive to hypoxia, e.g. in the rostral ventro-lateral medulla (RVLM).[26] The neural activity as a whole behaves as a chemoreceptor because the chemoreceptor stimulant drug almitrine mimics the effects of hypoxia in inhibiting FBM, irrespective of the integrity of the peripheral chemoreceptors.[27] As expected from the discussion above, the stimulatory effect of the drug on the peripheral chemoreceptors only becomes manifest when lesions were placed in the lateral pons,[28] unmasking its peripheral actions.

PERIPHERAL CHEMORECEPTOR FUNCTION *IN UTERO*

The concept that peripheral chemoreceptors could produce effects on breathing can be traced to experiments conducted over 50 years ago[20] in which breathing was shown to be stimulated in exteriorized mid-gestation animal fetuses by hypoxia or cyanide.[29] In late gestation the descending inhibitory effects on breathing arising from the fetal brainstem in hypoxia and HVECoG dominate. It was perhaps the increasing interest in these processes that caused the scientific community to lose sight of the implications of the earlier observations. The idea became prevalent that the carotid chemoreceptors were quiescent *in utero* and were activated at birth, perhaps by the increase in sympathetic nervous activity. In addition, when it became clear that normal fetal arterial PO_2 in late gestation, both in the sheep and the human fetus, was ca. 3 Kpa (25 mmHg), it was thought that if the chemoreceptors were functional they would be so

intensely stimulated that powerful reflex effects would be induced continuously. This was clearly not the case, although it had been shown that brainstem transection removed inhibitory effects on breathing[20,22] and permitted stimulation of breathing activity during hypoxia. It was therefore essential to readdress the question of arterial chemoreceptor function *in utero*. It was found that both carotid[30] and aortic[31] chemoreceptors were spontaneously active at the normal arterial PO_2 in fetal sheep and that they responded with an increase in discharge if PO_2 fell or PCO_2 rose. There were several very important implications of these findings. First, it was clear that the peripheral chemoreceptors would be able to stimulate fetal breathing under some circumstances but that it was the balance between this stimulatory input and the normally dominant, inhibitory input from higher centers which determined the characteristics of fetal breathing. Second, it redirected attention to the role the carotid chemoreceptors play in initiating cardiovascular reflex responses to hypoxia.[32,33] Lastly, the observation that the fetal peripheral chemoreceptors discharge spontaneously (at ca. 5 Hz) at the normal fetal arterial PO_2 made it clear that the rise in PO_2 at birth would silence them. Their sensitivity to PO_2 would then have to reset to the adult range postnatally, and this has generated research into the mechanisms of this resetting.[34,35]

PHARMACOLOGICAL CONTROL

A range of agents that mimic hypoxia, by lowering tissue PO_2 in the central nervous system, inhibit fetal breathing movements, e.g. CO poisoning,[36] oligomycin B,[37] and anemia.[38] Adenosine is also released in neural tissue during hypoxia and exerts a range of actions: it stimulates the peripheral chemoreceptors, but reduces respiratory output in the fetus and neonate. The stimulation of FBM by adenosine after caudal brainstem transection[39] is explicable in terms of the removal of descending inhibitory processes discussed earlier in this chapter. In addition, the role of glutamate as an excitatory amino acid in the fetus and the neonate has recently been addressed.[40,41]

Adrenergic agonists and antagonists have also been used to investigate catecholamines in the control of FBM. Murata *et al.*[42] showed that noradrenaline inhibits FBM in the rhesus monkey while isopreterenol, a β-adrenergic agonist, stimulates FBM. However, Bamford *et al.*[43] showed that the α_2-agonist clonidine increases and the α_2-antagonist idazoxan inhibits FBM fetal sheep. α_2-Adrenoreceptors exert a presynaptic inhibition on noradrenaline release suggesting that noradrenaline stimulates, rather than inhibits, FBM as indicated by Murata *et al.*[42] In a subsequent study, Bamford and Hawkins[44] showed that the α_2-adrenergic antagonist MSDL 657743 also stimulated FBM in normoxia and also maintained FBM during hypoxia in the fetal sheep. Giussani *et al.*[45] have reported a similar effect after treatment with phentolamine, an α_1- and α_2-antagonist. Furthermore, Joseph and Walker[46] blocked the re-uptake of noradrenaline from the synaptic cleft in fetal sheep and showed that FBM were initially increased and then decreased, presumably owing to a depletion of presynaptic stores of noradrenaline. The conclusion is that noradrenaline stimulates FBM, but that the predominant action of these drugs is on the presynaptic α_2-adrenergic receptor, which when stimulated inhibits endogenous release of noradrenaline.

Prostaglandins exert a powerful influence on FBM and postnatal breathing. Prostaglandin E_2 (PGE_2) decreases the incidence of FBM[47] whereas meclofenamate and indomethacin, inhibitors of prostaglandin synthesis, increase FBM.[48–50] The effect of prostaglandins appears to be central, as it is independent of the peripheral chemoreceptors[51] and because central administration of meclofenamate stimulates FBM.[52,53] The same effects can be produced postnatally, with PGE_2 decreasing, and meclofenamate and indomethacin increasing, ventilation in lambs.[54,55] However, the change in the concentration of PGE_2 that occurs around birth cannot be solely responsible for either the decrease in FBM seen immediately before birth,[56,57] or the onset of continuous breathing postnatally.[58] The well-established effects of ethyl alcohol to reduce the incidence of FBM[59] are not mediated by prostaglandin[60] but by adenosine.[61]

Bennet *et al.*[62] showed that large doses of thyroid releasing hormone (TRH) can induce stimulation of FBM. This effect may be at the level of the respiratory neurons where TRH can be localized, but its physiological significance is not known. This may also be true of the effects of the cholinergic agonist, pilocarpine, and serotonin (5-HT) precursor L-5-hydroxytryptophan (L-5-HTP)[63,64] Both of these agents stimulate FBM, but pilocarpine induces LVECoG and L-5-HTP induces HVECoG. This stresses again the coincidental rather than causal relationship between FBM and LVECoG. 5-HTP has been implicated in neural mechanisms controlling adult sheep, but the site of action in the fetus is not known. A range of opiates has effects on FBM[65] but the physiological localization of their effects has not been established.

The high rate of progesterone synthesis by the placenta in late gestation exposes the fetus to high concentrations of progesterone and its metabolites. Progesterone can influence fetal behavior, and normal progesterone production tonically suppresses arousal or wakefulness in the fetus.[66,67]

Lastly, one of the striking aspects of FBM is that they cease 24–48 hours before parturition. The mechanism involved is not known. Kitterman *et al.*[48] excluded a rise in plasma PGE_2 and Parkes *et al.*[68] showed that it did not occur if the fall in plasma progesterone was prevented.

LUNG GROWTH ASSOCIATED WITH FETAL BREATHING MOVEMENTS

Fetal breathing movements are necessary for fetal lung growth and maturation. By opposing lung recoil, FBM help to maintain the lung expansion that is now known to be essential for normal growth and structural maturation of the fetal lungs. FBM induce complex and variable changes in thoracic dimensions; these induce small alterations in the shape of the lungs that may act as a stimulus to lung growth. The prolonged absence or impairment of FBM is likely to result in a reduced mean level of lung expansion, which can

lead to hypoplasia of the lungs.[69] Moreover, static distension decreases steady-state SP-A and SP-B mRNA levels in whole lung whereas cyclic stretching increases SP-B and SP-A expression two- to four-fold and enhances 3H-choline incorporation into saturated phosphatidylcholine.[70]

CHANGES AT BIRTH

At birth, breathing activity must become continuous in order to fulfill its gas exchange function. After occlusion of the umbilical cord the neonatal ECoG still cycles between low and high voltage states, which seem to have identical spectral characteristics to the fetal states. LVECoG activity is associated with the absence of nuchal muscle activity, rapid eye movements, and inhibition of polysynaptic reflexes, and HVECoG is associated with the presence of nuchal muscle activity, lack of rapid eye movements, and enhanced polysynaptic reflexes.[71] However, despite the fact that after birth the HVECoG state seems to be similar to the equivalent fetal state, breathing activity is present. The reason for this is not known. It may be that answering this question will require detailed spectral analysis of the ECoG from different areas of the brain before birth and during the first hours of postnatal life. It is worth noting that some mammals, such as the rat, cat, and rabbit, develop organized behavioral states 2–3 weeks after birth; however they do not breathe continuously *in utero* and these species demonstrate the same transition to continuous breathing after birth as do more precocial species.

Studies of the mechanisms involved in the establishment of continuous breathing at birth have followed two lines: (1) attempts to induce continuous breathing *in utero*, or (2) observation of establishment of continuous breathing during situations aimed at mimicking birth.

It is well established that the inhibition of FBM during HVECoG can be overridden, as demonstrated by the presence of continuous breathing during metabolic acidosis,[72,73] administration of prostaglandin synthetase inhibitors,[48,49,53] 5-hydroxytryptophan,[64,74] catecholamines,[75] pilocarpine,[63] thyrotrophin releasing hormone,[76] corticotrophin releasing factor,[61] central or peripheral fetal cooling,[77,78] and by lesions within the central nervous system (CNS). These experiments show that FBM can become continuous through the operation of various mechanisms including disinhibition during HVECoG, changes in the balance between stimulatory and inhibitory neuromodulators, increased arousability, and changes in chemoreceptor sensitivity.[79] Some, but not all, of these mechanisms are likely to play an important role at birth.

Experiments designed to observe changes in breathing activity after cord occlusion have led to two main hypotheses: (1) the exclusion of fetal-placental circulation leads to the disappearance of hormones or neuromodulators which exert continuous tonic inhibition (through the CNS) during fetal life, and that this allows continuous breathing postnatally.[80–83] There are reports indicating that prostaglandins originating from placental tissue can inhibit fetal breathing activity.[84] Although this is a possible explanation, it is not yet demonstrated that such a substance is responsible for the modulation by ECoG of FBM. It was shown that breathing movements of goat fetuses maintained in an extrauterine incubation system for more than 24 hours were episodic, suggesting that intermittent breathing movements are intrinsic to the fetus, independent of placenta-derived factors;[85] (2) breathing activity is dependent on the level of $PaCO_2$ *in utero* and at birth.[15] It is known that during hypocapnia, fetal and neonatal breathing is reduced.[15,78,80] Hypercapnia stimulates breathing activity but *in utero* this is inhibited during quiet sleep.[81] However, this inhibition can be overridden after lesions in the lateral pons[19] or when hypercapnia is combined with cooling.[78] This might be explained by changes in the CO_2 sensitivity of central and/or peripheral chemoreceptors or due to changes in the balance between central inhibitory and excitatory mechanisms caused by an increase in afferent input at birth. In this hypothesis, both changes in afferent input from chemo- and thermoreceptors to the CNS, and/or changes in CNS sensitivity to these inputs, are important in the transition from fetal to neonatal breathing. Changes in the plasma level of a placental neuromodulator at birth may then serve to maintain postnatal breathing after its initiation. More insight into these mechanisms may offer an explanation for the occurrence of apnoeic periods after birth.

POSTNATAL BREATHING

Studies to identify brainstem mechanisms that regulate breathing have been conducted in the neonate, in which hypoxia also inhibits breathing but after a transient chemoreceptor-mediated stimulation. Therefore, the reasoning is that similar inhibitory processes to those that operate in the fetus produce the postnatal inhibition of ventilation by hypoxia. Transection of the brainstem through the rostral pons does indeed remove the secondary fall in ventilation,[86] as does placement of lesions in the lateral pons.[87] However, these studies did not identify any clear group of neurons involved in mediating the effect. Investigators focused their attention on the red nucleus, located above the pons in the mesencephalon. The transection studies implicate structures in either the rostral pons or caudal mesencephalon, so it is likely that the red nucleus would have been affected. In neonatal rabbits, electrical stimulation of the red nucleus produces a profound inhibition of respiratory output, and bilateral lesions in the red nucleus prevent the inhibition of respiratory output in hypoxia while not affecting the cardiovascular responses. Evidence that neurons in the red nucleus are involved in this effect comes from the observation that chemical stimulation with glutamate also produces an inhibition of respiratory output.[88] Interestingly, the efferent pathway for these cells, rubrospinal tract, runs in precisely the ventrolateral region of the pons lesioned by Gluckman and Johnston in their fetal studies.[23]

The observations on the red nucleus are interesting because in postnatal life it has been implicated in producing the hypotonia of postural muscles, which occurs in rapid eye movement (REM) sleep. Such hypotonia also occurs in the fetus[30] but at that time it is associated with presence, and not absence, of FBM. Once again, behaviorally related and

hypoxia-induced inhibition of FBM appears to be distinct. In addition, the brainstem reticular formation and related nuclei associated with sleep and arousal have not been greatly studied in the postnatal period. In one study, Moore *et al.*[89] reported that cooling the locus coeruleus by a few degrees, sufficient to reduce neuronal activity but not conducted action potentials, prevented the secondary fall in ventilation in hypoxia in neonatal lambs. The locus coeruleus has been implicated in producing arousal at birth.[90] There are also reports that structures as high in the brain as the thalamus are implicated in the descending inhibition of breathing during hypoxia.[91]

While the effects of acute hypoxia on FBM have been widely studied, the effects of prolonged hypoxemia are quite different. Over a period of 6–12 hours, FBM return to their control incidence as does cycling of the ECoG.[92] Studies reveal that the peripheral chemoreceptors are necessary for the return of FBM during sustained hypoxia produced by reduced uterine blood flow, but the mechanisms involved are not known.[93]

In summary, spontaneous breathing movements are present during fetal life and they are important for normal development of the fetal lungs. Early in gestation they seem to represent free-running activity of the respiratory centers, not controlled by peripheral mechanisms but probably dependent on a tonic CO_2 drive. Maturation of sleep states brings into play powerful brainstem inhibitory mechanisms that control this activity.

Fetal breathing activity is present during physiological and normal fetal conditions and it can be monitored noninvasively by ultrasound, therefore its monitoring could be used to interrogate fetal well-being. A recent Cochrane systematic review did not support its usefulness when included in a biophysical profile to detect high-risk fetuses.[94] However, the monitoring of fetal breathing activity could be used to predict premature labor.[95]

Birth clearly involves some irreversible processes, the transition to continuous breathing being one. However, breathing remains linked to behavioral and sleep states in the neonate as in the fetus and clearly there is continuity of some control processes from late gestation to early postnatal life. Some of these processes mature relatively slowly after birth, such as resetting of chemoreceptor hypoxia sensitivity and the diminishing influence of descending inhibitory effects on breathing in hypoxia. Understanding these effects will be of vital importance to prevention of sudden infant death syndrome (SIDS) and the care of newborn, especially preterm babies.

THE FETAL CIRCULATION AND ITS TRANSITION AT BIRTH

The fetal circulation is characterized by high pulmonary vascular resistance (PVR), low systemic vascular resistance (SVR), presence of an additional low resistance vascular bed (i.e. the placental bed), and right-to-left shunting via the foramen ovale and ductus arteriosus (DA). Local vascular resistance determines distribution of blood flow to the lungs, systemic organs, and placenta. The placental vascular bed receives about 40–50% of the combined ventricular output whereas the lungs receive less than 10%. In response to fetal hypoxemia, distribution of cardiac output and venous return is altered in an effort to maintain perfusion and O_2 delivery to the vital organs such as the heart, brain, and adrenal glands.[96,97] Thus, during maternofetal hypoxia, the percentage of systemic venous blood not sent to the placenta for oxygenation is decreased, whereas the proportion of umbilical venous blood contributing to fetal cardiac output is increased.[96,97]

The human placenta was widely thought of as a passive organ in which blood flow depends only on the pressure difference between the umbilical arteries and veins connecting it to the fetus.[98,99] However, more recent evidences indicate that the regulation of vasomotor tone in the vessels of the fetoplacental circulation is important to maintain an adequate blood supply that makes possible maternofetal gas and solute exchange.[98–100] As fetoplacental blood vessels lack autonomic innervation, control of vascular tone is mainly influenced by circulating and/or locally released vasoactive agents as well as by physical factors, such as flow or oxygen tension.[101] Accordingly, constriction and relaxation of fetoplacental arteries and veins have been demonstrated in response to a number of agonists and physical stimuli. Moreover, various authors have suggested that the fetoplacental vasculature shows some form of flow matching similar to hypoxic pulmonary vasoconstriction. This mechanism, termed hypoxic fetoplacental vasoconstriction,[100,102,103] would divert blood flow to the placental areas with better maternal perfusion as hypoxic pulmonary vasoconstriction diverts pulmonary blood flow to the better ventilated areas of the lung.[103–105]

Clamping of the umbilical cord at birth eliminates the placental circulation producing a conspicuous increase in SVR. Parallel, as the lung assumes the respiratory function, the pulmonary circulation undergoes a striking transition characterized by an immediate eight- to ten-fold rise in pulmonary blood flow and a sustained decrease in PVR.[106–109] The postnatal fall in PVR and rise in SVR results in a reversal of the relationships present in the fetus. Increasing blood return to the heart via the pulmonary veins raises the pressure of the left atrium above that of the right, causing a functional closure of the foramen ovale. While the DA is still patent, the flow of blood through it will change to a left-to-right shunt but the DA normally achieves functional closure within 48 hours after birth. Because the foramen ovale and ductus arteriosus are only functionally closed and the pulmonary circulation is very sensitive to vasoconstrictive stimuli, the neonatal circulatory pattern can readily revert to the fetal pattern. In the following paragraphs the different circulatory events that take place during the transition between fetal and postnatal life will be analyzed in more detail.

CLOSURE OF THE DUCTUS VENOSUS

The ductus venosus is a shunt between the umbilical vein and the inferior vena cava which allows highly oxygenated and

nutrient-rich umbilical venous blood to bypass the liver and reach the central circulation rapidly. A large proportion of inferior vena cava return crosses the foramen ovale into the left atrium to the left ventricle, and is thus distributed to the coronary and cerebral circulations. The PO_2 of blood supplying the heart, brain, head, and neck is higher by 4–5 mmHg than that of blood in the descending aorta. Although the ductus venosus has received less attention than the DA, it is now well accepted that it plays a major role in the regulation of fetal circulation. Inlet of the vessel is under active control and a compensatory mechanism, supported by transient dilatation, is supposed to increase oxygenated blood flow through the ductus venosus during hypoxia or reduced umbilical flow.[110] Absence of the ductus venosus is associated with a high incidence of fetal anomalies and adverse outcomes, including associated malformations, chromosomal aberrations, *in utero* heart failure and absence of the portal vein.[111] Functional closure of the ductus venosus, which is followed by anatomic closure, is virtually complete within a few weeks of birth. However, the ductus venosus of almost all neonates remains open for a certain period after birth with important variations in the volume of blood flow.[112] Closure of the ductus venosus is more delayed in preterm neonates and patent ductus venosus appears to be related to alterations in ammonia detoxification, blood coagulation, and regulation of serum total bile acid concentration.[112]

CLOSURE OF THE FORAMEN OVALE

Anatomically, the foramen ovale comprises overlapping portions of septum primum and septum secundum, acting as a one-way flap valve allowing continuous right-to-left flow during fetal life.[113] Immediately after birth, with the acute increase in pulmonary blood flow, left atrium pressure rises to exceed right atrium pressure, pushing septum primum rightward, against septum secundum, shutting the flap of the foramen ovale. Afterwards, septum primum fuses to septum secundum, completing septation of the atria. However, in 20–25%, incomplete fusion leads to the persistence of the flap valve, leaving a patent foramen ovale.[113] In general, individuals with patent foramen ovale are never identified because they have no symptoms. However, there is increasing interest in the evaluation and treatment of patent foramen ovale, which has been associated with various pathologic conditions, such as cryptogenic stroke, decompression sickness, platypnea-orthodeoxia syndrome and migraine.[114]

FALL IN PULMONARY VASCULAR RESISTANCE

The ability to adapt to changes in the availability of O_2 underpins vital changes to the circulation during the transition from fetal to independent, air-breathing life.[115] The fetal lung is continuously exposed to a low O_2 tension which induces a vigorous hypoxic pulmonary vasoconstriction.[107,116,117] The fetal pulmonary circulation can sense small changes in Po_2, which is at least partly responsible for maintaining high PVR *in utero*.[107,116,117] The acute response to hypoxia in the fetal lamb is characterized by increased pulmonary and systemic arterial pressures and a fall in pulmonary blood flow.[118] This response is mediated by carotid chemoreceptors,[119] is already present before 0.7 term, and increases with gestational age.[120] However, acute elevation of fetal PVR is likely to be due to direct effects of lowered PO_2 on smooth muscle and modulated by various neural and humoral mediators.[107,121]

Besides the increase in oxygen tension, several other mechanisms contribute to the normal fall in PVR at birth, including the establishment of a gas–liquid interface in the lung, rhythmic distension of the lung, and shear stress.[106,107,122] These physical stimuli act, at least partially, through the production of vasoactive products, especially the release of potent vasodilator substances, such as nitric oxide (NO) and prostaglandin I_2.[106,109,123] Normally, pulmonary arterial pressure falls to the half of the systemic pressure by 24 h and then progressively decreases to adult levels within 2–6 weeks.[124] Therefore, the process of pulmonary circulatory transition is not limited to the first moments of extrauterine life, but it extends during the following weeks.[124]

Failure of the pulmonary circulation to undergo a normal transition results in persistent pulmonary hypertension of the newborn (PPHN), a clinical syndrome of various neonatal cardiopulmonary disorders, which are characterized by sustained elevation of PVR after birth, leading to right-to-left shunting of blood across the ductus arteriosus or foramen ovale and severe hypoxemia.[107,109] PPHN is a pathophysiological phenomenon occurring in a heterogeneous group of diseases with a wide diversity of etiologies. These range from transient reversible pulmonary hypertension attributable to perinatal insults to irreversible fixed structural malformations of the lung. Diseases associated with the syndrome of PPHN can be classified in three categories:[106,108]

1. maladaptation, in which vessels are presumably of normal structure but have abnormal vasoreactivity;
2. excessive muscularization, in which smooth muscle cell thickness is increased and muscle extends distally to vessels that usually are not muscular;
3. underdevelopment, in which lung hypoplasia is associated with decreased number of pulmonary arteries.

Either as a primary condition or secondary to other pulmonary or extrapulmonary diseases, PPHN is an important cause of cardiorespiratory failure and is responsible for a relevant percentage of morbidity in the neonatal intensive care units.[106,108]

CLOSURE OF THE DUCTUS ARTERIOSUS

Low oxygen tension, high levels of circulating PGE_2, and locally produced PGE_2 and PGI_2 are the main factors maintaining patency of the DA *in utero*.[125–127] During fetal life, the DA normally has an intrinsic tone due to components that are both dependent on and independent of extracellular

calcium.[125] Endothelin-1 also appears to play a role in the intrinsic tone of the ductus.[127–129]

Several events promote the constriction of the DA in the full term newborn: (1) the increase in arterial PO_2, (2) the decrease in blood pressure within the ductus lumen (due to the postnatal decrease in PVR), (3) the decrease in circulating PGE_2 (due to the loss of placental prostaglandin production and the increase in prostaglandins removal by the lung), as well as the decrease in the number of PGE_2 receptors in the ductus wall.[125,126,129] The timing of closure of the DA after birth varies between species, but in humans it is usually completed within 48 hours.[129] In the full term infant, closure of the DA at birth occurs in two phases. The first phase, the 'functional' closure of the lumen, occurs within the first hours after birth by smooth muscle constriction. Constriction produces ischemic hypoxia of the vessel wall, and this hypoxia inhibits local production of PGE_2 and NO and induces production of growth factors. This leads to the second phase that involves 'anatomic' occlusion of the lumen over the next several days due to extensive neointimal thickening and loss of smooth muscle cells (SMC) from the inner muscle media.[125,127–129]

Failure of DA closure after birth is a common complication of premature delivery that is still presenting challenges in terms of diagnosis, assessment, and treatment options.[127] Even when it does constrict, the premature ductus frequently fails to develop profound hypoxia and anatomic remodeling and is, therefore, susceptible to reopening.[129] Failure of DA closure in very preterm infants is associated with several comorbidities, such as necrotizing enterocolitis, intracranial hemorrhage, pulmonary edema/hemorrhage, bronchopulmonary dysplasia, and retinopathy of prematurity.[125–127]

LUNG DEVELOPMENT: STRUCTURAL DEVELOPMENT, SURFACTANT, AND LUNG FLUID

Lung development

The primary goal of lung development is to create a large gas exchange surface area, a thin air–blood barrier, a mature surfactant system, a conductive airway tree, and a set of vascular tubes to supply the organism with sufficient oxygen and to remove excess CO_2. Lung development comprises six different stages.[130]

During the embryonic stage (3–7 weeks post-conception) the lung primordium appears as a ventral diverticulum of the foregut and elongates caudally. The resulting bud branches for the first time and gives rise to the main bronchi of the two lungs. These bronchi divide dichotomously and form the future bronchi.

During the pseudoglandular stage (5–17 weeks in the human) the whole bronchial tree is formed by dichotomous branching. Also, differentiation of epithelial cells starts with the appearance of ciliated cells, goblet and basal cells, and production of cartilage.

During the canalicular stage (16–26 weeks in human) the air–blood interface is formed by the appearance of vascular canals or capillaries that multiply in the interstitial compartment. In addition, differentiation of pulmonary epithelial cells into type II cells, the producers of surfactant, is seen as well as a subsequent development of type I cells, which contribute to the formation of the thinned prospective air–blood barrier.

Entering the saccular stage (24–38 weeks in human) is crucial for extrauterine survival. On the one hand there is dilation and expansion of the acinar tubules and buds into thin, smooth walled, transitory alveolar sacules and ducts. On the other hand there is reduction of the surrounding mesenchymal tissue which allows for sufficient gas exchange. Further branching of the alveolar ducts occurs and the peripheral regions of the lung increase in size. Preparation for real alveolarization begins with the development of intersaccular and interductal septa. Maturation of type II epithelial cells continues and surfactant production starts. Further differentiation of other alveolar and bronchial cells occurs.

The alveolar stage (36 weeks of gestation to two years postnatal age) starts before birth but lasts well into the postnatal period. The hallmark of this stage is secondary septation, namely the formation of new interalveolar walls. They originate from low ridges projecting into the airspaces. Typically, elastic fibers are located at the tip of the crests where the secondary septa originate.[131] Originally the septa still consist of a doubled capillary layer separated by a sheet of connective tissue.

During the last stage of lung development, the stage of microvascular maturation (the first 2–3 years after birth) the septa are restructured into a mature interalveolar wall, consisting of minimal interstitial tissue and a capillary monolayer.[130,132] At the end of this stage most of the alveolar capillary endothelium and flattened type I epithelium are in direct contact supporting optimal gas exchange.

At birth the lung contains up to 50 million alveoli and most of the remaining alveoli are formed by so-called 'bulk alveolarization' during the alveolar stage, mainly postnatally. However, it is very well possible that a stage of late alveolarization exists, as described by Burri,[132] where about 50% of the adult 300 million alveoli are formed. Especially in the subpleural areas in the periphery of the lung, new alveolar septa can be newly formed at a slower pace, but later than the bulk alveolarization phase.

In most cases it is easy to link lung abnormalities or syndromes to the stage of lung development.[133] For example, treacheo-esophagal fistulae, pulmonary agenesis or aplasia, and extralobar pulmonary sequestration originate during the embryonic stage of lung development. Pulmonary cysts, renal pulmonary hypoplasia, and lung hypoplasia due to congenital diaphragmatic hernia originate during the pseudoglandular and canalicular stage. Alveolar capillary dysplasia originates during the canalicular and saccular stage. Pulmonary hypoplasia due to oligohydramnion also originates during the canalicular and saccular stage. In general, branching will be permanently impaired by insults prior to 16 weeks of gestation while the number of alveoli will be reduced by a

later insult. From the stages of lung development it is also easy to understand the border of survival in extreme prematurity. Although there is some overlap between the stages, in general the saccular stage starts at 24 weeks, not surprisingly the gestational age where significant survival starts. Still, at this stage of lung development surface area for gas exchange is small, epithelia are not sufficiently flattened and interstitium is still present between the epithelial layer and the endothelial layer. As the alveolarization phase has not taken place yet, many insults can disturb this process leading to fewer and larger alveoli, typical of the so-called 'new bronchopulmonary dysplasia'.[134] Many prenatal and postnatal factors can influence this process such as chorioamnionitis, interauterine growth retardation, oxygen toxicity, positive pressure ventilation, infections, a patent ductus arteriosis, and some therapeutical interventions such as the use of postnatal corticosteroids.[134]

Surfactant

In 1959, Avery and Mead[135] showed that pulmonary surfactant deficiency is a major factor in the pathophysiology of respiratory distress syndrome (RDS). Since then the physiology and metabolism of surfactant has been extensively studied. In 1980 Fujiwara[136] administered exogenous surfactant successfully to preterm infants with RDS for the first time followed by numerous clinical trials in the 1990s.[137] In addition, a disturbed surfactant metabolism plays a role in many neonatal lung diseases such as meconium aspiration syndrome and congenital diaphragmatic hernia.[138]

The primary function of surfactant is to decrease the surface tension at the air–liquid interface in the alveoli and distal bronchioli, to promote lung expansion during inspiration, and to prevent alveolar collapse at expiration. A secondary role of surfactant is innate host defence.[139] Surfactant is produced by alveolar type II cells, which are situated at the corners of the alveolar spaces. It is a complex mixture of about 90% lipids and 10% proteins.[140] Of the surfactant lipids, 80–90% are phospholipids, of which phosphatidylcholine (PC) is quantitatively the most important, accounting for 70–80% of the total. The four surfactant proteins are simply named surfactant protein (SP) A, B, C, and D.[141] SP-A enhances uptake of surfactant by the type II cells and together with SP-D plays a role in innate immune defense: it binds pathogens and influences the activity of immune cells such as macrophages.[142] Both proteins are large glycoproteins. In contrast, SP-B and SP-C are small, very hydrophobic proteins and are essential for the spreading of surfactant phospholipids at the air–liquid interface of the alveoli. The role of SP-B is so essential that a congenital deficiency is lethal due to severe respiratory insufficiency.[143] Surfactant is synthesized by type II alveolar cells from precursors such as fatty acids, choline, glucose, and amino acids in the endoplasmatic reticulum and via the Golgi apparatus is then stored in lamellar bodies.[144] These lamellar bodies serve as the intracellular storage form of surfactant and are secreted into the alveolar space. After secretion they unravel to form lattice-like structures, named tubular myelin. From this structure the monolayer of surfactant at the air–liquid interface is generated. This monolayer is the essential surface-tension-lowering component. Alveolar surfactant can be cleared by different pathways.[145] Surfactant can be removed from the lung by macrophages or via the upper airways or can be recycled by uptake by the type II cell and reinsertion in the lamellar bodies, which are ready for resecretion. In the neonate more than 90% of surfactant is recycled in this way, in contrast to the adult where recycling is about 50%.[146,147]

Surfactant kinetics have been studied in animals with the use of radioactively labeled substrates.[148] In recent years stable isotope techniques were used to study surfactant metabolism in human infants. Labeled precursors, such as [U-^{13}C]glucose, [1-^{13}C]acetate, or [U-^{13}C]palmitic acid were infused intravenously and incorporation of label was measured by mass spectrometry in surfactant PC isolated from tracheal aspirates.[138] In term ventilated neonates without lung disease the first appearance of label in surfactant was found after about 9 hours with a maximal enrichment at about 44 hours.[149–151] In comparison, preterm infants with RDS showed a much slower surfactant synthesis and metabolism with a first enrichment after about 17 hours and maximal enrichment at about 75 hours.[149,152–154] When the fractional synthesis rate of surfactant was calculated, preterm infants with RDS only had a value of 4%/day compared to 15%/day or more in term infants.[149–154] Catabolism and pool sizes of surfactant were studied by giving a bolus of labeled surfactant PC endotracheally. Half-life was calculated by the disappearance of the label from tracheal aspirates and pool size from the dilution of the label. Preterm infants only had less than 10 mg/kg of surfactant, which is consistent with animal models of RDS.[155] No feedback inhibition was found of surfactant therapy on endogenous surfactant synthesis.[156] It was also proven in human infants that prenatal corticosteroids stimulate surfactant synthesis, as was extensively known from *in vitro* studies and animal experiments.[157,158] Controversy has long existed about a possible surfactant deficiency in neonates with congenital diaphragmatic hernia (CDH). In several animal models of CDH a decrease in surfactant was found.[159–161] In humans, surfactant was measured from tracheal aspirates or bronchoalveolar lavages with contradictory results.[162–165] Studies with stable isotopes did not completely clarify the issue. Cogo *et al.*[166] found a decrease in pool size in infants with CDH but Janssen *et al.*[167] found no decrease in pool size (about 73 mg/kg) in infants on extracorporeal membrane oxygenation (ECMO). However, surfactant synthesis was decreased in the patients in this study comparable with the synthesis of preterm infants with RDS (fractional synthesis 2.4%/day versus 8%/day in control infants).[168] In patients with less severe CDH, Cogo found no decreased synthesis rate of surfactant.[150,169] Similar studies were performed in neonates with meconium aspiration syndrome (MAS). Some infants with MAS have severe respiratory insufficiency. From animal studies it is well known that meconium inhibits surfactant function. With stable isotope techniques it was shown that the sickest infants on ECMO have a decreased surfactant synthesis.[151,170]

From a clinical perspective the incidence of RDS is inversely related to gestational age. This reflects the low amount of surfactant leading to RDS in infants with a low gestational age. Although surfactant production starts at the beginning of the saccular stage (at around 24 weeks) it remains low until 32–34 weeks of gestation and then rapidly increases towards term. As mentioned before, preterm infants with RDS are treated with surfactant nowadays, which has been shown to decrease mortality and air leaks.[137] Also, in infants with severe MAS, surfactant therapy was shown to be beneficial in that it decreases the need for ECMO. In infants with CDH, the use of surfactant therapy is still controversial which is consistent with the studies on surfactant metabolism mentioned above. Standard use of surfactant in CDH is not currently recommended.[137]

Lung liquid secretion and absorption

From early in gestation, fluid is present in the embryonic lung.[171] This fluid is secreted by the developing lung epithelia and is very important for normal lung development and growth.[172] At birth, transition to air breathing requires removal of the lung liquid for gas exchange.

Strong evidence for active secretion of lung liquid was found by the observation that the Cl^- concentration of fetal lung liquid was higher than that of plasma.[173] Indeed, later it was shown that Cl^- secretion is the driving force for the secretion of lung liquid.[174] In fetal sheep the rate of liquid secretion increases from about 1.5 mL/kg per hour at mid-gestation to about 5 mL/kg per hour in late gestation.[175] The pressure in the lung is approximately 2 mmHg higher than the pressure in the amniotic fluid, caused by a restriction to the outflow of fluid by the vocal cords and the larynx and nasopharynx.[175–177] The essential role of this lung liquid for lung development[178] was shown by experimental continuous drainage of lung liquid from fetal sheep lungs which resulted in lung hypoplasia.[179] The opposite was found after tracheal ligation with overdistention of the fetal lung resulting in lung hyperplasia.[180,181] Also, in humans, early and severe oligohydramnion leads to lung hypoplasia because of continuous drainage of lung fluid from the lungs. Plugging of the fetal trachea is an experimental therapy to overcome lung hypoplasia in CDH.[182]

At birth, rapid removal of the fetal lung liquid is essential for air breathing. Liquid clearance starts before birth during the process of labor. The basic mechanism is a switch from Cl^- secretion to Na^+ absorption. This switch is triggered by a surge in fetal catecholamine secretion during labor. Activation of the β-adrenoreceptor recruits and stimulates Na^+, K^+-adenosine triphosphatase (ATPase) at the basoateral membrane and Na^+ channels of the luminal membrane.[172,183] The main Na^+ channel is the epithelial Na^+ channel, or ENaC, which has been cloned.[183] Of course part of the fluid is squeezed out during the birth process. Active liquid absorption is continuous after birth and most of the liquid is cleared from the full-term newborn lung within 2 hours after birth. Infants born by Cesarean section without labor have a slowed lung liquid clearance and sometimes show signs of respiratory distress called transient tachypnea of the newborn (TTN).[184–187] The switch from liquid secretion to liquid absorption is disturbed in preterm infants because of immaturity of the absorption processes described above. This adds to the respiratory problems of preterm infants with RDS. Prenatal corticosteroids have been shown to improve liquid absorption,[183,188–190] besides the well-known positive effect on surfactant synthesis.

Clinical anatomy of the newborn

MARK D STRINGER

INTRODUCTION

A newborn infant more than triples in height and increases in weight some 20-fold before reaching maturity. During the process, structures change in size and position. Some, which are critically important during fetal development, disappear. Most persist but grow at different rates and at different ages. It is therefore not surprising that newborn anatomy differs from adults; some of these differences are particularly important for the pediatric surgeon (Table 3.1 and Fig. 3.1). This chapter summarizes the applied anatomy of the newborn, emphasizing aspects that are clinically relevant and different to adults.

GROWTH AND PROPORTIONS

Growth can be defined as 'the progressive development of a living being or any of its parts from its earliest stage to maturity, including the attendant increase in size'.[1] It involves changes in size and mass, and includes processes such as cell division, specialization, and apoptosis. Growth can be proportional but is often differential. For example, the head of a full-term newborn infant accounts for about 25% of its body length and 20% of its body surface area. In adults, these figures are about 13 and 9%, respectively (Fig. 3.2). Similarly, the pelvis and lower limbs are proportionately small in the neonate.[2] Body surface area to weight ratio decreases with age: the absolute surface area of a neonate is about 0.25 m^2 compared to 1.73 m^2 in an adult. Neonates are consequently more vulnerable to heat loss.

The mean length of the full-term newborn measured from crown to heel is around 48–50 cm and weight 2.7–3.8 kg. About 75–80% of this weight is water and 15–28% is fat.[3] By one year of age, total body water has decreased to adult values of around 60% of body weight.

CARDIOVASCULAR SYSTEM

Circulatory changes after birth

In the fetus, oxygen rich blood is transported from the placenta via the umbilical vein to the left branch of the portal vein lying within the umbilical recess of the liver (Fig. 3.3). The ductus venosus arises from the posterior aspect of the left branch of the portal vein directly opposite the opening of the umbilical vein and passes superiorly and laterally between the left lobe and caudate lobe of the liver to terminate in the left hepatic vein near its entry into the inferior vena cava (IVC). A valve along the anterior margin of the opening of the IVC into the right atrium directs the oxygenated blood through the foramen ovale to the left atrium. Deoxygenated systemic blood returning from the fetal superior vena cava and coronary sinus is directed preferentially to the right ventricle. However, not more than 20% of the fetal cardiac output reaches the lungs[4] because the ductus arteriosus shunts blood from the pulmonary trunk to the aortic arch, just distal to the origin of the left subclavian artery. At term, the ductus arteriosus is about 8–12 mm long and 4–5 mm wide at its origin from the beginning of the left pulmonary artery; the thoracic aorta by comparison measures about 5–6 mm in diameter.[3] The walls of the ductus arteriosus are rich in smooth muscle fibers. In the fetus, ductal patency is maintained by locally produced prostaglandins, which inhibit muscle contraction in response to oxygen.

At birth, the lungs inflate and, as a result of mechanical effects and oxygen-induced pulmonary vasodilatation, pulmonary vascular resistance falls. The ductus arteriosus starts to close. Blood is diverted from the pulmonary trunk into the pulmonary circulation. Increased venous return to the left atrium causes a rise in left atrial pressure. Right atrial pressure falls as a result of reduced venous return secondary to occlusion of the umbilical vein. These changes in atrial pressure force the thin primary atrial septum against the free lower margin of the secondary atrial septum (which lies to the

Table 3.1 Key anatomical differences between neonates and adults.

Cardiovascular system	Recent transition from fetal circulation
	Relatively large heart
	Potential for congenital heart defects
	Prominent thymic shadow on chest x-ray
Respiratory system	Obligate nose breathing
	Short neck with high larynx
	Ability to breathe while suckling
	Subglottis is narrowest part of the airway
	Highly compliant chest wall
	Greater reliance on diaphragm for breathing
Abdomen	Relatively wide abdomen
	Short inguinal canal
	Propensity to inguinal hernias and undescended testes
	Small amount of intra-abdominal fat
	Proportionately large liver
	Poor radiological distinction between small and large bowel
	Small pelvic cavity
	Intra-abdominal bladder and body of uterus
	Proportionately large suprarenal glands
Musculoskeletal system	Proportionately large head, small pelvis, and lower limbs
	Open fontanelles
	Relatively underdeveloped face and mandible
	Horizontal auditory tube
	No spinal curvatures (other than shallow sacral curve)
	Absence of most secondary ossification centers
	Shallow acetabulum
	Relatively small gluteal muscles
Nervous system	Relatively large brain with full complement of neurones but incomplete myelination of axons
	Proportionately large cerebral ventricles
	Spinal cord terminates at lower level
Skin	Variable subcutaneous fat (some brown fat)
	Thin skin, immature sweating
	Greater body surface area to weight ratio
	Head accounts for 20% of body surface area

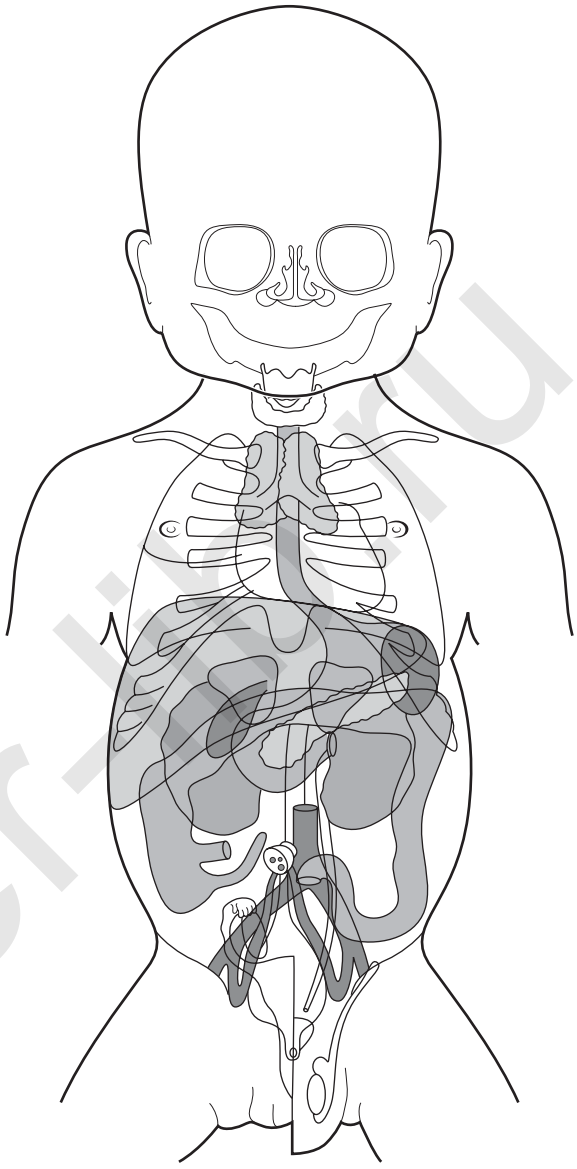

Figure 3.1 Diagram illustrating the relative proportions of viscera in the newborn (based on information from Ref. 19).

right) resulting in functional closure of the foramen ovale. A permanent seal usually develops during the first year of life.

Cardiovascular adaptation to neonatal life therefore requires the functional closure of three fetal conduits:

1. Foramen ovale. Incomplete fusion of the primary atrial septum with the free lower margin of the secondary atrial septum occurs in up to 25% of individuals,[5] resulting in a small potential atrial communication, a patent foramen ovale (PFO). Typically, this has no consequences because of the flap-like arrangement of the opening and differential atrial pressures. However, a PFO may rarely be associated with paradoxical embolism (passage of an embolus from the venous system through an abnormal communication between the chambers of the heart causing a systemic arterial embolus, e.g. an embolic stroke) and an increased risk of decompression sickness in divers.[6] After closure of the foramen ovale, the valve of the IVC that was prominent in the fetus becomes flimsy or disappears.
2. Ductus arteriosus. In full-term neonates with no congenital heart disease, the ductus arteriosus starts to close immediately after birth. Smooth muscle contraction within the ductus is probably mediated by several mechanisms: an increased arterial oxygen concentration, suppression of endogenous prostaglandin I_2 synthesis, plasma catecholamines, and neural signaling. In addition, ductal blood flow is reversed as a result of increased systemic vascular resistance (due to absence of the placental circulation), and decreased pulmonary vascular resistance. Functional closure is complete within 3 days in more than 90% of

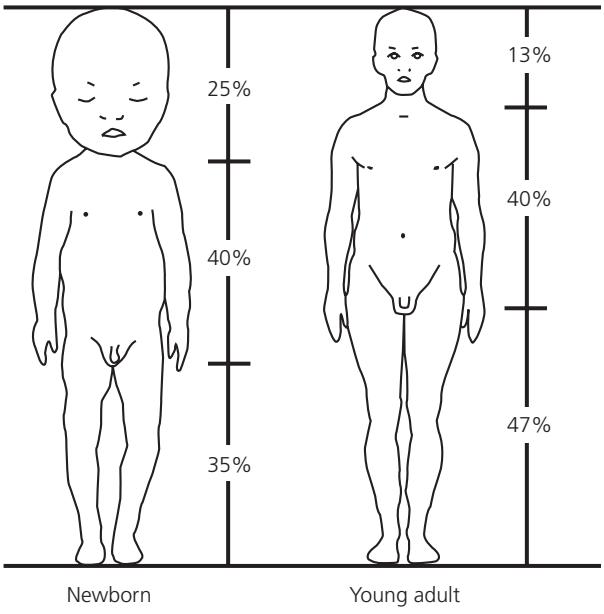

Figure 3.2 The relative proportions of the head, trunk, and lower limbs in a neonate and adult (adapted from Ref. 2).

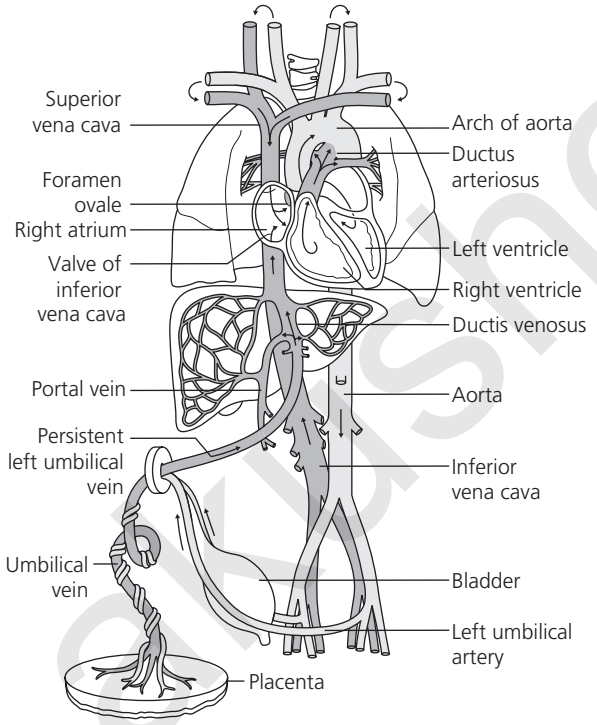

Figure 3.3 The fetal circulation.

term infants.[7] Structural closure occurs more gradually, leaving the fibrous ligamentum arteriosum connecting the origin of the left pulmonary artery to the underside of the aortic arch. Persistent ductal shunting can occur in preterm infants with respiratory distress.[7]

3. Ductus venosus. Spontaneous closure of the ductus venosus begins immediately after birth[8] and is usually complete by about 17 days of age.[9,10] Closure may be temporarily delayed in the presence of congenital heart disease, presumably as a result of elevated venous pressure. In the adult, the remnant ligamentum venosum runs within the fissure separating the anatomic left lobe of the liver and the caudate lobe. Persistent patency of the ductus venosus is rare, more common in boys, and may cause long-term problems such as hepatic encephalopathy.[11]

The heart

In the full-term neonate, cardiac output measured by Doppler studies is about 250 mL/kg per min, mean systolic blood pressure in the first week is 70–80 mmHg (lower in preterm infants), and heart rate settles within hours of delivery to 120–140 beats/min. As the pulmonary circulation is established, the work of the right side of the heart decreases and the left increases, reflected by changes in ventricular muscle thickness; at birth, the mean wall thickness of both ventricles is about 5 mm whereas in adults the left ventricle is about three times as thick as the right.[3] The neonatal heart is relatively large in relation to the thorax and lungs and consequently it occupies a larger proportion of the lung fields on a chest radiograph compared to an adult (Fig. 3.4).

Congenital cardiac malformations account for up to a quarter of all developmental anomalies (eight per 1000 live births[4]) and include dextrocardia (isolated or part of situs inversus), isomerism, and structural defects (septal defects, abnormal atrioventricular or ventriculoarterial connections, and valvular anomalies). Ventriculoseptal defects are the most frequent, more often affecting the membranous than the muscular part of the interventricular septum. A true atrial septal defect occurs when there is a failure of normal development of the septum primum and/or atrioventricular endocardial cushions. Coarctation of the aorta is often

Figure 3.4 Supine anteroposterior neonatal chest x-ray. Note the prominent superior mediastinal thymic shadow which is asymmetric on this rotated film (white arrows). Compared to an adult, the hemidiaphragms are relatively flat, the ribs are more horizontal, and the heart size is relatively large (although the transverse cardiothoracic ratio should still be less than 60%[12]).

included within the spectrum of congenital heart disease. Typically, there is narrowing or occlusion of the juxta-ductal segment of aorta just distal to the origin of the left subclavian artery, although preductal (involving the aortic arch and its branches) and even postductal coarctation can occur.

Neonatal central venous catheters are generally positioned such that the catheter tip lies outside the cardiac outline on a chest radiograph in order to reduce the small but serious risk of atrial perforation and cardiac tamponade.

Umbilical vessels

The normal umbilical cord contains two thick-walled umbilical arteries and, near the 12 o'clock position, one larger but thin-walled umbilical vein. The presence of a single umbilical artery may be associated with other congenital anomalies, particularly renal, vertebral, and anorectal malformations,[13] and an increased risk of perinatal mortality.[14] However, routine karyotyping and renal sonography in an infant with an isolated single umbilical artery is not indicated.[14,15]

At birth, the umbilical vessels constrict rapidly in response to a fall in umbilical cord temperature and hemodynamic changes. Occlusion of the umbilical artery is facilitated by the 'folds of Hoboken', constriction rings along the length of the umbilical artery produced by oblique or transverse bundles of myofibroblasts.[16] Numerous mediators of umbilical vessel vasoconstriction have been proposed, including bradykinin and endothelin-1, some of which are produced locally within the umbilical cord. After birth, the obliterated umbilical arteries become the paired medial umbilical ligaments, usually visible under the peritoneum of the anterior abdominal wall below the umbilicus; the proximal parts of each umbilical artery remain patent as the superior vesical artery. The intra-abdominal segment of the umbilical vein becomes the ligamentum teres. The urachus has normally involuted before birth, leaving the fibrous median umbilical ligament.

The umbilical artery and vein can be catheterized within 24–48 hours of birth to provide vascular access for resuscitation, intravascular monitoring, fluid administration, blood transfusion, and parenteral nutrition.[17] The tip of an umbilical artery catheter is usually positioned above the diaphragm but below the ductus arteriosus ('high' position equivalent to T6–9 vertebral level). Sometimes, the catheter tip is sited below the origin of the renal and inferior mesenteric arteries but above the aortic bifurcation ('low' position at L3–4 vertebral level).

Arteries

The femoral artery is palpable midway between the anterior superior iliac spine and pubic tubercle in the neonate;[18] it is therefore more lateral than in an adult where the surface marking is midway between the anterior superior iliac spine and symphysis pubis.[3] The renal arteries are at a higher vertebral level in the neonate (T12–L1) compared to the adult (upper border of L2)[3] and the aortic bifurcation is at the upper rather than the lower border of L4.

RESPIRATORY SYSTEM

Upper airway

Relative to an adult, the newborn infant has a large head, short neck, small face and mandible, and large tongue.[19] The entire surface of the tongue is within the oral cavity, unlike the adult where its posterior third is in the oropharynx. Neonates are obligate nose breathers and do not begin to breathe orally until about four months of age. All these features predispose to airway obstruction.

The neonatal nasopharynx curves smoothly backwards and downwards to join the oropharynx, rather than almost at a right angle as in adults (Fig. 3.5). The hyoid bone and larynx are high in the neck. Consequently, the upper margin of the neonate's epiglottis extends to the level of the soft palate and the posterior nares are in direct continuity with the larynx. This allows the infant to breathe while suckling. Ingested liquids pass lateral to the epiglottis via the piriform fossae. Despite immature coordination of swallowing and breathing, the risk of aspiration is reduced by the high position of the larynx. The higher, more anterior position of the larynx also means that it is easier to intubate the trachea with a straight-bladed laryngoscope. As the infant grows, the larynx descends and the epiglottis loses contact with the soft palate. Gender differences in laryngeal shape and size only begin to appear at about three years of age.[19] The narrowest part of the infant's upper airway (about 3.5 mm in a term neonate) is the subglottis at the level of the cricoid cartilage, rather than the vocal cords as in adults.

Trachea and bronchial tree

The trachea is short, measuring as little as 3 cm in premature neonates, making positioning of an endotracheal tube critical. The tip of the tube is usually sited between the clavicles, 1–2 cm above the carina, which corresponds to the vertebral body of T1. As in adults, the trachea starts at the level of the sixth cervical vertebra but bifurcates relatively higher at T3/4 (rather than T4/5 in adults). The trachea is rich in elastic tissue[20] and readily deformable. The right main bronchus is wider and steeper than the left and the carina is more likely to lie to the left of the midline. Contrary to some reports, an aspirated foreign body is therefore more likely to enter the right lung.[21] The left brachiocephalic vein lies at a relatively higher level and is at greater risk of injury during tracheostomy.

The bronchial tree is developed by the 16th week of intrauterine life; thereafter, conducting airways increase in size but not number.[22] Postnatal lung growth is dominantly by alveolar development. Lung volume increases rapidly during infancy. Most alveoli have been formed by two years of age and only increase in size thereafter.[23,24] Before the infant takes its first breath, the terminal bronchioles and alveoli are filled with fluid, mostly produced in the lung. There is more fluid in the lungs of a newborn infant delivered by Cesarean section than after vaginal delivery. For the alveoli to expand adequately surface tension must be reduced; this is achieved by the release of surfactant from type II pneumocytes lining the alveoli. Surfactant also prevents alveolar collapse on expiration, which explains why very premature infants with inadequate surfactant production develop respiratory distress. Remodeling of the pulmonary vessels begins immediately after birth to reduce pulmonary vascular resistance.

Thorax and mechanics of breathing

The neonatal thorax has the shape of a truncated cone and is more rounded in circumference. Unlike the adult in whom the compliance of the chest wall and lung are similar, the neonate's chest wall is up to five times more compliant than its lungs.[3] Consequently, it is easily deformable, a fact that is readily apparent in the presence of respiratory distress.

The respiratory rate of a newborn at term is about 40–44 breaths/min. The ribs are more horizontal and contribute less to chest expansion. Infants rely mainly on diaphragmatic breathing. The diaphragm is relatively flat at birth (Fig. 3.4) and becomes more dome-shaped with growth. Diaphragmatic contraction tends to pull the ribs inwards; concomitant outward movement of the abdomen (thoracoabdominal paradox) is a normal finding in newborns. The work of breathing is greater in a neonate than an adult and still greater in a preterm infant.

The neonatal thymus is large (up to 5 cm wide and 1 cm thick) but variable in size at birth. It is a prominent feature on a chest x-ray (Fig. 3.4). The gland overlies the trachea, great vessels (especially the left brachiocephalic vein), and the upper anterior surface of the heart. After the first year of life it becomes progressively less vascular, and the lymphoid tissue is increasingly replaced by fat.

ABDOMINAL WALL AND GASTROINTESTINAL TRACT

Abdominal and pelvic cavities

The neonatal abdomen is relatively wide and protruberant because the diaphragm is flatter and the pelvic cavity smaller. The distance between the costal margin and iliac crest is proportionately greater in the neonate. For these reasons, transverse supraumbilical incisions provide good surgical access. The inguinal canal in the newborn is short and relatively vertical since the superficial inguinal ring almost overlies the deep ring. The canal lengthens with growth. The rectus abdominis muscles may be relatively wide apart creating devarication, which improves with growth.

Compared to an adult the true pelvis in the neonate is small, both relatively and absolutely, more circular in cross section, orientated more vertically, and has a less pronounced sacral curve. The peritoneal cavity is shallow anteroposteriorly because there is no lumbar lordosis and the paravertebral gutters are poorly developed. The urinary bladder, ovaries, and uterus are all partly intra-abdominal and the rectum occupies most of the true pelvis (Fig. 3.6). The greater omentum is delicate and membranous, rarely extending much below the level of the umbilicus. Indeed, the neonate has altogether less fat in the mesenteries and around the viscera.

Gastrointestinal tract

At term, the newborn esophagus measures about 8–10 cm in length from cricoid to diaphragm;[19] the upper and lower oesophageal sphincters each extend over about 1 cm.[25] Lower esophageal sphincter pressure is particularly low during the first month or two of life. The narrowest part of the upper digestive tract is where the cricopharyngeus muscle blends with the upper esophagus, a potential site of esophageal perforation during the passage of a nasogastric tube.[26]

The anterior surface of the stomach is overlapped by the left lobe of the liver, which extends almost to the spleen. The capacity of the neonatal stomach is 30–35 mL at term but reaches 100 mL by the fourth week. Gastric emptying is relatively slow and poorly coordinated in the first few weeks. The small bowel of the newborn is distributed more horizontally because of the shape of the abdominal cavity. The mean length of the small intestine from the duodenojejunal flexure to the ileocecal junction is around 160 cm when measured at term along its antimesenteric border *in vivo*[27], but considerably longer when measured at autopsy.[28]

The mean *in vivo* length of the colon from the ileocecal junction to the upper rectum is 33 cm at term.[27] The cecum, ascending and descending colon are relatively short compared to the adult and the transverse colon, sigmoid colon, and rectum relatively long. The cecum tapers to a proportionately large appendix with a relatively wide orifice. The anal canal has well-defined anal columns and prominent anal sinuses;[29] stasis within these sinuses may be a cause of perianal sepsis, particularly in male infants.[30]

(a)

(b)

Figure 3.6 Midline sagittal section of a plastinated neonatal (a) and adult (b) female pelvis. Note the relative positions of the bladder (B) and uterus (U), the curvature of the sacrum (S), and the angle of the pelvis (dotted line between sacral promontory and pubic bone (P)). V = vagina, R = rectum. Courtesy of the WD Trotter Anatomy Museum, University of Otago.

The neonatal small bowel has few circular folds (valvulae conniventes) and the neonatal colon has no haustra. This makes it difficult to distinguish the small and large bowel on plain abdominal radiographs. Their relative position (central versus peripheral) and caliber are a guide but a contrast study may be required to accurately differentiate small from large bowel.

Liver and spleen

The neonatal liver weighs about 120 g at term and comprises about 4% of body weight (compared to 2% in the adult); it more than doubles in weight during the first year. The relatively large liver fills much of the upper abdomen. Its inferior border extends 1–2 cm below the costal margin. The premature baby's liver is particularly fragile and vulnerable to injury (e.g. from an abdominal retractor). The neonatal gallbladder is more intrahepatic and its fundus may not extend below the liver margin.

The tip of the newborn's spleen is often palpable just below the left costal margin. The pancreatic tail is in contact with the spleen, usually at its hilum, in more than 90% of cases, a much greater proportion than in adults.[31] Accessory spleens are found at autopsy in about 14% of fetuses and neonates as compared to 10% of adults[32] but it is uncertain whether this is a true increased prevalence.

GENITOURINARY SYSTEM

Genitourinary anomalies are among the most common congenital malformations and so it is especially important to understand normal anatomy in the newborn.

Kidneys and suprarenal glands

At birth the kidneys are about 4–5 cm in length compared to a mean length of 11 cm in adults. Fetal lobulation of the kidneys is still present at birth. Individual nephrons consist of a renal corpuscle with (1) a central glomerulus concerned with plasma filtration and (2) a renal tubule that produces urine by selective reabsorption of the filtrate. At birth there are about one million renal corpuscles in the cortex of each kidney. Postnatally, cortical nephron mass increases but no new nephrons are made. The glomerular filtration rate (GFR) is low in newborns, particularly in the premature, but in the term infant the GFR doubles by 2 weeks of age and reaches adult values (120 mL/min per 1.73 m^2) by 1–2 years.[33]

The suprarenal glands are relatively large at birth with a proportionately thick cortex. Their average combined weight is 9 g compared with 7–12 g in an adult. Both glands shrink in the neonatal period.

Bladder and ureter

The bladder is largely intra-abdominal at birth (Fig. 3.6) with its apex midway between the pubis and the umbilicus in the unfilled state. Suprapubic aspiration and manual expression of urine are therefore relatively easy. The bladder does not achieve its adult pelvic position until about the sixth year.[3] The intravesical segment of the ureter (intramural and submucosal portions) lengthens from about 0.5 cm in neonates to 1.3 cm (the adult value) by 10–12 years of age. An abnormally short submucosal tunnel is one of the causes of vesicoureteric reflux (VUR) in preschool children; this type of VUR tends to resolve spontaneously with growth.[34]

Genitalia and reproductive tract

By about the sixth month *in utero*, the testis lies adjacent to the deep inguinal ring connected to the developing scrotum by the gubernaculum. About one month later, the testis begins its inguinoscrotal descent surrounded by the elongating processus vaginalis. At term, about 4% of boys have an undescended testis(es); the figure is higher in premature infants. By three months of age, the prevalence of cryptorchidism has fallen to 1.5%. The timing and process of closure of the processus vaginalis are both uncertain.[35] Surgical studies have shown that a patent processus vaginalis is present in around 60% of contralateral groin explorations in infants with a unilateral inguinal hernia in the first two months, falling to around 40% after two years of age. Autopsy studies have indicated that the processus is patent in about 80% of newborns, decreasing to about 15–30% in adults. Boys with cryptorchidism have higher patency rates.

The prostate and seminal vesicles are well developed at birth. The penis and scrotum are relatively large and the scrotum has a broad base and relatively thick walls. The prepuce begins to separate from the glans *in utero* but is usually only partially retractile at birth.

In baby girls, the ovary lies in the lower part of the iliac fossa and only descends into the ovarian fossa within the true pelvis during early childhood as the pelvis deepens. At birth the ovaries are relatively large and contain the full complement of primary oocytes, each surrounded by a single layer of follicular cells forming primordial follicles. Of the seven million oocytes estimated to be present in the female fetus, only one million remain at birth and this number decreases further to approximately 40 000 by puberty.

In the term infant, the uterus is about 3–5 cm long and the cervix forms two-thirds or more of its length (Fig. 3.6). Female newborns have a relatively prominent clitoris and labia and the vagina, which is about 3 cm in length, is relatively thick-walled with a fleshy hymen. After withdrawal of maternal hormones, the uterus and vagina shrink in size.

MUSCULOSKELETAL SYSTEM

Skull and face

The skull vault is formed by intramembranous ossification, the facial skeleton is derived from neural crest membrane bones, and the skull base and some bony pharyngeal arch derivatives (e.g. hyoid bone and ossicles) by endochondral ossification.[3] During birth, the margins of the frontal and parietal bones are able to slide over each other. In the first 2 days of life, palpable over-riding of the bones of the vault is common. Persistent ridging of suture lines may indicate craniosynostosis. Growth at the coronal suture is mostly responsible for fronto-occipital expansion of the skull; premature fusion causes brachycephaly if bilateral and plagiocephaly if unilateral. Growth at the metopic and sagittal sutures increases skull breadth, the metopic suture fusing at around 18 months of age and the sagittal at puberty. Premature fusion produces the elongated skull of sagittal craniosynostosis, the most common form of craniosynostosis. Premature babies have a tendency to develop a long thin head (dolichocephaly) secondary to postnatal gravitational molding but this is not caused by premature sutural fusion.

Fontanelles are formed where several skull vault bones meet. The two most prominent are the anterior fontanelle overlying the superior sagittal venous sinus at the junction of the metopic and sagittal sutures (bregma), and the posterior fontanelle at the junction of the sagittal and lambdoid sutures (lambda).[36] The size of the anterior fontanelle at birth is very variable; if unduly large, it may be an indication of congenital hypothyroidism or a skeletal disorder.[37] The timing of closure is also variable but the anterior fontanelle is obliterated by two years of age in 95% of children[38] and the posterior by two months of age.[39]

Postnatal growth of the skull vault is accompanied by disproportionate growth of the facial skeleton and mandible (Fig. 3.7). At birth, the bony external ear canal is poorly developed and the mastoid process is absent. The facial nerve is therefore more at risk of injury where it emerges from the stylomastoid foramen (e.g. from obstetric forceps). At birth, the two halves of the mandible are united by a symphysis that fuses in early childhood. The rami are at a more obtuse angle to the body of the mandible. The mandible subsequently changes shape as the teeth erupt and the muscles of mastication and chin develop.

The maxillary and ethmoid sinuses are present at birth but the sphenoid sinus is poorly developed and the frontal sinuses are absent.[19] The auditory tube is almost horizontal, increasing the risk of middle ear disease; it becomes more vertical during childhood. The hard palate is short, only slightly arched, and ridged by transverse folds which assist with suckling. The nasolacrimal duct which drains tear secretions from the conjunctival sac to the inferior meatus of the nasal cavity is relatively short and wide at birth but may be obstructed due to incomplete canalization. This can cause excessive tearing, discharge, and infection.

Vertebral column, pelvis, and limbs

The vertebral column in the neonate has no fixed curvatures other than a mild sacral curve. After birth, the thoracic curvature develops first and then, as the infant learns to control its head, sit, stand and walk, curvatures in the lumbar and cervical spine develop which help to maintain the centre of gravity of the trunk when walking. The sacral promontory 'descends' and becomes more prominent. Hemopoiesis occurs in the liver, spleen, and bone marrow in the fetus, but is largely restricted to the bone marrow of the vertebrae, ribs, sternum, proximal long bones, and diploe of the skull after birth.

Of the 800 or so ossification centers in the human skeleton, just over half appear after birth; these include most secondary ossification centers (Fig. 3.8). Cartilage is abundant at birth. None of the carpal bones have ossification centers. The only secondary centers of ossification in the long bones at birth are in the femoral and tibial condyles and humeral head.[19] The iliac crest, acetabular floor, and ischial tuberosity are all cartilaginous.

The mastoid process has not developed at birth. Courtesy of the WD Trotter Anatomy Museum, University of Otago.

The acetabulum is relatively large and shallow at birth and has a characteristic Y-shaped triradiate cartilaginous epiphyseal plate between the ilium, ischium, and pubis. Nearly one-third of the neonatal femoral head lies outside the acetabulum, making the hip joint easier to dislocate. Developmental dysplasia of the hip affects about one in 100 live births and is more common in girls. The neonatal femoral neck is short and the femoral shaft is straight. The proximal femoral growth plate in early infancy is intra-articular so that

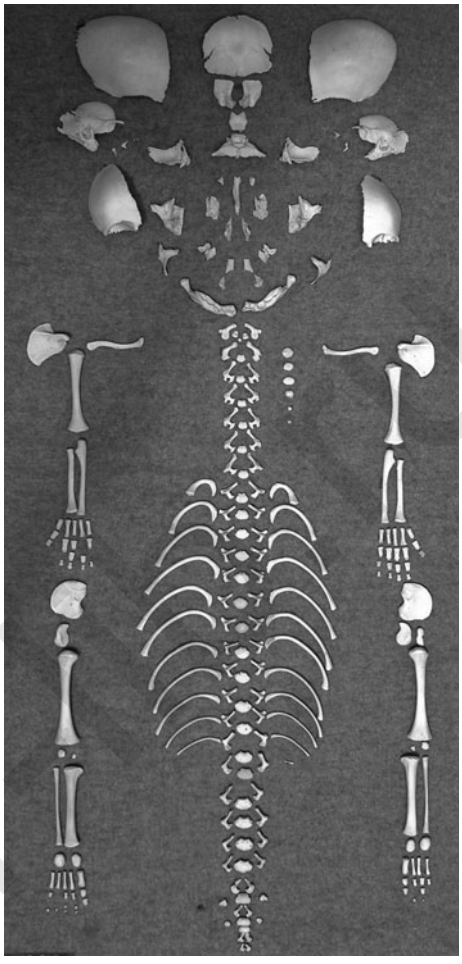

Figure 3.8 The bony skeleton of a newborn baby. There are no carpal bones at birth, there are separate ossification centers for the hip, and secondary centers of ossification in the long bones are absent except for the lower end of the femur and upper end of tibia. Specimen prepared by Professor JH Scott in 1895. Courtesy of the WD Trotter Anatomy Museum, University of Otago.

infection in the proximal femoral metaphysis may cause a septic arthritis. The lower limb muscles in the newborn are relatively underdeveloped and the gluteal muscle mass is small. The thighs tend to be abducted and flexed, the knees flexed, and the foot dorsiflexed and inverted. In congenital talipes equinovarus (club foot), there is impaired development of the talus causing inversion and supination of the foot and adduction of the forefoot.

NERVOUS SYSTEM

At term, the neonatal brain weighs between 300 and 400 g, accounting for about 10% of body weight (compared to 2% in the adult).[19] Brain growth is especially rapid during the first year, when it reaches 75% of its adult volume. The number of neurones is already established at birth and brain growth is due to an increase in size of nerve cell bodies, further development of neuronal connections, proliferation of neuroglia and blood vessels, and myelination of axons.

Myelination is at its peak in the first six months of life but continues until maturity.[3] The arrangement of sulci and gyri at birth is similar to the adult, although the central sulcus is slightly further forward and the ventricles are proportionately larger. Mean head circumference at term is 34 cm.

The termination of the spinal cord in the neonate may reach as low as L3 whereas it is usually around the lower border of L1 in the adult. The supracristal plane between the tops of the iliac crests is slightly higher (L3/4 rather than L4); a lumbar puncture in the newborn should not be performed above this level.

SKIN AND SUBCUTANEOUS TISSUE

Body fat is laid down in the fetus from about 34 weeks' gestation and, with appropriate intrauterine nutrition, increases until term. Plantar fat pads give the neonate a flat-footed appearance. Brown fat is a modified form of adipose tissue concentrated at the back of the neck, in the interscapular region, and in pararenal areas. It is composed of adipocytes with mitochondria that have large and numerous cristae adapted for heat production. However, the neonate's ability to regulate temperature is poorly developed.

At birth, breast tissue is similarly developed in girls and boys. It may appear prominent due to the influence of maternal hormones, even leading to the secretion of a small amount of fluid (witch's milk). Supernumerary nipple(s) may be found along the mammary ridges (milk lines) which extend from the axilla to the groin.

Neonatal skin is relatively thin but the ability to see peripheral veins is very dependent on the thickness of the subcutaneous tissues. Common sites for peripheral venous cannulation (and long line access) include: the dorsal arch veins of the hands and feet; the cephalic vein at the wrist; the volar aspect of the wrist (where the veins are small and fragile); the cubital fossa; the saphenous vein immediately anterior to the medial malleolus or behind the medial aspect of the knee; and the superficial temporal vein anterior to the ear.

The epidemiology of birth defects

EDWIN C JESUDASON

INTRODUCTION

Globally, birth defects are emerging as a leading cause of infant death. During the last century, surgical correction of such defects helped define the new specialty of pediatric surgery. In the same era, congenital rubella syndrome and the thalidomide disaster promoted the epidemiological investigation of birth defects and established the field of teratology. In the twenty-first century, improved birth defects surveillance can help delineate the causes of unsolved anomalies, improve fetal counseling (and therapy), identify anomaly associations (that illuminate both management and underlying developmental biology) and facilitate outcomes comparison by appropriate classification of surgical caseload.

BIRTH DEFECTS HELPED DEFINE PEDIATRIC SURGERY

The surgical correction of birth defects helped create the specialty of pediatric surgery during the middle of the last century. Around this time, pioneering neonatal operations were successfully performed to allow survival of babies with, for example, esophageal atresia or congenital diaphragmatic hernia (CDH). Indeed, along with innovations such as parenteral nutrition, the concentration of surgical, anesthetic, nursing, and critical care expertise now allows high survival to be achieved for many previously fatal anomalies. Moreover, for certain conditions that retain high mortality and/or morbidity, fetal surgery represents a promising experimental procedure to further reduce the harm of birth defects. Given these successes it would be tempting to assume that the problem of birth defects was largely solved.

BIRTH DEFECTS ARE LEADING CAUSES OF GLOBAL INFANT MORTALITY

However, given the huge progress made against infectious disease in particular, birth defects are now emerging as a leading cause of infant mortality. Moreover, this state of affairs pertains not only to places with expensive healthcare systems but in fact anywhere that infant mortality rates have fallen below about 50 per thousand births.[1] Hence, as progress against other infant killers continues, it is likely that birth defects will gradually become one of the most significant global causes of infant mortality. In addition, birth defects are a leading contributor to both premature birth (itself a major cause of infant mortality) and chronic disability (with its substantial personal and societal costs). Tragically, many such problems are already preventable: for example, the birth defects associated with congenital rubella syndrome might be virtually eradicated by an effective program of maternal immunization.[2] Moreover, a subset of neural tube defects continue to occur due to inadequate implementation of preconceptual folate prophylaxis.[3,4] However, the epidemiological challenges for clinicians extend beyond the known, preventable defects to unsolved conditions and their changing circumstances (e.g. increased gastroschisis prevalence, Fig. 4.1).[5,6]

BIRTH DEFECTS EPIDEMIOLOGY AND TERATOLOGY EMERGED FROM OUTBREAK INVESTIGATION

With birth defects emerging as leading infant killers, the need for epidemiological investigation of birth defects is increasing. Although birth defects have been described with horror and fascination since antiquity, teratology and scientific birth defects epidemiology date, like pediatric surgery, from the mid-twentieth century. Key historical developments include the recognition of congenital rubella syndrome (noted by clinical ophthalmological examination) and the thalidomide disaster (phocomelia and other defects associated with maternal thalidomide administration for morning sickness).[7,8] These episodes vividly illustrated the devastating consequences of prenatal infection and drug exposure, respectively. Moreover, these chastening experiences highlighted the urgent need to formalize birth defects

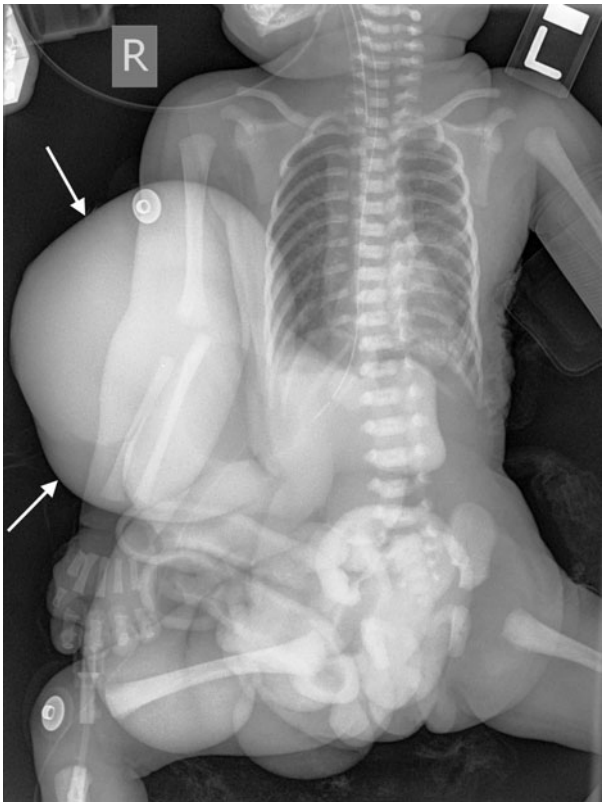

Figure 4.1 Gastroschisis – a birth defect on the move? Data from birth defect registries indicate an unexplained increase in gastroschisis prevalence. It remains to be seen if the severity of gastroschisis is also increasing: in this severe and unusual example, in addition to the gut, the liver (arrowed) lies outside the neonatal abdomen. Furthermore, the thorax is narrowed; this child needed ventilation immediately from birth (image used courtesy of the author).

surveillance. Such birth defects monitoring can now be said to serve a range of important purposes including outbreak early-warning, identification of possible environmental or genetic causes, rational planning for neonatal surgical provision, facilitation of prenatal counseling based on accurate data, establishment of associations between birth defects (that guide management and yield clues as to underlying developmental biology) and comparison of outcomes (that thereby guide us toward best practice).[9]

CAUSATION OF BIRTH DEFECTS REMAINS OFTEN COMPLEX AND UNCERTAIN

Before considering the methods of birth defects surveillance, it is worth sketching the developmental biology that underpins birth defects from a surgeon's perspective.[10] Causes of birth defects can be classified as parental, fetal, and environmental. An example of the former includes the impact of maternal age on Down syndrome prevalence.[11] Alternatively, maternal diseases such as diabetes are well-described risk factors for birth defect formation.[12] The role of paternal age and/or exposures remain more difficult to clarify.[13] Fetal causes might include genetically determined inborn errors of metabolism such as those causing intersex anomalies in congenital adrenal hyperplasia, chromosomal lesions such as Edwards etc., and twinning (with its increased risk of birth anomalies). Environmental causes include those related to prenatal drug exposure (alcohol, smoking, illicit drugs, thalidomide, valproate, phenytoin, warfarin, etc.) as well as the impact of intrauterine infections (e.g. toxoplasmosis, rubella, cytomegalovirus).[14–16] The impact of assisted reproductive technologies such as *in vitro* fertilization and intracytoplasmic sperm injection on birth defects prevalence are actually quite difficult to assess.[17] Suggestions that anomaly rates are higher in such assisted pregnancies need to contend with the confounding increased rates of multiple pregnancy. Also, given the parents need to use assisted reproductive technology, it may be that they are importantly different to parents conceiving naturally: increased anomaly risk could therefore be due to parental abnormality/predisposition rather than a result of the techniques themselves. More controversially still, other environmental contributors to birth defects may include 'endocrine disrupters': these estrogenic compounds are conjectured to contribute to anomalies of sexual development in fetal males (e.g. hypospadias) as well as putative impairment of adult male sperm quality.[16] In light of such difficulties in attributing cause, it is beneficial to recognize that only the minority of birth defects are known to arise from a simple genetic or environmental cause. At present, the remainder appear to have multifactorial origins: in such circumstances it is helpful to consider birth defect causation as the result of complex interactions between genes and environment. Hence many cases of spina bifida may result from micronutrient deficiency in the context of predisposing enzyme polymorphisms.[18] Similarly, teratogenic drugs may interact with pharmacogenomic predispositions to help explain why certain pregnancies are affected.[19] Beyond considerations of even complex causation, it remains likely that simple chance has a major role to play (similar to stochastic effects seen in radiation biology).[20]

BIRTH DEFECTS APPEAR TO ARISE TYPICALLY (BUT NOT EXCLUSIVELY) IN THE FIRST TRIMESTER

Developmental biologists refer to 'competence windows' to describe periods in development when particular cells and tissues are capable of responding appropriately to certain growth and transcription factors.[21] In a similar manner, developing organs are contended to have particular temporal windows when an otherwise nonspecific teratogenic stimulus will impact disproportionately on formation of that organ system. During the first trimester, organ morphogenesis predominates while later trimesters are devoted to organ growth and maturation. Unsurprisingly, therefore, sensitivity to teratogens is held to peak during the first trimester. Hence pregnant women are advised to avoid medications during this part of gestation in particular. Teleologically, 'morning sickness' that peaks during the first trimester is postulated to help reduce ingestion of potential teratogens during this period of maximum vulnerability. While the model of first

trimester teratogenesis appears appropriate for many birth defects, it is now clear that certain anomalies may arise during later development as a result of fetal events, for example amniotic band formation, intussusceptions, or vascular accident. Gastroschisis and intestinal atresiae may be considered in this latter category.[22–24] Indeed the contrast between exomphalos and gastroschisis in terms of associated anomalies (and hence prognosis) can be considered due to the different times they are usually held to originate in development. Exomphalos is considered an embryonic lesion that is accompanied by contemporaneous lesions of organogenesis in other systems such as the heart. In contrast, like associated intestinal atresiae, gastroschisis is thought to result from a discrete fetal vascular accident and hence lack extraintestinal manifestations. An alternative view, however, is that intestinal atresiae result only rarely from fetal accidents such as intussusception and are in fact better understood as failures of mesenteric vascular development.[25] A similar contrast between duodenal atresia and small bowel atresia may be likewise understood as the result of their differing onsets and etiologies. Duodenal atresia was historically explained as an embryonic failure of luminal recanalization; although this 'solid core' theory has been contradicted by more recent animal studies, the association between duodenal atresia and other defects (e.g. cardiac lesions, oesophageal atresia, and Down syndrome) supports an embryonic origin of this malformation.[26,27] In contrast, small bowel atresiae are claimed to follow mesenteric vascular occlusion usually in fetal life.[28] Hence, aside from gastroschisis, associated structural lesions are unlikely. Between these two 'extremes' are birth defects where an embryonic lesion has deleterious 'knock-on' effects later in fetal development: based on experimental models, the neurological sequelae of spina bifida are postulated to result from not only the primary failure of neural tube closure but also from consequent exposure of the neural placode to amniotic fluid.[29] Similarly, lung hypoplasia in CDH may emerge as an embryonic lesion prior to CDH only for compression by the visceral hernia to exacerbate the pulmonary lesion.[30] In circumstances such as these, where the pathology is thought to progress during fetal life, prenatal surgical correction has been a logical proposal to meet the challenge of refractory mortality and morbidity.[31] Results of ongoing clinical trials in these areas are awaited.

CLASSIFICATION OF BIRTH DEFECTS FOR EPIDEMIOLOGICAL PURPOSES

Birth defect epidemiology involves the registration of anomalies by type. At present, birth defects registries such as the European Surveillance of Congenital Anomalies (EUROCAT), use a classification scheme based around organ systems (see Table 4.1), specific diagnoses, and International Classification of Diseases (ICD) codes (see Table 4.2: both tables are derived from data published by EUROCAT – www.eurocat.ulster.ac.uk/pubdata/tables.html). Cooperation between registries helps by pooling data and also by building consensus on, for example, exclusion of minor anomalies without major and/or long-term sequelae (e.g. cryptorchidism or congenital hydrocele) or how abnormalities of gut fixation in CDH might be recorded. Although anomalies are currently classified by structural anomaly (e.g. CDH, esophageal atresia) or defined diagnosis (e.g. Down syndrome), it is likely that in the future, anomalies may be classified or at least subgrouped by genotypic differences rather than anatomic details alone. Such distinctions may be prognostically and therapeutically important: for example, in contrast to isolated omphaloceles, exomphalos in Beckwith–Wiedemann syndrome is associated with hypoglycemia, macrosomia, and increased tumor risk due to disordered gene imprinting.[32] Hence the anatomic defect (exomphalos) becomes less important than the genetics and its multisystem sequelae. Similarly, it is postulated that subgroups of spina bifida may be folate resistant due to underlying genetic/enzymatic variation.[18,33] Designing preconceptual prophylaxis for birth defects may need to acknowledge pharmacogenomically distinct subgroups to avoid benefits within one subgroup being overlooked due to a larger surrounding non-responder cohort.

Table 4.1 Birth prevalence of malformations 1980–2007 grouped by EUROCAT category. Note rates for each category are inclusive of cases with chromosomal lesions and derived from registries with full EUROCAT membership.

Organ system	Live birth + fetal death + termination/10 000 births (to 2 s.f.)
All	220
Congenital heart disease	67
Limb	42
Chromosomal	31
Urinary	28
Nervous system	23
Digestive system	19
Genital	16
Oro-facial clefts	15
Musculo-skeletal	11
Other malformations	10
Respiratory	5.7
Abdominal wall defects	4.9
Genetic syndromes + microdeletions	4.8
Eye	4.6
Ear, face, neck	4.1
Teratogenic syndromes with malformations	1.1

Having a system of classification is, however, only part of the task. Notification and classification in practice are subject to local variations. When resources exist for expert-mediated classification of birth defect by diagnosis, this approach to birth defects epidemiology appears the best currently available.[34] However, even some North American registries lack clinician input in the classification/assignment of observed birth defects. The consequence(s) of this omission for data quality remain to be determined. In the contrasting circumstances of rural China, expert-led assignment of cases has been substituted by simple photographic recording of

Table 4.2 Birth prevalence of malformations of relevance to pediatric surgery (1980–2007) grouped by diagnosis from registries with full EUROCAT membership. Note rates for each category are inclusive of cases with chromosomal lesions; (b) these are birth prevalences (including fetal death/terminations) and not necessarily the prevalences at pediatric surgical units.

Anomaly	Live birth + fetal death + termination/10 000 births
Down	18
Hypospadias	13
Congenital hydronephrosis	8.9
Spina bifida	5.3
Edward's	3.8
Anorectal malformations	3.0
Diaphragmatic hernia	2.8
Exomphalos	2.7
OA/TOF	2.3
Gastroschisis	1.9
Bilateral renal agenesis	1.6
Duodenal atresia/stenosis	1.2
Hirschsprung's disease	0.94
Posterior urethral valves/ prune belly	0.87
Indeterminate sex	0.76
Intestinal atresia/stenosis	0.75
Bladder extrophy/ epispadias	0.58
CCAM	0.56
Situs inversus	0.56
Amniotic band	0.46
Biliary atresia	0.28
Conjoined twins	0.18

malformations: this system allows the registry to function but also allows difficult cases to be assigned later after remote assessment of images by experts.[35] In addition, the photographs potentially allow the classifiers to calibrate their judgments against those from other registries.

COUNTING OF BIRTH DEFECTS IS AFFECTED BY THE DEFINITION OF STILLBIRTH

Birth defects epidemiology becomes difficult whenever the classification of defects is not uniform or straightforward. However, an equal challenge remains the counting of birth defects. This task is complicated by practical barriers to case ascertainment (e.g. inadequate resources), the definition of stillbirth and the effects of prenatal diagnosis and terminations.

Recording of anomaly prevalence lies at the core of birth defects epidemiology. To account for the unknowable incidence of a defect among vast numbers of naturally miscarried pregnancies, epidemiologists measure the prevalences of defects within a defined birth cohort; i.e. the number of live and stillborn cases of the defect, as a proportion of all births (live and stillborn). This definition depends on the artificial distinction between miscarriage and stillbirth: EUROCAT's recommendation is that spontaneous pregnancy losses prior to 20 weeks' gestation are counted as miscarriages (and do not contribute to anomaly prevalence) while similar losses at 20 weeks of gestation and beyond are counted as stillbirths (and included in prevalence statistics). Despite these guidelines, several countries have established different demarcations (e.g. 24 or 28 weeks or even 500 g weight). Clearly some estimate of prenatal birth defects is required to avoid seriously underestimating overall prevalences.[36] However, the demarcation of stillbirths begins to complicate matters. Countries where later gestational cut-off points are used may underestimate birth defect prevalence compared to registries where 20 weeks is used. Hence minor changes in convention can lead to large but artificial differences in anomaly prevalence.

While a definition of stillbirths is needed for data collection, the sharp demarcation (whether 20 weeks or later) also appears arbitrary from a biological perspective. Consider a hypothetical prenatal medical therapy that reduces the prevalence of a specific birth defect. When the anomaly is rare (as most are), it may be difficult to determine whether an observed reduction in prevalence is truly due to fewer malformations or is instead due to the promotion of earlier loss of affected pregnancies (i.e. prior to the 20 week or other agreed margin). This latter phenomenon, termed 'terathanasia', has even been invoked to explain how folate supplementation reduces neural tube defect prevalence.[37]

Prenatal diagnosis: the greatest challenge to birth defect epidemiology?

While classification of birth defects and definition of stillbirth make anomaly surveillance complex, the impact of prenatal diagnosis is arguably still more important. Prenatal diagnosis (in particular nonspecific ultrasound screening) confounds birth defects surveillance in a number of ways: (1) it increases identification of birth defects within the cohort of assessment (still and liveborn) by diagnosing those who may otherwise have perished prenatally (and uncounted), or those who may have presented beyond the neonatal period (if at all). Consider prenatal identification of cystic lung lesions: some would never have been diagnosed (either regressing spontaneously or persisting asymptomatically) while even symptomatic lesions would often have presented later (beyond the scope of the birth defects registry); (2) prenatal diagnosis alters antenatal management and results in terminations (or fetal intervention) that affect the numbers of birth defects being counted; most registries therefore attempt to keep separate data on terminations for birth defects. However, where prohibitions on termination exist, such data becomes still harder to find; (3) prenatal diagnosis may be inaccurate but unchecked: pathological verification after termination may be incomplete or absent yet the diagnosis is included in the birth defect tally; (4) resources and expertise to perform prenatal sonography vary with location (thereby hampering national and international comparison of birth defects prevalences). In summary, therefore, the apparently simple task of counting live and stillborn cases for

birth defects surveillance is fraught with difficulty once (a) the arbitrary definition of stillbirth is imposed and (b) ubiquitous prenatal imaging prompts both terminations and identification of previously occult 'cases'.

Given these challenges in data collection, epidemiologists are aided by being able to compare a variety of surveillance databases. Many European registries are incorporated into the EUROCAT initiative. Similarly several other registries feed into birth defects surveillance data furnished by the World Health Organization (WHO). Their Birth Defects Atlas is an interesting publication available in the public domain (www.who.int/genomics/publications/en/). Most importantly, it is instructive to read and consider the caveats that EUROCAT and WHO place upon their data. The interpretational issues raised highlight not only the problems discussed in the previous sections but also allude to the ongoing challenge of inadequate resources and expertise for birth defects reporting. This in turn impairs the data accuracy and may help explain insufficient action upon findings. Recent papers in the *British Medical Journal* reinforce the logistical shortcomings of birth defects reporting in the UK.[38]

PEDIATRIC SURGEONS OFTEN REPORT INSTITUTIONAL SERIES OF BIRTH DEFECTS

Given the difficulties in collecting and interpreting data from population-based registries, it should come as no surprise that similar issues afflict institutional series that are the staple of pediatric surgeons' reporting. Again, ascertainment is the most significant problem: prenatal diagnosis, terminations, or deaths prior to transfer of high-risk cases can give the misleading impression that changed institutional practice is impacting on outcome (when in fact it is pre-institutional interventions that are changing the results). Moreover, pediatric surgeons like to estimate disease severity in their cohort to show that their (good) results are not simply the product of low-risk caseload (Fig. 4.2). However, in such circumstances it can be highly misleading to use the frequency of interventions (e.g. decision to patch and/or use extracorporeal membrane oxygenation (ECMO) or nitric oxide in CDH) to estimate severity in a birth defect cohort: use of these techniques may in fact owe more to institutional protocols rather than any pathophysiological differences between cases. A number of studies have highlighted that institutional series remain subject to biases and confounding.[39–41]

THE CHALLENGE FOR MODERN PEDIATRIC SURGERY

Despite its confounding influence on modern birth defects surveillance, the impact of prenatal diagnosis will not disappear. On the contrary, advances in prenatal imaging may only serve to identify more 'defects' of unknown significance. Moreover, functional fetal imaging and genotyping may evolve to allow better prenatal prognostication and hence case selection for future fetal therapies.[42] In the midst of all these potentially exciting developments, pediatric surgeons retain a key role: using the best available birth defects epidemiology, we may gradually learn which defects need what intervention and when. To achieve this, pediatric surgeons need to keep abreast of birth defects epidemiology and work collaboratively with other surgeons, perinatologists, obstetricians and public health physicians. As a model for such cooperative endeavors, the Children's Cancer Leukemia Group (CCLG) is led by collaborating pediatric oncologists and surgeons: they achieve remarkably high recruitment rates of pediatric cancer cases into multicenter trials that are helping transform clinical management. A similar consortium approach to birth defects and their surgical correction may allow pediatric surgeons to retain a central role in this evolving field. As a beginning, the British Association of Paediatric Surgeons Congenital Anomalies Surveillance System (BAPS-CASS) and the National Perinatal Epidemiology Unit are undertaking an annual UK census of a selected birth defect for each year. Hence, as birth defects emerge as the leading cause of infant mortality, such projects will establish how pediatric surgeons can work together to understand these human healthcare problems.

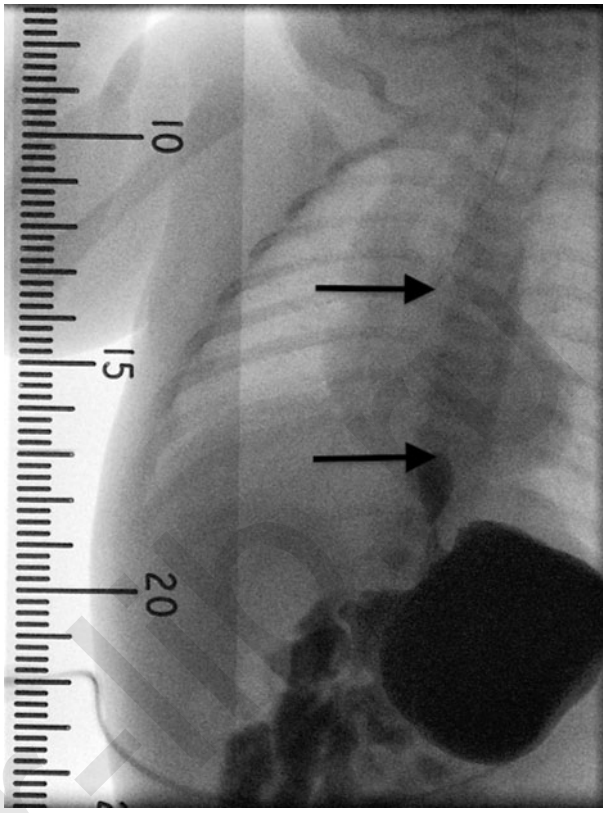

Figure 4.2 Birth defect registries and disease severity. Birth defect registries generally do not distinguish anomaly severity (despite implications for service provision and outcome measures). This gap assessment x-ray for pure esophageal atresia (EA) shows the tip of the oral tube pressed down (upper arrow) and refluxed contrast in the distal pouch (lower arrow). Treated by the author with a single-stage 'Bax' jejunal interposition at 7 weeks of age, this anomaly is registered just like the more common EA with distal fistula, despite the very different management and resources required.

Perinatal diagnosis of surgical disease

TIPPI C MACKENZIE AND N SCOTT ADZICK

INTRODUCTION

Prenatal diagnosis has undergone an explosion of growth in the past decade. The primary impetus for this rapid expansion has come from the widespread use of prenatal ultrasonography. Most correctable malformations that can be diagnosed *in utero* are best managed by appropriate medical and surgical therapy after maternal transport and planned delivery at term. Prenatal diagnosis may influence the timing (Box 5.1) or the mode (Box 5.2) of delivery, and in some cases, may lead to elective termination of the pregnancy. In rare cases, various forms of *in utero* therapy may be possible (Table 5.1).

Prenatal diagnosis has defined a 'hidden mortality' for some lesions such as congenital diaphragmatic hernia, bilateral hydronephrosis, sacrococcygeal teratoma, and cystic hygroma. These lesions, when first evaluated and treated postnatally, demonstrate a favorable selection bias. The most severely affected fetuses often die *in utero* or immediately after birth, before an accurate diagnosis has been made. Consequently, such a condition detected prenatally may have a worse prognosis than the same condition diagnosed after delivery.[1] The perinatal management of the patients involves many different medical disciplines, including obstetricians, sonographers, neonatologists, geneticists, pediatric surgeons, and pediatricians. It is essential that the affected family be managed using a team approach, and that information and experience be exchanged freely.

In this chapter we discuss the prenatal diagnosis of neonatal surgical lesions. First, a brief summary of the diagnostic methods currently available is given, then a review of prenatal diagnosis by organ system is presented.

Box 5.1 Defects that may lead to induced preterm delivery

- Obstructive hydronephrosis
- Gastroschisis or ruptured omphalocele
- Intestinal ischemia and necrosis secondary to volvulus, meconium ileus, etc.
- Sacrococcygeal teratoma with hydrops

Box 5.2 Defects which may require cesarian delivery

- Myelomeningocele
- Giant omphalocele
- Large sacrococcygeal teratoma
- Giant neck masses or lung lesions (EXIT procedure)

Table 5.1 Diseases amenable to fetal surgical intervention in selected cases.

Malformation	Effect on development	*In utero* treatment
Congenital diaphragmatic hernia	Pulmonary hypoplasia, respiratory failure	Tracheal occlusion and release
CCAM or BPS	Pulmonary hypoplasia, hydrops	Thoracoamniotic shunting, lobectomy, steroids
Sacrococcygeal teratoma	Massive arteriovenous shunting, placentomegaly, hydrops	Excision
Urethral obstruction	Hydronephrosis, lung hypoplasia	Vesicoamniotic shunting, laser ablation of PUV
Myelomeningocele	Damage to spinal cord, paralysis	Closure of defect

ULTRASOUND

Ultrasound testing has become a routine part of the prenatal evaluation of almost all pregnancies. It is especially important to perform ultrasound for pregnancies with maternal risk factors (e.g. age over 35 years, diabetes, previous child with anatomic or chromosomal abnormality) and if there is an elevation in maternal serum alphafetoprotein (MSAFP). Most defects can be reliably diagnosed in the late first or early second trimester by a skilled sonographer. Nuchal translucency measurements are an independent marker of chromosomal abnormalities, with a sensitivity of about 60%.[2] This abnormality may be detected on transvaginal ultrasound at 10–15 weeks' gestation, thus providing an early test for high-risk pregnancies. Nuchal cord thickening may also be a marker for congenital heart disease[3] and may be a valuable initial screen to detect high-risk fetuses for referral for fetal echocardiography. It is important to remember that sonography is operator-dependent; the scope and reliability of the information obtained is directly proportional to the skill and experience of the sonographer.

MAGNETIC RESONANCE IMAGING

Until recently, the long acquisition times required for magnetic resonance imaging (MRI) were not conducive to fetal imaging because fetal movements resulted in poor quality images. Obtaining adequate images with the traditional spin-echo techniques required fetal sedation or paralysis.[4] With the development of ultrafast scanning techniques, the artifacts caused by fetal motion have almost been eliminated.[5] This technique is now an important part of prenatal evaluation of fetuses referred to our institution and has greatly enhanced our ability to diagnose and treat fetal malformations.

AMNIOCENTESIS

The first report of the culture and karyotyping of fetal cells from amniocentesis was by Steele and Breg in 1966.[6] Since then, it has become the gold standard for detecting fetal chromosomal abnormalities by karyotyping. It is usually performed at 15–16 weeks' gestation and involves a very low risk of fetal injury or loss. Attempts at early amniocentesis (11–12 weeks' gestation) have been complicated by a higher pregnancy loss, increased risk of iatrogenic fetal deformities, and increased postamniocentesis leakage rate.[7] For this reason, the most reliable method for first trimester diagnosis remains chorionic villus sampling. Our ability to detect particular mutations associated with single gene disorders as well as syndromes such as 22q deletion continues to improve.

CHORIONIC VILLUS SAMPLING

Chorionic villus sampling (CVS) may be performed at 10–14 weeks' gestation and involves the biopsy of the chorion frondosum, the precursor for the placenta. Either a transcervical or transabdominal approach may be used, both under ultrasound guidance. The cells obtained may be subjected to a variety of tests including karyotype, genetic probes, or enzyme analysis. Due to the high mitotic rate of the chorionic villus cells, results for karyotyping may be obtained in less than 24 hours. Disadvantages include diagnostic errors due to maternal decidual contamination or genetic mosaicism of the trophoblastic layer of the placenta. When preformed by experienced operators, the pregnancy loss rate is equivalent to second trimester amniocentesis.[8]

BIOCHEMICAL MARKERS

Maternal blood and amniotic fluid can be screened for the presence of various biochemical markers that indicate fetal disease. About two-thirds of women in the United States currently undergo screening for Down syndrome and other chromosomal abnormalities with the 'triple test,' which includes measuring serum alpha-fetoprotein with human chorionic gonadotropin and unconjugated estriol.[9] This screening is performed in the early second trimester, and the detection rate for Down syndrome is 69%, with a 5% false positive test.[10] A positive result on the serum screening test indicates a need for chromosome analysis by amniocentesis.

PERCUTANEOUS UMBILICAL BLOOD SAMPLING

Obtaining umbilical venous blood can also be used to determine the karyotype and diagnose various metabolic and hematological disorders. The procedure is performed at around 18 weeks' gestation under ultrasound guidance. Karyotype results may be obtained within 24–48 hours. In various large series, the mortality from the procedure has been reported to be 1–2%, with increasing mortality with long procedure times and multiple punctures.[11–13]

FETAL CELLS IN THE MATERNAL CIRCULATION

Since the advent of fluorescence-activated cell sorting (FACS), there has been growing interest and progress in detecting circulating fetal cells or cell-free nucleic acids in maternal blood for diagnostic purposes.[14] While the number of intact cells in the circulation is limited, amplification of fetal cell-free nucleic acids using real-time polymerase chain reaction (PCR) has growing utility in early prenatal diagnosis.[15] Fetal DNA can be detected reliably by 9 weeks and increases with gestational age.[16] This method can be used for gender determination in the first trimester (if Y chromosome sequences are found the fetus is male and if not, is assumed to be female) and can thus be helpful in counseling for X-linked disorders. Rhesus factor determinations are also accurate and can avoid unnecessary treatment of Rh-negative mother if the fetus is also negative. In the future, it may be expanded to detecting paternally inherited single gene

mutations. Although this is an extremely promising area of investigation, there are currently significant limitations in distinguishing fetal from maternal DNA. Therefore, invasive testing remains the standard of care for prenatal diagnosis of aneuploidies and other genetic abnormalities.

PRENATAL DIAGNOSIS OF SPECIFIC SURGICAL LESIONS

Neck masses

Fetal airway obstruction could be a result of extrinsic compression of the airway by lesions such as cervical teratoma or cystic hygroma, or intrinsic defects in the airway such as congenital high airway obstruction syndrome (CHAOS). Although large congenital neck masses causing airway obstruction previously carried an enormous perinatal mortality,[17] the advent of the *ex utero* intrapartum treatment (EXIT) procedure[18,19] has improved their outcome by providing a means of controlling the airway during delivery and converting an airway emergency into an elective procedure (Fig. 5.1).

Cystic hygroma diagnosed *in utero* is a severe diffuse lymphatic abnormality which is frequently associated with hydrops, polyhydramnios, and other abnormalities.[20] Chromosomal abnormalities are very common (62% overall) with the most common being Turner's sydrome.[21] There are two groups of prenatally diagnosed cervical lymphangiomas: those diagnosed in the second trimester are usually in the posterior triangle of the neck, have a high incidence of associated abnormalities, and carry a very poor prognosis.[22] Those diagnosed later in gestation are most often isolated lesions and generally do not lead to hydrops. Hydrops is an ominous finding in fetuses with cystic hygroma,[17] as is the presence of aneuploidy and septations in the mass.[23] However, fetuses with normal karyotype, non-septated masses, and no evidence of hydrops may have a good prognosis.[24] Therefore, it is important to monitor the fetus for development of hydrops by serial evaluations. Some fetuses with neck masses also have severe pulmonary hypoplasia with its attendant morbidities and this possibility should be addressed during prenatal counseling.[25]

Figure 5.1 *Ex utero* intrapartum treatment (EXIT) procedure for giant neck mass.

Teratomas are asymmetrical lesions which are frequently unilateral, with well-defined margins. They may also be multiloculated, irregular masses with solid and cystic components. Most teratomas contain calcifications. MRI is a very useful adjunct to ultrasound in evaluating giant neck masses. We have used it successfully for showing the relationship of the mass to the airway in preparation for EXIT procedure.[26] T1-weighted images may help differentiate teratomas from lymphangiomas.[27]

The EXIT procedure, originally designed for removal of tracheal clips,[18] has proven life-saving for many fetuses with giant neck masses.[19,28,29] This procedure involves performing a maternal hysterotomy and obtaining control of the fetal airway while the fetus remains on placental support. In order to prevent uterine contractions during the procedure, the mother is given inhalational anesthetic and tocolytics, warm saline is infused through a level I device, and only the head and shoulders of the fetus are delivered. After attaching a pulse oximeter to the fetal hand to monitor heart rate and oxygen saturation, direct laryngoscopy and, if possible, endotracheal intubation is performed. If the airway cannot be secured in this way, a rigid bronchoscope is inserted to determine the anatomy. If secure airway establishment is still unsuccessful, a tracheostomy can be performed. After securing the airway, surfactant is administered for premature fetuses, the cord is clamped, and the infant is taken to an adjacent operating room for resuscitation and possible immediate resection of the mass. In our review of the EXIT procedure,[28] 31 fetuses underwent the procedure with 30 survivors. In 25 patients, endotracheal intubation was accomplished, five patients needed a tracheostomy, and one patient expired due to parental refusal for a tracheostomy.

The EXIT procedure has also been useful in the perinatal resuscitation of fetuses with a range of anomalies expected to cause hemodynamic compromise at birth, such as giant lung masses (EXIT to congenital cystic adenomatoid malformation (CCAM) resection),[30] CHAOS,[31] severe congenital heart disease with congenital diaphragmatic hernia (CDH) (EXIT to extracorporeal membrane oxygenation (ECMO)),[32] and even thoracopagus conjoined twins with a single functioning heart.[33] One important caveat in its use is communication between the surgery and anesthesia teams: deep inhalational anesthesia (necessary to maximize uteroplacental blood flow) can predispose to extensive maternal bleeding, as was recently reported.[34]

Sacrococcygeal teratoma

Sacrococcygeal teratoma (SCT) is the most common newborn tumor, occurring in 1/35 000–40 000 births.[35] The American Academy of Pediatrics Surgical Section (AAPSS) classification[36] defines four types with differing prognoses: type 1 tumors are external, with at most a small presacral

component and carry the best prognosis; type 2 tumors are predominantly external with a large intrapelvic portion; type 3 lesions are predominantly intrapelvic with abdominal extension with only a minor external component; and type 4 lesions are entirely intrapelvic and abdominal. The latter have the worst prognosis since they are difficult to diagnose, sometimes less amenable to surgical resection, and are frequently malignant at the time of diagnosis because of the delay in diagnosis. Overall, prenatally diagnosed SCT has a worse prognosis than those diagnosed at time of birth.

On prenatal ultrasound, SCT appears as a mixed solid and cystic lesion arising from the sacral lesion. The tumor frequently contains calcifications. Since there is acoustic shadowing by the fetal pelvic bones, it is not always possible to determine the most cephalad portion of the tumor by ultrasound. Ultrafast fetal MRI is superior,[37,38] since it can determine the intrapelvic dimensions of the tumor as well as the presence of hemorrhage (Fig. 5.2). Those fetuses with mainly solid and highly vascular SCT have a higher risk of developing hydrops.[39,40] High output cardiac failure may occur as a result of the hemodynamic effects of the large blood flow to the tumor[41,42] and anemia from hemorrhage into the tumor may compound this problem. In severe cases, the mother with placentomegaly develops 'mirror syndrome,' a severe pre-eclamptic state with vomiting, hypertension, proteinuria, and edema. This phenomenon may be mediated by the release of vasoactive compounds from the edematous placenta**.** As with other fetal masses, the development of hydrops is a grave sign, with almost 100% mortality without fetal intervention.[43,44]

Figure 5.2 Magnetic resonance imaging of large sacrococcygeal teratoma.

The prediction of which fetuses with SCT are at highest risk for developing hydrops is therefore the crucial issue in prenatal management. A thorough prenatal evaluation with ultrasound (US), MRI, and fetal echocardiography is important in defining such a group. In a series of 23 cases seen at the Children's Hospital of Philadelphia (CHOP) between 2003 and 2006,[45] we observed that rapid tumor growth ($>150\,cm^3$/week) identifies a group of fetuses with a higher risk of prenatal mortality. The combined cardiac output (CCO) correlates with tumor growth, with those fetuses >600 mL/kg per min portending a higher risk of complications. The solid component of the mass is an important prognostic indicator: a recent report showed that when the solid tumor volume is normalized to the head volume, fetuses with a ratio <1 all survive whereas those with a volume >1 have 61% mortality.[46] A similar classification scheme based on size, growth, and vascularity has also been reported.[47]

Prenatal interventions for SCT include cyst aspiration (for those with a dominant cystic component), amnioreduction (for those with severe, symptomatic polyhydramnios with an amniotic fluid index (AFI) >35), amnioinfusion (for those with bladder outlet obstruction, to facilitate placement of a vesioamniotic shunt), or open fetal surgery for resection of the mass. In our current management algorithm, the latter option should only be considered for fetuses with impending high output failure, rapid growth, type I lesion amenable to resection, and gestational age between 20 and 30 weeks. Since our initial report of the first successful case of fetal SCT resection,[48] we have reported four additional cases, with three survivors.[49] One patient died postoperatively due to cardiac failure from indomethacin-mediated closure of the ductus arteriosus. Other complications included an embolic event leading to renal agenesis and jejunal atresia (one), chronic lung disease (one), and tumor recurrence (one). Minimally invasive prenatal interventions such as laser vessel ablation and alcohol sclerosis have been reported for the management of hydropic fetuses, albeit with limited success (6/7 *in utero* or neonatal deaths).[50] For fetuses older than 30 weeks and impending hydrops, emergent delivery with postnatal resection should be considered. The combined perinatal mortality from both of our recent series is 43% (19/44) excluding terminations,[45] illustrating the severity of this disease.

CONGENITAL CHEST LESIONS

CCAM and bronchopulmonary sequestration

CCAM represents a spectrum of disease characterized by cystic lesions of the lung.[51] Macrocystic lesions are larger than 5 mm in diameter and may be solitary cysts that grow to several centimeters (Fig. 5.3). Microcystic disease has multiple cystic lesions less than 5 mm in diameter. Prenatal US can generally distinguish individual cysts in macrocystic disease while microcystic lesions usually have the appearance of an echogenic, solid lung mass.[52] Bronchopulmonary sequestration (BPS) is an aberrant lung mass which is

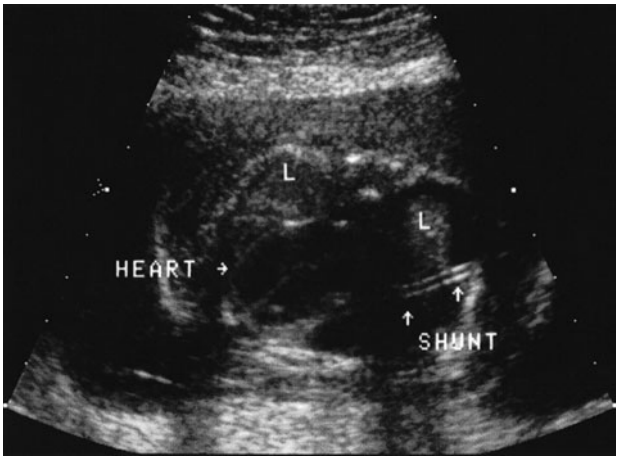

Figure 5.3 Ultrasound image of large congenital cystic adenomatoid malformation following the placement of a thoracoamniotic shunt. L, lung.

non-functional and usually has a systemic blood supply. It may be difficult to distinguish microcystic CCAM from BPS on US. Indeed, there is growing evidence that the two lesions may be related embryologically, with several reported cases of hybrid lesions which have CCAM-like architecture and a systemic blood supply.[53,54] Some of these lesions may decrease in size or 'disappear' altogether during fetal life[55] but postnatal evaluation is still warranted to detect residual disease for resection[56] because of the risk of pulmonary infections and the development of tumors such as pleuropulmonary blastoma.

MRI is useful in delineating normal lung from abnormal.[57] In CCAM, the number and size of cysts contribute to the signal intensity on T2-weighted images.[5] MRI can also define BPS from surrounding lung due to its high signal intensity and homogeneous appearance.[57] To date, ultrasound has been more accurate in demonstrating systemic feeding vessels. MRI may also be helpful in making the correct diagnosis in cases where US is ambiguous. In a series of 18 lung lesions which were viewed with both US and MRI, multiple chest abnormalities were misdiagnosed as CCAM on the US, including CDH, tracheal atresia, pulmonary agenesis, neurenteric cyst, bronchial stenosis, and BPS.[57] MRI helped form the correct diagnosis in these cases and was thus crucial for perinatal management.

Polyhydramnios is a frequent accompanying finding in fetuses with large chest masses. This is likely due to esophageal compression caused by the large thoracic mass, decreasing the fetal ability to swallow amniotic fluid.[58] The most important prognostic indicator in fetuses with CCAM is the development of hydrops. Hydrops is secondary to obstruction of the vena cava or cardiac compression from extreme mediastinal shift.[59] Historically, the development of hydrops has indicated a grave prognosis with 100% mortality[58] and it is important to predict which fetuses are at high risk for this complication. The volume of the CCAM compared to the head circumference (CCAM volume ratio, CVR) is an important prognostic indicator: fetuses with a CVR greater than1.6 are more likely to develop hydrops.[60]

For fetuses with large macrocystic CCAMs with a dominant cyst, or large pleural effusion causing pulmonary hypoplasia, thoracoamniotic shunting may be life-saving: in our series of 19 high-risk fetuses who underwent prenatal shunt placement,[61] survival was 67% (6/9) in the pleural effusion group and 70% (7/10) for the CCAM group, with an average age of delivery at 33+ weeks. However, we have reported an increased risk of chest wall anomalies if shunts are placed prior to 20 weeks' gestation.[62]

Fetuses with large microcystic CCAMs (thus not amenable for shunting) and signs of hydrops are more problematic. After 32 weeks' gestation, delivery with immediate resection is the optimum management. In fact, given the high risk of perinatal circulatory collapse secondary to mediastinal shift and inability to ventilate, we currently perform an EXIT procedure with resection of the mass on placental support.[30] EXIT to ECMO strategy for severe masses has also been described.[63] For those fetuses <32 weeks with hydrops, open fetal surgery with thoracotomy and resection of the mass may be offered at select centers. At CHOP, we have performed 24 cases of *in utero* resection of fetal lung lesions for hydrops between 21 and 31 weeks' gestation.[52] There were 13 healthy survivors, all of whom had resolution of hydrops at 1–2 weeks after the operation. Eleven fetuses had *in utero* demise, with six intraoperative deaths. Intraoperative hemodynamic compromise secondary to acute changes in cardiac output upon delivery of the mass has led us to adopt a method of continuous intraoperative cardiac monitoring, with volume resuscitation of the fetus and administration of atropine prior to thoracotomy.[64] Grethel and colleagues have reported a similar experience at the University of California, San Francisco (UCSF), in which open resection of the mass in fetuses with hydrops led to the survival of 15 of 30 fetuses.[65] While minimally invasive methods such as intrathoracic YAG laser therapy have been described,[66] technical limitations leading to damage to adjacent normal lung and ribs should prohibit offering such treatments until proven in animal models.

The recognition that maternal administration of steroids can reverse hydrops has been an exciting new development in the antenatal management of CCAM, with survival of all three hydropic fetuses in the initial report.[67] The experience at CHOP has also been favorable:[68] eleven fetuses (ten microcystic, one macrocystic) were given maternal betamethasone, with survival of all five hydropic fetuses and all seven fetuses with CVR >1.6 (compared to a mortality of 100 and 56%, respectively, in historical controls). Only one patient still needed fetal intervention while one needed resection on EXIT due to large size of the mass; the remaining nine fetuses underwent vaginal delivery with postnatal resection without complication. The salutary effects of steroids cannot simply be ascribed to reductions in the size or rate of growth of the CCAM as there was variable growth in these patients and a natural growth plateau is well-described.[56,69,70] Further studies into the basic biology of CCAM to understand how steroids may influence alveolar maturation or hydrops are areas of active research interests in many laboratories. However, a recent report on the experience with 15 fetuses

with large CCAM who received steroids[71] did not show a beneficial effect in 6/13 hydropic fetuses, while three additional fetuses in the group of initial responders still needed fetal intervention (two thoracoamniotic shunts, one open fetal surgery). Our current algorithm for the management of hydropic fetuses with CCAM prior to 32 weeks is to administer steroids with close observation and open lobectomy if hydrops fails to resolve.

Congenital diaphragmatic hernia

Herniation of abdominal viscera into the chest *in utero* occurs most commonly due to failure of the pleuroperitoneal folds to fuse normally. The left side is affected five times more commonly than the right. The ultrasonographic diagnostic criteria include herniated abdominal viscera, abnormal upper abdominal anatomy, mediastinal shift away from the side of herniation, and, in severe cases, polyhydramnios. The extent of pulmonary hypoplasia is proportional to the timing of herniation, the size of the diaphragmatic defect, and the amount of viscera herniated. Despite earlier impressions that CDH was infrequently associated with other serious congenital lung lesions, recent reports state that other major anomalies occur in 10–50% of cases, including a high proportion of chromosomal abnormalities and cardiac anomalies.

Distinguishing CDH from other congenital chest conditions and gastrointestinal lesions can be difficult. The presence of abdominal contents intrathoracically on a transverse sonographic scan at the level of a four-chamber view of the heart is required for diagnosis. In the case of a right-sided defect, the presence of liver, and especially gallbladder, in the chest makes the diagnosis more clear cut. MRI is superior in defining the position of the liver in CDH (above or below the diaphragm), which carries important prognostic significance (Fig. 5.4).[72,73] MRI is also better at determining the exact diagnosis, when ultrasound may mistake CDH for congenital lung masses. Since the extent of pulmonary hypoplasia is an important prognostic indicator, MRI has the potential to become a very useful tool for more accurate measurement of hypoplastic and contralateral lung volumes as well as the extent of liver herniation.[74–76]

The best predictor of outcome in CDH has been the right lung to head circumference ratio (LHR), defined as right lung area (measured at the level of the transverse four-chamber cardiac view) divided by head circumference (Fig. 5.5).[77] The utility of LHR in predicting survival has been validated prospectively[78] and in a recent multicenter trial,[79] with LHR <1 portending a very poor prognosis. The position of the liver is an independent prognostic indicator. For example, in our experience, fetuses who have an intrathoracic liver ('liver up') need ECMO more frequently than those with the liver down (80 versus 25%) and have a higher mortality (45 versus 93%).[80] Given the age-related changes in normal lung area compared to head circumference through gestation, another commonly used approach is to normalize the LHR to the expected mean LHR for that gestational age, thus obtaining an 'observed to expected' ratio.[81] Furthermore, the timing of these measurements is important and the 'prognostic LHR' should be measured between 24 and 28 weeks' gestation. Right-sided CDH is less common than on the left, but is a more severe disease with a particularly high rate of prenatal complications such as polyhydramnios, premature rupture of membranes, and preterm labor.[82]

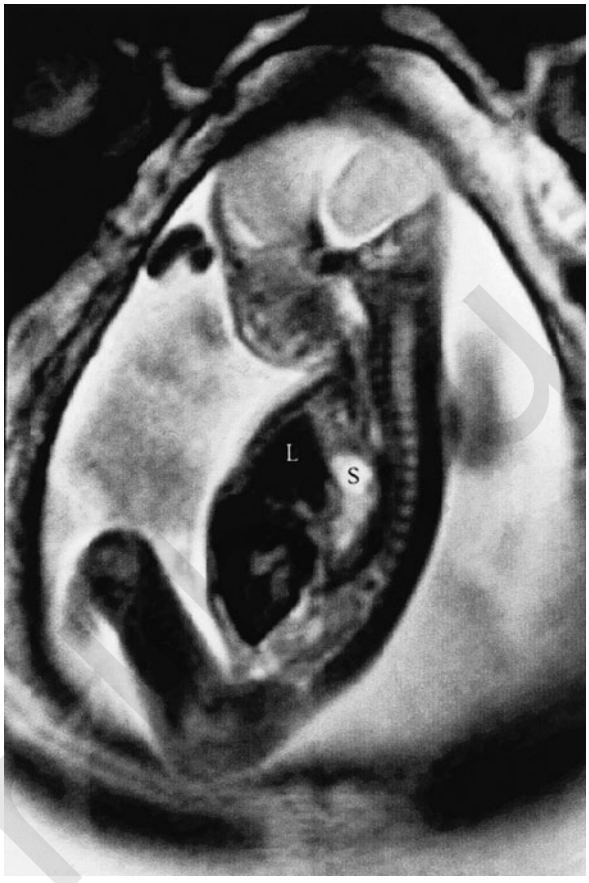

Figure 5.4 Magnetic resonance imaging of a congenital diaphragmatic hernia showing liver (L) and stomach (S) in the chest.

Figure 5.5 Ultrasound of congenital diaphragmatic hernia at the level of the transverse four-chamber view of the heart (H) showing measurements used for LHR calculation on the right lung (L).

The realization that infants with severe CDH succumb to pulmonary hypertension (more so than pulmonary hypoplasia) has fueled interest in measuring prenatal surrogates of this parameter to guide counseling and management. Fetal echocardiography may be used to measure pulmonary artery diameter,[83,84] peak early diastolic reversed flow velocity,[85] as well as pulmonary artery reactivity to maternal hyperoxygenation.[86]

The strategy for *in utero* treatment of CDH has undergone many permutations in the last two decades, with the current approach involving tracheal occlusion using a percutaneous, fetoscopically placed balloon (FETO) and subsequent reversal of occlusion prior to delivery (reviewed in Refs 87 and 88). The basis for this approach is the recognition that fetal tracheal occlusion leads to compensatory lung growth due to decrease in lung liquid egress, as confirmed in lamb models of CDH.[89] Given the embryology of lung growth, occlusion earlier in gestation, prior to the pseudoglandular stage of lung development, may lead to more reliable lung growth. The outcome in fetuses after tracheal occlusion has been favorable in both the lamb model[90] and in initial clinical reports.[91,92] Although a subsequent randomized clinical trial comparing prenatal tracheal occlusion (using a clip or balloon, but without reversal) did not show a treatment benefit,[93] this may have been secondary to a generous inclusion criteria (LHR <1.4) as well as preterm labor, still the Achilles heel of fetal surgery. Furthermore, reversal of occlusion may confer more benefit. The European experience with fetal occlusion and reversal has been quite favorable. Deprest and colleagues reported on 24 fetuses (LHR <1, liver up) that underwent FETO between 26 and 28 weeks, with 12 undergoing reversal at 34 weeks and 12 undergoing delivery via EXIT.[94] Survival to discharge was 50% overall (83% in the *in utero* reversal group; 33% in the EXIT group) compared to 9% in historical controls with the same disease severity. The mean gestational age at delivery was 33.5 weeks although preterm premature rupture of membranes (PPROM) was still seen in 17% of patients at 28 weeks and 33% at 32 weeks. A similar approach is also currently offered at UCSF for fetuses with LHR $=1.0$ with liver up.

GASTROINTESTINAL LESIONS

Esophageal and bowel atresias

Esophageal atresia is typically diagnosed on prenatal ultrasound by the presence of a small or absent stomach bubble and polyhydramnios, but no ultrasound finding is sensitive or specific for esophageal atresia.[95] Esophageal atresia is associated with anatomic and chromosomal abnormalities in 63% of cases,[96] most notably trisomy 18 and VACTERL (vertebral anomalies, anal atresia, cardiac anomalies, tracheoesophageal fistula, renal agenesis, and limb defects).

Duodenal atresia has a characteristic 'double bubble' appearance on prenatal ultrasound, resulting from dilatation of the stomach and proximal duodenum. The incidence of associated malformations is high (57% in one recent series[97](classically with Down syndrome and endocardial cushion defects) and those who are prenatally diagnosed are more likely to have associated anomalies.[97] In a recent review of all small intestinal atresias, Hemming *et al.*[98] reported that 25% have chromosomal anomalies and 25% have other structural anomalies.

There are many bowel abnormalities which may be noted on prenatal ultrasound (dilated bowel, ascites, cystic masses, hyperperistalsis, polyhydramnios); however, none is absolutely predictive of postnatal outcome. Patients with obstruction frequently have findings of increased bowel diameter (especially in the third trimester), hyperperistalsis, or polyhydramnios, but ultrasound is much less sensitive in diagnosing large bowel anomalies than those in the small bowel.[99] Since the large bowel is mostly a reservoir, with no physiologic function *in utero*, defects in this region, such as anal atresia or Hirschsprung's disease, are very difficult to detect, although low MSAFP may be a marker for anal atresia.[100] Bowel dilatations may be associated with cystic fibrosis; therefore, all such fetuses should undergo postnatal evaluation for this disease.[99]

ABDOMINAL WALL DEFECTS

Omphalocele is thought to be secondary to failure of the abdominal viscera to return to the abdomen in the 10th week of gestation.[101] It characteristically has a viable sac composed of amnion and peritoneum containing herniated abdominal contents. The defect is in the midline, usually near the insertion point of the umbilical cord. Ultrasound may demonstrate the internal viscera and sometimes the liver within the sac. Ascites may also be present. Since chromosomal and structural abnormalities are very common in omphalocele (cardiac and renal anomalies, chromosomal anomalies including Beckwith–Wiedemann syndromes and Pentalogy of Cantrell), fetuses with this defect should be screened by karyotype in addition to a detailed sonographic review and echocardiogram.[102] Omphalocele is rarely seen as part of the omphalocele, extrophy of the bladder, imperforate anus, and spinal anomalies (OEIS) sequence,[103] requiring multiple operations with considerable morbidity Patients with giant omphaloceles (containing predominantly liver, with a defect >5 cm) can have a prolonged course with high long-term morbidity, especially with respiratory and feeding difficulties.[104]

Gastroschisis is more often an isolated lesion with a right para-umbilical defect.[102] There is no membrane covering the exposed bowel. On ultrasound, the bowel appears free-floating and the loops may appear thickened due to peel formation from exposure to amniotic fluid (Fig. 5.6). Dilated loops of bowel may be seen from obstruction secondary to protrusion from a small defect or from the presence of an atresia, seen in 8–10% in most series. The pathophysiology of bowel damage is likely due to amniotic fluid exposure and bowel constriction, the latter leading to ischemia and venous obstruction.[105,106] There is a high rate of *in utero* fetal demise,[107] highlighting the need for careful serial monitoring once the diagnosis is made. Many infants have intrauterine growth retardation: 70% are below the

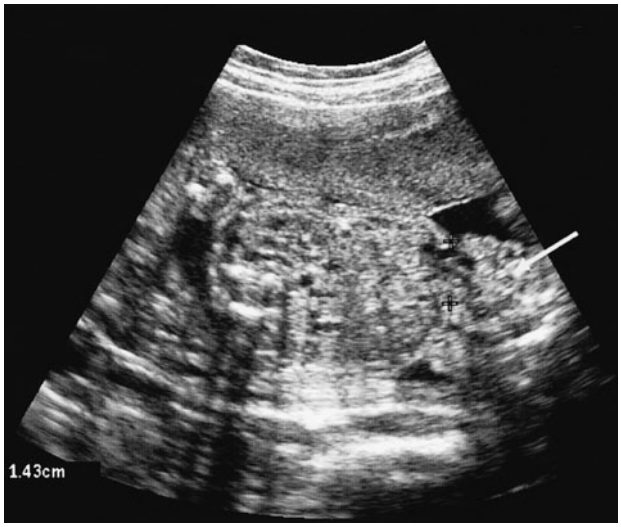

Figure 5.6 Ultrasound of fetus with gastroschisis with cross-marks showing the abdominal wall defect and arrow indicating extra-abdominal bowel.

50th percentile at birth (this number is overestimated on prenatal measurements, since the abdominal cavity is small because of the defect).[102]

Predicting outcome in fetuses with gastroschisis based on prenatal ultrasound findings remains a challenge. Analysis of infants with gastroschisis has led to the definition of two groups of patients: simple (isolated gastroschisis, very low mortality) versus complex (those who also have bowel atresias, perforation, volvulus, or bowel necrosis and a higher mortality (28% in Ref. 108; 8.7% in Ref. 109)). It is therefore crucial to develop prenatal diagnostic criteria for prediction of postnatal outcome. In addition, the timing of delivery has been an unanswered question: the urgency to prevent *in utero* bowel damage must be tempered with the risks of prematurity in these infants, many of whom are small for gestational age. Both ultrasound and biochemical characteristics have been examined to address this issue. Examination of amniotic fluid for markers of fetal distress such as meconium[110] and β-endorphin[111] may carry prognostic significance but is not currently used in clinical practice. Ultrasound characteristics such as bowel dilatation, bowel wall thickening, and mesenteric flow have been studied by many groups as possible prognostic indicators. We recently reviewed our experience with 64 cases of gastroschisis seen at CHOP between 2000 and 2007.[112] Fifty-three were simple and 11 were complex (17%). There were three *in utero* mortalities (two fetal demises and one termination) with an overall postnatal mortality of 9%. Interestingly, prenatal ultrasound findings were not predictive of the postnatal course for any of the parameters examined (simple versus complex, primary versus silo, hospital length, time to enteral feedings, etc).

The question of whether Cesarian section delivery would protect the exposed bowel from further damage during delivery has been considered but does not appear to confer any outcome benefit.[113,114] Thus, the mode of delivery for abdominal wall defects can be vaginal except in cases of giant omphalocele, in whom the risk of liver rupture and dystocia mandate a Cesarian section. The issue of whether transport prior to delivery impacts outcome (secondary to ongoing ischemia and damage to the exposed intestines during transport) has also been studied and, interestingly, does not appear to make a difference in one series.[115] Our current strategy for management is serial ultrasounds to monitor for signs of fetal distress, with planned delivery at term and either primary or silo closure.

PRENATAL DIAGNOSIS OF RENAL ANOMALIES

Prenatally diagnosed hydronephrosis (HN) represents a broad spectrum of diseases with widely disparate prognoses (reviewed in Ref. 116). The ultrasound findings of HN include dilated renal pelvis and calyces, with or without dilatation of the bladder and ureter, depending on the cause of HN (Fig. 5.7). The Society for Fetal Urology defines four grades with increasing severity, with grade 1 being split pelvis only, and grade 4 being dilated pelvis with distended calyces and thinned parenchyma.[117] In addition, an anterior-posterior diameter >10 mm has been suggested as being predictive of fetuses who will need some postnatal intervention.[118] The differential diagnosis of prenatal hydronephrosis includes ureteropelvic junction (UPJ) obstruction, multicystic kidney, primary obstructive megaureter, ureterocele, ectopic ureter, and posterior urethral valves.[119] Severe, bilateral hydronephrosis leads to oligohydramnios with a fetus small for gestational age. Because of the lack of amniotic fluid, ultrasound diagnosis may be difficult and MRI may help define the cause of hydronephrosis.[5]

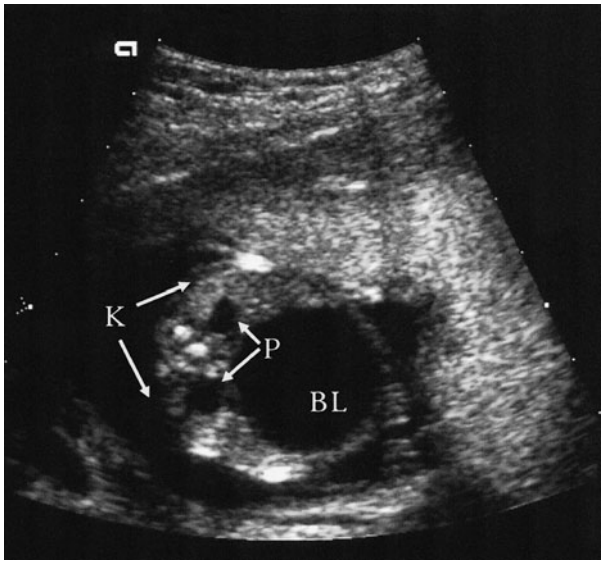

Figure 5.7 Ultrasound of hydronephrosis showing enlarged bladder (BL), compressed renal parenchyma (K), and dilated renal pelvises (P).

UPPER URINARY TRACT OBSTRUCTION

The most common cause of prenatal HN is UPJ obstruction. The prognosis of prenatally diagnosed HN is excellent, if there is unilateral disease[120] and if the renal pelvic diameter is less than 10 mm.[121] In one large series, 80% were normal at three years and 17% were normal at birth, suggesting spontaneous resolution of the problem.[122] Only 17% needed surgical intervention. Prenatally diagnosed HN requires follow-up with ultrasound at birth and at one month. If there is any evidence of abnormality, a voiding cystourethrogram, and diuretic renal scintigram should be performed.[123]

LOWER URINARY TRACT OBSTRUCTION

The most common cause of lower urinary tract obstruction is posterior urethral valves (PUV); it is also seen in prune belly syndrome and urethral atresia.[124] The most important factor in the morbidity and mortality from fetal urethral obstruction is pulmonary hypoplasia secondary to oligohydramnios.[125] For patients with posterior urethral valves, prenatal diagnosis defines a subgroup of patients with very poor prognosis, with 64% incidence of renal failure and transient pulmonary failure, compared to 33% in the postnatally diagnosed group.[126] Serial fetal urine analysis may provide prognostic information in this group of fetuses. Drainage of the bladder three times at 48–72 hour intervals with measurement of sodium, chloride, osmolality, calcium, α-2 microglobulin, and total protein should be performed to determine renal function. In this strategy, the later taps indicate the characteristics of recently produced urine and a decrease in the electrolytes, proteins, and tonicity correlate with a favorable outcome.[124]

The rationale for prenatal intervention originates from sheep models of the disease, in which bladder outlet obstruction in fetal lambs reproduced the pulmonary hypoplasia and renal dysplasia seen in patients with bilateral obstructive uropathy.[127] Correction of the obstruction led to normal lung growth.[128] Fetal intervention in prenatal obstructive uropathy is only warranted in male fetuses with oligohydramnios, bladder distention, and bilateral hydronephrosis (with no other abnormalities), who have improving urine profiles with serial bladder drainage.[129] In female fetuses, lower urinary tract obstruction (LUTO) is generally part of a complex cloacal anomaly and fetal intervention has not been beneficial. Male fetuses may be considered for vesico-amniotic shunting or fetal cystoscopy with cystoscopic ablation of posterior urethral valves.[130] More recently, fetal microcystoscopy and mechanical disruption has been reported.[131] This method is promising in that it provides a more physiologic method for bladder drainage.

Although vesico-amniotic shunting in a fetus with oligohydramnios can be technically challenging, the survival benefit of prenatal shunting in carefully selected populations of fetuses has been reported, with 43% of patients having normal renal function two years after birth.[132] We recently reported our series of 18 patients who had vesico-amniotic shunts for PUV (seven), prune belly syndrome (seven) and urethral atresia (four).[133] Eight patients have good renal function, four have mild renal insufficiency, and six required hemodialysis with subsequent transplantation. Respiratory problems and frequent urinary tract infections were seen in eight and nine patients, respectively. While short-term outcomes are variable in different reports,[120] a recent meta-analysis[134] determined that *in utero* drainage improved survival compared to postnatal management alone in the group of fetuses with poor prognosis. Patients who have been shunted can still die from pulmonary hypoplasia as well as renal failure. Given the need to select only those fetuses that would benefit from fetal intervention, a randomized controlled trial for prenatal management of LUTO (PLUTO) is currently under way in Europe.[135]

MYELOMENINGOCELE

Myelomeningocele (MMC) is a neural tube defect characterized by the protrusion of the spinal cord and meninges through open vertebral arches. It is the most common form of spina bifida, which affects one in 2000 births per year. Maternal serum testing identifies 75–80% of pregnancies with MMC by 16 weeks of age.[136] If an increase in serum alphaprotein (AFP) is noted, amniocentesis is performed to assess amniotic fluid AFP and acetycholinesterase to confirm the diagnosis.[137] The ultrasound characteristics include the 'lemon' and 'banana' signs which are scalloping of the frontal bone and abnormal anterior curvature of the cerebellar hemispheres, respectively.[138] Most fetuses have an associated Arnold–Chiari malformation, characterized by the caudal displacement of the vermis and cerebellum with midbrain herniation through the foramen magnum. Ultrasound confirmation can be made as early as 18 weeks, which allows localization of the defect as well as assessment of limb function, the presence of clubbing or of the Arnold–Chiari malformation (Fig. 5.8).

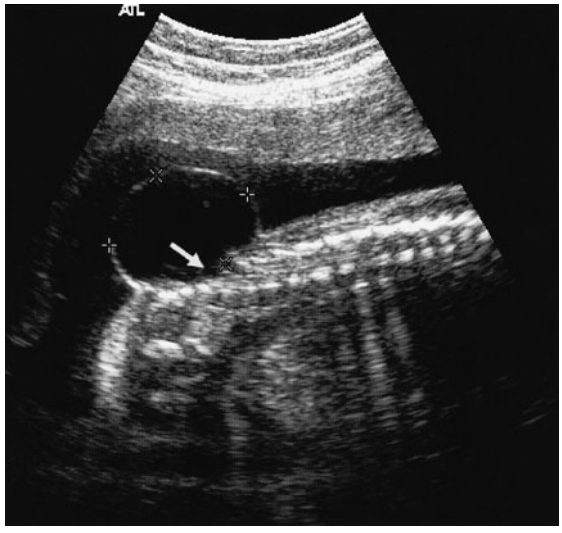

Figure 5.8 Ultrasound of fetus with myelomeningocele showing the sac (crossmarks) over the spinal defect (arrow).

Figure 5.9 Magnetic resonance imaging of fetus with myelomeningocele showing hindbrain herniation (arrow).

Analysis of the potential benefits of fetal repair of MMC has been accomplished in sheep models of the defect,[139–141] thus providing a compelling reason for *in utero* repair, the first non-lethal disease to be considered for this treatment. The goals of fetal repair are to prevent the chemical and mechanical trauma to the exposed spinal cord, to resolve the hindbrain herniation frequently seen with this defect, to decrease the need for postnatal ventriculoperitoneal shunt, and to allow time for possible neural regeneration after repair. We reported the first open repair of fetal MMC which led to improved neurological outcome[142] and resolution of the Arnold–Chiari malformation (Fig. 5.9). Long-term analysis of patients who underwent *in utero* repair has indicated that this may lead to a decreased need for ventriculoperitoneal shunting[143,144] as well as improved brainstem function[145] and neurodevelopmental outcomes.[146] The initial promising observations have led to the institution of a randomized clinical trial comparing prenatal repair to postnatal treatment alone. This trial is partly funded by the National Institutes of Health in the United States and is called the Management of Myelomeningocele Study (MOMS). It is currently underway at CHOP and UCSF. If fetal repair is not performed, fetuses with MMC should be delivered by planned Cesarian section to avoid trauma to the cord during the birth process.[147,148]

CONCLUSIONS

Prenatal ultrasound has led to a rapid increase in the number of pediatric surgical conditions diagnosed *in utero*. Prenatal detection and serial sonographic study of fetuses with anatomic lesions now make it possible to define the natural history of these abnormalities, determine the pathophysiologic causes that affect outcome, and formulate management based on prognosis. Since many congenital anomalies are associated with others, it is important to perform a careful ultrasound evaluation and karyotype analysis when one abnormality is discovered.

Careful evaluation of patients followed pre- and postnatally, as well as studies of congenital defects in animal models, has defined select populations of fetuses who may benefit from prenatal intervention. In most cases, these are fetuses that would not be expected to survive the prenatal period given the natural history of their disease. Further progress in prenatal diagnosis and monitoring as well as continued re-evaluation of outcomes will doubtless tune our current algorithms regarding the management of these congenital anomalies. Pediatric surgeons have a unique opportunity to continue to shape this exciting field in the new millennium.

Fetal counseling for surgical malformations

KOKILA LAKHOO

INTRODUCTION

Pediatric surgeons are often called to counsel parents once a surgical abnormality is diagnosed on a prenatal scan. The referral base for a pediatric surgeon now includes the perinatal period. Expertise in surgical correction of congenital malformations may favorably influence the perinatal management of prenatally diagnosed anomalies by changing the site of delivery for immediate postnatal treatment, altering the mode of delivery to prevent obstructed labor or hemorrhage, early delivery to prevent ongoing fetal organ damage, or treatment *in utero* to prevent, minimize or reverse fetal organ injury as a result of a structural defect.[1,2] Crombleholme *et al.*[3] have confirmed the favorable impact of prenatal surgical consultation in influencing the site of delivery in 37% of cases, changing the mode of delivery by 6.8%, reversing the decision to terminate a pregnancy by 3.6%, and influencing the early delivery of babies by 4.5%.

The pediatric surgeon performing prenatal consultations must be aware of differences between the prenatal and postnatal natural history of the anomaly. There is often a lack of understanding of the natural history and prognosis of a condition presenting in the newborn and the same condition diagnosed prenatally.[4,5]

The diagnosis and management of complex fetal anomalies require a multidisciplinary team encompassing obstetricians, neonatologists, geneticists, pediatricians, pediatric surgeons, and occasional other specialists with expertise to deal with all the maternal and fetal complexities of a diagnosis of a structural defect.[6] This team should be able to provide information to prospective parents on fetal outcomes, possible interventions, appropriate setting, time and route of delivery, and expected postnatal outcomes. The role of the surgical consultant in this team is to present information regarding the prenatal and postnatal natural history of an anomaly, its surgical management, and the long-term outcome.[2,6,7]

CONGENITAL MALFORMATION

Congenital malformations account for one of the major causes of perinatal mortality and morbidity. Single major birth defects affect 3% of newborns and 0.7% of babies have multiple defects. The prenatal hidden mortality is higher since the majority abort spontaneously. Despite improvements in perinatal care, serious birth defects still account for 20% of all deaths in the newborn period and an even greater percentage of serious morbidity later in infancy and childhood.[8] The major causes of congenital malformation are chromosomal abnormalities, mutant genes, multifactorial disorders, and teratogenic agents.

PRENATAL DIAGNOSIS

Prenatal diagnosis has remarkably improved our understanding of surgically correctable congenital malformations. It has allowed us to influence the delivery of the baby, offer prenatal surgical management, and discuss the options of termination of pregnancy for seriously handicapping or lethal conditions. Antenatal diagnosis has also defined an *in utero* mortality for some lesions such as diaphragmatic hernia and sacrococcygeal teratoma so that true outcomes can be measured. Prenatal ultrasound scanning has improved since its first use 30 years ago, thus providing better screening programs and more accurate assessment of fetal anomaly. Screening for Down syndrome may now be offered in the first trimester (e.g. nuchal scan combined test) (Fig. 6.1), or second trimester (e.g. quadruple blood test). Better resolution and increased experience with ultrasound scans has led to the recognition of ultrasound soft markers which have increased the detection rate of fetal anomalies but at the expense of higher false-positive rates.[9]

Routine ultrasound screening identifies anomalies and places these pregnancies in the high risk categories with

Figure 6.1 Nuchal thickening.

maternal diabetes, hypertension, genetic disorders, raised alphafeto protein (AFP), etc. High risk pregnancies may be offered further invasive diagnostic investigations such as amniocentesis or chorionic villous sampling (CVS). Structural abnormalities difficult to define on ultrasound, such as hindbrain lesions, or in the presence of oligohydramnios are better imaged on ultrafast magnetic resonance imaging. With the increasing range of options and sophistication of diagnostic methods, parents today are faced with more information, choice, and decisions than ever before, which can create as well as help to solve dilemmas. The different tests and screening procedures commonly in use are outlined below.

Ultrasound examination

Ultrasound scan is routinely performed at 18–20 weeks' gestation as part of the prenatal screening for all pregnancies in England and Wales. Older mothers are routinely screened but in addition are offered invasive testing. Pregnancies with maternal risk factors such as raised AFP levels, genetic disorders, family history of chromosomal abnormalities, or monochorionic twins that carry a high risk for chromosomal anomalies are offered earlier scans in the first trimester. Abnormalities such as diaphragmatic hernia may be detected as early as 11 weeks' gestation. First trimester scans are also useful for accurately dating pregnancies and defining chorionicity in multiple pregnancies.

Recently, nuchal translucency (NT) measurements have emerged as an independent marker of chromosomal abnormalities with a sensitivity of 60%,[10] structural anomalies (particularly cardiac defects),[11] and for some rare genetic syndromes.[12] It involves measuring the area at the back of the fetal neck at 11–14 weeks' gestation (Fig. 6.1). The mechanisms by which some abnormalities give rise to this transient anatomical change of nuchal translucency are poorly understood.[13] Although some abnormalities can be seen at the time of the nuchal scan (11–14 weeks), most are detected at the 18–20 week anomaly scan. Some abnormalities such as gastroschisis have a higher detection rate on a scan than others, e.g. cardiac abnormalities.

If the NT measurement is increased and the karyotype is normal there is a higher risk for a cardiac anomaly and these high-risk fetuses may be referred for fetal echocardiography, which provides better prenatal cardiac assessment than the routine screening scan.[14] Ultrasound surveillance is essential during the performance of invasive techniques such as amniocentesis, CVS, and shunting procedures. It is also useful for assessing fetal viability before and after such procedures. Some abnormalities, such as tracheo-oesophageal fistula, bowel atresia, diaphragmatic hernia and hydrocephaly, may present later in pregnancy and thereby are not detected on the routine 18 week scan.

Overall, around 60% of structural birth defects are detected prenatally[10] but the detection rate varies from 0% (isolated cleft palate) to close to 100% (gastroschisis) depending on the defect. True wrong diagnoses are rare but false-positive diagnoses do occur; some are due to natural prenatal regression, but most are due to ultrasound 'soft markers'.

Ultrasound 'soft markers' are changes noted on prenatal scan that are difficult to define. Examples are echogenic bowel,[15] hydronephrosis, and nuchal thickening. Their presence creates anxiety among sonographers since the finding may be transient with no pathological relevance or may be an indicator of significant anomalies such as chromosomal abnormalities, cystic fibrosis (echogenic bowel), Down syndrome (nuchal thickening), or renal abnormalities (hydronephrosis). Once soft markers are detected, whether should they be reported or further invasive tests offered is a dilemma faced by obstetricians. Reporting these markers has increased detection rates at the expense of high false-positive rates.

Ultrasound is routinely performed as a prenatal screening test. The reliability of the information obtained is dependent on the expertise and experience of the person performing the scan. In a recent study, congenital anomalies noted at birth were diagnosed on prenatal scan in 64% of cases with 0.5% opting for termination.[16]

Invasive diagnostic tests

Amniocentesis[17] and CVS[18] are the two most commonly performed invasive diagnostic tests.

AMNIOCENTESIS

Amniocentesis is commonly used for detecting chromosomal abnormalities and less often for molecular studies, metabolic studies, and fetal infection. It is performed after 15 weeks' gestation and carries a low risk of fetal injury or loss (0.5–1%). Full karyotype analysis takes approximately 2 weeks but newer rapid techniques using fluorescent *in situ* hybridization (FISH) or polymerase chain reaction (PCR) can give limited (usually for trisomies 21, 18, 13) results within 2–3 days.

CHORIONIC VILLOUS SAMPLING

CVS is the most reliable method for first trimester diagnosis and may be performed at 10–14 weeks' gestation. The test involves ultrasound-guided biopsy of the chorionic villi. The added risk for fetal loss is approximately 1–2%. The samples obtained may be subjected to a variety of tests including full karyotype, rapid karyotyping (FISH–PCR), enzyme analysis, or molecular studies. Approximate timing of chromosomal results is 1–2 weeks for karyotyping and 2–3 days for FISH and PCR.

PRENATAL MATERNAL SERUM SCREENING

Interest in detecting circulating fetal cells in maternal blood for diagnostic purposes has grown since the advent of fluorescence-activated cell sorting (FACS).[19] The observation by Brock and Sutcliffe[20] of high levels of AFP in amniotic fluid of pregnancies complicated by open neural tube defects (NTDs) popularized this test. However, with increasing accuracy of ultrasound diagnosis, maternal serum screening of AFP solely for identification of NTDs cannot be justified. The more popular maternal serum screening test is the triple test (hCG, AFP, estrogen) used in combination with the nuchal scan.

FETAL BLOOD SAMPLING

Rapid karyotyping of CVS and amniotic fluid samples FISH and PCR has replaced fetal blood sampling for many conditions. However, fetal blood sampling (FBS) is still required for the diagnosis and treatment of hematological conditions and some viral infections. When required, it is best performed by ultrasound-guided needle sampling after 18 weeks' gestation rather than the more invasive fetoscopic technique. Mortality from this procedure is reported to be 1–2%.[21]

FETAL SURGERY

There is a spectrum of interventions ranging from simple aspiration of cysts to open fetal surgery. Minimally invasive techniques such as ablation of vessels in sacrococcygeal teratoma, fetoscopic ablation of posterior urethal valves, tracheal occlusion for congenital diaphragmatic hernia, etc. are currently under trial. However, laser ablation in twin-to-twin transfusion is now well established.

Genetic diagnoses

Antenatal detection of genetic abnormalities is increasing, especially in high-risk pregnancies. Previously undiagnosed conditions such as cystic fibrosis, Beckwith–Wiedemann syndrome, Hirschsprung's disease, sickle cell disease, etc. may be detected prenatally following invasive testing and genetic counseling and assessment offered early in pregnancy.

Future developments

The aim of prenatal diagnosis and testing is to have 100% accuracy without fetal loss or injury and no maternal risk. National plans to improve Down syndrome screening using ultrasound and biochemical combination tests are now in place in the UK. Research into new markers for chromosomal abnormalities is ongoing. The fetal nasal bone is one such example, which may assist in detecting babies with chromosomal abnormalities.[22]

Management of Rhesus disease is showing promise whereby fetal blood groups may be determined from maternal blood samples through detection of free fetal DNA.[23] The search for fetal components in maternal blood is an exciting and expanding field of research since past and present efforts to isolate and use them for diagnosis have met with little success.[24] Rapid detection techniques versus traditional cultures for karyotyping are currently under debate at present.[25]

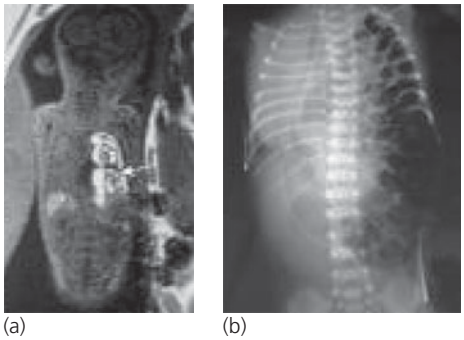
Three-dimensional images from new ultrasound machines may have a useful role in diagnosis and assessment of facial deformities such as cleft lip and palate. Magnetic resonance imaging (MRI) may assist in better defining some lesions difficult to view on conventional prenatal scanning such as the presacral teratoma, posterior urethral valves in the presence of oligohydramnios and hindbrain lesions.

SPECIFIC SURGICAL CONDITIONS

Congenital diaphragmatic hernia

Congenital diaphragmatic hernia (CDH) accounts for one in 3000 live births and challenges the neonatologist and pediatric surgeons in the management of this high-risk condition (Fig. 6.2). Mortality remains high (more than 60%) when the 'hidden' mortality of *in utero* death and termination of pregnancy are taken into account.[26] Lung hypoplasia and pulmonary hypertension account for most deaths in isolated CDH newborns. Associated anomalies (30–40%) signify a grave prognosis with a survival rate of less than 10%.[27]

In the UK, most CDH are diagnosed at the 20 week anomaly scan with a detection rate approaching 60%, although as early as 11 weeks' gestation has been reported.[28]



(a) (b)

Figure 6.2 Congenital left diaphragmatic hernia shown on prenatal magnetic resonance imaging on the left and postnatal radiograph on the right.

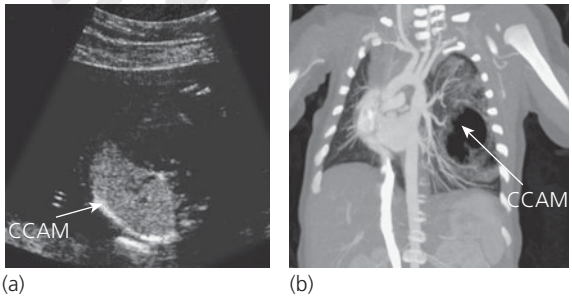
MRI has a useful role in accurately differentiating CDH from cystic lung lesions[29] and may be useful in measuring fetal lung volumes as a predictor of outcome.[30] Cardiac anomalies (20%),[31] chromosomal anomalies of trisomy 13 and 18 (20%),[32] and urinary, gastrointestinal, and neurological (33%)[33] can coexist with CDH and should be ruled out by offering the patient fetal echocardiogram, amniocentesis, and detailed anomaly scan. These associated anomalies and, in isolated lesions, early detection, liver in the chest, polyhydramnios, and fetal lung head ratio (LHR) of less than one are implicated as poor predictors of outcome.[34] In these patients with poor prognostic signs, fetal surgery for CDH over the last two decades has been disappointing, however benefit from fetal intervention with tracheal occlusion (FETO) awaits randomized studies.[35,36] Favorable outcomes in CDH with the use of antenatal steroids have not been resolved in the clinical setting.[37] Elective delivery at a specialized center is recommended with no benefit from Cesarean section.[38,39]

Postnatal management is aimed at reducing barotrauma to the hypoplastic lung by introducing high frequency oscillatory ventilation (HFOV) or permissive hypercapnea,[39] and treating the severe pulmonary hypertension with nitric oxide. No clear benefits for CDH with extracorporeal membrane oxygenation (ECMO) have been concluded in a 2002 Cochrane ECMO study.[40]

Surgery for CDH is no longer an emergency procedure. Delayed repair following stabilization is employed in most pediatric surgical centers.[41] Primary repair using the transabdominal route is achieved in 60–70% of patients with the rest requiring a prosthetic patch. Complications of sepsis or reherniation with prosthetic patch requiring revision is recorded in 50% of survivors.[42]

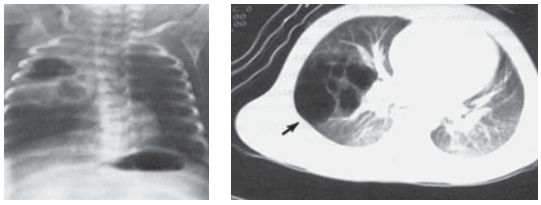
Cystic lung lesions

Congenital cystic adenomatoid malformations (CCAM), bronchopulmonary sequestrations (BPS) or 'hybrid' lesions containing features of both are common cystic lung lesions noted on prenatal scan. Less common lung anomalies include bronchogenic cysts, congenital lobar emphysema and bronchial atresia. Congenital cystic lung lesions are rare anomalies with an incidence of one in 10 000 to one in 35 000 (Figs 6.3 and 6.4).[43,44]



(a) (b)

Figure 6.3 Prenatal diagnosis of congenital cystic adenomatoid malformation (CCAM) and reconstruction computed tomography scan of a large CCAM of the left upper lobe.



(a) (b)

Figure 6.4 Chest radiograph and congenital cystic adenomatoid malformation of right upper lobe.

Prenatal detection rate of lung cysts at the routine 18–20 week scan is almost 100% and may be the most common mode of actual presentation. Most of these lesions are easily distinguished from congenital diaphragmatic hernia, however sonographic features of CCAM or BPS are not sufficiently accurate and correlate poorly with histology.[45] MRI, though not routinely used, may provide better definition for this condition, however inaccuracies were reported in 11% of cases.[46]

Bilateral disease and hydrops fetalis are indicators of poor outcome, whereas mediastinal shift, polyhydramnios, and early detection are not poor prognostic signs.[47–49] In the absence of termination the natural fetal demise of antenatally diagnosed cystic lung disease is 28%. Spontaneous involution of cystic lung lesions can occur[50] but complete postnatal resolution is rare,[45] and apparent spontaneous 'disappearance' of antenatally diagnosed lesions should be interpreted with care, as nearly half of these cases subsequently require surgery.[45,49]

In only 10% of cases does the need for fetal intervention arise. The spectrum of intervention includes simple centesis of amniotic fluid, thoracoamniotic shunt placement, percutaneous laser ablation, and open fetal surgical resection.[51,52] Maternal steroid administration has also been reported to have a beneficial effect on some CCAMs although the mechanism is unclear.[53] A large cystic mass and hydrops in isolated cystic lung lesions are the only real indication for fetal intervention.[47,49]

Normal vaginal delivery is recommended unless maternal condition indicates otherwise. Large lesions are predicted to become symptomatic shortly after birth (as high as 45% in some series), thus delivery at a specialized center would be appropriate, however smaller lesions are less likely to be symptomatic at birth and could be delivered at the referring institution with follow up in a pediatric surgery clinic.[54]

Postnatal management is dictated by clinical status at birth. Symptomatic lesions require urgent radiological evaluation with chest radiograph and ideally computed tomography (CT) scan (Fig. 6.2) followed by surgical excision. In asymptomatic cases postnatal investigation consists of chest CT scan within one month of birth, even if regression or resolution is noted on prenatal scanning.[45,49,54] Plain radiography should not be relied upon since it will miss and underestimate many lesions.[54]

Surgical excision of postnatal asymptomatic lesions remains controversial, with some centers opting for conservative management.[55,56] The approach to treating this asymptomatic group has evolved in some centers, whereby a

CT scan is performed within one month post-birth, followed by surgery before six months of age due to the inherent risk of infection and malignant transformation.[54] Small lesions less than 1 cm may be managed expectantly, bearing in mind that the true resolution of these lesions is exceptional.[45,54] Successful outcomes of greater than 95% have been reported for these surgically managed asymptomatic lung lesions.[45,49,54]

Abdominal wall defects

Exomphalos and gastroschisis are both common but distinct abdominal wall defects with an unclear etiology and a controversial prognosis. Attention may be drawn to their presence during the second trimester because of raised maternal serum AFP level, or abnormal ultrasound scan.

EXOMPHALOS

Exomphalos is characteristically a midline defect, at the insertion point of the umbilical cord, with a viable sac composed of amnion and peritoneum containing herniated abdominal contents (Fig. 6.5). Incidence is known to be one in 4000 live births. Associated major abnormalities which include trisomy 13, 18, and 21, Beckwith–Wiedemann syndrome (macroglossia, gigantism, exomphalos), Pentology of Cantrell (sternal, pericardial, cardiac, abdominal wall, and diaphragmatic defect), cardiac, gastrointestinal, and renal abnormalities are noted in 60–70% of cases,[57] thus karyotyping, in addition to detailed sonographic review and fetal echocardiogram, is essential for complete prenatal screening. Fetal intervention is unlikely in this condition. If termination is not considered, normal vaginal delivery at a center with neonatal surgical expertise is recommended and delivery by Cesarean section only reserved for large exomphalos with exteriorized liver to prevent damage.[57]

Surgical repair includes primary closure or a staged repair with a silo for giant defects. Occasionally, in vulnerable infants with severe pulmonary hypoplasia or complex cardiac abnormalities, the exomphalos may be left intact and allowed to slowly granulate and epithelialize by application of antiseptic solution.[58] Postnatal morbidity occurs in 5–10% of cases.[59] Malrotation and adhesive bowel obstruction does contribute to mortality in isolated exomphalos, however the majority of these children survive to live normal lives.[60]

GASTROSCHISIS

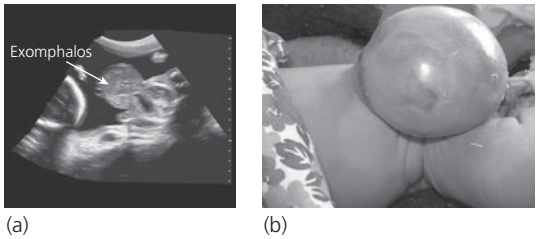
Gastroschisis is an isolated lesion that usually occurs on the right side of the umbilical defect with evisceration of the abdominal contents directly into the amniotic cavity (Fig. 6.6). The incidence is increasing from 1.66 per 10000 births to 4.6 per 10000 births affecting mainly young mothers, typically less than 20 years old. Associated anomalies are noted in only 5–24% of cases, with bowel atresia the most common coexisting abnormality.[61,62] On prenatal scan with a detection rate of 100%, the bowel appears to be free floating, and the loops may appear to be thickened due to damage by amniotic fluid exposure causing a 'peel' formation. Dilated loops of bowel (Fig. 6.3) may be seen from obstruction secondary to protrusion from a defect or atresia due to intestinal ischemia.[63,64]

Predicting outcome in fetuses with gastroschisis based on prenatal ultrasound finding remains a challenge. There is some evidence that maximum small bowel diameter may be predictive,[65] however thickened matted bowel[66] and Doppler measurements of the superior mesenteric artery are not accurate predictors of outcome.[67] To reduce the rate of third trimester fetal loss, serial ultrasounds are performed to monitor the development of bowel obstruction and delivery around 37 weeks is recommended at a center with neonatal surgical expertise.[68]

A recent study by Logghe *et al.*[68] has challenged elective preterm delivery with a randomized control trial. Delivery by Cesarean section has no advantage to the normal vaginal route. Despite efforts to plan elective delivery, 50% of cases will require emergency Cesarean section due to the development of fetal distress.[69]

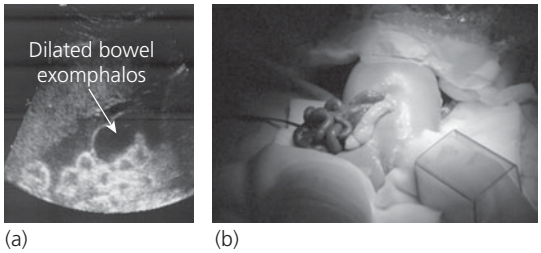
Various methods of postnatal surgical repair include the traditional primary closure, reduction of bowel without anesthesia,[70] reduction by preformed silo,[71] or by means of a traditional silo. Coexisting intestinal atresia could be repaired by primary anastamosis or staged with stoma formation. Variation in achieving full enteral feeding due to prolonged gut dysmotility is expected in all cases.

The long-term outcome in gastroschisis is dependent on the condition of the bowel. In uncomplicated cases the outcome is excellent in more than 90% of cases.[72] The mortality of live born infants is 5% with a further 5% suffering short bowel syndrome and 10% requiring surgery for adhesive bowel obstruction.[72] Late third trimester fetal loss should always be mentioned during fetal counseling.



(a) (b)

Figure 6.5 Prenatal and postnatal images of exomphalos.



(a) (b)

Figure 6.6 Prenatal and postnatal images of gastroschisis.

Tracheo-esophageal fistula and esophageal atresia

Repair of trachea-esophageal fistula (TOF)/esophageal atresia (EA) is a condition which measures the skill of pediatric surgeons from trainee to independent surgeon (Fig. 6.7). The incidence is estimated at one in 3000 births. Prenatally, the condition may be suspected from maternal polyhydramnios and the absence of a fetal stomach bubble at the 20-week anomaly scan. Prenatal scan diagnosis of TOF/EA is estimated to be less than 42% sensitive with a positive predicted value of 56%.[15,73,74] Additional diagnostic clues are provided by associated anomalies such as trisomy (13, 18, 21), vertebral, anorectal, cardiac, tracheo-esophageal, renal, limbs (VACTERAL) sequence and coloboma, heart defects, atresia choanae, retarded development, genital hypoplasia, ear abnormality (CHARGE) association. These associated anomalies are present in more than 50% of cases and worsen the prognosis, thus prenatal karyotyping is essential.[75] Duodenal atresia may coexist with TOF/EA. The risk of recurrence in subsequent pregnancies for isolated TOF/EA is less than 1%.[76] Delivery is advised to be at a specialized center with neonatal surgical input.

Postnatal surgical management is dependent on the size and condition of the baby, length of esophageal gap, and associated anomalies. Primary repair of the esophagus is the treatment of choice however, if not achieved, staged repair with upper esophageal pouch care and gastrostomy or organ replacement with stomach or large bowel are other options. Associated anomalies require evaluation and treatment.

Long-term outcomes are indicated by improved perinatal management and inherent structural and functional defects in the trachea and esophagus.[77] In early life, growth of the child is reported to be below the 25th centile in 50% of cases, respiratory symptoms in two-thirds of TOF/EA, and gastro-esophageal reflux recorded in 50% of patients.[78–80] Quality of life is better in the isolated group with successful primary repair as compared to those with associated anomalies and delayed repair.[81]

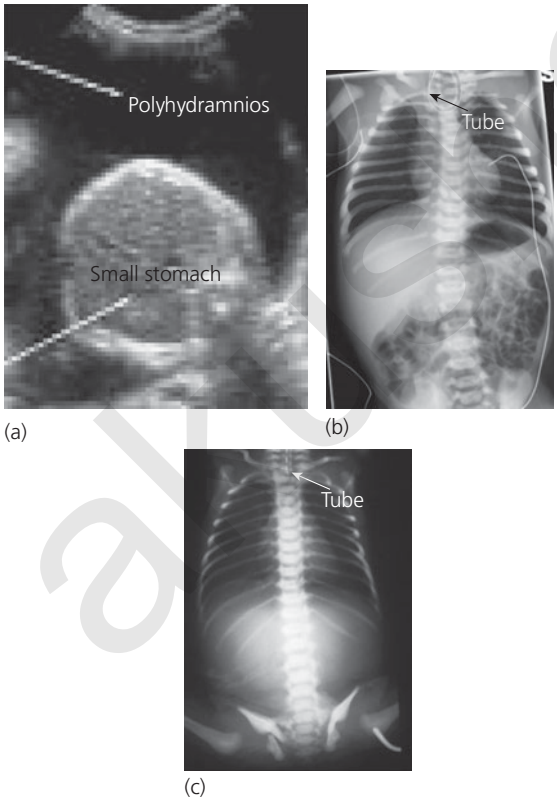


Figure 6.7 (a) Prenatal imaging of suspected tracheo-esophageal (TOF) with polyhydramnios and small stomach. (b) Plain radiograph showing esophageal pouch tube and distal gas confirming TOF with esophageal atresia. (c) Plain radiograph showing esophageal pouch tube and no abdominal gas confirming isolated esophageal atresia.

Gastrointestinal lesions

The presence of dilated loops of bowel (>15 mm in length and 7 mm in diameter) on prenatal ultrasound scan is indicative of bowel obstruction.

Duodenal atresia has a characteristic 'double bubble' appearance on prenatal scan, resulting from the simultaneous dilatation of the stomach and proximal duodenum.[82] Detection rate in the second trimester anomaly scan is almost 100% in the presence of polyhydramnios and the 'double bubble' sign. Associated anomalies are present in approximately 50% of cases with most notably trisomy 21 in 30% of cases, cardiac anomalies in 20%, and the presence of the VACTERL.[82]

The incidence of duodenal atresia is one in 5000 live births. The postnatal survival rate is >95%[15] with associated anomalies, low birth weight, and prematurity contributing to the <5% mortality. Temporary delay in enteral feeding occurs due to the dysmotility in the dilated stomach and duodenum.

There are many bowel abnormalities which may be noted on prenatal scanning (dilated bowel, ascites, cystic masses, hyperparistalsis, polyhydramnios, and echogenic bowel,[83] however none is absolutely predictive of postnatal outcome. Patients with obstruction frequently have findings (especially in the third trimester) of bowel dilatation (Fig. 6.8), polyhydramnios, and hyperparistalsis, but ultrasound is much less sensitive in diagnosing large bowel anomalies than those in the small bowel.[15] Since the large bowel is mostly a reservoir, with no physiologic function *in utero*,

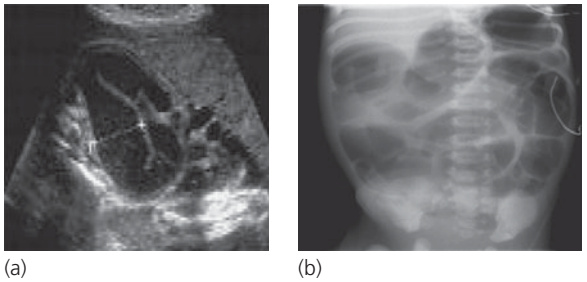

Figure 6.8 Prenatal and postnatal imaging of intestinal atresia.

defects in this region such as anorectal malformations or Hirschsprung's disease are very difficult to detect. Bowel dilatation and echogenic bowel may be associated with cystic fibrosis, therefore all such fetuses should undergo postnatal evaluation for this disease.[6] Prenatally diagnosed small bowel atresia does not select for a group with a worse prognosis and survival rates are 95–100%.

Abdominal cysts

Abdominal cystic lesions are not uncommonly diagnosed at antenatal ultrasound examination. A cystic mass identified in this way may represent a normal structural variant or a pathological entity requiring surgical intervention postnatally. Despite increasingly sophisticated equipment some congenital anomalies have significant false-positive rates on ultrasound and fetal cystic abdominal masses in particular can be difficult to diagnose accurately.[83] Excluding cysts of renal origin, the differential diagnosis includes ovarian cysts, enteric duplication cysts, meconium pseudocyst, mesenteric cysts, and choledochal cysts. Less common diagnoses include extralobar pulmonary sequestration and pancreatic, splenic, urachal, and adrenal cysts. Almost all cysts are benign and many are self-limiting, however these cysts create a high level of anxiety for the prospective parents, especially suspected adrenal cysts. Regular antenatal consultation and fetal counseling by the appropriate team may reduce parental anxiety levels. There is a very small role for fetal intervention. Resolution of these cysts were reported in 25% of cases and 30% came to surgical intervention.[83] Postnatal imaging is essential (Fig. 6.9).

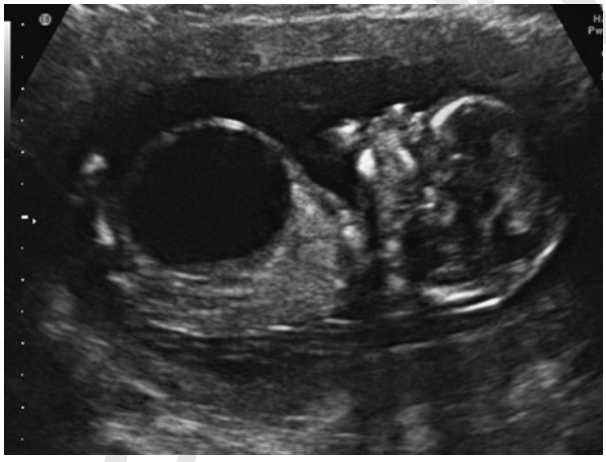

Figure 6.9 Nonspecific prenatal cyst showed complete resolution on postnatal imaging.

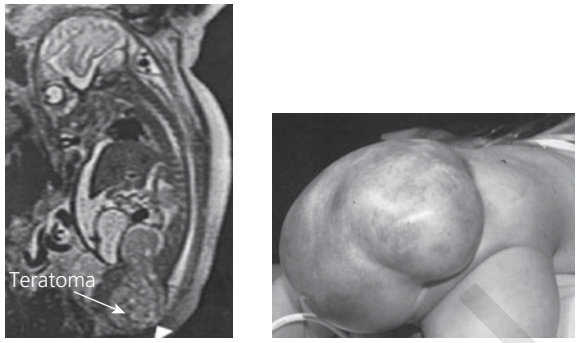
Sacrococcygeal teratoma

Sacrococcygeal teratoma (SCT) is the most common neonatal tumor, accounting for one in 35000–40000 births (Fig. 6.10). Four types have been defined:[84]

1. type 1 external tumor with a small presacral component;
2. type 2 external tumors with a large presacral component;



(a) (b)

Figure 6.10 Prenatal MRI and postnatal image of sacrococcygeal teratoma.

3. type 3 predominantly presacral with a small external component;
4. type 4 entirely presacral.

The latter carry the worst prognosis due to delay in diagnosis and malignant presentation. Doppler ultrasound is the diagnostic tool, however fetal MRI provides better definition of the intrapelvic component.[85] SCT is a highly vascular tumor and the fetus may develop high cardiac output failure, anemia, and ultimately hydrops with a mortality of almost 100%.[86,87] Fetal treatment of tumor resection or ablation of feeding vessel has been attempted in hydropic patients.[88] Cesarean section may be offered to patients with large tumors to avoid the risk of bleeding during delivery. Postnatal outcomes following surgery in type 1 and 2 lesions are favorable, however type 3 and 4 tumors may present with urological problems and less favorable outcomes. Long-term follow up with AFP protein and serial pelvic ultrasounds is mandatory to exclude recurrence of the disease.

Renal anomalies

Urogenital abnormalities are among the most common disorders seen in the perinatal period and account for almost 20% of all prenatally diagnosed anomalies.[89] The routine use of antenatal ultrasound scans has resulted in the early detection of these conditions and in selected cases has led to the development of management strategies including fetal intervention aimed at preservation of renal function. Two major issues are the indications for intervention in bladder outlet obstruction and early pyeloplasty in infancy in cases with hydronephrosis.[90]

Prenatal evaluation of a dilated urinary tract is based on serial ultrasound scans as well as measurement of urinary electrolytes. Ultrasonography provides measurements of the renal pelvis, assessment of the renal parenchyma, as well as the detection of cysts in the cortex. In severe disease, lack of amniotic fluid may make ultrasound assessment of the renal tract difficult and MRI may be helpful.[91] Oligohydramnios is indicative of poor renal function and poor prognosis owing to the associated pulmonary hypoplasia. Urogenital anomalies coexist with many other congenital abnormalities and

amniocentesis should be offered in appropriate cases. It is estimated that 3% of infants will have an abnormality of the urogenital system and half of these will require some form of surgical intervention.[92]

Upper urinary tract obstruction

Antenatal hydronephrosis accounts for 0.6–0.65% of pregnancies.[93] The most common cause of prenatal hydronephrosis is pelviureteric junction obstruction (PUJ), others being transient hydronephrosis, physiological hydronephrosis, multicystic kidney, posterior urethral valves, ureterocele, ectopic ureter, etc. The prognosis of antenatally diagnosed hydronephrosis in unilateral disease and in renal pelvic diameter of <10 mm is excellent. Spontaneous resolution is noted in 20% of patients at birth and 80% at three years of age.[94] Only 17% of prenatally diagnosed hydronephrosis needs surgical intervention. Postnatal management of hydronephrosis requires ultrasound at birth and at one month of age, and further evaluation with radiology and scintigraphy if an abnormality is suspected.[95]

Lower urinary tract obstruction

Posterior urethral valves (PUV) are the most common cause for lower urinary tract obstruction in boys with an incidence of one in 2000–4000 live male births (Fig. 6.11). The diagnosis of PUV is suspected on the prenatal ultrasound finding of bilateral hydronephrosis, associated with a thickened bladder and decreased amniotic fluid volume. Serial fetal urine analysis may provide prognostic information on renal function.[96] Prenatal diagnosis for patients with PUV is a poor prognostic sign with 64% incidence of renal failure and transient pulmonary failure, compared to 33% in the postnatally diagnosed patients.[97] Pulmonary hypoplasia secondary to oligohydramnios largely contributes to the morbidity and mortality from fetal urethral obstruction. Outcomes of fetal intervention with vescicoamniotic shunting[98,99] or fetal cystoscopic ablation of urethal valve[100] is still under review and awaits a multicenter trial.

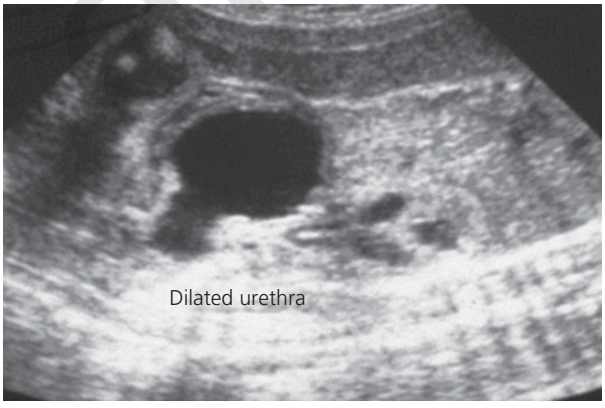


Figure 6.11 Keyhole sign of posterior urethal valves.

Postnatal management includes ultrasound confirmation of the diagnosis, bladder drainage via a suprapubic or urethral route, and contrast imaging of the urethra. Primary PUV ablation, vescicostomy, or ureterostomy are postnatal surgical options. The overall outcome from this disease is unfavorable.

CONCLUSION

The boundaries of pediatric surgical practice have been extended by prenatal diagnosis. The care of patients with surgically correctable defects can now be planned prenatally with the collaborative effort of obstetricians, geneticists, neonatologists, and pediatric surgeons. Essential to prenatal counseling is the understanding of the specific surgical condition's prenatal natural history, the limitations of prenatal diagnosis, the detection of associated anomalies, the risks and indications of fetal intervention programs, and postnatal outcomes. Prenatal counseling is an essential component of pediatric surgical practice and should be ensured in the training program for future pediatric surgeons.

Fetal and birth trauma

PREM PURI AND PIOTR HAJDUK

FETAL TRAUMA

Traumatic injuries in pregnancy are a major cause of nonobstetrics maternal and neonatal morbidity and mortality.[1–7] About 40 years ago,[5,8] it was estimated that 6–8% of pregnant women were affected by accidental injury. This number is likely to be greater now because more active lifestyles led by pregnant women in today's society may put them at increased risk of injury.[3] When a pregnant woman presents with a major trauma, two lives are at risk. The survival of the fetus depends primarily on maternal survival[9] but occasionally the extent of maternal injury does not correlate with the degree of fetal injury.[1,10,11]

Treatment priorities for traumatic pregnant women remain the same as in patients who are not pregnant, although resuscitation and stabilization should be modified to account for the anatomical and physiological changes of the pregnancy.[12,13] The first consideration in the management of maternal trauma in an accident is to ensure the survival of the mother, as is recommended by the Advanced Trauma Life Support Program.[12]

Assessment of the fetus forms part of the secondary survey of the mother, and should be performed in conjunction with an obstetrician as beyond 24–28 weeks' gestational age the fetus is potentially viable if urgent delivery is required.[12]

Assessment of the fetus includes: the date of the last menstrual period, measuring the fundal height, examination for uterine contractions and tenderness, fetal movements, and fetal heart rate. An important part is the vaginal examination for amniotic fluid or blood.

Fetal distress can occur at any time and without warning. The fetus should be continually monitored to ensure early recognition of fetal distress by using the ultrasonic Doppler cardioscope. Signs of fetal distress include: bradycardia (<110 bpm), inadequate accelerations in fetal heart rate in response to uterine contraction, and late decelerations in fetal heart rate in response to uterine relaxation.

In blunt maternal–fetal trauma, placental abruption is the leading cause of death with maternal survival.[14,15] Occasionally, minor maternal trauma may disrupt the placenta 'lifeline' by shearing the relatively rigid placenta from the more elastic uterine wall, thereby leading to fetal distress and subsequent fetal death.[10] The clinical signs of placental abruption include vaginal bleeding, uterine irritability, abdominal tenderness, increasing fundal height, maternal hypovolemic shock, and fetal distress. Although the common classical presentation of placental abruption involves vaginal bleeding and abdominal pain, some cases of traumatic abruption occur without these symptoms and fetal distress may not develop for several hours.

The fetus should be considered salvageable in the face of severe or even mortal maternal injury, and more than 150 cases of successful post-mortem Cesarean section delivery and numerous deliveries of normal neonates just before maternal death have been described.[16,17] Fetal injuries after trauma may be treatable, but only if they are recognized. Penetrating trauma by gunshot or stab wounds, although rare,[10] are usually obvious, and thus appropriate surgical intervention has to be undertaken (Fig. 7.1a,b). Although most cases of penetrating fetal trauma are fatal to the fetus, some cases of fetal salvage have been reported.[18,19] In contrast, surgically treatable fetal injury may go unrecognized after blunt maternal trauma, while these injuries are much more frequent. Thus, one can recognize that after 28 weeks' gestation, Cesarean section for fetal salvage is indicated in the presence of placental abruption with fetal distress, treatable life-threatening fetal injury, or if there is obvious impending or recent maternal death.

A pediatric surgeon should participate in the evaluation and management of both the pregnant patient and the neonate delivered after maternal trauma, together with the obstetrician and neonatologist. Pregnant women should be hospitalized after trauma for appropriate evaluation and fetal monitoring, in the hope of decreasing trauma-related fetal deaths. In recent years, it is expected that every pediatric surgeon would be familiar with the treatment of pediatric trauma. The treatment of the traumatic pregnant woman and the fetus must be part of this skill, especially if the fetus is to be considered a patient.

BIRTH TRAUMA

Birth injuries are defined as injuries associated with mechanical forces producing hemorrhage, edema, tissue disruption, or alteration of organ function occurring during the intrapartum period.[20] With the improvement in obstetric techniques, increased frequency of Cesarean section in potentially difficult deliveries, decreased use of difficult forceps and utilization of fetal heart rate, and determination of acid–base status to monitor the fetus during labor, the incidence of birth injuries has decreased in recent years.[21] Furthermore, use of prenatal ultrasonography has allowed early identification of the risk factors for possible birth trauma, including fetal size and position and enlarged fetal organs or masses. Nevertheless, birth injuries still occur and represent an important problem for the clinician; the incidence of birth trauma is reported to be two to eight per 1000 live births.[22,23]

Birth injury is usually associated with unusual compressive or traction forces in association with abnormal presentation of the fetus. Factors that predispose birth injury include primiparity, cephalopelvic disproportion, dystocia, prematurity, prolonged labor, macrosomia, abnormal presentation, forceps application, version, and extraction.[20,22,23] The newborn at greatest risk for birth injury is the one in breech presentation.

Types of birth trauma

HEAD INJURIES

Caput succedaneum

Caput succedaneum is a diffuse edematous, occasionally hemorrhagic swelling of the scalp, superficial to the periosteum, occurring secondary to compression of the presenting part during prolonged labor. Usually, caput succedaneum requires no treatment and the swelling disappears spontaneously in a week or so. Rarely, hemorrhage into soft tissue may cause anemia that requires blood transfusion or may lead to hyperbilirubinemia or both.[24]

Cephalhematoma

Cephalhematoma is a subperiosteal collection of blood most often found in the parietal region and sharply delineated by the surrounding suture lines (Fig. 7.2). In 10–25% of cephalhematomas there is an underlying skull fracture which is usually of linear type and clinically unimportant.[25] The precise mechanism of production of cephalhematoma is not well established. Repeated buffeting of the fetal skull against the maternal pelvis during a prolonged labor and mechanical trauma caused by the use of forceps and vacuum extractor in delivery have been implicated as important factors. Cephalhematomas have been reported to originate *in utero*, antepartum.

Figure 7.2 Large cephalhematoma.

Petrikovsky *et al.*[26] found seven cases of cephalhematomas identified prenatally on 16292 fetuses during comprehensive ultrasound examinations. Premature rupture of the membranes was seen and was suggested as an associated factor.

Most cephalhematomas resolve spontaneously within a few weeks. Aspiration of the hematoma is contraindicated because of the risk of introducing infection. Drainage and antibiotic therapy are only indicated in the rare case of superinfection of the cephalhematoma.[23] Occasionally, serious complications such as anemia, jaundice, abscess, septicemia, meningitis, osteomyelitis, disseminated intravascular coagulation, shock with acute hemorrhage, and depressed skull fractures have been reported in association with cephalhematomas.[20,27–29] Management involves careful observation for these complications.

Skull fractures

Most of the skull fractures are linear, occurring in association with cephalhematomas and usually involving the parietal bones (Fig. 7.3a). No specific treatment is required for linear fractures, but skull x-rays should be repeated when the infant reaches 2–4 months of age to rule out 'growing fracture of the skull' associated with a leptomeningeal cyst (Fig. 7.3b). A leptomeningeal cyst can occur rarely if the trauma causing the linear fracture tears the underlying dura, thereby permitting herniation of the meninges and brain. This requires surgical intervention to avoid progressive brain damage.[28,30]

Depressed skull fractures are most often caused by pressure of the fetal head against the maternal pelvis or in association with forceps delivery (Fig. 7.4). Several nonsurgical techniques for elevation of depressed skull fracture in the newborn have been described, including suction with a breast pump or vacuum extractor,[31–33] and by digital manipulation. Indications for surgical elevation of depressed skull fracture include:[34]

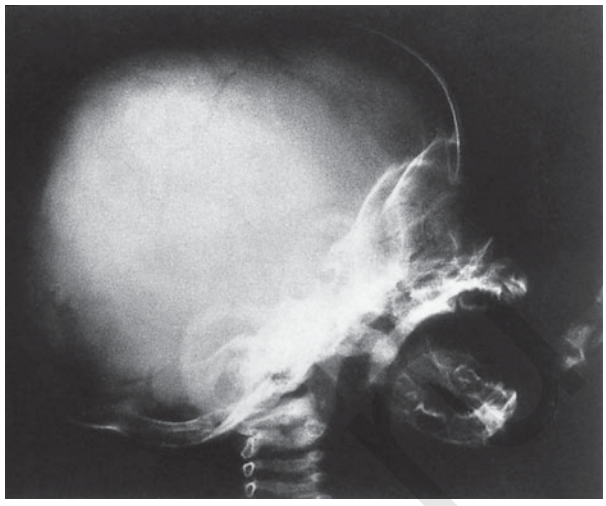
- radiographic evidence of bone fragments within the brain;
- neurological deficit;
- signs of increased intracranial pressure;
- failure to elevate the fracture by closed manipulation.

Intracranial hemorrhage

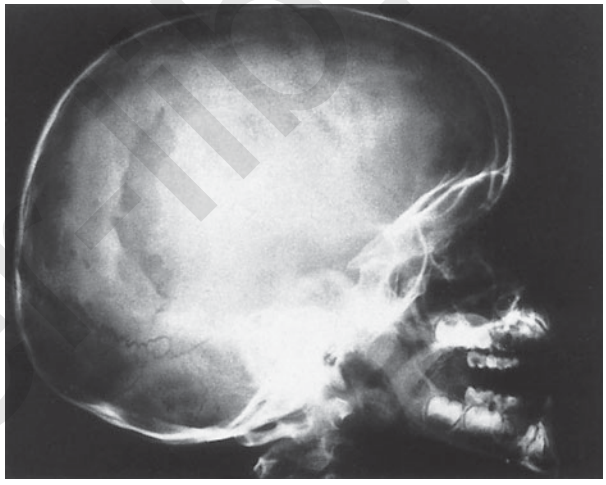
Intracranial hemorrhage following birth trauma may occur in the subarachnoid space, the subdural space, or within the brain.

Subarachnoid hemorrhage is the most common form of birth-related traumatic intracranial hemorrhage in the newborn.[25] Blood in the subarachnoid space can be documented by lumbar puncture and the diagnosis confirmed by computed tomography (CT) scan.[35] In the vast majority of cases, traumatic subarachnoid hemorrhage is benign and does not require any treatment. Occasionally it may result in a communicating hydrocephalus.

Subdural hemorrhage is caused by rupture of the cerebral veins bridging the subdural space, occurring as a result of excessive molding of the baby's head during labor or delivery. Most subdural hematomas are infratentorial and bilateral,



(a)



(b)

Figure 7.3 (a) Linear fracture of left parietal bone at birth. (b) Three years later the patient presented with a pulsatile swelling in the left parietal region. X-ray shows an extensive bone defect due to leptomeningeal cyst.

Figure 7.4 Depressed fracture or right parietal bone following forceps delivery.

but occasionally they have been described in the posterior fossa. Principal factors that predispose to the occurrence of subdural hematoma include large-size infants,[25] breech delivery,[36] and forceps extraction in primiparous women.[37] Clinical features of neonatal subdural hemorrhage may include pallor, vomiting, irritability, seizures, unequal pupils, drowsiness, hypotonia, high-pitched cry, tense fontanelle, and retinal hemorrhages. The diagnosis is confirmed by a subdural tap, CT scan (Fig. 7.5), or magnetic resonance imaging (MRI).[38] Although ultrasound (US) is a standard practice for detecting germinal matrix hemorrhage in the preterm neonate,[39] it is unlikely to be as accurate as a CT scan in diagnosing peripheral lesions in subarachnoid or subdural space.[40] MRI imaging, in general, has high sensitivity for intracranial hemorrhage, and, with its lack of ionizing radiation, is the favorable technique for the further evaluation of birth trauma over CT, especially for a neonate.[41,42] The treatment consists of repeated tapping of the subdural space using a 20-gauge needle at the lateral margin of the anterior fontanelle. In most cases, subdural collections can be treated successfully with repeated taps. Rarely, membrane stripping or subdural space shunting may be required to deal with persistent subdural collections.

Figure 7.5 Computed tomography brain scan without i.v. contrast medium in a newborn, showing blood in the subarachnoid space (large white arrow) and blood in the floor of fourth ventricle (small white arrow).

Intracerebral hemorrhage

Traumatic intracerebral hemorrhage is the least common of intracranial hemorrhage in the newborn.[25] The clinical features are those of increased intracranial pressure. The diagnosis can be made with cerebral ultrasonography, CT scan or MRI, and regression or complications can be monitored with serial studies.[38]

SPINAL CORD INJURIES

The incidence of birth injury to the spinal cord is difficult to determine because most neonatal post-mortem examinations do not include complete examination of the spinal cord.[43] The leading cause of neonatal spinal cord injury is delivery of the fetus with marked hyperextension of the neck in a breech presentation. Approximately 75% of reported spinal cord injuries occurred in infants delivered vaginally in the breech presentation.[44] Other predisposing factors are prematurity, shoulder dystocia, intrauterine hypoxia, and precipitous delivery.[45] The application of compressive forceps to the fetal spine during fundal pressure to relieve shoulder dystocia has been reported to result in lower thoracic spinal cord injury in the newborn.[46] The site of spinal cord injury following breech delivery is usually in the lower cervical and upper thoracic region, while injury following vertex presentation is usually located in the upper or midcervical level.[25] The injury is usually caused by stretching of the cord and not by compression. The most common mechanism responsible for spinal cord injury is the use of excessive longitudinal traction on the trunk while the head is still engaged in the pelvis.[33] The spinal cord is relatively inelastic compared with the vertebral fracture or dislocation, or both, and cord transection.

The clinical manifestations of spinal cord injury may fit into one of the following four recognized groups, depending on the severity of the damage incurred:[27,47]

1. babies who are stillborn or die immediately after birth due to a high cervical or brainstem lesion;
2. neonates who die shortly after birth due to respiratory depression and complications and who generally have upper and midcervical lesions;
3. long-term survivors who have flaccid paralysis in the neonatal period and proceed to develop spasticity and hyper-reflexia in the ensuing months;
4. those with minimal neurological signs or spasticity who are often classified as having cerebral palsy.[48]

The symptoms in these patients result from partial spinal cord injury or cerebral hypoxia. When spinal cord injury is suspected, definition of the underlying pathology can be difficult using standard diagnostic procedures, including plain x-ray and CT, with or without myelography. MRI, with its excellent definition and low risk of complication, is the best diagnostic tool available to evaluate clinically suspected spinal cord pathology.[49,50] Spinal ultrasound is a good imaging method for guiding diagnosis of traumatic spinal cord lesions.[51]

Treatment of spinal cord injuries is supportive and includes physiotherapy, braces, and urological, orthopedic, and psychological care. Surgery has little to offer to patients with these types of injuries. Great emphasis should be placed on prevention of spinal cord injury in the newborn.

PERIPHERAL NERVE INJURIES

Injury to the peripheral nerves in the newborn is usually caused by excessive traction or direct compression of nerves

during delivery. The nerves most commonly involved are the brachial plexus, facial nerve, and phrenic nerve.

Brachial plexus injury

With the improvement in obstetric techniques, the incidence of birth-related brachial plexus injuries has decreased considerably in recent years. The incidence of brachial plexus birth palsy is estimated to be between 0.4 and four per 1000 live births.[52–54] The injury is usually caused by traction and stretching of the plexus. All lesions occur in the plexus above the level of the clavicle and range from simple neuropraxia, classified by Sunderland[55] as grade I, to full neurotemesis when associated with root avulsion, classified as grade V. Perinatal risk factors include large-for-gestational age infants (macrosomia), multiparous pregnancies, previous deliveries resulting in brachial plexus birth palsy, prolonged labor, breech delivery, and assisted (vacuum or forceps) difficult deliveries, shoulder dystocia, and/or asphyxiated infant.[52,56,57] Whereas a mechanical basis for brachial plexus injury is well accepted, delivery by Cesarean does not exclude the possibility of birth palsy.[53]

Brachial plexus injury has been divided into three main types depending on the site of the injury:

1. Erb's palsy, which results from injury of the fifth and sixth cervical nerve roots, is by far the most common type of injury. The affected arm hangs limply adducted and internally rotated at the shoulder, and extended and pronated at the elbow with flexed wrist in the typical 'waiter's tip' posture (Fig. 7.6). The Moro, biceps, and redial reflexes are absent on the affected side. The grasp reflex is intact. These clinical findings are the result of paralysis of the deltoid, supraspinatus, infraspinatus, brachioradialis, and supinator brevis muscles.
2. Klumpke's paralysis results from injury of the eighth cervical and first thoracic nerve roots and is extremely rare as an isolated entity. The intrinsic muscles of the hand and flexors of the wrist and fingers are affected. The grasp reflex is absent. Injury involving the cervical sympathetic fibers of the first thoracic root may result in ipsilateral Horner syndrome.
3. Injury to the entire brachial plexus results in a flaccid arm with absence of sweating, sensation, and deep tendon reflexes. The differential diagnosis includes fracture of the clavicle or humerus, traumatic epiphysiolysis of the proximal epiphysis of the humerus, and shoulder dislocation.[58] These injuries can of course occur in addition to the plexus paralysis.[59] Another associated injury is a phrenic nerve palsy.[60] A radiograph of the shoulder, upper arm, and clavicle should be taken. A chest x-ray should be obtained because of the possibility of an associated phrenic nerve palsy. Electromyography, although of limited value, may be useful in determining the extent and site of injury and evaluating the prognosis.[58,61]

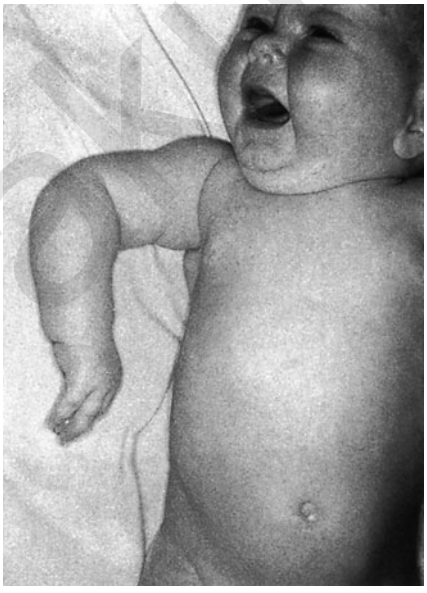


Figure 7.6 Erb's palsy. Characteristic deformity of right arm.

Serial physical examination of children with brachial plexus injury is recommended, because it is essential to predict recovery and determine the need for additional therapeutic or surgical intervention. Passive range of motion and active muscle strength should be assessed. Assessing infants often requires approximation of function by observing spontaneous activity and assessing reflexes (Moro reflex, asymmetric tonic neck, and symmetric tonic neck).[54] Most neonates with brachial plexus injury make a complete or partial recovery on conservative treatment.[25,54,60] The main principle of management is to maintain the range of 'motion' in the affected joints. Treatment should be delayed for a period of 3–4 weeks after the trauma, in which immobilization of the hand and stretched nerve fibers will allow a spontaneous cure. During the first 4 weeks, the arm has to be adducted to the thorax. Abduction and external rotation position of the shoulder must be prevented due to considerable tension on the brachial plexus in that position. In the other joints, careful passive physiotherapy should be carried out. Thereafter, a gentle range of motion exercises to shoulder, elbow, wrist, and small joints of the hand may have to be started.

The prognosis of brachial plexus paralysis is better in the Erb's patient than in the patient with the Klumpke variety and in both of these groups is better than in total paralysis. In the majority of Erb's palsy cases, a partial or complete recovery can be achieved.[62] Surgical exploration and repair of brachial plexus birth injuries are recommended only when there is no recovery of the biceps by three months of age. An electromyography and myelogram with CT scanning are performed preoperatively.[58] Advances in microsurgical techniques and reconstruction of the injured plexus by grafting from the sural nerve can significantly improve the functional result.[58,63,64] Recent use of synthetic collagen nerve conduits has shown very good results in select short-segment brachial plexus repairs.[65] The advantages of synthetic grafts over conventional autologous grafts include eliminating donor site morbidity, increasing the amount of graft material available, and providing direct conduits for neural growth factors produced by the proximal segment to reach the distal segment.

Facial nerve injury

Facial palsy secondary to birth trauma is usually unilateral and most commonly follows compression of the peripheral portion of the nerve, either near its emergence from the stylomastoid foramen or where the nerve transverses the ramus of the mandible. The mechanism of injury is usually either direct trauma from forceps or compression of the side of the face and nerve against the sacral promontory. The affected infant has absent or decreased forehead wrinkling, a persistently open eye, a decreased nasolabial fold, and flattening of the corner of the mouth on the affected side (Fig. 7.7). Treatment is conservative, since spontaneous recovery occurs within one month in most cases of birth-related facial palsy.[23,57] Initial treatment should be directed at protecting the corneal epithelium from drying with the use of methylcellulose drops instilled every 4 hours. Rarely, there is need for surgical intervention and neurolysis or a nerve cable transplant for the injured or degenerative facial nerve, after confirming the diagnosis by electromyographic and electroneurographic tests.[66]

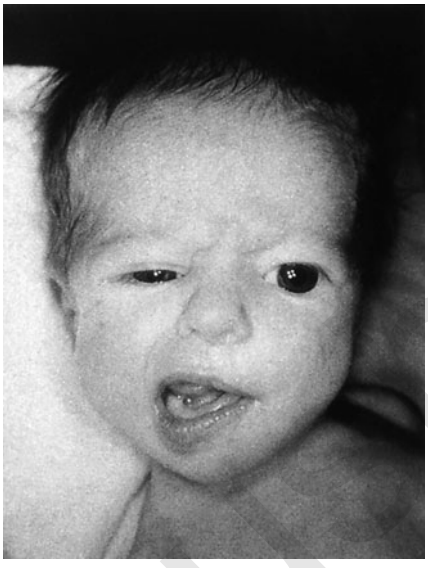

Figure 7.7 Left facial nerve palsy following difficult forceps. Note obliteration of left nasolabial fold with typical deformity of mouth and wide-open left eye.

Phrenic nerve injury

Diaphragmatic paralysis in the neonate results from stretching or avulsion of the fourth and fifth cervical roots, which form the phrenic nerve. The most common cause of phrenic nerve injury is a difficult breech delivery. The majority of injuries are unilateral. Bilateral diaphragmatic paralysis is rare.[67] Approximately 75% of cases of birth-related phrenic nerve injury have an associated brachial plexus injury.[68,69]

The clinical features of diaphragmatic paralysis are nonspecific and include respiratory distress with tachypnea, cyanosis, and recurrent atelectasis or pneumonia. Chest x-ray demonstrates an elevated hemi diaphragm about two intercostal spaces higher than the adjacent diaphragm (Fig. 7.8a). Diagnosis is confirmed on fluoroscopy, which shows an immobile diaphragm or an abnormal elevation of the diaphragm during inspiration constituting paradoxical movement.[70] Real-time ultrasonography can also be employed to diagnose phrenic nerve paralysis and can be performed in the intensive care unit in very young babies (Fig. 7.8b).

Initial supportive management usually includes mechanical ventilation, oxygen, chest physiotherapy, antibiotics, and nasogastric tube feedings to avoid failure to thrive and to ensure weight gain. Some patients who have severe or increasing respiratory distress may be managed by continuous positive airway pressure (CPAP).[71,72]

Most infants with diaphragmatic paralysis make a complete recovery after conservative treatment (Fig. 7.8c). Surgery may be required if there is persistent paralysis after 2 weeks of mechanical ventilation or three months of medical treatment. The procedures employed include plication of the diaphragm via thoracoscopy or thoracostomy[25,72] or incision and replacement of the diaphragm.[73]

INTRA-ABDOMINAL INJURIES

Birth trauma involving intra-abdominal organs is relatively uncommon. The organs most commonly involved are the liver, spleen, adrenal, and kidney.

Liver

The liver is the most commonly injured abdominal organ during the birth process. Factors that predispose to liver trauma include breech presentation, infants with hepatomegaly, large infants, prematurity, and coagulation disorders.[23] The mechanism of birth-related liver injury is thought to be either: (1) thoracic compression and pulling of the hepatic ligaments with consequent tearing of the liver parenchyma; or (2) direct pressure on the liver leading to subcapsular hemorrhage or rupture.[23]

Hepatic trauma more commonly results in subcapsular hemorrhage than actual rupture of the liver. The infant with subcapsular hemorrhage usually appears to be normal for the first 3 days of life, when the capsule ruptures and there is extravasation of blood into the peritoneal cavity. This is followed by sudden circulatory collapse, abdominal distension, and a rapid drop in the hematocrit value. If the processus vaginalis is patent, blood may be seen in the scrotum, suggesting hemoperitoneum. In patients with primary rupture of the liver, major intraperitoneal bleeding occurs immediately, resulting in severe shock and abdominal distension. Abdominal x-rays are not usually very helpful, but may show uniform opacity of the abdomen, indicating free intraperitoneal fluid. Abdominal ultrasonography may confirm the diagnosis and is also useful in differentiating a solid liver tumor from an unruptured subcapsular hemorrhage. A CT scan is recommended, but only if the patient is hemodynamically stable (Fig. 7.9a–d). Abdominal paracentesis is the procedure of choice for rapid diagnosis of hemoperitoneum. Immediate management consists of blood transfusion to restore the blood volume and recognition and correction of any coagulation disorder. This is followed by an immediate laparotomy, with evacuation of the hematoma and repair of any laceration by sutures or by fibrin glue.[74]

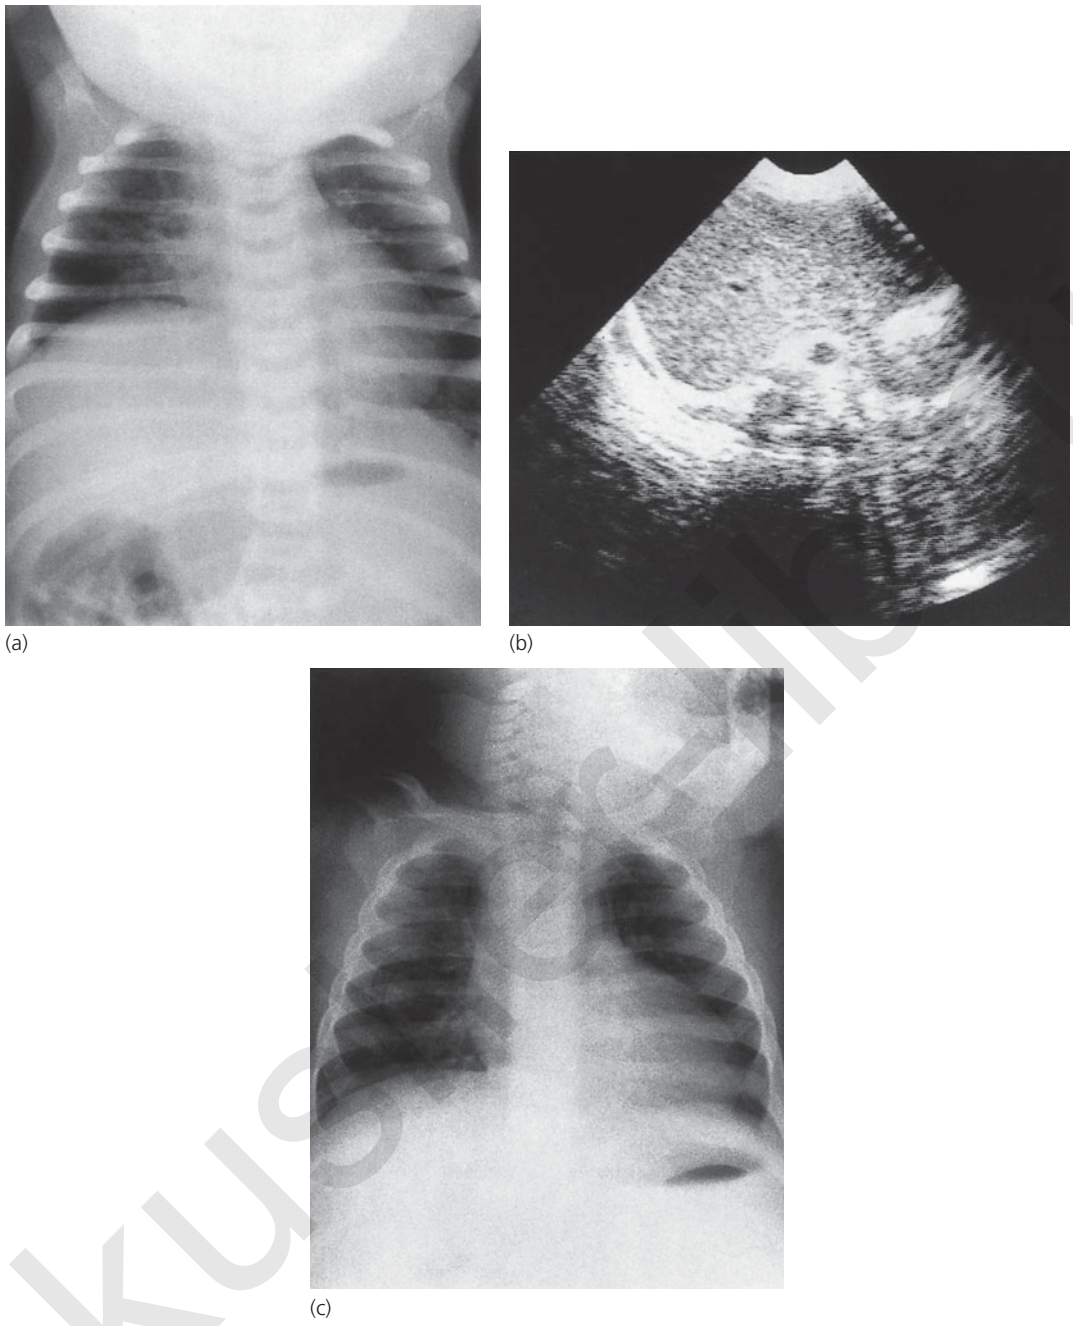

Figure 7.8 Phrenic nerve paralysis. (a) Chest x-ray shows elevated right diaphragm. (b) Transverse real-time sonogram showing blurring in the region of left diaphragm due to respiratory movement. Right diaphragm did not move and is sharply outlined along the liver. (c) Chest x-ray three months later shows normal right diaphragm after conservative treatment.

Spleen

Rupture of the spleen in the newborn occurs much less often than does rupture of the liver. The predisposing factors and mechanism of injury are quite similar to those of rupture of the liver. Although splenomegaly increases the risk, the vast majority of splenic injuries occur in spleens of normal size.[28] The presenting features are cardiovascular collapse and abdominal distension. Abdominal x-ray may indicate free fluid in the peritoneal cavity. Ultrasound scan, abdominal, and pelvic CT are recommended to confirm diagnosis.

Nonoperative management of pediatric splenic injuries is now recognized as the treatment of choice in most of cases.[75] This typically involves following vital signs, serial hematocrits, and physical examination. Blood transfusions are administered as required. Hemodynamically unstable newborns, usually with immediate massive hemorrhage, may require exploratory laparotomy.[75] In recent years, repair of the spleen has been advocated because of the risk of subsequent serious infections following splenectomy.[76] Since there is a critical mass of spleen which prevents overwhelming post-splenectomy infection (OPSI),[77,78] every surgeon should do the utmost to preserve

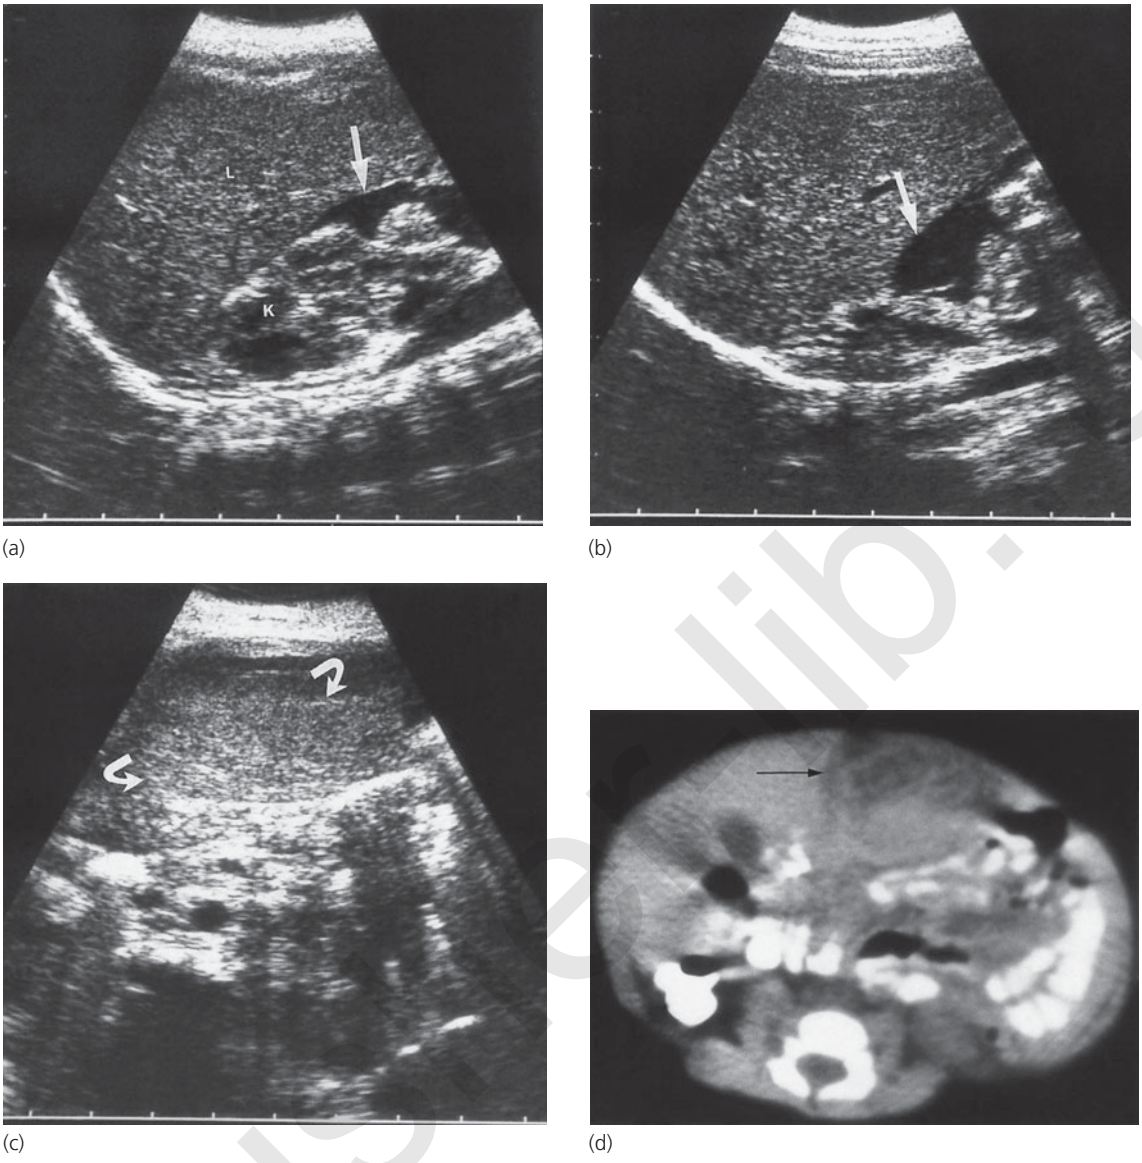

Figure 7.9 Newborn who developed a distended abdomen post-delivery. (a,b) Sonographic scan at 36 hours shows echo-poor material due to fresh hemorrhage (white arrow) between the anterior aspect of the right kidney (K) and the inferior aspect of the right lobe of liver (L). (c) Scan through left lobe of liver demonstrating an area of increased echogenicity in keeping with hemorrhage at site of laceration (curved arrows). (d) Laceration in left lobe confirmed on computed tomography scan (black arrow).

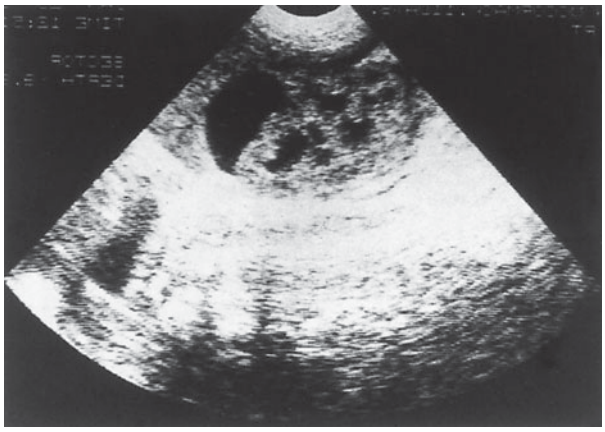
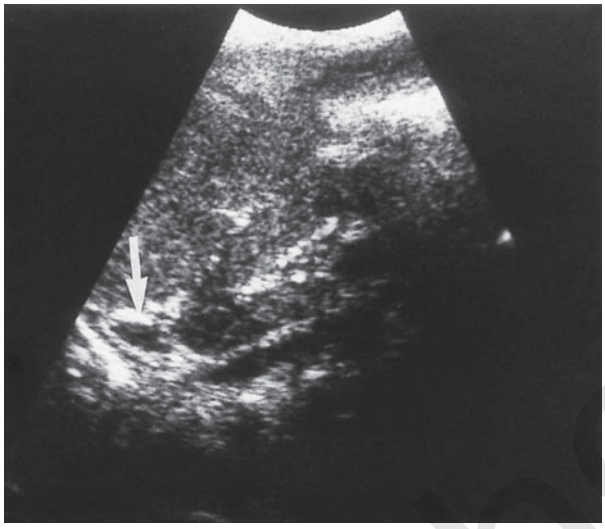
as much of the injured spleen as possible. Fibrin glue, splenorrhaphy, or partial splenectomy are the preferred surgical procedures.[23,79–81] This conservative surgical approach is advocated not only because of the OPSI, but also because of the absence of regeneration of the injured spleen after partial splenectomy, which has been proven in animals.[82]

Adrenal

Neonatal adrenal hemorrhage occurs most commonly following a prolonged and difficult labor, culminating in a traumatic delivery. Other contributing factors include asphyxia, prematurity, placental hemorrhage, hemorrhagic disease of the newborn, septicemia, renal vein thrombosis, increased vascularity, and congenital syphilis.[83–88] The right adrenal is involved in over 70% of cases, with bilateral involvement in 5–10%.[89,90] The presenting features vary with the degree of bleeding. The classical adrenal hemorrhage usually presents between birth and the fourth day of life as an abdominal mass with fever and jaundice or anemia.[88] The differential diagnosis may include adrenal cyst, neuroblastoma, and Wilms' tumour. Diagnosis of neonatal adrenal hemorrhage may be confirmed with a combination of ultrasound and i.v. pyelogram. Sonography would reveal a suprarenal mass that initially is echogenic, and subsequent changes to a cyst-like structure probably indicating fragmentation of the clot (Fig. 7.10a,b). An i.v. pyelogram should demonstrate downward displacement of the kidney on the affected side. An early total body opacification film may show a lucent region above the kidney. A 'rim' suprarenal calcification may be seen on abdominal radiographs 2–4 weeks after hemorrhage.[83,91]



(a)



(b)

Figure 7.10 (a) Right suprarenal echo-poor mass representing a right adrenal hemorrhage (between cursors) in an infant who suffered birth asphyxia. (b) Scan performed one month later, showing that hemorrhage has almost cleared. Small residual echo-poor area persists (white arrow).

In patients with retroperitoneal hemorrhage, treatment consists of blood transfusion, close observation, and follow-up ultrasound studies. In infants with massive intraperitoneal hemorrhage, surgical intervention consists of abdominal paracentesis, laparotomy, evacuation of hematoma, ligation of bleeders, or adrenalectomy if indicated. It must be remembered that the underlying pathology may be a neuroblastoma[92,93] and a biopsy should always be taken. Infrequently, a suspicion of an adrenal abscess ensues. In such a situation, a drainage procedure must be performed either percutaneously with ultrasound guidance or by operative exploration.

KIDNEY

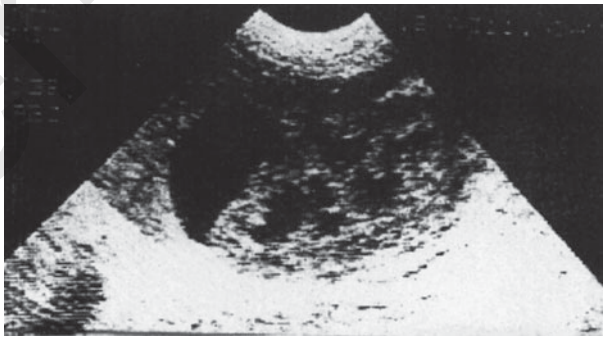
Birth-related trauma is rare. Rupture of the kidney in the newborn is usually associated with an underlying congenital anomaly.[94] The presenting signs are hematuria and renal mass. An i.v. pyelogram may show absence of excretion or leakage of contrast through the renal parenchyma into the perirenal space. Renal ultrasonography may demonstrate renal rupture (Fig. 7.11) or ascites. Treatment consists of conservative management if possible. Only in cases of severe bleeding or a total rupture of parenchyma or pelvis is a laparotomy indicated, with the correction of underlying congenital anomaly whenever it is necessary.

BONY INJURIES

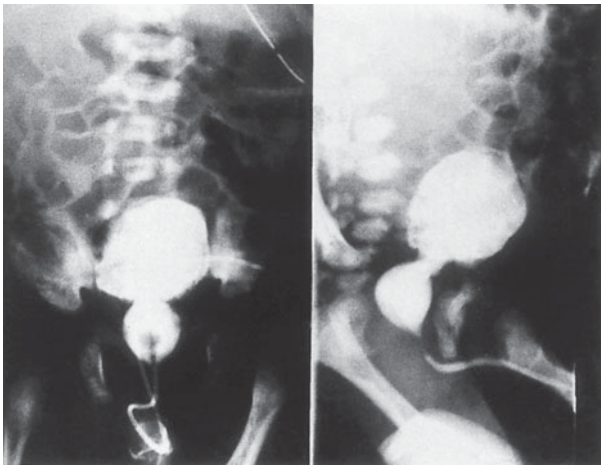
Fractures due to birth trauma almost always involve the clavicle, humerus, or femur. Epiphyseal separations usually involve upper and lower humeral and upper femoral epiphyses. Dislocations caused by birth trauma are rare.

Fracture of the clavicle

Fracture of the clavicle is the most common fracture in the newborn, usually occurring during a difficult delivery associated with large infants, breech presentation, and shoulder dystocia.[95] Most fractures are of the greenstick type, occurring in the middle third of the clavicle, but occasionally the fracture is complete (Fig. 7.12). Undisplaced fractures require no treatment. Fractures with marked displacement should be immobilized with a figure-of-eight bandage. Recovery is usually excellent.



(a)



(b)

Figure 7.11 (a) Longitudinal sonogram showing an echolucent area in upper pole of right kidney consistent with an intracapsular rupture. Both ureters were hydronephrotic with dilated bladder on sonography. (b) Voiding cystogram in the same patient confirmed posterior urethral valves.

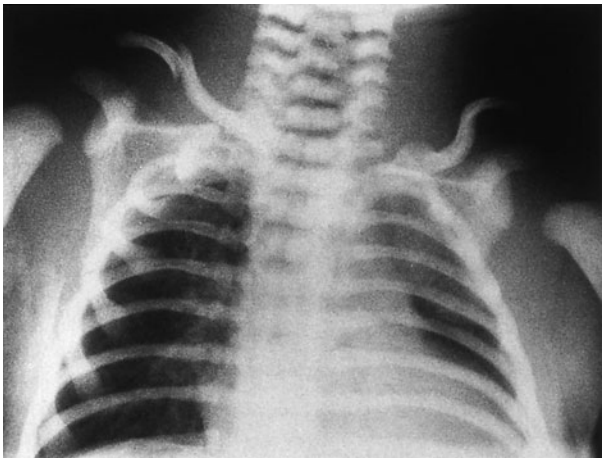


Figure 7.12 Fracture of right clavicle. Typical fracture of middle third of clavicle following forceps delivery.

Fracture of the humerus

Fractures of the humerus usually occur in the middle third of the shaft and are either transverse or spiral. They are usually greenstick fractures, but occasionally complete fracture with overriding of fragments may occur. The most common mechanisms responsible for fracture are believed to be traction on the extended arm in the breech presentations and axillary traction to disengage an impacted shoulder in vertex presentations. Treatment consists of strapping the arm to the chest. Complete healing of the fracture fragments usually occurs by 3 weeks.

Fracture of the femur

Femoral shaft fractures usually occur in the middle third and are transverse. The injury usually follows a breech delivery. X-ray invariably shows overriding of the fracture fragments. Treatment consists of Bryant's traction for 3–4 weeks. The prognosis in femoral fractures is usually excellent.

Epiphyseal separations

The epiphyseal separation or fracture occurs through the hypertrophied layer of cartilage cells in the epiphysis. The most common cause is a difficult breech delivery.[96] A fracture through the proximal epiphyseal plate of the humerus is the most common epiphyseal cartilage injury. Fractures entirely confined to the epiphyseal cartilage cannot be demonstrated radiologically. However, in many cases the fracture extends through a part of the metaphysis, separating a tiny bony fragment. This fragment is attached to the epiphysis and if no displacement of the epiphysis has occurred, the fragment may be the only radiographic evidence of fracture. An increased distance of the metaphysis from the joint compared with the opposite side can also indicate fracture through the epiphyseal plate. After 1–2 weeks, callus becomes visible, confirming the nature of the injury. Diagnosis at the initial stage has to be made primarily on clinical findings of pain on passive motion, swelling, and impaired movement around the joint. Recent reports suggest that epiphyseal separation can be studied by sonography and without the common use of arthrography.[96,97] Treatment of a fracture of the proximal epiphysis of the humerus consists of immobilization of the arm by the side with a sling in 90° flexion.

Epiphysiolysis of the proximal femur is sometimes confused with congenital dislocation of the hip and septic arthritis, and can occur not only after normal delivery but also after delivery by Cesarean section.[98] Treatment for a fracture of the proximal epiphysis of the femur is by traction and spica cast for two months.

TRAUMA TO THE GENITALIA

The breech delivery is the common cause of tissue injuries involving the external genitalia. Edema, ecchymoses, and hematomas of the scrotum or the labia majora can occur. No treatment is needed. Spontaneous resolution of edema occurs within 24–48 hours and of discoloration within 4–5 days.

If the tunica vaginalis is injured and blood fills its cavity, a hematocele is formed. The differential diagnosis should include neonatal torsion and patent processus vaginalis.[99,100] An iatrogenic injury to the scrotum with resultant castration during breech extraction has been reported.[101]

Transport of the surgical neonate

PREM PURI AND RESHMA DOODNATH

INTRODUCTION

The successful outcome of an operation performed on a newborn with congenital anomalies depends not only on the skill of the pediatric surgeon, but also on that of a large team consisting of a pediatrician, anesthetist, radiologist, pathologist, biochemist, nurses, and others necessary for dealing satisfactorily with the newborn subjected to surgery. The pediatric transport team is a natural physical extension of the pediatric intensive care unit and should be able to provide advanced critical care management for children at remote sites and during transport to a tertiary center.[1] Advances in neonatal intensive care (NIC) dictate that effective and efficient treatment of the sickest neonates can only be available by concentrating resources such as equipment and skilled staff in a few specialist pediatric centers which have responsibilities to a particular region.[2,3] There has been a marked change over the past 20 years with regards to the knowledge, capabilities, and delivery of neonatal transport.[4] Neonates with congenital malformations will therefore have to be transported safely to these centers, sometimes over considerable distances.

PRENATAL TRANSFER

It has been stated before that prenatal transport of term fetuses with antenatally diagnosed surgical abnormalities does not improve the outcome if the quality of care before and during transport is good.[5] The distance involved does not influence the outcome. However, several other studies support the *in utero* transportation of the high risk fetus, particularly the very low birth weight (VLBW) babies and those with life-threatening neonatal surgical problems.[6–9] Hypothermia remains a main problem in these babies and it adversely affects neonatal outcome.[10] Poor post-transfer temperature seems to be an independent predictor of death.[10,11] Therefore, whenever possible, antenatal *in utero* transfer remains the method of choice for threatened delivery of an extremely preterm delivery before 28 weeks' gestation.[10,12]

PRE-TRANSFER MANAGEMENT

Transferring a newborn without proper stabilization is associated with increased morbidity and mortality. The golden rule still is that no neonate should be transported unless his or her condition has been sufficiently stabilized to survive the expected duration of the journey.[9] The transport environment is usually noisy and access to the patient is restricted, and so, careful attention to pre-transfer management will provide a higher margin of safety during the journey, when it may be difficult to provide adequate treatment should problems arise.[5] All babies must be properly resuscitated before the journey is undertaken.[9] All drugs, fluids, and equipment that is necessary for transfer should be carried by the transport team (Box 8.1).[13]

Box 8.1 Items necessary for transfer of surgical neonate

- Monitors – ECG, BP, pulse oximeter, temperature
- Infusion pumps
- Resuscitation drugs and equipment
- Portable oxygen supply
- Ventilator
- Document folder with all relevant information of patient and parents
- Maps – if ambulance crew are driving in unfamiliar area
- Portable telephone

Airway management

It should be ensured that the airway is clear and that the baby is well oxygenated, and that ventilation can be maintained

during transport. If any risk for deterioration of spontaneous breathing is present, the child should be intubated before departure[5] as emergency intubation while travelling is often difficult or hazardous. Except in patients with a fractured base of skull, nasal obstruction, or significant coagulopathy, every child should be intubated nasotracheally.[13] All intubated patients need to be suctioned regularly/hourly.

Temperature regulation

Thermoregulation requires critical attention. Hypothermia causes an increase in the neonate's metabolic rate with a subsequent increase in glucose and oxygen use ensuing acidosis and, if not reversed, persistent pulmonary hypertension of the neonate develops.[8] A core body temperature below 36.4°C (97.5°F) in neonates has been correlated with poor brain and somatic growth and increased mortality.[14] This can all be avoided by warming the baby to a core temperature of at least 35°C and using a pre-warmed transport incubator in a pre-warmed ambulance, with the thermal environment adjusted so as to maintain correct rectal temperature.[15] Hyperthermia above 37°C (98.6°F) should be avoided.[16]

Circulation

Two reliable and secure routes of venous access should be in place. Many surgical newborns have abnormal losses of water, electrolytes, and proteins, which must be replaced to prevent hypovolemia and shock. Intravenous fluids must be initiated immediately and sometimes initiation of inotropic vasopressors such as dopamine or dobutamine may be warranted.[5,6,8] A urinary catheter should be inserted to closely monitor urinary output in any patient in whom there will be excessive fluid losses.

Every neonate requiring transport must have an adequately sized functioning nasogastric tube to prevent vomiting and aspiration. It should be taped securely in position and kept on open drainage or attached to a low-pressure suction pump which should be aspirated every 10–20 minutes to prevent occlusion.[5] Glucose homeostasis must also be maintained and close monitoring of glucose blood levels should be performed regularly and corrected if necessary.[8]

Documentation

Furthermore, a number of essential data should be transferred with the infant. A copy of the infant's chart with completed medical notes, all x-rays/ultrasound scans, and nursing documentation (urine output, passage of stools, eye prophylaxis, hepatitis vaccine, other medication administration) should accompany the patient. All laboratory reports should be included, and the time noted when tests were carried out. It should be clearly documented whether vitamin K was given. Prophylactic broad-spectrum antibiotics should be started if there is a risk of infection. A sample of maternal blood (5–7 mL clotted) should be sent to facilitate cross-matching. A parental consent for operation, signed by the mother if the parents are not married, should be sent together with a contactable phone number to be able to explain to the parents the surgical condition of their child and the operative procedure. Where possible, a cord blood specimen should be sent, along with a copy of maternal records including complete maternal history, labor, and delivery records.

TRANSPORT TEAM

It is now widely accepted that specific transport training is required by staff who will be called upon to transfer neonatal patients.[17] Local and individual circumstances will determine whether the referring or specialist center will send a transport team. The composition of the team may also vary from institution to institution. The team should ideally consist of a transport physician/pediatrician and a trained neonatal nurse familiar with and able to anticipate potential problems associated with specific lesions.[8,10] They should be familiar with all equipment and its function and should be experienced in stabilizing an infant in suboptimal conditions. A more recent option is the use of Advanced Neonatal Nurse Practitioners (ANNPs), who have been shown to provide comparable care to trainee pediatricians.[17] Careful delineation of responsibility is important. Some institutions have formed a nursing transport team trained and experienced in the transfer of sick neonates. They guide the doctors and operate the equipment.[11]

TRANSPORT VEHICLES

Selection of a transport vehicle is dependent on the distance traveled, geography, weather conditions, the nature of the infant's problem, and the need for speed.[2] A variety of conveyances are in popular use, including ground ambulances, helicopters, and fixed-wing aircraft. Ambulance transport is generally preferable to that by helicopter, but it is rather slow.

Air transport has several disadvantages. A major disadvantage is that separate ground transport must be arranged at both ends to move the baby between the airport and the hospital. The exception arises in those circumstances in which helicopter landing sites are available at both receiving and referring institutions. Vibration is not usually detrimental to the infant, but can dislodge lines and tubes and adversely affect monitoring equipment.[18] Excessive noise may give rise to communication issues and it is important to ensure that staff headsets are equipped with the correct impedance microphone for that particular aircraft.[18] Noise, vibration, and poor lighting make in-flight monitoring of the infant difficult in a rotary-wing aircraft (helicopter).[8,9,19] This problem is not experienced to such a significant degree in a fixed-wing aircraft. Overall, the noise and vibrations may cause distress and discomfort to the infant, leading to a

deteriorating clinical condition and thus it is logical to minimize these as much as possible.[18]

The transport incubator should be securely strapped in case of turbulence of the plane. The infant in the incubator should be well fixed with a lockable piece of cloth. Moreover, the space in a plane is limited and can cause difficulties in manipulating the airway.[8,9]

The negative effects of altitude on the neonate's body can be detrimental.[19] With increasing altitude, the partial pressure of oxygen decreases, therefore diffusion of oxygen across the alveolar membranes becomes more difficult, arising in decreasing oxygen saturation in the infant. To maintain the same level of oxygenation, a higher percentage of oxygen may be required. Moreover, the barometric pressure will also decrease with increasing altitude, the volume of gas will increase and any air trapped in a body cavity will expand. This could have a dramatic effect on pulmonary function[8] and small insignificant air leaks can become dangerous. This is particularly important in the setting of pneumothoraces, pneumoperitoneum, or intramural gas.[18] It is therefore important to ensure that all air leaks are drained if possible. It is also very important to have well-functioning medical and nursing equipment in the event that this emergency arises.[10]

Monitoring is essential during transfer because clinical assessment can be limited due to suboptimal lighting, noise, vibration, and lack of space. Invasive and noninvasive measures of arterial pressure, pulse oximetry, electrocardiograph (ECG), core temperature measurement, and pressure transducers for central venous and intracranial pressure readouts must be present. All monitors and syringe pumps should be battery operated.[6] A range of airway and ventilatory equipment, including self-inflating resuscitation bags, masks, airways, laryngoscope handles and blades, uncuffed neonatal endotracheal tubes of various size, humidifiers, portable suction apparatus, and oxygen supplies, must be available in case airway problems should occur. There must be a source of suction for clearing blocked endotracheal tubes. Intravenous infusion pumps, along with an appropriately stocked box including i.v. supplies, intraosseous needles, chest tubes, and umbilical catheter kits with sterile equipment and emergency drugs should be present.[8] After each transport, a record which documents equipment that is used should be filled in and the equipment unit checked and restocked. The equipment kit should be controlled weekly by the neonatal transport nurse on duty and servicing of the transport incubator and the monitoring equipment should be carried out.[10]

Because of the very different nature of air travel compared to ground travel, it is imperative that staff receive training specifically directed at both the environment and specific problems that they may encounter in each situation. These include logistics (landing sites), airborne environment, and safety issues specific to each situation.[17]

TRANSPORT INCUBATORS

Standard requirements for transport incubators are established in an International Standard.[20,21] The currently available portable incubator (Fig. 8.1) is designed and equipped for transporting sick newborns.[22] It is a central piece of equipment that has to provide warmth, visibility, and access. The incubator should be able to maintain a specific temperature under a variety of different ambient conditions (e.g. −15°C/5°F to 28°C/82°F).[20] The patient compartment of the transport incubator must be equipped with a front flap for loading and so that there is good access to the neonate in the event of an emergency.[20] It should also be able to run on batteries, and must be equipped with its recharger. Guidelines state that the energy of the battery should be sufficient for a minimum of 90 minutes in an ambient temperature of 15°C/59°F.[21] It should be equipped with a cardiorespiratory monitor, pulse oximeter, infusion pump, oxygen analyzer, oxygen and air cylinders, double Plexiglas walls, and shock-absorbing wheels.[8] In the case of transporting very sick neonates and preterm babies, ventilation may be required. In these cases, the incubator should be equipped with a mechanical ventilator which is time-cycled, pressure-limited, and capable of delivering conventional ventilations and constant positive airway pressure (CPAP).[20] When securing the neonate in the incubator, one must bear in mind the size of the infant, extreme sensitivity of preterm skin, reduced muscle tone, low body profile, and body weight distribution.[23]

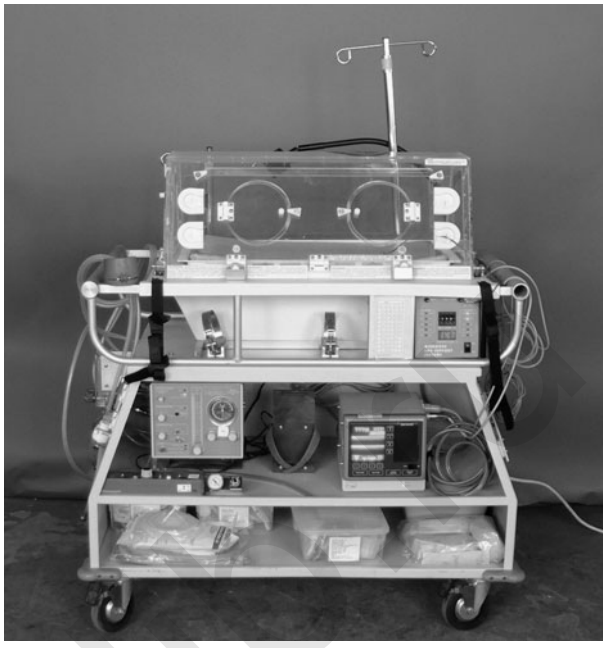

Figure 8.1 A portable incubator.

TRANSPORT PROCEDURE

The perfect transfer does not exist yet. It involves early and effective communication between the referring and specialist center, stabilization of the baby pre-transfer, and provision of special needs and care during transport.[5] All too often, transport is hastily arranged and conducted in a vacuum of communication, resulting in preventable catastrophes such as vomiting and aspiration, hypothermia, hypovolemia, and airway obstruction,[7] and in the majority of cases, most

adverse events arise from poor planning and preparation. Ideally, transfer is arranged at as senior a level as possible, i.e. a telephone conversation between a specialist pediatric registrar or consultant pediatrician in the referring center and specialist surgical registrar or consultant pediatric surgeon in the receiving center.[24] A standardized transfer-form booklet was introduced by the current authors in their institution. A form is filled in during the initial conversation with the referring center. It contains all the necessary medical and practical details regarding actual transfer and specific management of the surgical problem of the newborn. By increasing awareness of potential problems, referring hospitals will be less inclined to neglect precise instructions concerning specific surgical conditions.

RECEIVING CENTER

Continuation of care is essential to improving neonatal outcome. On arrival at the tertiary center, a brief report of prenatal, labor, and delivery history should be given by the transport nurse to the newborn intensive care nurse, together with details of the newborn's resuscitation and any problems experienced during transfer.[8] The accompanying pediatrician should review the baby and all documents together with the accepting surgeon and anesthetist, if necessary. The parents should be introduced to all staff who will be involved in the care of their baby. Every procedure should be explained in a clear and comprehensive language to avoid confusion and parental fear. The consent form should be updated if necessary. Blood tests and radiological examinations can be ordered subsequently.

SPECIAL CONSIDERATIONS

Gastroschisis

The baby with gastroschisis is at a higher risk for hypothermia, excessive fluid loss, shock, and infection due to lack of a covering peritoneal/amniotic membrane which gives rise to exposed viscera and peritoneal surfaces. Therefore, radiant heating should be available in the room and the baby should be kept in a warmed incubator with the incubator's temperature monitored frequently. Intestinal strangulation, necrosis, and obstruction may also occur due to the small size of the paraumbilical defect. Treatment starts immediately after delivery in order to prevent fluid loss and hypothermia (Box 8.2). Intubation and ventilation is carried out if required, and immediate resuscitation with adequate i.v. fluids (120 mL/kg/24hours) to overcome substantial water, electrolyte, and protein loss is started. Because the fluid losses are primarily of serum and interstitial fluids, these neonates require isotonic fluids resuscitation, which consists of colloids, saline, or lactate Ringer's solution.[25,26] Pulse rate and mean arterial pressure are observed and blood is taken and glucose level measured. At the same time, vitamin K is given and broad-spectrum antibiotics (ampicillin, gentamicin, and metronidazole) are commenced to reduce contamination of the exposed intestinal loops. A nasogastric tube is passed for intestinal decompression and prevention of pulmonary aspiration. A urinary catheter is passed to decompress the bladder and to monitor urinary output. In many instances, the viscera are wrapped in sterile gauze that has been soaked in warm sterile saline and then the abdomen, along with the covered defect, are wrapped in dry sterile gauze. This may, however, induce hypothermia as the gauze cools. If the gauze is allowed to dry, this may stick to the intestinal surface and cause serosal injury when trying to be removed.[27] Ideally, the bowel should be placed in a sterile clear plastic bag or silo (Fig. 8.2). If this is not available, the bowel is localized in the center of the abdomen and cling film is used to encircle the exposed intestine and is wrapped around the infant. These measures minimize heat loss and trauma to the exposed viscera.[28] The positioning of the infant is very important for preventing bowel ischemia. If the infant is supine and the

Box 8.2 Stabilization of a newborn with anterior abdominal wall defect prior to transfer to a referral center

Warm environment
Evaluate respiratory status

Omphalocele: wrap dry gauze around sac
Intravenous fluids, correct deficits
Antibiotics
Vitamin K

Figure 8.2 Gastroschisis with silo placement.

bowel lies on one side, there is a risk of ischemia to the bowel if the superior mesenteric artery becomes kinked. Hence, the best position is to keep the intestines directly above the abdominal wall defect so that the superior mesenteric artery exits straight from the defect.[27]

Omphalocele

As with any abdominal wall defect, the care of the neonate begins with resuscitation. The initial objectives for the neonatologist are to assess and treat respiratory distress, to protect the sac from rupture and infection, and to minimize heat loss.[29,30] A nasogastric tube is passed immediately to decompress the stomach and bowel. Intravenous fluids, broad-spectrum antibiotics, and vitamin K should be started. The defect must be inspected to ensure that the sac is intact.[31] The sac should be stabilized in the middle of the abdomen to prevent kinking of the vessels and covered with a sterile, dry, non-adherent dressing to prevent trauma and heat loss. If the sac is ruptured, then the exposed bowel is treated as it is for gastroschisis.[31]

Pierre Robin syndrome

Babies with Pierre Robin syndrome carry a high risk of tongue swallowing and asphyxiation. The baby should be nursed prone to prevent the tongue from falling back into the airway, and an oropharyngeal airway inserted.[7]

Choanal atresia

Neonates with choanal atresia suffer from intermittent hypoxia. The baby should be nursed with an appropriately sized oral airway with the end or teeth cut off to keep the mouth open.[5] One must ensure the airway does not go too far into the pharynx as it may enter the esophagus and occlude the airway. This must be secured in place to prevent dislodging.

Myelomeningocele

The infant with myelomeningocele should be nursed prone in order to prevent trauma and pressure on the spinal area. A warm, sterile, saline-soaked dressing is placed over the lesion and cling film wrapped around the baby to prevent drying and dehiscence. If the sac is ruptured and cerebrospinal fluid (CSF) is leaking, or if the myelomeningocele is open, it should be covered with Betadine-soaked gauze and i.v. broad-spectrum antibiotics started. Care must be taken to prevent fecal contamination in sacral lesions.[8] Careful observation and documentation of neurological function is essential before, during, and after transportation, including evaluation of the sensorimotor level and assessment of the degree of hydrocephalus.[8,29]

Bladder extrophy

At birth, the umbilical cord should be ligated close to the abdominal wall and the umbilical clamp removed to prevent mechanical damage to the bladder mucosa and excoriation of the bladder surface.[6,32,33] Trauma and damage to the exposed bladder mucosa and plate should be avoided by covering the defect with cling film wrapped around the baby to prevent the mucosa from sticking to clothing or diapers. This will allow urine to escape while establishing a barrier between the environment and the fragile bladder mucosa. Old urine, mucus, and any detritus should be washed from the surface of the bladder with sterile saline warmed to body temperature at each diaper change and a clean layer of cling film applied, also during transfer.[32,33] Prophylactic antibiotics should be started immediately.

Cloacal extrophy

The same measurements to protect the omphalocele sac as discussed under omphalocele are applicable.

Esophageal atresia with tracheo-esophageal fistula

Most babies with esophageal atresia become symptomatic soon after birth. Symptoms include excessive drooling, coughing, or choking with the first feed. Once the diagnosis of esophageal atresia is suspected, the baby should be transferred to a tertiary referral center for further investigation and surgery. Some babies will require endotracheal intubation and ventilation. These infants are particularly at risk because mechanical ventilation is relatively ineffective due to the presence of a fistula. Therefore, the tip of the endotracheal tube should be placed proximal to the carina but distal to the fistula. Urgent transfer and ligation of the fistula are essential. Generally, the infant should be handled with care and crying avoided to reduce the risk of aspiration and abdominal distension and thereby, respiratory distress.[6] Moreover, the baby should be well oxygenated at all times and kept in a warm environment. Regurgitation of gastric contents through the fistula during transport can be prevented by keeping the head of the baby in a slightly elevated position or nursing the baby prone or in a right lateral position and thereby decreasing the work of breathing and improving oxygenation.[6,34] The blind upper esophageal pouch should be kept empty. A Replogle sump catheter should be placed in the pouch and connected to low-intermittent or low-continuous suction in order to prevent accumulation of saliva. The perforations along the side of the catheter are located only near the tip and therefore minimize the possibility of suctioning oxygenated air away from the larynx.[35] However, these double lumen esophageal tubes have a tendency to become blocked with mucus and therefore should be irrigated at frequent intervals during transport. Intravenous fluids should be started to provide maintenance and supplemental fluids and electrolytes to compensate esophageal secretion losses. Infection should be prevented and any

existing pneumonitis treated by broad-spectrum antibiotics. Vitamin K should be administered prior to transfer.

Congenital diaphragmatic hernia

The initial objective for the neonatologist and anesthetist is to stabilize the critically ill neonate before transport to the referral center (Box 8.3). A nasogastric tube should be passed immediately on diagnosis to decompress the gastrointestinal tract and to prevent further compression of the lung. Endotracheal intubation should be performed promptly in a baby with respiratory difficulty or poor gas exchange. Full sedation and paralysis and gentle ventilation will reduce the risk of barotraumas in the setting of hypoplastic, delicate lungs. Mask ventilation should be avoided because it will distend the stomach and further compromise the respiratory status. Hyperventilation, using low pressures and high oxygen content, correction of acidosis and prevention of thermal and metabolic stress are recommended to prevent pulmonary hypertension.[8] Some infants need high frequency oscillatory ventilation (HFOV) when conventional ventilation proves ineffective. The rational is that small tidal volumes and gas transport by augmented diffusion result in a lower shear stress and less barotraumas.[36] These patients may, however, pose a problem, as there is no oscillatory ventilation option commonly available on transport ventilators.[37] Clinical teams will usually have to convert oscillation to standard ventilation for the duration of transfer.[37] Careful attention to fluid balance with i.v. fluids, fresh-frozen plasma (FFP) and dopamine, if necessary, should be started to maintain adequate peripheral perfusion without causing pulmonary overload.[36] Prophylactic antibiotics should be started and vitamin K administered. Venous access through the umbilicus is useful for obtaining mixed venous blood gas specimens and monitoring central venous pressures if passed across the liver into the right atrium. Arterial access with an umbilical artery catheter will allow monitoring of systemic blood pressure and blood gas measurements at the postductal level. The baby will also need a right radial arterial line to measure preductal blood gases, and a preductal pH $\geq$7.2 and arterial oxygen pressure of $\geq$6.5 kPa with an oxygen saturation of 85–90% is acceptable.[36] This can be inserted on arrival at the referral center. Acute deterioration of the infant's condition can occur during transfer due to a pneumothorax. Equipment for intercostal drainage must be available since it can be a life-saving maneuver.[8,34]

Box 8.3 Stabilization of a neonate with congenital diaphragmatic hernia prior to transport

Maintain warm environment
Nasogastric tube
Intubation and ventilation
Intravenous fluids
Arterial blood gases
Antibiotics
Vitamin K

There has been tremendous growth in the use of extracorporeal life support for neonatal cardiopulmonary failure in the last decade. Extracorporeal membrane oxygenation (ECMO) has been used as a salvage procedure with an 80% survival rate in high-risk neonates with congenital diaphragmatic hernia who fail to respond to mechanical ventilation and meet entry criteria. ECMO is able to partly take over oxygenation and carbon dioxide removal, and thereby may allow respiratory settings to be adjusted to the mechanical and gas exchange properties of the diseased lung. In this way the goals of lung and protective mechanical ventilation can be reached.[38] The number of centers providing ECMO is still limited, so special services are needed to transport critically ill neonates to these centers. These special transport teams should be familiar with the pathophysiology of cardiac and respiratory failure and be equipped to continue the monitoring and treatment started at the referral center. They must also be able to maintain that level of care during transport, and to treat complications of the disease or therapy itself.[39,40] Now, transportable ECMO systems exist that can effectively stabilize and transport high-risk neonates to an ECMO-competent center.[41] The use of inhaled nitric oxide (NO) leads to a reduction in endogenous production of NO and its value in patients with congenital diaphragmatic hernia (CDH) is unclear.[36] Recent studies have shown that there is an immediate short-term improvement in oxygenation seen in some treated infants and this may be of benefit in stabilizing infants for transport and initiation of ECMO. However, for term and near-term infants with CDH and hypoxic respiratory failure unresponsive to conventional therapy, inhaled NO did not reduce the need for ECMO.[42]

Intestinal obstruction

Intestinal obstruction can occur as a result of a number of conditions, e.g. malrotation, duplication of the alimentary tract, intestinal atresias, necrotizing enterocolitis, Hirschsprung's disease, meconium ileus, and anorectal anomalies. The principles of care are the same irrespective of the level or cause of the obstruction.[6] The main objectives are to decompress the bowel and prevent aspiration, accurately estimate and correct fluid losses and minimize heat loss. A nasogastric tube should be passed to minimize distension and suction carried out every 15–30 minutes and left on free drainage between aspirations prior to and during transport. Serum electrolytes and proteins sequester in the intestinal wall and lumen, and isotonic i.v. fluids and colloids should be started to correct acid–base and volume deficits.[27] These must be reviewed and adjusted on a 6–8-hourly basis according to the needs of the infant.[5] Broad-spectrum antibiotics should be started prophylactically.

Necrotizing enterocolitis

Neonates with necrotizing enterocolitis (NEC) are usually transferred only if surgery is required in case of perforation

of gangrenous bowel resulting in pneumoperitoneum or progressive clinical deterioration with evidence of peritonitis.[5] Usually they are critically ill with sepsis and shock. The transfer is done preferably while the infant's condition is as stable as possible. Prompt resuscitation with crystalloids, colloids, or blood to correct acidosis is started prior to departure. Ventilation with intermittent positive pressure and inotropic support is often required.[6] Blood pressure and blood glucose must be closely monitored in these patients. A sump nasogastric tube on continuous suction is passed and suctioned regularly prior to and during transport. Broad-spectrum antibiotics to cover for Gram-positive, Gram-negative and anaerobic coverage are started.[27]

CONCLUSION

The approach to the care of the high-risk newborn has changed dramatically in the past 20 years. The newborn with a serious congenital malformation requires assessment and stabilization by experienced staff prior to and during transport to the regional center. Several studies have demonstrated that stabilization of the high-risk newborn before transport is associated with a reduction in perinatal morbidity and mortality. The pediatric transport team plays a vital role in the transport of these patients to tertiary pediatric facilities. The overall aim of transport of the surgical neonate should be to bring the services of the Pediatric Intensive Care Unit to the patient's bedside during transport to a specialist centre.

Preoperative assessment

PREM PURI AND JOHN GILLICK

INTRODUCTION

Many congenital defects that are of interest to the pediatric surgeon can now be detected before birth, thus the preoperative assessment of the newborn with a possible congenital anomaly starts *in utero*. When serious malformations incompatible with postnatal life are diagnosed early enough, the family may have the option of terminating the pregnancy in some countries. It is extremely beneficial for parents if the pediatric surgeon who is likely to manage the infant postnatally is available antenatally to provide information, be involved in management decisions, and counsel the family before birth.[1] The main goal of prenatal diagnosis is to improve the prenatal care by maternal transport to an appropriate center and delivering the baby in the timing and mode that are appropriate for the specific fetal malformation. Multidisciplinary meetings in which obstetric, neonatal, and pediatric surgical expertise is present are commonplace in most large pediatric institutions. They undoubtedly improve postnatal outcome, but as always effective communication between all disciplines is vital. Prenatal intervention for certain congenital anomalies has been reported extensively in recent years. The success of fetal surgery has varied from condition to condition; for instance antenatal closure of myelomeningocoele is associated with a lesser requirement for subsequent ventricular shunting but no significant improvement in neurologic deficit.[2] Likewise vesico-amniotic shunting for posterior urethral valves has not proved to be the 'cure-all' it was once hoped to be,[3] but it seems clear that fetal surgical intervention is here to stay and is likely to continue to expand its repertoire.[4,5] At present, however, almost all congenital malformations can be successfully managed after birth.

During the past two decades there have been significant advances in modes and techniques for prenatal diagnosis. These modes include: amniocentesis, amniography, fetoscopy, fetal sampling, and ultrasonography. The latter, enabling direct imaging of fetal anatomy, is a noninvasive technique, safe for both the fetus and the mother.[6] With further advances in screening techniques, and combining various antenatal screening modalities, such as the Serum, Urine and Ultrasound Screening Study (SURUSS) for Down syndrome,[7] the efficacy and safety of antenatal screening has improved. However, it is important to remember that sonography is operator dependent and the reliability of the information obtained is directly proportional to the skill and experience of the sonographer. For example, it is important to distinguish duodenal from jejunal obstruction in a fetus with polyhydramnios, because duodenal obstruction is associated with Down syndrome and requires further genetic evaluation while jejunal obstruction does not.

The real-time sonography may yield important information on fetal malformation, fetal movement, and fetal vital functions such as breathing movements and heart rate variability. Again, this information may guide postnatal intervention.[8,9] Serial sonographic evaluations are particularly useful in following the progression or regression of any fetal disease. All this important information is an integral part of the preoperative assessment of a newborn with any kind of congenital malformation (Figs 9.1 and 9.2).

Neonates born with congenital malformations are usually in urgent need of surgery and, in addition to their surgical problem, may suffer from a multitude of medical problems. Furthermore, they are at a period when significant physiological and maturational changes involving transition from fetal to extrauterine life are occurring. The surgical and anesthetic intervention at this time may affect this transition by interfering with normal homeostatic controls of circulation, ventilation, temperature, fluid, and metabolic balance. To facilitate a smooth preoperative course, close cooperation among the neonatologist, pediatric surgeon, and pediatric anesthesiologist is necessary.

All neonates undergoing surgery must be carefully assessed preoperatively, giving particular attention to the following:

- history and physical examination;
- maintenance of body temperature;
- respiratory function;
- cardiovascular status;

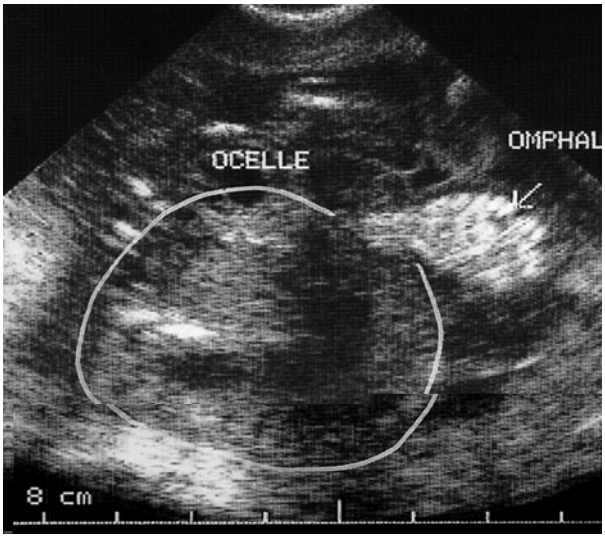

Figure 9.1 Transvaginal ultrasonogram showing a 15-week-old fetus with omphalocele (arrow). Bowel loops protrude through the abdominal wall defect.

Figure 9.2 Transvaginal ultrasonogram showing a 16-week-old fetus with diaphragmatic hernia. The dilated stomach (arrow) appears in the left hemithorax adjacent to the heart.

- metabolic status;
- coagulation abnormalities;
- laboratory investigations;
- vascular access;
- fluid and electrolytes, and metabolic responses.

HISTORY AND PHYSICAL EXAMINATION

The history of a newborn starts months before delivery, as many of the congenital malformations (e.g. Bochdalek hernia, omphalocele, gastroschisis, sacrococcygeal teratoma, and others) nowadays are known to the pediatric surgeon prenatally. The increasing importance of antenatal pediatric surgical input in counseling parents has been recently reported.[10,11] Not only are the anatomical and structural anomalies important, but even more so are metabolic abnormalities or chromosomal aberrations, which must be diagnosed prenatally or immediately after birth.

Anticipation of a problem in the delivery room is often based on prenatal diagnosis. For example, identification of a trisomy 21 in the fetus will increase the neonatologist's awareness in evaluating the infant for those abnormalities closely associated with this chromosomal defect, e.g. evaluation for duodenal atresia and congenital heart disease. Conversely, prenatal identification of specific fetal anomalies should signal the pediatrician to evaluate the infant for a chromosomal abnormality.[12]

The most important recent advance in prenatal detection of anatomical problems has been the development of fetal ultrasonography, and in experienced hands this mode of imaging can be used to detect a wide range of fetal problems and guide postnatal prognosis,[13] ranging from relatively minor abnormalities to major structural defects. However, this anatomical prenatal diagnosis is only one of the tools that aid in planning care management. An accurate and well-documented family history may increase the suspicion that an infant is at risk for an anatomical defect linked to an inherited disorder. In other cases, only the evidence of polyhydramnios should significantly increase suspicion of congenital anomalies.

Most problems are best managed expectantly by natural labor and vaginal delivery. Opinion remains divided on the benefits of elective Cesarean section for abdominal wall defects, with some authorities finding only limited usefulness,[14] and others suggesting that elective preterm delivery for gastroschisis results in an improved surgical outcome.[15] Certain malformations, however, such as conjoined twins, giant omphalocele, sacrococcygeal teratoma, or large cystic hygroma, often require Cesarean section for delivery.[16]

After birth, the assessment of the degree of prematurity, which is an integral part of the physical examination, and the specific type of congenital anomaly must be identified and recorded because of the profound anesthetic and post-operative implications that are involved. The normal full-term infant has a gestational age of 37 weeks or more, and a body weight greater than 2500 g. Infants born with a birth weight of less than 2500 g are defined as being of low birth weight (LBW). Babies may be of LBW because they have been born too early (preterm – earlier than 37 weeks' gestational age), or because of intrauterine abnormalities affecting growth (growth retardation). Small-for-gestational-age (SGA) infants are those whose birth weight is less than the 10th percentile for their age. Infants may, of course, be both growth retarded and born preterm.

The principle features of prematurity are:

- a head circumference below the 50th percentile;
- a thin, semi-transparent skin;
- soft, malleable ears;
- absence of breast tissue;

- absence of plantar creases;
- undescended testicles with flat scrotum and, in females, relatively enlarged labia minora.

The physiological and clinical characteristics of these babies are:

- apneic spells;
- bradycardia;
- hypothermia;
- sepsis;
- hyaline membrane disease;
- blindness and lung injury due to use of high levels of oxygen;
- patent ductus arteriosus.

In the SGA infant, although the body weight is low, the body length and head circumference approach that of an infant of normal weight for age. These babies are older and more mature. Their clinical and physiological characteristics are:

- higher metabolic rate;
- hypoglycemia;
- thermal instability;
- polycythemia;
- increased risk of meconium aspiration syndrome.

In relation to these differences, three important observations have been reported:

1. LBW infants have a mortality ten times that of full-sized infants.
2. More than 75% of overall perinatal mortality is related to clinical problems of LBW infants.
3. The rate of anatomical malformation in LBW infants is higher than for infants at term.[17]

MAINTENANCE OF BODY TEMPERATURE

The mean and range of temperature for newborns are lower than previously described and most temperatures $\leq 36.3^{\circ}C$ are, in fact, within the normal range.[18] Newborn infants, particularly premature infants, have a poor thermal stability because of a higher surface area/weight ratio, a thin layer of insulating subcutaneous fat, and a high thermoneutral temperature zone. The newborn readily loses heat by conduction, convection, radiation, and evaporation, with the major mechanism being radiation. Shivering thermogenesis is absent in the neonate, and the heat-producing mechanism is limited to non-shivering thermogenesis through the metabolism of brown fat.[19] Cold stress in these neonates leads to an increase in metabolic rate and oxygen consumption, and calories are consumed to maintain body temperature. If prolonged, this leads to depletion of the limited energy reserve and predisposes to hypothermia and increased mortality. Hypothermia can also suggest infection and should trigger diagnostic evaluation and antibiotic treatment if required.[18]

Illness in the newborn, particularly when associated with prematurity, further compounds the problems in the maintenance of body temperature. The classic example for such an illness is the newborn with omphalocele or gastroschisis. In their group of 23 neonates with gastroschisis, Muraji *et al.*[20] found that hypothermia (31–35.4°C), which was found in seven patients upon arrival at the hospital, was the most serious preoperative problem. To minimize heat losses, it is desirable that most sick neonates be nursed in incubators within a controlled temperature. These incubators are efficient for maintaining the baby's temperature, but do not allow adequate access to the sick baby for active resuscitation and observation. Overhead radiant heaters, servo-controlled by a temperature probe on the baby's skin, are preferred and effective in maintaining the baby's temperature; they also provide visual and electronic monitoring and access for nursing and medical procedures. Hyperthermia should be avoided, because it is associated with perinatal respiratory depression and detrimental outcomes in the short-term period post-delivery.[21]

The environmental temperature must be maintained near the appropriate thermoneutral zone for each individual patient because the increase in oxygen consumption is proportional to the gradient between the skin and the environmental temperature.[22] This is 34–35°C for LBW infants up to 12 days of age and 31–32°C at 6 weeks of age. Infants weighing 2000–3000 g have a thermoneutral zone of 31–34°C at birth and 29–31°C at 12 days. In an incubator, either the ambient temperature of the incubator can be monitored and maintained at thermoneutrality, or a servo system can be used. The latter regulates the incubator temperature according to the patient's skin temperature, which is monitored by means of a skin probe on the infant. The normal skin temperature for a full-term infant is 36.2°C, but because of many benign factors such as excessive bundling, ambient temperature may affect body temperature. Diurnal and seasonal variations in body temperature have also been described.[18] Thus, the control of the thermal environment of the newborn and especially the ill baby with congenital malformations is of the utmost importance to the outcome.

RESPIRATORY FUNCTION

Assessment of respiratory function is essential in all neonates undergoing surgery. The main clinical features of respiratory distress are restlessness, tachypnea, grunting, nasal flaring, sternal recession, retractions, and cyanosis. These symptoms are occasionally present in the delivery room due to anatomical abnormalities involving the airway and lungs and require the most urgent therapy.[23] Table 9.1 lists some common conditions that may be present with respiratory distress at birth. These conditions include: diaphragmatic hernia (Bochdalek), lobar emphysema, pneumothorax, esophageal atresia with or without tracheoesophageal fistula, congenital airway obstruction, congenital cystic adenomatoid malformation of the lung, meconium

Table 9.1 Approach to respiratory distress post-delivery.

Condition	Prenatal and perinatal associations	Clinical features	Chest radiographic findings[a]	Initial therapy
Respiratory distress syndrome (RDS)	Prematurity, lung immaturity, asphyxia, maternal diabetes, male sex	Increasing respiratory distress after birth, tachypnea, grunting, rib retractions or nasal flaring	Diffuse reticulogranular pattern, air bronchograms	Oxygen, assisted ventilation
Air leak syndromes				
Pneumothorax	RDS, meconium aspiration, endotracheal resuscitation, diaphragmatic hernia, assisted ventilation	Acute onset of sternal recession, tachypnea, cyanosis, shift in apex beat position	Intrapleural air, mediastinal shift; varying degrees of lung collapse which is always symmetrical toward the hilum	Oxygen, needle aspiration, chest drain; additional tubes may be needed when large leaks from the lung tissue are present
Diaphragmatic hernia (Bochdalek)	Polyhydramnios	Sudden respiratory distress usually soon after birth, dyspnea, cyanosis, scaphoid abdomen, shift in heart sounds, decreased breaths sounds in one hemithorax (usually left)	Bowel pattern in one hemithorax, mediastinal shift with compression of the contralateral lung. Abdominal bowel gas is sparse or absent	Nasograstic decompression; intubation and ventilation
Lung abnormalities				
Lobar emphysema	Occasionally associated with congenital malformations of the heart and great vessels	Rapidly progressive respiratory distress with dyspnea and cyanosis. Absent or diminished breath sounds over the affected side and displacement of the mediastinum	Hyperinflation of the affected side – usually left upper (increased translucency). Mediastinum may be shifted	Thoracotomy and lobectomy required. During induction of anesthesia, the ventilator pressures must be kept as low as possible until the chest is open
Congenital cystic adenomatoid malformation (CCAM)	Fetal hydrops, polyhydramnios, pulmonary hypoplasia, mediastinal shift, type II – associated anomalies including prune belly syndrome and pectus excavatum. 25% of infants are stillborn	Severe respiratory distress as above, often within hours of birth	Homogeneous mass or multicystic lesion on chest x-ray, mediastinal shift. The normal location of the stomach is of help in differentiating CCAM and diaphragmatic hernia	Thoracotomy and lobectomy
Esophageal atresia with tracheo-esophageal fistula	Polyhydramnios, associated malformations (VACTERL), excessive nasopharyngeal saliva	Mild respiratory distress. Early chest auscultation is normal. The abdomen may show progressive distension. (In the common case of atresia and fistula)	Wide, air-filled pouch in the neck or upper mediastinum. Aspiration may be noted, usually in the right upper lobe. Radio-opaque nasogastric tube will be seen to stop and coiled in the blind pouch. The abdomen frequently shows hyperaeration of the intestines	Position of the infant with head elevated 45° or prone position. Place Replogle tube in the blind proximal pouch and connect it to continuous suction. Antibiotics. Evaluate associated congenital malformations
Airway abnormalities				
Choanal atresia and supralaryngeal lesions	None	Cyanosis at rest, pink when crying; inability to pass catheter through nares; noisy upper airway	None	Placement or oral airway

[a]Combined chest and abdominal film is recommended in every newborn baby presenting with respiratory distress. An opaque nasogastric tube in the stomach has an important role both in diagnosis and treatment.

aspiration syndrome, and aspiration pneumonia. It is important to recognize that more than one condition may be present in the same patient.

If there is any clinical suspicion or sign of respiratory insufficiency, a chest x-ray should be obtained immediately after the resuscitation to determine the cause of respiratory distress. All babies with respiratory distress should have a radio-opaque nasogastric tube passed and an x-ray taken that includes the chest and abdomen in order to localize the esophagus, stomach, and bowel gas, and to avoid misdiagnosis, for example, a diaphragmatic hernia which can be mistaken for a cystic adenomatoid malformation of the lung.[24] Blood gas studies are essential in the diagnosis and management of respiratory distress. Arterial PO_2 and PCO_2 indicate the state of oxygenation and ventilation, respectively. In the newborn,[25] repeated arterial blood samples may be obtained either by catheterization of an umbilical artery or by cannulation of radial, brachial, or posterior tibial arteries. An important alternative is noninvasive monitoring techniques with transcutaneous PO_2 monitors or pulse oximeters.[26] Monitoring of arterial pH is also essential in patients with respiratory distress. Acidosis in the neonate produces pulmonary arterial vasoconstriction and myocardial depression. Respiratory alkalosis causes decreased cardiac output, decreased cerebral blood flow, diminished oxyhemoglobin dissociation, and increased airway resistance with diminished pulmonary compliance.[27]

Respiratory failure is the leading cause of death in the neonate. High-frequency ventilation, use of surfactant, use of inhaled nitric oxide (iNO) and extracorporeal membrane oxygenation (ECMO) have been shown to improve survival dramatically in selected neonates.[28–31] ECMO provides long-term cardiopulmonary support for patients with reversible pulmonary and/or cardiac insufficiency. It is well accepted as a standard of treatment for neonatal respiratory failure refractory to conventional techniques of pulmonary support.[29] Typically, patients considered for ECMO are 34 gestational weeks or older or weigh more than 2000 g, have no major cardiac lesions, intracranial hemorrhages less than grade 2, no significant coagulopathies, and have had mechanical ventilation for fewer than 10–14 days. Our knowledge of the benefits and associated risks of neonatal ECMO continue to evolve.[32]

Congenital diaphragmatic hernia (CDH) represents one of the most common surgical conditions requiring the intervention of ECMO. Recently, the discovery of significant adverse outcomes following ECMO's application in CDH neonates has begun to temper its usage.[32] More recently, a respiratory strategy based on permissive hypercapnea has proven to be successful. This strategy focuses on avoiding volutrauma/barotraumas/oxygen toxicity while using preductal oximetry to guide therapeutic interventions. Oxygen is administered to maintain the preductal SaO_2 >90% (PO_2 >60 mmHg), with a corresponding PCO_2 of less than 60 mmHg and pH of more than 7.2 An important feature of this strategy is the minimal use of a muscle relaxant. Muscle paralysis not only eliminates the infant's inherent respiratory effort but also predisposes the infant to develop tissue edema, while also accelerating lung injury.[33,34]

Surfactant replacement is commonly used in the clinical management of neonates with respiratory distress syndrome (RDS). It may also be effective in other forms of lung disease, such as meconium aspiration syndrome (MAS), neonatal pneumonia, the 'adult' form of acute respiratory distress syndrome (ARDS), and CDH. It ensues that alveolar stability is promoted, atelectasis is reduced, edema formation is decreased, and the overall work of respiration is minimized.[30]

Nitric oxide (NO) is available for treatment of persistent pulmonary hypertension of the neonate (PPHN). It decreases pulmonary vascular resistance leading to diminished extrapulmonary shunt and has a microselective effect which improves ventilation/perfusion matching. Unfortunately the beneficial effects of NO in premature infants are less clear cut, with a risk of intracranial hemorrhage being observed in some studies.[31,35] In newborns with severe lung disease, high frequency oscillatory ventilation (HFOV) is frequently used to optimize lung inflation and minimize lung injury. Further studies are needed in order to elucidate the benefits of HFOV compared to conventional ventilation in term or near-term infants with pulmonary dysfunction.[36]

In summary, the type of respiratory care in particular neonates will always depend upon clinical and radiological findings supported by blood gas estimations.

CARDIOVASCULAR STATUS

At birth, the circulation undergoes a rapid transition from fetal to neonatal pattern. The ductus arteriosus normally closes functionally within a few hours after birth, while anatomical closure occurs 2–3 weeks later.[37] Prior to birth the pulmonary arterioles are relatively muscular and constricted. With the first breath, total pulmonary resistance falls rapidly because of the unkinking of the vessels with expansion of the lungs and also because of the vasodilatory effect of inspired oxygen. However, during the first few weeks of life, the muscular pulmonary arterioles retain a significant capacity for constriction, and any constricting influences such as hypoxia may result in rapid return of pulmonary hypertension.[23]

The management of neonates with congenital malformation is frequently complicated by the presence of congenital heart disease. At this time of life, recognition of heart disease is particularly difficult. There may be no murmur audible on first examination, but a loud murmur can be audible a few hours, days or a week later.[38] A newborn undergoing surgery should have a full cardiovascular examination and a chest x-ray. The presence of cyanosis, respiratory distress, cardiac murmurs, abnormal peripheral pulses, or congestive heart failure should be recorded. If there is suspicion of a cardiac anomaly, the baby should be examined by a pediatric cardiologist. In recent years the use of the noninvasive technique of echocardiography allows accurate anatomical diagnosis of cardiac anomalies, in many cases prenatally.[8]

METABOLIC STATUS

Acid–base balance

The buffer system, renal function, and respiratory function are the three major mechanisms responsible for the maintenance of normal acid–base balance in body fluids. Most newborn infants can adapt competently to the physiological stresses of extrauterine life and have a normal acid–base balance. However, clinical conditions such as RDS, sepsis, congenital renal disorders, and gastrointestinal disorders may result in gross acid–base disturbances in the newborn. Four basic disturbances of acid–base physiology are metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis. In a newborn undergoing surgery, identification of the type of disorder, whether metabolic or respiratory, simple or mixed, is of great practical importance to permit the most suitable choice of therapy, and for it to be initiated in a timely fashion.[39] The acid–base state should be determined by arterial blood gases and pH estimation, and must be corrected by appropriate metabolic or respiratory measures prior to operation.

Hypoglycemia

The mechanisms of glucose homeostasis are not well developed in the early postnatal period; this predisposes the neonate, especially the premature neonate, to the risk of both hypoglycemia and hyperglycemia. Prenatally, the glucose requirements of the fetus are obtained almost entirely from the mother, with very little derived from fetal gluconeogenesis. Following delivery, the limited liver glycogen stores are rapidly depleted and the blood glucose level then depends on the infant's capacity for gluconeogenesis, the adequacy of substitute stores and energy requirements. From a glucose metabolism point of view, the neonate is considered to be in transition between the complete dependence of the fetus and the complete independence of the adult.[40] Box 9.1 identifies infants who are at risk for developing hypoglycemia according to three mechanisms: (1) those with limited glycogen stores, (2) hyperinsulinism, and (3) diminished glucose production. Premature and LBW infants (especially SGA infants) are at increased risk of hypoglycemia due to immature postnatal metabolic and hormonal adaptation.[41] Surgical stress and concomitant feeding practices may further exacerbate matters. Interestingly, operative stress in neonates causes significantly less energy expenditure than comparable procedures in adult practice.[42]

Box 9.1 Categories of hypoglycemia

Limited glycogen stores
- Prematurity
- Prenatal stress
- Glycogen storage disease

Hyperinsulinism
- IDM (infant of diabetic mother)
- Nesidioblastosis/pancreatic islet adenoma
- Beckwith–Wiedemann syndrome
- Erythroblastosis fetalis/exchange transfusion
- Maternal drugs

Diminished glucose production
- SGA
- Rare inborn errors

From Ogata[38] with permission.

Hypoglycemia is usually defined as a serum glucose level <1.6 mmol/L in the full-term neonate and <1.1 mmol/L in the LBW infant during the first 3 days of life. After 72 hours, serum glucose concentration should always be above 2.2 mmol/L.

Hypoglycemia may be asymptomatic or associated with a number of nonspecific signs such as apathy, apnea, a weak or high-pitched cry, cyanosis, hypotonia, hypothermia, tremors, and convulsions. The differential diagnosis includes other metabolic disturbances or sepsis. The possibility of hypoglycemia must be anticipated to prevent avoidable brain damage.

All neonates undergoing surgery should have an infusion of 10% glucose at a rate of 75–100 mg/kg body weight per 24 hours and blood glucose levels should be monitored every 4–6 hours by Dextrostix estimation and/or by blood sugar determinations. Blood glucose level should be maintained above 2.5 mmol/L at all times. The symptomatic infant should be treated urgently with 50% dextrose, 1–2 mL/kg intravenously, and maintenance i.v. dextrose 10–15% at 80–100 mL/kg per 24 hours.

Hypocalcemia

Hypocalcemia is usually defined as a serum calcium value <1.8 mmol/L. However, occasionally the ionized fraction of the serum calcium may be low, but without a great reduction of the total serum calcium level concomitantly and with the end result of clinical hypocalcemia. This may occur in newborns undergoing exchange transfusion, or in any surgical baby receiving bicarbonate.

Hypocalcemia occurs usually during the first few days of life, with the lowest levels of serum calcium seen during the first 48 hours. The most common causes of neonatal hypocalcemia include decreased calcium stores and decreased renal phosphate excretion. The LBW infants are at greater risk, particularly if they are premature, or associated with a complicated pregnancy or delivery. Hypocalcemia may be asymptomatic or associated with nonspecific signs such as jitteriness, muscle twitching, vomiting, cyanosis, and convulsions. Asymptomatic hypocalcemia can be effectively treated by a continuous infusion of 10% calcium gluconate 75 mg/kg per day and can be prevented by adding calcium gluconate to daily maintenance therapy. The symptomatic patients should be treated by slow i.v. administration of 10% calcium gluconate, 6 mL in a LBW infant and 10 mL in a full-term infant, with monitoring of heart rate to prevent too rapid an injection. Serum calcium levels should be maintained within the 2.0–2.63 mmol/L (8–10.5 mg%) range.

Hypomagnesemia

Hypomagnesemia may occur in association with hypocalcemia in SGA infants and neonates with increased intestinal losses. If there is no response to correction of calcium deficiency, a serum magnesium level should be obtained. The treatment of hypomagnesemia is by i.v. infusion of 50% magnesium sulphate 0.2 mL/kg every 4 hours until the serum magnesium level is normal (0.7–1.0 mmol/L).

Hyperbilirubinemia

Jaundice in the newborn is a common physiological problem seen in 25–50% of all normal newborn infants and in a considerably higher percentage of premature and SGA infants.[43] It is the result of a combination of shortened red cell survival, with a consequent increase in bilirubin load, and an immature glucuronyl transferase enzyme system with a limited capacity for conjugating bilirubin. This results in transient physiological jaundice which reaches a maximum at the age of 3–4 days, but returns to normal levels at the end of the first week and the bilirubin level does not exceed 170 mmol/L.

Hyperbilirubinemia in the newborn may have a pathological basis such as severe sepsis, Rh and ABO incompatibilities, and congenital hemolytic anemias. Neonatal hemolytic jaundice usually appears during the first 24 hours of life, whereas physiological jaundice, as mentioned before, reaches a peak between 2 and 5 days of life. Other causes for prolonged hyperbilirubinemia, including those often associated with surgical conditions are: biliary obstruction, hepatocellular dysfunction, and upper intestinal tract obstruction. The diagnosis of extrahepatic biliary obstruction should be done as early as possible, because early operations for biliary atresia are essential to obtain good short-term as well as long-term results.[44] The major concern in neonatal hyperbilirubinemia (high levels of unconjugated bilirubin) is the risk of kernicterus (bilirubin deposition in the brain) that can result in brain damage.

Predisposing factors for jaundice include: hypoalbuminemia (circulating bilirubin is bound to albumin), hypothermia, acidosis, hypoglycemia, hypoxia, caloric deprivation, and the use of drugs (e.g. gentamicin, digoxin, furosemide). When the serum bilirubin concentration approaches a level at which kernicterus is likely to occur, hyperbilirubinemia must be treated. The infant's gestational age must be taken into account, as kernicterus can occur in the absence of profound hyperbilirubinaemia in premature infants. In most patients, other than those with severe hemolysis, phototherapy is a safe and effective method of treating hyperbilirubinemia. When the serum indirect bilirubin level rises early and rapidly and exceeds 340 mmol/L, hemolysis is usually the reason, and exchange transfusion is indicated.

COAGULATION ABNORMALITIES

Coagulation abnormalities in the neonate should be sought preoperatively and treated. The newborn is deficient in vitamin K and this should be given as 1 mg prior to surgery in order to prevent hypoprothrombinemia and hemorrhagic disease of the newborn. Thus, 1 mg vitamin K should be administered by i.m. or i.v. injection to every newborn undergoing surgery. Neonates with severe sepsis, such as those with necrotizing enterocolitis, may develop disseminated intravascular coagulopathy with a secondary platelet deficiency. Such patients should be given fresh-frozen plasma, fresh blood, or platelet concentrate preoperatively.

Bleeding has been one of the major risks associated with neonatal ECMO.[45] However, recently the addition of the fibrinolysis inhibitor, aminocaproic acid, along with strict control of coagulation while on ECMO has been reported to decrease bleeding while undergoing CDH repair on ECMO,[46] Lately, there is an interest in developing heparin-bonded circuits, which would allow ECMO without systemic heparinization.[47]

The potential of an increased rate of intraventricular hemorrhage (IVH) has also been reported in preterm neonates following NO therapy. NO leads to a prolonged bleeding time and an inhibition of platelet aggregation.[35]

LABORATORY INVESTIGATIONS

A newborn undergoing surgery should have blood drawn on admission for the various investigations, including full blood count, serum sodium, potassium and chloride, urea, calcium, magnesium, glucose, bilirubin, and group and cross-match. Blood gases and pH estimation should also be obtained to assess acid–base state and the status of gas exchange. The availability of micromethods in the laboratory has minimized the amount of blood required to do the above blood tests. The coagulation status of infants who have been asphyxiated may be abnormal and should be evaluated.[48] Neonatal sepsis can result in disseminated intravascular clotting and severe thrombocytopenia. A platelet count $<50\,000/mm^3$ in the neonate is an indication of preoperative platelet transfusion. Blood cultures should be obtained wherever there is any suspicion of sepsis.

VASCULAR ACCESS

Most newborns with surgical conditions cannot be fed in the operative and early postoperative period. It is essential, therefore, to administer fluids in these patients by the i.v. route. With the availability of 22–24 gauge plastic cannulas, percutaneous cannulation of veins has become possible even in small premature infants. Scalp veins and veins of the dorsum of the hand and palmar surface of the wrist are the most common sites used for starting i.v. infusion. With the improvements of techniques and equipment, it is now rarely necessary to perform a 'cut-down' in order to administer i.v. fluids.

Longer-term venous access can be obtained with fine percutaneous intravascular central catheters inserted at bedside without general anesthesia; so-called PICC lines (percutaneously inserted central venous catheters). These catheters

can be successfully inserted by dedicated nursing personnel[49] and provide long-term venous access with a reduced incidence of thromboembolic complications. To minimize thrombotic complications, it is important to ensure that the catheter tip resides in a central vein.[50]

Adequacy of the intravascular volume and the function of the heart can be assessed by a central venous catheter (CVC), which can be inserted through the umbilical vein, internal jugular vein, subclavian and femoral vein. Usually catheters are placed using the Seldinger technique. This central line is often mandatory and a basic monitoring device for the anesthetist at the time of operation, and sometimes can be performed at the theatre immediately before starting the operation. It is a useful instrument for fluid resuscitation, administration of medication, and central venous pressure monitoring. The next step in the venous access hierarchy is the tunneled central line (commonly Hickman or Broviac). These are commonly placed in either a neck or groin vein in neonates. Catheters inserted in a groin site in Neonatal Intensive Care Unit (NICU) babies seem to have a lower incidence of complications.[51] PICC and tunneled central lines are relatively comparable in terms of efficacy and complications, however if access is required for longer than 15 days a tunneled central line is more suitable.[52] However, CVC lines are not free from risks. Incidence of sepsis in neonates with central lines has been reported at 24%, and in these patients the presence of a stoma is strongly linked with sepsis.[53] Most catheter-related bloodstream infections respond to appropriate antibiotic treatment and/or catheter removal.[54]

Critically ill neonates will require an arterial line especially at the time of operation, either because of the surgery, when it is expected to result in significant fluid shift and hemodynamic instability, or because of a significant underlying cardiopulmonary disease of the newborn. This arterial line is for monitoring the hemodynamic and biochemical status, especially throughout the operative procedure. Right radial artery percutaneous catheterization is preferred because it allows sampling of preductal blood for measurement of oxygen tension. If the neonate has already had an umbilical artery catheter, it is safer to use it strictly for the purpose of blood pressure monitoring and blood sampling and not for the administration of drugs.

A good fixation of all these venous and arterial lines is essential as these newborns have to be transported frequently, and reinsertion of these vascular lines can be very difficult.

In an emergency, temporary vascular access can also be obtained by the intraosseous route.[54]

FLUID AND ELECTROLYTES, AND METABOLIC RESPONSES

Estimation of the parental fluid and electrolyte requirements is an essential part of management of newborn infants with surgical conditions. Inaccurate assessment of fluid requirements, especially in premature babies and LBW infants, may result in a number of serious complications.[55] Inadequate fluid intake may lead to dehydration, hypotension, poor perfusion with acidosis, hypernatremia, and cardiovascular collapse. Administration of excessive fluid may result in pulmonary edema, congestive heart failure, opening of ductal shunts, bronchopulmonary dysplasia, and cerebral intraventricular hemorrhage.

In order to plan accurate fluid and electrolyte therapy for the newborn, it is essential to understand the normal body 'water' consumption and the routes through which water and solute are lost from the baby. In fetal life around 16 weeks' gestation, total body water (TBW) represents approximately 90% of total body weight, and the proportions of extracellular and intracellular water components are 65 and 25%, respectively.[56] At term, these two compartments constitute about 45 and 30%, respectively, of total body weight, indicating that: (1) a shift from extracellular water to intracellular water occurs during development from fetal to neonatal life, and (2) relative TBW and extracellular fluid volume both decrease with increasing gestational age.[56] Small for gestational age infants have greater total body water than corresponding appropriate for gestational age infants.[57]

In very small premature infants water constitutes as much as 85% of total body weight and in the term infant it represents 75% of body weight. The total body water decreases progressively during the first few months of life, falling to 65% of body weight at the age of 12 months, after which it remains fairly constant.[58] The extracellular and intracellular fluid volumes also change with growth. These changes are shown in Table 9.2.

The objectives of parenteral fluid therapy are to provide:

- maintenance fluid requirements needed by the body to maintain vital functions;
- replacement of pre-existing deficits and abnormal losses;
- basic maintenance requirement of water for growth.

Maintenance fluid requirement consists of water and electrolytes that are normally lost through insensible loss, sweat, urine, and stools. The amount lost through various sources must be calculated to determine the volume of fluid to be administered. Insensible loss is the loss of water from the pulmonary system and evaporative loss from the skin. Approximately 30% of the insensible water loss occurs through the pulmonary system as moisture in the expired gas; the remainder (about 70%) is lost through the skin.[58]

Table 9.2 Changes in total body water (TBW) and body compartments during development.

Age	TBW (% body weight)	Extracellular fluid (% body weight)	Intracellular fluid (% body weight)
Premature	75–80	–	?–
Newborn	70–75	45	35
3 months	70	35	35
1 year	60	27	40–45
Adolescence			
Male	60	20	40–45
Female	55	18	40

Numerous factors are known to influence the magnitude of insensible water loss. These include the infant's environment (ambient humidity and ambient temperature[22]), metabolic rate,[59] respiratory rate, gestational maturity, body size, surface area, fever, and the use of radiant warmers and phototherapy.[60] In babies weighing less than 1500 g at birth, insensible loss may be up to three times greater than that estimated for term infants.[61] Fanaroff and colleagues found insensible water loss in infants weighing less than 1250 g to be 60–120 mL/kg per day.[62] Chief among the factors that affect insensible water loss are the gestational age of the infant and the relative humidity of the environment.[63] Recently it has been reported that the application of a semipermeable polyurethane membrane ('Tegaderm') to skin of extremely LBW infants shortly after birth decreased postnatal fluid and electrolyte disturbances and significantly improved their outcome by reducing severity of lung disease and decreasing mortality.[64]

Respiratory water loss is approximately 5 mL/kg per 24 hours and is negligible when infants are intubated and on a ventilator. Water loss through sweat is generally negligible in the newborn except in patients with cystic fibrosis, severe congestive heart failure, or high environmental temperature. Fecal water losses are 5–20 mL/kg per day.

RENAL FUNCTION, URINE VOLUME AND CONCENTRATION IN THE NEWBORN

The kidneys are the final pathway regulating fluid and electrolyte balance of the body. The urine volume is dependent on water intake, the quantity of solute for excretion and the maximal concentrating and diluting abilities of the kidney. Renal function in the newborn infant varies with gestational age and should be evaluated in this context. Very preterm infants younger than 34 weeks' gestational age have a reduced glomerular filtration rate (GFR) and tubular immaturity in the handling of the filtered solutes when compared to term infants. Premature infants between 34 and 37 weeks gestational age undergo rapid maturation of renal function similar to term infants with rapid establishment of glomerulotubular balance early in the postnatal period.[65] Extremely premature infants followed to school-age, however, demonstrate a reduced GFR compared to term infants, presumably due to impaired postnatal nephrogenesis.[66]

The full-term newborn infant can dilute urine to osmolarities of 30–50 mmol/L and can concentrate it to 550 mmol/L by approximately one month of age. The solute for urinary excretion in infants varies from 10–20 mmol per 100 cal metabolized, which is derived from endogenous tissue catabolism and exogenous protein and electrolyte intake. In this range of renal solute load, a urine volume of 50–80 mL/100 cal would provide a urine concentration of between 125 and 400 mmol/L. If the volume of fluid administered is inadequate, urine volume falls and concentration increases. With excess fluid administration, the opposite occurs. We aim to achieve a urine output of 2 mL/kg per hour, which will maintain a urine osmolarity of 250–290 mmol/kg (specific gravity 1009–1012) in newborn infants. For older infants and children, hydration is adequate if the urine output is 1–2 mL/kg per hour, with an osmolarity between 280 and 300 mmol/kg.

Accurate measurements of urine flow and concentration are fundamental to the management of critically ill infants and children, especially those with surgical conditions, and extensive tissue destruction or with infusion of high osmolar solutions. In these situations, it is recommended that urine volume be collected and measured accurately.

SERUM ELECTROLYTES AND METABOLIC RESPONSES IN NEONATAL SURGICAL PATIENTS

Electrolyte and metabolic responses to surgical trauma in neonates must be assessed against the background of the normal metabolic responses of an infant to extrauterine life. Table 9.3 represents a reasonable composite of some of the changes occurring in the metabolism of electrolytes, nitrogen, water, and calories in healthy newborn infants.[67] After birth, the neonate must make a transition from the assured continuous transplacental supply of glucose to a variable fat-based fuel economy. The normal infant born at term accomplishes this transition through a series of well-coordinated metabolic and hormonal adaptive changes. In premature and growth-retarded infants there is impaired ketogenesis, in addition to imprecise neonatal insulin secretion in response

Table 9.3 Metabolic and electrolyte changes of the healthy newborn.[a]

Variable	Phase I	Phase II	Phase III
Age	1–3 days	3–6 days	6–7 days
Intake	Low consumption of breast milk	Intake of breast milk rose progressively	Intake of breast milk stable
Body weight	Decrease	Begin to rise	Increase
K^+ metabolism	Negative balance	Positive balance[b]	Positive balance
Na^+ metabolism	Negative balance	Positive balance	Positive balance
Cl^- metabolism	Negative balance	Positive balance	Positive balance
H_2O metabolism	Negative balance	Negative balance	$\pm$ Balance[c]
Urine volume	Small output	Increased	Stable
N metabolism	Negative balance	Positive balance	Positive balance
Caloric metabolism	Negative balance	Positive[d]	Positive balance

From Wilkinson *et al.*,[48] with permission.

[a]This group of ten male newborn babies include five who were healthy and five who suffered degrees of fetal distress.

[b]Potassium probably gives the most sensitive indication of metabolic changes at this time of life. The day on which potassium balance first became positive varied a good deal.

[c]Balance may be slightly positive or slightly negative.

[d]Transition to positive balance. In preterm infants all three phases can last longer and have more profound changes.

to blood glucose.[41] In response to sepsis or surgical trauma it seems that neonates divert the products of protein synthesis/breakdown from growth to tissue repair. Following surgical stress, oxygen consumption and energy expenditure in neonates return to baseline figures after 12–24 hours.[42] This is greatly different to the situation in adult surgical practice.

Table 9.4 shows fluid and electrolyte disturbances, their mechanisms, and treatment of common neonatal surgical conditions.

PREOPERATIVE MANAGEMENT OF VARIOUS SURGICAL NEONATAL CONDITIONS

Preoperative management is critical to the success of surgical intervention and the postoperative restoration of normal function. It has been observed that patients who have operations conserve sodium postoperatively.[68] In fact, this sodium concentration is usually caused by hypovolemia, which has its genesis in preoperative dehydration, because of various surgical conditions. The remedy is to provide parenteral maintenance fluid preoperatively when oral restriction of fluid is required. Some patients may need fluid resuscitation preoperatively, and their extracellular fluid volume must be restored. Assessment of adequacy of the intravascular space can be done by measurement of pulse, blood pressure, capillary filling in the skin, core temperature, temperature of the skin, urine output, specific gravity, and urinary sodium level. In addition to vital signs, an accurate weight, and especially changes in weight, electrolyte levels and calcium and blood gas analyses should be obtained. Attempts should be made to correct any abnormalities encountered during this assessment.

Newborn surgical patients shift large amounts of protein and water into tissues or into potential spaces such as the peritoneal or pleural cavity. These so-called third-space losses

Table 9.4 Fluid and electrolyte disturbances in common neonatal surgical conditions.

Neonatal condition	Fluid and electrolyte disturbances	Mechanism	Treatment
Tracheo-esophageal fistula	Mild dehydration Hyponatremia	External loss of salivary secretions, lack of intake	Volume replacement with dextrose–saline
Pyloric stenosis Pyloric atresia Peritonitis	Dehydration, hypokalemia, hypochloremia, metabolic alkalosis	Loss of gastric secretions, hydrogen ions, potassium and chloride	Volume replacement with dextrose–saline and potassium chloride
Necrotizing enterocolitis	Severe dehydration	Shift of fluids into third space, loss of sodium in stool or emesis. Low blood pressure with poor peripheral perfusion	Fast volume replacement
Perforated viscous	Hyponatremia Metabolic acidosis, hyperkalemia, high levels of BUN		Blood or blood products Dextrose–saline
Upper intestinal obstruction Duodenal atresia Malrotation (Ladd's bands) Midgut volvulus Low intestinal obstruction	Mild to severe dehydration Hypothermia, *hypochloremia, hypocalcemia*	Loss of gastric and duodenal fluids: hydrogen ions, chloride, and bicarbonate	Volume replacement with dextrose–saline and potassium chloride
Ileal atresia Hirschsprung's disease Imperforate anus Abdominal wall defects	Dehydration, hyponatremia, metabolic acidosis, hypokalemia	Loss of fluids into the intestine. Enterocolitis	Fluid replacement by dextrose–saline, plasma, and blood as needed
Omphalocele Gastroschisis	Severe dehydration, metabolic acidosis, hyponatremia	Loss of serum from the intestinal wall in gastroschisis. Aspiration of large volume of bile by nasogastric catheter. Low perfusion	Urgent fluid replacement by plasma, albumin, Ringer's lactate

are hard to quantify. Inadequate replacement of these losses can cause hypovolemia and shock. This is commonly seen in peritonitis (e.g. necrotizing enterocolitis, perforated viscus) and other congenital abnormalities such as gastroschisis and omphalocele. Infusion of colloid in the form of fresh-frozen plasma, 5% albumin, packed red cells, whole blood, or plasma-like product is required to maintain intravascular integrity in the face of protein and fluid losses. Enterocolitis complicating Hirschsprung's disease or other intestinal obstructive lesions can cause massive losses of fluid and electrolytes and result in hypovolemia, hyponatremia, metabolic acidosis, and hypokalemia. In the presence of severe enterocolitis secondary to obstruction, with accompanying large fluid losses into the intestine, adequate preoperative fluid replacement is mandatory to ensure a reasonable outcome. Intraoperative homeostasis should be maintained through administration of appropriate volumes of isotonic crystalloid and colloid.[69] The benefits of colloid over crystalloid solutions in pediatric practice are as yet unproven and are based on results extrapolated from adult practice.

Vomiting of gastric contents as a result of gastric outlet obstruction caused by a duodenal obstruction, pyloric stenosis, intestinal bands, or malrotation results in a chronic loss of gastric contents and primary hydrogen and chloride ions, in turn resulting in hypochloremic alkalosis. Chronic hypochloremic alkalosis results in hypokalemia. In renal compensation, hydrogen ions are conserved at the expense of potassium loss. Preoperative management of patients with gastric outlet obstruction includes fluid replacement and at least potential correction of the hypochloremic alkalosis by infusion of chloride and potassium chloride (Table 9.4). This preoperative metabolic correction greatly enhances surgical outcome. Table 9.5 represents the electrolyte content of bodily fluids, which are lost by various routes, and must be corrected with the appropriate balance to be replaced accurately.

Bilateral obstruction uropathy exhibits a number of important and sometimes complex abnormalities of electrolyte metabolism and acid–base regulation. Depending on the severity of a lesion, patients can have dehydration, fluid overload, hypernatremia, hyponatremia, hyperkalemia, renal tubular acidosis, and azotemia with variable degrees of renal failure. Patients with water and salt-losing nephropathy need additional salt and water supplements. Patients with defective dilutional capacity and renal failure require fluid restriction. Patients with renal tubular acidosis require bicarbonate supplementation with or without potassium exchange resins.

FLUID MANAGEMENT PROGRAM

Based on a consideration of the sources of water loss, an average parenteral fluid design for an infant receiving no oral feeding should provide about 40 mL of water per 100 cal metabolized for insensible loss and 50–80 mL/100 cal for urine, with about 5 mL/100 cal for stool water, resulting in a total volume of 100–125 mL/100 cal for the maintenance fluid losses under baseline conditions per 24 hours. LBW infants will require considerably more fluid because of an increasing insensible loss. Neonates weighing less than 1000 g may need 160 mL/kg per 24 hours and those over 1000 g may require 110–130 mL/kg per 24 hours. With premature infants, a fluid intake >170 mL/kg per 24 hours is associated with an increased risk of congestive cardiac failure, patent ductus arteriosus, and necrotizing enterocolitis.

Serial measurements of body weight are a useful guide to total body water in infants. Fluctuations over a 24-hour period are primarily related to loss or gain of fluid, 1 g body weight being approximately equal to 1 mL water. Errors will occur if changes in clothing, dressings, and tubes are not accounted for and if scales are not regularly calibrated.

The assessment of hydration status in every newborn surgical patient is essential for the infant's outcome. This can best be obtained by changes in body weight, measurement of urine flow rate, concentration of urine, hematocrit, and total serum protein. Estimation of serum electrolytes, urea, sugar, and serum osmolarity gives a good indication of the hydration status.

Anesthesia

DECLAN WARDE AND NICHOLAS EUSTACE

INTRODUCTION

Over the past 70 years or so, provision of anesthesia for the neonate requiring surgery has developed from being a relatively haphazard affair to achieving the status of a recognized subspecialty. The improved survival rates seen following surgery, where even the smallest and sickest infants are concerned, have been due in no small part to advances in anesthetic management. Equally important has been an increased appreciation of the need for an efficient smooth-working team. The success of neonatal surgery depends on maximum cooperation between surgeon, anesthetist, neonatologist, and nursing and paramedical personnel. It is appropriate therefore that everyone involved in the care of neonates, whether working inside or outside the operating theater, should be familiar with the basic techniques used in maintaining a favorable physiologic milieu in the face of surgical intrusion, while at the same time ensuring adequate anesthesia. This chapter will consider the preoperative evaluation and preparation of the surgical neonate, anesthetic equipment, choice of anesthetic agent and technique (with reference to the pharmacology of the newborn), induction of anesthesia and endotracheal intubation, maintenance and reversal of anesthesia, perioperative monitoring and fluid therapy, the anesthetic implications of congenital anomalies and, finally, specific considerations for the premature infant undergoing surgery.

PREOPERATIVE PREPARATION AND EVALUATION

Much neonatal surgery is performed on an emergency basis. However, operation is rarely so urgent as not to allow for adequate evaluation and stabilization beforehand. The cornerstone of preoperative anesthetic management is a detailed knowledge of the infant's history combined with a thorough physical examination. Consideration must also be given to the specific surgical procedure to be undertaken and its implications in terms of potential blood loss, monitoring requirements, and postoperative care.

History

Although many neonates requiring surgery are aged only a few hours, considerable information that is useful as regards anesthetic management will have been accumulated by the time of the anesthetist's visit. This information should be obtained from the parent(s) (if available) and medical and nursing colleagues. Of profound importance is an accurate estimation of gestational age, as prematurity has profound implications for the anesthetist (see later). Trends in blood pressure and heart rate, body weight, fluid intake and output, laboratory measurements, x-ray appearances, and the extent of any respiratory support required will normally be readily available and are very helpful both in planning anesthetic technique and in anticipating problems. A knowledge of recent or current drug therapy is also important.

Physical examination

The anesthetist should make a brief appraisal of the infant's overall condition and follow this with a careful assessment of individual body systems. Overhydration or hypovolemia can be detected by assessment of skin turgor, the anterior fontanelle, and liver size. Peripheral vasoconstriction may indicate either hypovolemia or acidosis. Jaundice will normally be self-evident, but anemia and cyanosis can be difficult to detect in the neonate. Pulmonary function is also less easily evaluated than in older children and adults, but any of the following may indicate impending respiratory failure: nasal flaring, tachypnea, chest wall recession, grunting respiration, or apneic spells. Airway anatomy should be carefully assessed in order that potential difficulties with endotracheal intubation can be anticipated. One should look for *other* associated congenital anomalies in the surgical neonate. This is particularly so when examining the cardiovascular system

(e.g. one-third of infants with esophageal atresia also have some form of congenital heart disease). Accurate preoperative neurological assessment is mandatory in infants presenting for anesthesia for neurosurgery.

Laboratory investigations

Minimum laboratory data required include full blood count, blood urea and serum electrolytes, blood glucose and calcium, coagulation profile, and urine specific gravity. Arterial blood gas analysis for pH, oxygen and carbon dioxide partial pressure (PO_2 and PCO_2), and bicarbonate levels is also frequently indicated. The preoperative hemoglobin level should be at least 12 g/dL – if lower, consideration should be given to transfusion with packed red blood cells prior to anesthesia and surgery. Any dehydration, hypovolemia, hypoglycemia, hypocalcemia, or hypo- or hyperkalemia should be corrected. pH, PO_2, PCO_2, and body temperature should be normalized.

Premedication

Sedative premedication is not used in neonates. However, many pediatric anesthetists consider it advisable to administer an anticholinergic drug in order to reduce secretions and to protect against bradycardia. Atropine is the most widely used drug, usually in a dose of 0.02 mg/kg by intravenous (i.v.) injection immediately prior to induction of anesthesia.

Prior to transfer to the operating theater, the anesthetist should confirm that:

- the infant has been fasting for at least 3 hours (but not for much longer unless an i.v. fluid infusion is in progress);
- blood has been crossmatched (if indicated);
- vitamin K, 0.5–1 mg i.m., has been administered (to allow for possible deficiency in vitamin K-dependent clotting factors);
- the stomach has been decompressed (especially in cases of intestinal obstruction).

Estimated blood volume, allowable blood loss, and maintenance fluid requirements should be calculated. Where it is anticipated that multiple vascular access routes will be required (e.g. for central venous pressure or direct arterial pressure monitoring), it may be advisable to establish these in the intensive care unit (ICU) before transfer to the operating theater, as it is usually easier to maintain an infant's body temperature in the ICU environment. Overall fitness must be assessed in the light of the urgency of surgery. This may require consultation between anesthetist, surgeon, and other interested personnel. If transfer to the operating theater is considered to be unacceptably hazardous, for example in the case of some extremely ill and low birth weight infants, it may be advantageous to undertake surgery in the ICU itself.[1,2]

TRANSFER TO THE OPERATING THEATER

The time during which the neonate is transferred to the operating theater is one which is not without hazard. Risks are minimized if he or she is accompanied by experienced medical and nursing personnel and if the theater is close at hand. Transfer should be in either an incubator or an isolette with overhead heater to reduce heat loss. Any treatment in progress (e.g. i.v. fluid or drug infusion, respiratory support) should be continued by the use of battery-operated infusion pumps and portable respiratory equipment. Monitoring should not be interrupted during this critical phase.

OPERATING THEATER AND ANESTHETIC EQUIPMENT

The prime objectives of neonatal anesthesia are the provision of sleep, analgesia, life support, intensive surveillance, and appropriate operating conditions for the infant requiring surgery. In order for these to be achieved it is imperative that both operating theater environmental conditions and anesthetic equipment be appropriate. It has been shown that maximum heat loss occurs between the time of arrival of the neonate in theater and the skin incision. Measures should be taken to minimize the risk and extent of this occurrence. Before the infant arrives, the theater, which should be draught free, should be warmed to a temperature of 24 or 25°C. Once the baby is removed from the incubator or isolette, he or she should be placed on a water or air mattress which has been heated to 40°C and kept covered as much as possible – plastic drapes and blankets are particularly useful in this regard. The warming mattress used must be electrically safe and accurately monitored, have an easily adjustable thermostat and a fail-safe cut-out device in the event of thermostat failure. If an overhead radiant heater is available, it should be set to maintain skin temperature at 36°C. Other measures which assist in maintaining body temperature during this critical period include warming and humidifying inspired anesthetic gases and warming i.v. and skin preparation fluids.

Breathing systems

An appropriate anesthetic circuit for use in infants needs to be light, have minimal resistance and dead space, allow for warming and humidifying of inspired gases and be adaptable to spontaneous, assisted, or controlled ventilation. While the T-piece system originally designed by Philip Ayre[3] and later modified by Rees[4] is still used by some, circle systems are currently more popular. Connectors and tubes should also offer minimal flow resistance and dead space.

Most endotracheal tubes used during neonatal anesthesia are manufactured of polyvinyl chloride. A knowledge of the probable diameter and length of tube appropriate for any given infant is essential, but must always be confirmed clinically. The optimal diameter is the largest which will pass easily through the glottis and subglottic region and will produce a slight leak when positive pressure is applied. A convenient guideline for length of orotracheal tube from gum to mid-trachea is 7 cm for an infant weighing 1 kg, with an

additional centimeter for each kilogram increase in weight.[5] Use of an endotracheal tube of too large a diameter may result in tracheal wall damage, while excess length leads to endobronchial intubation. The presence of a cuff limits the diameter of tube which can be used, with consequent increased resistance to airflow. For this reason, uncuffed tubes are invariably used in neonates. Once satisfactory positioning has been confirmed visually and by auscultation of both lungs, the tube should be taped securely to prevent accidental extubation. Consideration should be given to secondary fixation to the forehead to prevent rotational movement. Face masks are generally used for only brief periods in neonates, but should provide a good fit and have a low dead space. Oral airways are not generally necessary except in cases of choanal atresia, but have the advantage of splinting the endotracheal tube and preventing lateral movement.

The incidence of airway complications associated with the laryngeal mask airway (LMA) in infants is high.[6] However, the device can occasionally prove useful, especially when endotracheal intubation is difficult.[7–9]

Laryngoscopes

Because of the anatomical peculiarities of the infant's airway, most anesthetists prefer to use a laryngoscope with a straight blade, lifting the epiglottis forwards from behind to facilitate intubation. The Miller number 0 and 1 blades are suitable in most cases.

Ventilators

Most infants and children can be ventilated using standard adult ventilators provided the ventilator is of low internal compliance and equipped with pediatric breathing tubes. The ventilator should be capable of delivering small tidal volumes and rapid respiratory rates, and have an adjustable inspiratory flow rate and inspiratory:expiratory ratio so that peak airway pressure is kept as low as possible.[10] Pressure-controlled ventilation is widely used in order to minimize the risk of pulmonary barotrauma. A suitable temperature-controlled humidifier should be incorporated in the inspiratory side of the ventilator circuit. The ability to deliver air/oxygen mixtures through the ventilator or anesthetic circuit should be available.

Monitoring equipment

A complete range of monitoring equipment suitable for infant use is required.

CHOICE OF ANESTHETIC AGENT AND TECHNIQUE

Neonates perceive pain, while even babies born at 28 weeks' gestation mount a substantial and potentially harmful response to surgically induced stress.[11,12] Thus, few would argue with the contention that adequate anesthesia must be provided for all infants undergoing surgery. The anesthetic agents employed are similar to those used for older children and adults. However, the responses of the neonate to these potent drugs differ in a number of respects from those seen in older patients. An understanding of these differences is essential for the safe conduct of neonatal anesthesia and also influences choice of anesthetic agent and technique. The issue of possible neurotoxic effects of general anesthetics on the developing brain has received considerable attention in recent years and there seems little doubt that until there is more clarity as regards the actual degree of risk, any surgery which is truly elective should be deferred until the infant attains an as yet undefined older age.[13,14]

Inhalation agents

Inhalation induction of anesthesia with either air or nitrous oxide, oxygen and a volatile agent remains popular. Provided that respiration is not depressed, both induction of and emergence from anesthesia are rapid in infants. The reasons for this are multiple, but include the relatively higher cardiac output, greater alveolar ventilation, smaller functional residual capacity, and larger proportion of vessel-rich tissues relative to body mass seen in the newborn infant.[15–17] All potent inhalation agents lead to a dose-related depression of spontaneous respiration.[18] This is particularly important in the neonate, in whom the ventilatory response to hypoxia is one of hypoventilation. An additional consideration is that the minimal alveolar concentration (MAC) of inhaled agents required to prevent reflex responses to surgical stimulation varies with age.

HALOTHANE

Halothane was for many years the most widely used volatile anesthetic for inhalation induction in infants and young children. This is largely because it is usually associated with a smooth induction without irritant effects on the airway. It has been superseded in patients of all ages by agents which offer greater hemodynamic stability to the extent that it is currently unavailable in many parts of the world.

ISOFLURANE

Despite its lower blood gas solubility coefficient, inhalation induction with isoflurane is generally not as rapid or as smooth as with halothane. Indeed this agent has been shown to be associated with a significant incidence of hypoxic episodes during inhalation induction of anesthesia in older children.[19] Sedative premedication[20] and use of a high inspired isoflurane concentration from the outset[21] both reduce the incidence of these adverse occurrences, but are relatively contraindicated in the surgical neonate. Isoflurane has been shown to maintain systolic arterial pressure in the normal range even in preterm neonates and, unlike

halothane, does not sensitize the myocardium to the effects of circulating catecholamines. It has considerable potentiating effects on non-depolarizing muscle relaxants, so that lower doses of the latter can be used. Metabolic degradation of the agent is minimal and recovery rapid. In summary, isoflurane is an excellent agent for maintenance of anesthesia, perhaps the agent of choice in the neonate.

ENFLURANE

This agent is rarely used in neonatal and pediatric anesthesia because its irritant effects render it relatively unsatisfactory for inhalation induction.

DESFLURANE

Airway irritant effects also render desflurane unsuitable for inhalation induction in pediatric practice. However, recovery times in infants are shorter than those following other volatile anesthetics. The agent has been recommended for maintenance of anesthesia in the ex-premature infant prone to apnea and ventilatory depression.[22]

SEVOFLURANE

Sevoflurane has replaced halothane for the induction of anesthesia in neonates and children. It lacks the airway irritation associated with other newer inhalation agents and provides cardiovascular stability. Induction time with sevoflurane is shorter than with halothane in older children.[23] However, this does not appear to be the case where infants are concerned.[24] Infants undergoing inguinal herniotomy with sevoflurane anesthesia have a slower recovery than those in whom desflurane has been used with no difference in the incidence of postoperative respiratory events.[25] Higher concentrations of sevoflurane, commonly used for induction of anesthesia, can be associated with epileptiform EEG changes.[26] In older children the agent is associated with emergence delirium.[27]

NITROUS OXIDE

This gas does not provide adequate anesthesia when used alone with oxygen.[12] It is most often employed as a carrier which supplements potent volatile anesthetics, thereby reducing the concentration required and minimizing cardiovascular depressant effects. Animal work indicated that it might induce pulmonary vasoconstriction, with resultant increased right-to-left shunting in the newborn,[28] but this does not appear to be so.[29] It does cause moderate respiratory and cardiovascular depression. One limitation to the use of nitrous oxide in neonatal anesthesia is the fact that it is many times more soluble in blood than is nitrogen. As a result, the inhalation and subsequent diffusion of the gas causes an increase in the volume of compliant spaces. It follows that the agent should not be used in infants with congenital diaphragmatic hernia, lobar emphysema, or bowel obstruction.

Intravenous agents

THIOPENTONE

Despite the fact that it was introduced to anesthetic practice over 70 years ago and that many supposedly superior agents have since been developed, some still consider this drug to be the preferred agent for i.v. induction in infants. The induction dose (ED_{50} 3.4 mg/kg) is lower in neonates less than 14 days of age than in older infants.

PROPOFOL

Propofol is a highly lipophilic short-acting anesthetic agent. It has a rapid onset and short duration of action. It is currently unlicensed for use in neonates in many countries. Despite this, it is increasingly used for the induction of anesthesia in the newborn. The clearance of propofol in neonates is slower than in older pediatric patients to the extent that they are at risk of longer recovery.[30] A randomized study in infants found it to be more effective at facilitating intubation than a morphine, atropine, and succinylcholine combination.[31] It has been been used successfully in the management of pyloric stenosis.[32]

KETAMINE

This agent is associated with greater cardiovascular stability than many other anesthetic drugs.[33] However, its metabolism is considerably delayed in infants below one year of age. It has the advantages of having a profound analgesic effect and of being capable of being given by intramuscular injection.

Neuromuscular blocking agents

SUCCINYLCHOLINE

Succinylcholine has the advantage of having both a rapid onset (30 seconds) and short duration of action. Relatively higher doses (2 mg/kg) of this drug are required to produce full relaxation in infants than in adults (1 mg/kg). This is because of the neonate's larger extracellular fluid space, throughout which the drug is distributed. Succinylcholine is metabolized by plasma pseudocholinesterase. Although plasma levels of this enzyme are low in the first six months of life, activity is adequate to metabolize the drug, and recovery occurs after a similar time to that seen in adults (approximately 4 minutes).

Because of the number of side effects, including bradycardia, hyperkalemia, and triggering of malignant hyperpyrexia reactions associated with this agent,[34] it has been suggested that its use in young infants should be re-evaluated. However it remains widely used in neonates.[35]

Non-depolarizing muscle relaxants

For many years it was generally agreed that newborn infants exhibited an increased sensitivity to these agents, but recent

studies have demonstrated that full relaxation demands doses similar to those used in adults. A lower plasma concentration is required (presumably because of immaturity of the neuromuscular junction), but this is produced in any event by distribution of injected drug throughout the relatively larger extracellular fluid compartment. Alterations in plasma protein binding may also play a role in determining dose requirements which are much more variable than in adults.[36] It follows that careful titration of dose against response is advisable and that these drugs should be administered slowly to neonates. Use of a peripheral nerve stimulator as a guide to degree of relaxation is strongly recommended.[37]

ATRACURIUM AND VECURONIUM

These two agents were introduced because their duration of action was intermediate between that of succinylcholine and older non-depolarizing muscle relaxants such as pancuronium and because they offered increased cardiovascular stability. In addition, atracurium is attractive in that its metabolism is independent of hepatic and renal function, although it is dependent on pH and temperature. Recommended initial doses are 0.3–0.5 mg/kg for atracurium and 0.05–0.1 mg/kg for vecuronium. Because of their pharmacokinetic profiles, both drugs are suitable for use by continuous i.v. infusion, although atracurium infusion requirements show marked individual variation.[38]

Nightingale found the duration of effect of atracurium to be longer in infants less than 3 days of age.[39] Other studies have shown the dose-response curves of this agent to be parallel in infants, older children, and adults and in fact demonstrate recovery times to be shorter in infants.[40,41] Histamine release, an occasional problem with the drug in adults, has not caused problems in the pediatric population.[39]

Vecuronium, on the other hand, has been found to have a longer recovery time in infants compared to older children and adults and should be regarded as a long-acting muscle relaxant in this age group.[42]

MIVACURIUM

Mivacurium is a short acting non-depolarizing neuromuscular agent which is rapidly hydrolyzed by plasma pseudocholinesterase. The time course of block produced by the drug is more rapid in younger pediatric patients.[43] Satisfactory intubating conditions are not achieved as quickly as with succinylcholine but serious side effects occur less frequently.

ROCURONIUM AND SUGAMMAADEX

Rocuronium is a member of the aminosteroid family of neuromuscular blocking drugs similar to vecuronium. It has the advantage of providing a rapid onset of action similar to that of suxamethonium without the side effects associated with it. Its duration of action is similar to vecuronium. The recommended doses to provide optimal intubation conditions are 0.3–1 mg/kg.[44] It is felt that the duration of action of rocuronium in neonates is longer than in older children.[45]

Sugammadex is a selective muscle relaxant binding agent which was designed to specifically reverse the effects of aminosteroid muscle relaxants. It encapsulates rocuronium forming a tightly bound complex that prevents the muscle relaxant from acting at the receptors. Doses prescribed in adults are greater than 2 mg/kg when reversing profound muscle relaxation.[46] Data for neonates are currently unavailable.

D-TUBOCURARINE AND PANCURONIUM

These drugs were widely used in neonatal anesthetic practice in the past but have been replaced by alternatives with a shorter duration of action.

ANALGESIA

There is no doubt whatsoever that neonates perceive and respond to pain and that the intraoperative administration of potent analgesics to infants undergoing major surgery can be beneficial.[12] The neonate exhibits an exaggerated response to narcotic administration when compared with the older child.[47] The reasons for this include immaturity of hepatic enzyme systems leading to impaired conjugation and glucuronide excretion[48] and the greater permeability of the infant blood–brain barrier to these drugs.[49] Morphine elimination half-life is prolonged in babies less than 4 days old, while morphine clearance in the newborn in less than one-half that of older infants.[50] Despite concerns about adverse effects, such as respiratory depression, this drug continues to be the standard analgesic after major surgical procedures in young infants.[51,52]

It follows that where narcotic analgesics are administered to neonates, dosage regimens should be modified so that patient safety is not compromised. Morphine (0.05–0.1 mg/kg) and fentanyl (0.005–0.02 mg/kg) given intravenously are the two most widely used drugs, with the latter being particularly well tolerated haemodynamically.[33,53] Intraoperative infusions of ultra-short acting opioids such as remifentanil have been used successfully although recovery times were prolonged in some infants aged less than 7 days.[54,55]

Continuous infusions of i.v. morphine are popular for provision of postoperative analgesia in ventilated infants and those nursed in high-dependency areas. Infusion rates above 0.01 mg/kg per hour are rarely necessary. Respiratory monitoring should be continued for 24 hours after discontinuation of the infusion. The situation with regard to other infants is more difficult. It should be recognized that while failure to treat discomfort or pain effectively may have significant long-term effects, overaggressive treatment has its own morbidity.

Combined analgesic regimens, leading to adequate analgesia with lower doses of opioids and reduced side effects, have been proposed.[56,57] One study assessed the potential morphine sparing effect of acetaminophen in infants (0–2 months) after major thoracic or abdominal surgery. There was no significant benefit from acetaminophen over placebo as an adjuvant to i.v. morphine as assessed by additional

morphine boluses, incidence of increase in continuous morphine infusion, or incidence of continuous morphine infusion decrease in the second 24 hours after operation. There was no significant difference in total morphine consumption between acetaminophen and placebo groups.[58]

Codeine has been used for many years in the treatment of mild to moderate pain. However, protocols for its use in infants and children are not well-documented in the literature.[59] Non-steroidal anti-inflammatory drugs are not widely used for analgesia in infants.[60]

Regional anesthesia

It should not be forgotten that local or regional anesthetic techniques (e.g. thoracic, lumbar, or caudal epidural block, intrathecal block, intercostal block, wound infiltration, etc.) can often be used as an alternative method of providing analgesia for infants during and after surgery. They may be particularly valuable in the high-risk infant.[61–65] The recently described transverses abdominis plane (TAP) block has been used to provide analgesia following pyloromyotomy surgery.[66]

Induction of anesthesia and endotracheal intubation

Most pediatric anesthetists advocate that infants should have anesthesia induced and a muscle relaxant administered prior to attempts at endotracheal intubation. Induction technique depends on: (1) the age, size, and physical status of the infant, (2) the relative hazard of regurgitation, and (3) the personal preference of the anesthetist. In most instances, i.v. induction followed by administration of a short-acting muscle relaxant is satisfactory. Inhalation induction is an acceptable alternative. In either case, i.v. access should be established beforehand and the induction itself should be preceded by a short period of preoxygenation.

Intubation is best accomplished with the infant's head extended at the atlanto-occipital joint. This position allows the straightest and shortest distance between the lips and larynx.[67] The laryngoscope blade is inserted into the right side of the mouth, displacing the tongue to the left. As the blade is advanced the epiglottis comes into view. In the neonate this structure is long and floppy and it should be displaced anteriorly from behind to aid visualization of the larynx. If difficulty is encountered, the little finger of the left hand can be used to press gently on the larynx to improve visualization. The use of an atraumatic but rigid bougie can also be extremely valuable in these cases. Once intubation has been achieved, one should carefully auscultate both lungs to check for equal air entry, and the endotracheal tube should be securely fixed.

If it is considered at the time of induction of anesthesia that postoperative mechanical ventilation will be required, the tube should be inserted by the nasal rather than the oral route. It is difficult to manipulate a Magill's forceps in the mouth of a small infant, but flexing the neck usually facilitates passage of nasotracheal tubes.

MAINTENANCE OF ANESTHESIA

Because of the vulnerability of the infant's respiratory system, spontaneous respiration is not used for long periods in the anesthetized neonate. Mechanical ventilation helps ensure adequate gas exchange and also leaves the hands of the anesthetist free to perform other tasks. Suitable ventilators have already been discussed and, depending on the particular machine available, may be set in either pressure or volume cycled modes. With the former, suitable settings would include a fresh gas flow of 2–3 L/min, peak airway pressure of approximately 20 cmH_2O of water, a ventilatory rate of 30–40 per minute with an inspiratory time of approximately 0.6 seconds. With the latter, a delivered tidal volume of approximately 8–10 mL/kg at a rate of 30–40 breaths per minute is appropriate. Inspired gases should be warmed and humidified to prevent damage to the mucosal lining of the respiratory tract and to minimize heat loss. Manual ventilation allows rapid detection of airway obstruction or disconnection, and is particularly useful during thoracic surgery.

The most widely used agents for maintenance of anesthesia in the neonatal population are isoflurane and sevoflurane, usually combined with 50% oxygen in nitrous oxide or air, along with a small dose of relaxant.

Consideration should be given to the use of air/oxygen mixtures in preterm neonates.

REVERSAL AND EXTUBATION

If a volatile agent has been used for maintenance of anesthesia it should be discontinued shortly prior to the end of surgery. Once surgery has been completed, residual muscle relaxation is reversed by either neostigmine (0.06 mg/kg) or edrophonium (1 mg/kg) combined with either atropine (0.02–0.03 mg/kg) or glycopyrrolate (0.01 mg/kg). Sugammadex may also be used if rocuronium was the muscle relaxant used during surgery. Controlled ventilation is continued with 100% oxygen or with oxygen in air until spontaneous respiration has returned. Suctioning through the endotracheal tube is carried out if secretions are obviously present. The nostrils should be gently suctioned as a routine. The infant should not be extubated until fully awake and breathing adequately. In most cases, reversal of neuromuscular blockade and resumption of spontaneous respiration occur rapidly.[68] If difficulty is encountered this may be due to hypothermia, acidosis or hypoglycemia, or the fact that an incremental dose of relaxant has been given too close to the end of surgery.

MONITORING

The clinical condition of the anesthetized neonate can deteriorate more rapidly and with less warning than that of patients in any other age group. It follows that careful and continuous monitoring is essential. While no piece of machinery will adequately replace the careful anesthetist, there are a number of devices available which provide helpful

information that cannot be gleaned by clinical means alone. The monitoring employed in any particular case depends upon the physical status of the infant and the surgical procedure to be undertaken.

The following should be positioned prior to induction (and, indeed, regarded as the minimum equipment required for monitoring anesthetized neonates):

- ECG leads and electrodes;
- blood pressure cuff;
- core temperature probe;
- pulse oximeter probe;
- end-tidal carbon dioxide monitor;

Most neonates undergoing anesthesia and surgery require additional monitoring. The various options available will be discussed in relation to the particular body system being monitored.

Respiration

Chest wall movement should be observed continuously if at all possible. When mechanical ventilation is employed, airway pressure and minute volume alarms are mandatory. It should not be forgotten that alarms can fail. Oxygenation and adequacy of gas exchange are monitored continuously by pulse oximetry and breath by breath end-tidal anesthetic agent and carbon dioxide measurement. Serial arterial blood gas analysis is mandatory in critically ill infants undergoing major surgery.

Cardiovascular function

Observation of peripheral perfusion and palpation of a peripheral pulse are both useful but may be difficult to achieve because of problems of access. Blood pressure monitoring is essential because of the reduced cardiovascular reserve of the neonate and the risk of hypotension if high concentrations of inhaled anesthetics are used. Automated oscillotonometry is employed in most instances but concern has been expressed about the accuracy of the devices used when blood pressure is low. The cuff should be of appropriate width (approximately 4 cm).

If either the infant's physical status or the type of surgery to be performed necessitates continuous monitoring of blood pressure, a suitable vessel (usually the right radial artery) should be cannulated, the cannula being connected to a pressure transducer by narrow-bore tubing.

Central venous pressure monitoring is useful in infants with congenital heart disease, and also if significant blood loss (and replacement) is anticipated. The right internal jugular vein is usually the simplest to cannulate. Ultrasound is increasingly used to guide placement of central lines in neonates. Monitoring of left atrial pressure and/or pulmonary capillary wedge pressure is rarely indicated in the newborn.

Fluid balance

The goal of intraoperative fluid management is to sustain homeostasis by providing the appropriate amount of parenteral fluid to maintain adequate intravascular volume, cardiac output, and, ultimately, oxygen delivery to tissues at a time when normal physiological functions are altered by surgical stress and anesthetic agents.[69] Maintenance fluid requirements vary considerably within the neonatal period itself, but may be taken as being approximately 4 mL/kg per hour for infants older than 5 days of age. Assuming there is no preoperative fluid deficit, an i.v. infusion set at the usual maintenance rate should be commenced prior to induction of anesthesia. In practice, this will usually have been done in the ward. The composition of the administered fluid will vary according to the maturity of the baby and preoperative electrolyte and glucose levels. Because of the problems associated with hyperglycemic states in infancy and hyponatremia, care should be taken with the use of 10% dextrose infusions.[70,71] It is important to take into account the volume of drug diluents administered during anesthesia and surgery when calculating fluid balance.

Blood and fluid loss can be extensive and very difficult to measure during neonatal surgery. The former is best estimated by the use of small volume suction traps, by weighing small numbers of surgical swabs before they dry out, and by serial hematocrit measurements. During lengthy surgery, serum electrolytes and blood glucose should be measured at regular intervals. Urine output may be monitored by the use of adhesive collecting bags or bladder catheterization. Estimated third space loss may be replaced by continuous administration of lactated Ringer's solution at 3–5 mL/kg per hour.

While volume replacement should be undertaken when blood loss is expected to exceed 5–10% of circulating blood volume, concern has been expressed regarding the cost-benefit ratio of colloidal solutions such as albumen.[72] Because of the high hematocrit at birth, red cell replacement is seldom required during most routine neonatal surgical procedures. When required, the blood used should be as fresh as possible. The most convenient and accurate method of administration is by syringe, through a three-way tap in the i.v. line. Adequacy of volume replacement can be assessed by monitoring of blood pressure, heart rate, central venous pressure, acidosis on arterial blood samples, and urine output.

ANESTHESIA FOR SPECIFIC SURGICAL CONDITIONS

Esophageal atresia

Once a diagnosis of esophageal atresia (with or without fistula) has been made, the blind upper pouch should be continuously aspirated using a Replogle or similar tube. In general, operation may be safely delayed pending improvement of any aspiration pneumonia which has developed.[73]

Because of the high incidence of associated congenital heart disease, preoperative cardiology assessment, including echocardiography, is essential. Pre-thoracotomy bronchoscopy is practiced in some centers and may influence subsequent management.[74] Anesthesia is similar to that for other neonatal procedures, but special care must be taken with positioning of the endotracheal tube, the tip of which should be located above the carina but below any fistula present. Surgical retraction during the operation may compromise either respiratory or cardiac function, so that close monitoring is essential. If serious contamination has not occurred, or the anastamosis is not too tight, extubation may occasionally be possible at the end of the procedure.

Congenital diaphragmatic hernia

This condition was formerly regarded as one of the great emergencies of pediatric surgical practice, but it is now agreed that operation should be postponed until adequate gas exchange has been obtained and the infant is hemodynamically stable.[75,76]

Positive pressure ventilation using bag and mask should be avoided prior to endotracheal intubation, as expansion of the viscera contained within the hernia will cause further lung compression. Nitrous oxide should be avoided for the same reason. A reasonable anesthetic technique includes controlled ventilation with fentanyl 0.01–0.02 mg/kg, intermediate-acting muscle relaxant and 100% oxygen or oxygen in air as required. Great caution should be exercised in the use of volatile anesthetic agents. Airway pressures should be kept as low as possible. Should advanced ventilatory techniques such as high frequency oscillation or nitric oxide be required in order to achieve preoperative stabilization, these may be safely continued during surgery.[77,78] Most infants will require mechanical ventilation, sedation, and muscle relaxation in the postoperative period.

Intestinal obstruction

The various forms of neonatal intestinal obstruction account for approximately 35% of all surgical procedures in the newborn. The major anesthetic problems are those of fluid and electrolyte imbalance (which must be corrected preoperatively), abdominal distension (causing respiratory embarrassment), and the risk of regurgitation and aspiration of gastric contents into the lungs. Following decompression of the stomach, a rapid-sequence induction incorporating preoxygenation, thiopentone, or propofol and succinylcholine with gentle cricoid pressure is advised. Anesthesia is then continued in the usual way.

Exomphalos and gastroschisis

Exomphalos is associated with other midline defects, especially cardiac anomalies, so that preoperative echocardiography is required. This is not true of neonates with gastroschisis. Anesthetic concerns include heat and fluid loss from the exposed bowel and the fact that closure of the abdominal wall defect may push the diaphragm cephalad, thus compromising respiratory function. Special care must be taken to keep heat loss to a minimum. Fluid requirements are much greater than in normal neonates. To maintain plasma oncotic pressure, at least 25% of fluid intake should be given as colloid. Often gastroschisis is closed following staged procedures using a silastic silo. The extent of respiratory compromise can assist the anesthetist in advising the surgeon whether or not primary closure is feasible. A proportion of infants, especially after repair of gastroschisis, require postoperative mechanical ventilation. Increasingly, neonates born with a large exomphalos have the defect closed in stages over a prolonged period requiring a tracheostomy and long-term ventilation.

Congenital lobar emphysema

This condition may cause severe respiratory distress in the neonatal period. Induction of anesthesia for lobectomy should be as smooth as possible – struggling may trap large amounts of air in the affected lobe during violent inspiratory efforts.[79] Nitrous oxide can also increase the volume of trapped air considerably[80] and is contraindicated. Great care should be taken with controlled ventilation because of the risk of pneumothorax.

Myelomeningocele

If the defect is large, heat and fluid loss during surgery can pose problems and should be monitored as closely as possible. Surgery is carried out with the infant in the prone position and the chest and pelvis should be supported with pads so that the abdomen remains free from external pressure. Precautions should be taken to limit the patient's exposure to latex in theater.

SPECIAL CONSIDERATIONS FOR THE PREMATURE INFANT

Congenital defects occur more commonly in preterm infants, so that surgery is frequently required. Organs and enzyme systems are very immature and meticulous attention to detail during anesthetic and surgical management is imperative if survival rates are to be high. The large body surface area and lack of subcutaneous fat make maintenance of body temperature even more difficult than in term infants, so that a high neutral thermal environment is essential. Respiratory fatigue occurs very easily and may be exacerbated by residual lung damage following mechanical ventilation, persistent fetal circulation and oxygen dependency. The response to exogenous vitamin K is less satisfactory than in term infants and there is an increased risk of bleeding. In addition, anemia is common because of reduced erythropoiesis, a short

erythrocyte lifespan, and iatrogenic causes such as frequent blood sampling. Fluid and electrolyte management can be difficult – insensitive losses are high and hypoglycemia and hypocalcemia occur easily, while renal function and the ability of the cardiovascular system to tolerate fluid loads are reduced.

Premature infants with a history of idopathic apneic episodes preoperatively are more prone than other infants to develop life-threatening apnea during recovery from anesthesia.[81] It is recommended that infants born prematurely who undergo anesthesia and surgery while less than 60 post-conceptual weeks of age should have respiratory monitoring for at least 12 hours postoperatively in order to prevent apnea-related complications.[82] Intravenous caffeine 5 mg/kg given intravenously at induction appears to reduce the risk of apneic episodes, but respiratory monitoring is still required.[83]

Postoperative management

DESMOND BOHN

INTRODUCTION

The past 40 years have seen major advances in the management of critically ill surgical newborns. Advances in surgical and anesthetic management have led to corrective surgery being performed on complex lesions both prenatally and in low birth weight infants, placing a demand for higher levels of care in the postoperative period. While the surgery itself may be only of a relatively short duration, success or failure will inevitably depend on the level and skill of the postoperative care. During this period we have seen the introduction of innovative treatments for critically ill newborns, particularly in the management of acute hypoxemic respiratory failure including surfactant replacement therapy, extracorporeal membrane oxygenation (ECMO), and alternate ventilation which have resulted in improved survival of both term and preterm infants.

There are some distinct differences in the physiology of the newborn infant compared to the older child which may impact on postoperative management. Pulmonary vascular resistance is elevated in the first week of life, which increases the potential right to left shunting at ductal level. There are distinct differences in the coagulation system as plasma levels and activities are low at the time of birth and then increase in the first few months of life. Total body water is higher in the newborn, especially the preterm and glomerular filtration rate (GFR) is low in the first few days of life. Thermoregulation mechanisms are also poorly developed. The newborn increases cardiac output by increasing heart rate because stroke volume is relatively fixed. Finally, there are important hormonal-metabolic responses to surgery which have major implications for analgesia and sedation during and after surgery. While a comprehensive review of these topics is beyond the scope of this chapter, the significance of these physiological changes to the postoperative care of the newborn will be discussed.

RESPIRATORY MANAGEMENT

The respiratory system is probably the most vulnerable area in the maintenance of a normal physiological milieu. Abnormalities in the cardiovascular, renal, and central nervous systems are rapidly reflected in changes in function of the respiratory apparatus, which the newborn infant is ill equipped to deal with. The chest wall itself is highly compliant and increasing respiratory efforts, due to a fall in lung compliance, can result in increasing chest wall distortion and eventual apnea from respiratory muscle fatigue. Major abdominal or thoracic surgical procedures in the newborn renders the infant particularly vulnerable to develop respiratory failure, as surgery frequently has an adverse effect on the mechanics of the respiratory system. Repair of congenital abnormalities such as gastroschisis or congenital diaphragmatic hernia (CDH) frequently result in rises in intra-abdominal pressure, upward displacement of the diaphragms and a fall in total thoracic compliance.[1] Normal tidal respiration in the infant occurs around the closing capacity and therefore any loss of lung volume will result in further atelectasis and hypoxemia. Similarly, the use of inhalational anesthetic agents, narcotics, and muscle relaxants will adversely affect diaphragmatic function not only during surgery, but have an effect which extends well into the postoperative period. In order to prevent respiratory compromise in the immediate postoperative period, infants undergoing major abdominal or thoracic surgery will benefit from a period of ventilatory support, the duration of which will depend on the maturity of the infant, the underlying surgical problem, and the presence or absence of disease or abnormalities within the lung itself. Prolonged surgical procedures with large amounts of blood loss may also result in pulmonary edema secondary to large volume transfusion of blood products and electrolyte solutions.

POSITIVE PRESSURE VENTILATION

Mechanical ventilation in newborn infants came into widespread use in the early 1970s when it was appreciated that long-term intubation was both safe and feasible in small infants and that positive pressure ventilation was not necessarily damaging to the newborn lung. Very few of the

initial ventilators were specifically designed for use in children and the initial approach was to adapt adult ventilators to the child. Ventilator technology has improved significantly in the past 20 years and the currently available machines are adaptable enough to ventilate both adults and children, including infants. The most commonly used newer generation machines have a pneumatic system where oxygen and air are mixed at 50 psi. A microprocessor controls an inspiratory valve which when opened delivers heated humidified gas to the patient. The microprocessor also controls an expiratory valve which opens during expiration and filtered gas is vented to the atmosphere. The expiratory valve also controls the amount of positive end-expiratory pressure (PEEP) applied at end-expiration. The basic concept is to use positive pressure to generate a gas flow into the lung, sufficient to expand alveoli by overcoming the opposing forces generated by the elastic properties of the lung (compliance) as well as the resistance of endotracheal tube and airways. In the small child the endotracheal (ET) tube is the site of greatest resistance in the circuit. An outline description of the various types of ventilators is provided in Table 11.1.

PRESSURE PRESET VENTILATION

Time-cycled pressure limited ventilation is the most commonly used mode in neonates. A preselected pressure is set, defined as the peak inspiratory pressure (PIP), and is chosen depending on that required to deliver an adequate tidal volume, taking into account the compliance of the lung and the airway resistance. In uncomplicated postoperative ventilation adequate tidal volume can be delivered at a PIP of 15–20 cmH_2O. This may increase significantly when resistance in the lung or airway distal to the ET tube rises or when pulmonary or thoracic (lung plus chest wall) compliance falls. The airway pressure at end expiration (normally zero during spontaneous breathing) can be increased to 5–10 cmH_2O, depending on whether PEEP is required to prevent lung collapse at end expiration. Inflations are generally delivered at 30–120 bpm. When rates above 60 bpm are used this is termed high-frequency positive pressure ventilation (HFPPV). Inspiratory times vary between 0.3 and 0.5 seconds. In severe hypoxic lung disease the inspiratory time may be prolonged to increase the mean airway pressure (reverse I:E ratio ventilation). It is important to note that the tidal volume delivered by a ventilator in the pressure preset mode will change significantly according to conditions within the thorax. A fall in compliance or a rise in airway resistance results in the ventilator rapidly reaching its preselected inspiratory pressure. A reduction in delivered alveolar ventilation will inevitably follow, which can only be overcome by increasing the preset pressure. A large leak around the ET tube may prevent the ventilator reaching its cycling pressure. With pressure preset ventilation, PIP is constant but tidal volume may vary. Historically, mechanical ventilation in newborns has used the pressure control mode but with advances in ventilator technology volume ventilation has become an option.

Table 11.1 Commonly used forms of positive pressure ventilation and terminology.

Terminology	Descriptor	Comments
Volume ventilation or volume control ventilation	Preset TV. Patient cannot trigger the ventilator. Tidal volume is constant while peak inspiratory pressure (PIP) may vary	Most commonly used mode in adults and older children. Also effective in smaller children with minimal endotracheal tube leaks
Pressure ventilation or pressure control ventilation	Preset pressure. Patient cannot trigger the ventilator. PIP is constant but tidal volume may vary	Commonly used in neonates. Increasing use in adults to prevent ventilator-induced lung injury in patients with acute respiratory distress syndrome
Continuous positive airway pressure (CPAP)	Spontaneous breathing mode with no mechanically delivered breaths and positive end expiratory pressure. High gas flow delivered by a demand valve	First introduced to treat preterm infants with lung disease of prematurity. Now commonly used as a pre-extubation mode of respiratory support.
Assist control ventilation	Minimum rate and TV (or pressure) set. Patient may trigger inspiration at a more rapid rate	Common form of weaning from mechanical ventilation
Assisted ventilation	All breaths are patient triggered at the ventilator's set volume or pressure	Most commonly used as pressure support ventilation
Mandatory ventilation, intermittent mandatory ventilation (IMV) or synchronized intermittent mandatory ventilation (SIMV)	Machine-generated breath that is triggered, limited and cycled by the ventilator	Not commonly used
High frequency positive pressure ventilation (HFPPV)	Positive pressure delivered at rates >60/min by a conventional ventilator	Commonly used in neonates with severe hypoxic respiratory failure
Noninvasive ventilation (NIV), commonly known as bilevel positive airway pressure (BiPAP)	Positive pressure delivered by either nasal or face mask. Commonly used as a bilevel device with preselected inspiratory airway pressure (IPAP) and expiratory airway pressure (EPAP)	Increasingly used in patients with less severe lung disease and in premature infants. Avoids the need for intubation and risk of ventilator associated pneumonia (VAP)

VOLUME PRESET VENTILATION

The alternative ventilation system is a time-cycled, volume preset mode which will deliver a set tidal volume at a preselected rate determined by the operator. A tidal volume is chosen based on body weight and is usually in the range of 6–8 mL/kg, depending on the patient's resistance and compliance. In certain machines, the operator chooses the minute volume and ventilatory rate and the tidal volume can be calculated from these two settings. Alternatively, in other types of respirators the tidal volume and rate are selected and the minute volume calculated. The more modern machines have the ability to measure and display both the inspired and expired tidal volume at the peak of the airway, although in the event of a leak around the tube these numbers will not be accurate. As with the pressure type respirator, the duration of the inspiratory and expiratory time can be adjusted according to conditions within the thorax. With a minimal tube leak a fall in compliance or rise in airway resistance will not result in a small fall in alveolar ventilation as the machine will merely increase the pressure in order to overcome these changes. However, the PIP will rise. The respirator, however, will not compensate for leaks around the ET tube and a significant proportion of the preset volume will be vented around the tube when there is a large leak. In volume ventilation, tidal volume is constant while PIP may vary. These ventilators are most commonly used for ventilating older children where cuffed ET tubes can be used or tubes with small leaks are not a concern. They can also be used effectively in infants as long as the leak is not large. Also, with improved ET tube design, the option of using cuffed tubes in newborns can be exercised.

PATIENT–TRIGGERED VENTILATION AND SYNCHRONIZED VENTILATION

One of the major problems in the ventilation of neonates is dealing with patient/machine asynchrony. This type of asynchrony may result in suboptimal gas exchange, increased risk of barotraumas, and an increased incidence of intraventricular hemorrhage. One method of overcoming this is to use sedatives or neuromuscular blocking drugs, both of which carry with them an alternative set of problems. Neuromuscular blockade is associated with loss of vasomotor tone and circulatory insufficiency while the immature drug metabolism of the newborn may result in a prolonged effect of sedation. A more ideal solution to this problem is to use a form of synchronized patient-triggered ventilation that does not compete with the patient's own breathing pattern. The term 'triggering' in mechanical ventilation refers to the process that results in the opening of the inspiratory valve and the initiation of an inspiratory effort. This can be triggered in either the pressure or volume control modes as a patient-initiated assist/control (A/C), pressure support ventilation (PSV), synchronous intermittent mandatory ventilation (SIMV), or completely independent of the machine in the continuous positive airway pressure (CPAP) mode. The sensitivity of the inspiratory valve can be set by the operator. Patient-generated triggering is also favored because it facilitates weaning and allows the patient to use his or her respiratory muscles. Most experience in neonatal intensive care has been with the SIMV mode where the ventilator senses either airway flow or pressure and the set rate or mandatory breaths from the ventilator are triggered so they do not interfere with the expiratory phase of respiration. The potential drawback to this system was that it was frequently not sensitive enough to pick up the small negative inspiratory efforts frequently seen in the tachypneic newborn infant.

There have been a large number of randomized trials comparing different modes of ventilation in neonates with acute respiratory failure, most commonly in those with lung disease of prematurity. End points have included the incidence of bronchopulmonary dysplasia (BPD), air leak, duration of ventilation, and the incidence of intraventricular hemorrhage. Comparisons have been made between synchronized HFPPV, or triggered ventilation as A/C, SIMV, and SIMV plus pressure support with conventional mechanical ventilation. A recent meta-analysis of these trials concluded that both HFPPV and triggered ventilation were associated with reduction in air leak and shorter duration of ventilation.[2]

WEANING FROM VENTILATION

Weaning from mechanical ventilation has been considerably simplified by the widespread use of intermittent mandatory ventilation and other forms of ventilatory patient-initiated assist modes (pressure support). With these systems the infant may take spontaneous breaths from a gas flow provided either through a demand valve or from a separate spontaneous breathing circuit. In this manner the mandatory breaths are gradually reduced as spontaneous respiratory effort improves, until the child is breathing entirely spontaneously through a CPAP system. The pace of weaning depends on the type of surgery and any additional pathology within the lung and is set by observing the spontaneous respiratory rate and the measured blood gas response to changes in ventilation settings. In order to tolerate the transition from CPAP to extubation, the patient should be on FiO_2 0.4, PEEP 5 cmH_2O, with normal blood gases and a leak around the ET tube. A more recent innovation has been the introduction of pressure support ventilation where each spontaneously initiated breath generates a positive pressure from the machine to a preset inspiratory level. This helps to overcome the fixed resistance of small endotracheal tubes.

CONTINUOUS POSITIVE AIRWAY PRESSURE AND NONINVASIVE VENTILATION

An important advance in the management of respiratory failure in both newborns and older children has been the increasingly widespread use of noninvasive ventilation either in the form of a face mask or nasal cannulae. The high gas flow used in this system means that airway pressure remains positive throughout both the inspiratory and expiratory cycle. Functional residual capacity (FRC) is maintained, decreasing the work of breathing and preventing lung

collapse. There is an additional potential advantage in that avoiding invasion of the airway reduces the risk of nosocomial lung infections. The system has proved effective in the treatment of lung disease of prematurity as a primary mode of therapy. It has also been used to avoid reintubation in patients who remain tachypneic with increased work of breathing following extubation. The widespread use of CPAP in lung disease of prematurity is in fact the rediscovery of an old technique first described for the treatment of this condition by Gregory in 1971.[3] In its more modern iteration it is frequently referred to as 'bubble CPAP.' The system has proved effective in the treatment of lung disease of prematurity both as a primary mode of therapy and as a method of preventing extubation failure in premature infants.[4–10]

Noninvasive positive pressure ventilation commonly in the form of bi-level positive airway pressure (BiPAP) is defined as phasic increases in airway pressure delivered by face mask on a background of CPAP. These can be either synchronized or nonsynchronized. These systems have been used in neonates' additional support because of respiratory muscle fatigue and CO_2 retention. Although feeding intolerance, gastric distention, and/or perforation are concerns with this form of therapy, the incidence is no higher than in other forms of CPAP.[11,12]

ALTERNATIVE (NONCONVENTIONAL) MODES OF VENTILATION

High frequency ventilation

One of the major innovations in mechanical ventilation in children has been the use of high frequency ventilation (HFV) which allows patients to be ventilated at tidal volumes well below anatomical dead space and very low airway pressures (Table 11.2). HFV exists in two forms, either high frequency oscillatory ventilation (HFOV) or high frequency jet ventilation (HFJV). The former generates a high frequency sine wave which accelerates diffusion and elimination of CO_2 from the lung with very little in the way of bulk gas flow. Oxygenation is achieved by a high fresh gas flow into the circuit and, by adjusting this, the device is capable of generating mean airway pressures in excess of 30 cmH_2O. HFJV was first developed in clinical anesthesia to provide small tidal volume ventilation for procedures involving the larynx and tracheobronchial tree where the ability to achieve a normal CO_2 with low airway pressures provided ideal operating conditions. In HFJV the lung is ventilated by the rapid injection of gas into the airway at rates of 100–600 per minute with a supplemental air/oxygen gas flow entrained. Gas exchange occurs by a combination of very small amounts of bulk flow and enhanced diffusion.

High frequency oscillatory ventilation

One of the principal strategies for the prevention of ventilator-associated lung injury is the use of HFOV. This has been tested in a large number of randomized clinical trials in preterm infants. Although the original multicenter trial in 1989[13] suggested that there was an increased incidence of intraventricular hemorrhage associated with its use, subsequent trials have led to a general acceptance that it is a safe and effective form of ventilation without there being any clear demonstrable benefit in terms of increased survival or decreased incidence of chronic lung disease.[14–18] This may be because the lung recruitment strategies (the open lung approach) in the initial studies were not aggressive enough or introduced early enough. Most of the protocols in neonatal trials have used levels of mean airway pressure (MAP) of 1–2 cmH_2O above that on conventional mechanical ventilation (CMV) increased in small increments. The PROVO trial in 1996,[19] which was an early intervention study and used a clearly defined lung recruitment protocol with all patients receiving surfactant, was the first to show a reduction in chronic lung disease with HFOV (24 versus 44%), less surfactant usage and decreased hospital stay. Clearly, if one is to use HFOV, early intervention before the lung sustains significant damage is key and has been demonstrated by the excellent results published by Rimensberger[20] where premature infants at risk from infant respiratory distress syndrome (IRDS) were placed on HFOV in the delivery suite. The incidence of chronic lung disease, as defined as oxygen dependency at 36 weeks' postgestation age, was zero compared to 34% in historical controls. The optimal recruitment strategy also needs to be determined. Copying the recruitment maneuvers (30 cm H_2O for 15 seconds) used in the original experimental lung lavage model is frequently insufficient to achieve this in premature infants. Thome[21] has shown that lung volume recruitment on HFOV is both time and pressure dependent in these patients. He was able to show that stabilization of mean lung volume after modification of mean airway pressure took 2–25 minutes (median, 9 minutes) in premature infants. HFOV has also proved effective in the management of term and near term infants with persistent pulmonary hypertension of the newborn (PPHN), meconium aspiration, and in the preoperative stabilization of infants with CDH.[22–24]

Table 11.2 Characteristics of high frequency ventilators.

	HFOV	HFJV
Rate	180–900 per min	100–600 per min
TV	At high rates (>10 Hz) minimal TV. TV increases as rates decreases	TV 2–5 mL/kg
Expiration	Active	Passive
Gas movement	Diffusion	Diffusion plus bulk flow
Indications	Used in lung disease associate with low lung compliance (MAS, IRDS) as part of an open lung strategy. Also has been extensively used in CDH	IRDS, MAS, and bronchopleural fistula

Hz, cycles per second; IRDS, infant respiratory distress syndrome; MAS, meconium aspiration syndrome; TV, tidal volume.

High frequency jet ventilation

High frequency jet ventilation was first developed in clinical anesthesia to provide small tidal volume ventilation for procedures involving the larynx and tracheobronchial tree where the ability to achieve a normal CO_2 with low airway pressures provided ideal operating conditions. Although HFJV and HFOV operate on the same physiological principles of very small tidal volumes delivered at high rates, they should not be considered as merely two variations on the same theme. HFJV uses a high pressure gas source to deliver small tidal volumes at frequencies of 1–5 Hz. Apart from the slower rates used in HFJV, the other major difference is that expiration is passive in the former while it is active in HFOV. The published experience with jet ventilation in neonatal respiratory failure is considerably less than oscillation and until recently only documented its use as a rescue therapy in patients with either hypoxemia despite high PEEP or established air leak. The rationale for the switch is usually the avoidance of further barotrauma by the use of smaller tidal volumes while maintaining a high mean airway pressure, but with lower peak airway pressures. Improvements in oxygenation can be obtained by driving up the MAP but this usually involves some compromise to cardiovascular function because of the transmitted pressure. A randomized controlled clinical trial of HFJV in neonates with pulmonary interstitial emphysema (PIE) has shown an improvement in PIE and lower mortality rate in infants treated with HFJV compared to conventional ventilation.[25]

Several prospective randomized trials have compared HFJV in both premature and term infants with acute hypoxemic respiratory failure (AHRF).[25–27] The two studies on the premature infants showed conflicting results. Keszler[25] found better pulmonary outcomes in patients randomized to HFJV without a difference in survival while Wiswell[27] found no difference in pulmonary outcomes but increased risk of death and intraventricular hemorrhage associated with the use of HFJV. Engle,[26] in a randomized trial in term and near term infants, found improved oxygenation without any difference in survival.

There are some technical safety concerns about the adequacy of humidification both in this system as well as HFOV. In addition there are reported cases of tracheal damage (necrotizing tracheobronchitis) in severely ill newborn infants. The airway pressures measured in HFJV from the catheter within the trachea probably represent a significant underestimate of true MAP because of the Bernoulli effect and consequently there is likely to be a significant amount of auto-PEEP present.

Although HFJV and HFOV operate on the same physiological principles of very small tidal volumes delivered at high rates, they should not be considered as merely two variations on the same theme. Apart from the slower rates used in HFJV, the other major difference is that expiration is passive in the former while it is active in HFOV. Both techniques have the potential advantage of reducing the incidence of ventilator-induced lung injury and have been extensively used in newborn infants with lung disease of prematurity and meconium aspiration syndrome.

There is now 20 years of accumulated clinical experience with the use of HFV in neonatal lung disease, either as a primary or rescue therapy in lung disease of prematurity. The impact on the reduction in mortality associated with the widespread use of surfactant replacement therapy in this disease over the same era has meant that clinical trials of HFV compared with CMV were unable to demonstrate any survival benefit. The same can be said of clinical trials that use the incidence of chronic lung disease as their end point.[28,29] On the other hand, case series have suggested improved outcomes when used in the rescue mode in term and near term infants with CDH, meconium aspiration, and bronchopleural fistula.

RESPIRATORY GAS EXCHANGE

Carbon dioxide elimination

Adequate CO_2 elimination depends on the ratio between CO_2 production (metabolic rate) and alveolar ventilation (tidal volume − dead space). In the normal spontaneous respiration, the two sides of the equation balance and normal CO_2 homeostasis is preserved. An increase in CO_2 production, as seen during a rise in body temperature or sepsis, can normally be met by increased alveolar ventilation and the child achieves this by increasing its respiratory rate. Similarly, abnormalities within the thorax will result primarily in an increase in respiratory rate rather than volume in order to achieve the same alveolar ventilation. In mechanical ventilation, the $PaCO_2$ level can be controlled by adjusting both ventilator rate and the volume delivered by each respiratory cycle (alveolar ventilation = tidal volume − dead space × frequency). With a pressure preset ventilator, minute ventilation is increased by increasing the PIP and rate, while in the volume respirator $PaCO_2$ is controlled by adjusting rate and delivered volume.

Oxygen uptake

The diffusion gradient for oxygen within the lung is high as the PO_2 in the pulmonary artery is 40 mmHg (5.3 kPa) compared with alveolar PO_2 (PAO_2) of 105 mmHg (14 kPa) while breathing air. Despite this favorable gradient for oxygen diffusion, the alveoli must remain open for gas exchange to occur. In the normal lung, due to the hysteresis, the alveoli open during inspiration and remain open during most of expiration and only cease gas exchanging at end expiration. In the diffusely atelectatic lung, of which lung disease of prematurity is a prime example, the alveoli become unstable and tend to collapse at low lung volumes because of surfactant deficiency. The degree of alveolar expansion depends to a large part on mean airway pressure (Paw), which is a measure of the average pressure that the alveoli are exposed to during the respiratory cycle. This in turn is determined by a combination of the PIP, PEEP, and the duration of the inspiratory phase of the respiratory cycle. Attempts to improve oxygenation are based on the manipulation of one or more of these variables in order to increase Paw. The simplest and most time-honored of these measures

is to increase the amount of PEEP, which was first introduced to improve oxygenation in lung disease of prematurity. Abnormalities within the lung that cause a large difference between PAO_2 and PaO_2 (A-a DO_2) may also be compensated for by increasing the FiO_2.

Setting ventilator parameters

Choosing the options in ventilatory management of the newborn are in a large part determined by conditions within the patient. The objective is to maintain gases within a physiological range (PaO_2 8–12 kPa, $PaCO_2$ 5–6.5 kPa) using the lowest FiO_2 and airway pressure compatible with that aim. This may be relatively simple where the lungs are normal, but may require a completely different strategy in the presence of abnormalities within the abdomen or thorax. Therefore, one must take these considerations into account when selecting ventilator settings for the newborn infant. Generally speaking, the term infant with normal respiratory system compliance and airways resistance on a pressure preset ventilator would require a PIP of 10–20 cmH_2O, a rate of 30–40/minute, an FiO_2 0.25–0.35 and an inspiratory to expiratory ratio (I:E ratio) of 1:2 or 1:2.5 and a minimum of 3–5 cmH_2O PEEP as a routine. Using a volume respirator, a tidal volume of 6–8 mL/kg would be adequate in a newborn with normal lungs. Having selected these settings, the adequacy of gas exchange must be verified by an arterial blood gas sample to ensure that hyperventilation is avoided.

HYPERVENTILATION AND VENTILATOR-ASSOCIATED LUNG INJURY

Since the first introduction of intubation and ventilation for the treatment of neonates with acute respiratory failure, the objective has been to adopt a pattern of ventilation designed to produce blood gases within normal physiological parameters. Since the original description of the induction of a respiratory alkalosis to reverse ductal shunting in PPHN,[30] hyperventilation became one of the mainstays of treatment in neonatal respiratory failure. Although there may be a short-term benefit from this approach, there have been no prospective trials that have shown improved outcome with the use of hyperventilation. In addition, there is now increasing concern that this may result in serious adverse consequences. The high inflation pressures required to reduce the CO_2 can frequently result in a ventilator-induced injury to the lung, thereby compounding a pulmonary vascular problem with a pulmonary parenchymal problem. There are numerous animal models of ventilator-induced lung injury where pulmonary edema, hyaline membrane formation, and pulmonary epithelial cell injury can be produced in normal lungs with peak inflation pressures as low as 30 cmH_2O. As few as six manual inflations using high pressure at the time of birth have been shown to induce lung injury in an animal model.[31] In 1985, Wung was the first to suggest that PPHN could be treated effectively without the use of hyperventilation and showed excellent outcomes with pressure limited ventilation and hypercarbia.[32] This is true not only in the premature lung but also in the dysplastic lung of infants with CDH which are equally vulnerable to injury.[33] There are several series reporting improved survival using a pressure limited strategy which does not use hyperventilation to treat ductal shunting.[34–36] There is also increasing evidence that low $PaCO_2$s may adversely affect cerebral blood flow and injure the developing brain[37] and may partly account for the alarmingly high incidence of neurosensory deafness seen in these infants.[38–43] Conversely, hypercarbia increases cerebral protection in experimental models of neonatal brain injury.[37,44] The first human randomized trial that has addressed the issue of hypercarbia in neonates showed a decrease in ventilator days and no adverse events when permissive hypercapnia was compared with the conventional approach in 1999.[45] While the case for 'permissive hypercapnia' in improving the outcomes in the treatment of newborns with acute respiratory failure remains to be proven there is increasing recognition that hyperventilation may have adverse consequences for long-term brain function.[46] In terms of avoidance of ventilator-associated lung injury, the use of nasal CPAP together with early intervention with surfactant has been shown to improve the outcome in premature infants with moderately severe forms of IRDS.[8,9,47]

RESPIRATORY MONITORING

Blood gas measurement

Monitoring of respiratory function in the postoperative period requires measurement of gas exchange. The most reliable and accurate method is to measure PaO_2, $PaCO_2$, and pH from an arterial sample. The common sites for invasive arterial monitoring are umbilical artery (newborns) and radial or dorsalis pedis arteries in older children. In the newborn, a blood gas drawn from the right radial will measure pre-ductal PaO_2 values whereas the other sites will be post-ductal. On some occasions the left subclavian artery is juxta-ductal and will therefore measure similar values to the right. With the newer generation of automated blood gas machines, samples as small as 0.1 mL are sufficient for a full blood gas and pH profile. This is particularly important in premature infants in whom frequent sampling may necessitate 'top up' transfusions. An alternative method of measuring $PaCO_2$, PaO_2, and pH is to use 'arterialized' capillary blood taken from an area of skin that has been vasodilated by warming, usually the heel. This technique is generally reliable for $PaCO_2$ and pH. With arterial PaO_2 levels above 60–70 mmHg, accuracy drops off considerably.

Noninvasive oxygenation and CO_2 monitoring

The development of pulse oximetry has made it possible to measure arterial saturation and heart rate on a beat-to-beat basis and has proved to be a reliable and effective method of monitoring and trending oxygenation. The absolute values do not correlate well when measured at blood saturations of

less than 70% and in low cardiac output states where there is inadequate perfusion for a pulse to be recorded by the probe. Careful sensor placement is important to prevent distorting by light and the probes are sensitive to light artifact. It is a useful monitor to record the rapid response of PO_2 to interventions such as suctioning and changes in ventilation. Due to the shape of the oxygen hemoglobin dissociation curve, high PaO_2 levels (>95 mmHg, 12.6 kPa) will not be accurately reflected by saturation measurements. In the premature neonate (<1000 g), where high PaO_2 levels may predispose to the development of retinopathy of prematurity (ROP), the transcutaneous PO_2 ($TcPO_2$) probe is the preferred method of monitoring oxygenation as it indirectly measures the actual PaO_2.

The $TcPO_2$ technique uses a modified Clark electrode with a heating element that raises skin temperature to between 41 and 44°C in order to augment cutaneous blood flow. These devices correlate well with arterial oxygen in small infants who have little subcutaneous tissue, and are reliable where cardiac output and peripheral perfusion are adequate. However, quality declines in the older child and in low cardiac output states. Transcutaneous CO_2 monitoring uses the modified Severinghaus probe with a heating element, which heats the skin to 41–44°C. These have proved to be reliable in small infants. While transcutaneous PO_2 and PCO_2 monitoring are useful trending devices, absolute values should be occasionally checked against an arterial sample. Greater accuracy is obtained by careful maintenance of the probes and care in calibration and application to the skin. The risk of skin damage from the heating element requires that the measuring site be changed every 4–6 hours.

End-tidal CO_2 monitoring

Capnography is the measurement and display of CO_2 concentration in the airway using an infrared technique and has recently become a standard fixture on most mechanical ventilators. In the normal capnogram CO_2 is zero during inspiration and at the beginning of expiration as anatomical dead space gas is washed out. The concentration then rises as alveolar gas mixes with anatomical dead space gas and reaches a plateau with an upward slope when pure alveolar gas reaches the sensor. The end expiratory point of the plateau before the inspiratory cycle starts is the end-tidal pressure ($PetCO_2$) and approximates alveolar PCO_2 ($PACO_2$). This is usually approximately 5 mmHg less than the $PaCO_2$. The $PetCO_2$ provides useful information of the adequacy of alveolar ventilation in patients with normal lungs but in the presence of lung disease $PaCO_2$–$PetCO_2$ gradient widens.

MANAGEMENT OF THE INTUBATED PATIENT

Tube size and position

Newborns are commonly managed with nasotracheal tubes rather than oral tubes unless there is some congenital abnormality of or injury to the nasal area that precludes their use. They provide for greater patient comfort and acceptability and the tube may be more securely fastened to the face and upper lip. In older children oral tubes are satisfactory for brief periods of ventilation but nasal are frequently preferred. In terms of length, the tip of the tube should reach to the level of the clavicles on the chest film. Tubes that extend lower may enter a main bronchus, especially during flexion or extension movements of the head. A routine chest film should be obtained immediately after intubation or change of tube position to ascertain correct placement. The proximal end of the tube should protrude sufficiently far from the nose so that the tube connector does not impinge upon the external nares. Severe excoriation of nares and erosion of cartilage can occur with long-term intubation. In selecting a tube of correct diameter, the size should be sufficient to provide a small leak under positive pressure, but not large enough to provide an airtight seal. Tight fitting tubes left *in situ* for prolonged periods will lead to tracheal stenosis and vocal cord granuloma formation, requiring tracheostomy and extended postoperative care. At the same time, too large a leak will make positive pressure ventilation extremely difficult. In the term newborn 3, 3.5 or 4 mm tubes may be used depending on the size of the infant; 2.5 or 2 mm may be used in premature infants, but these are prone to block with secretions (Table 11.3). Cuffed tubes in pediatric sizes are now available with low pressure inflatable cuffs that have been used successfully in small children and newborns.

Endotracheal tube suctioning

Routine suctioning to maintain the patency of the endotracheal tube and prevent atelectasis is of prime importance, especially in newborns. However, even skillful suctioning can lead to a profound fall in PaO_2 and bradycardia, especially in patients who are already hypoxemic. Consequently, prior to suctioning, all patients should have their lungs inflated with 100% oxygen by manual hyperventilation. A catheter of a size that does not occlude the lumen of the endotracheal tube should be chosen so that the suctioning does not generate large enough negative pressures to cause atelectasis. End-hole catheters should be used rather that the side-hole type, which can trap and injure the respiratory tract mucosa. Suction should only be applied while the catheter is being withdrawn and for not longer than a few seconds. Between each suctioning, the patient should be ventilated with 100% oxygen. The onset of bradycardia during suctioning is an

Table 11.3 Endotracheal tube size selection.

Age	Endotracheal tube diameter (mm)
Preterm	2.0–2.5
Term newborn	3.0–3.5
1 month	3.5
1–6 months	3.5 or 4.0
1 year	4.5

immediate indication to stop and ventilate with oxygen, as it is almost always indicative of hypoxemia.

Endotracheal suctioning should always be performed as a sterile procedure using surgical gloves and a sterile catheter. The objective should be to pass the catheter down as far as it will go to beyond the carina and down either one or the other main bronchus, at the same time stimulating the patient to cough. The catheter tip may be encouraged to pass down either one or the other side by rotating the head to the opposite side. The presence of unduly thick secretions in the respiratory tract should alert one to the possibility of inadequate humidification. Intrapulmonary hemorrhage increases the chances of endotracheal tube blockage substantially and indicates the need for more frequent suctioning.

Humidification

Humidification is one of the least emphasized but most important aspects of respiratory care. The small diameter endotracheal tube in the newborn patient is notoriously prone to blockage from secretions, especially where they become inspissated due to inadequate humidification. Too much humidification leads to 'rainout', as the inspired gas cools during its passage between the humidifier and the infant's airway and can lead to the absorption of considerable amounts of water.

The goal of optimal humidity is to deliver fully saturated gases (44 mg/L H_2O) at a temperature of 37°C to the peak of the airway. This can only be achieved with the heated water bath type humidifier as opposed to the nebulizer type. The temperature of the water bath must be raised above body temperature, to about 40°C in order to deliver gases at 35–37°C at the ET tube. Between the humidifier and the ET tube, considerable condensation of water vapor may occur as the gases cool, which may impede gas flow. This problem has been overcome to some extent with the newer humidifiers which have a heated electric coil inside the inspiratory line. This maintains a consistent temperature throughout the inspiratory line by means of a dual servo mechanism with temperature sensors in both the water bath and at the patient's airway. There is therefore less cooling of gases in the respirator tubing and inspired gas is delivered to the ET tube fully saturated and at 37°C.

The condenser humidifier or 'Swedish nose' is also capable of supplying moisture and preventing heat loss from the respiratory tract. While obviously not as efficient as the water bath type, it is particularly useful for patient transport or for providing humidity to children who have been intubated for upper airway problems. As the condenser humidifier becomes increasingly saturated, the airway resistance tends to rise and they must be changed every 24 hours.

ACUTE HYPOXIC RESPIRATORY FAILURE IN THE NEWBORN: NONVENTILATOR THERAPIES

A number of innovative techniques have recently been introduced into the management of acute respiratory failure which include high frequency ventilation, inhaled nitric oxide, and, if all else fails, ECMO. It is very likely that a significant number of these therapies are being resorted to as rescue therapy from ventilator-induced injury. This speculation is supported by the figures from the Extracorporeal Life Support Organization (ELSO) Registry which show the annual number of cases is actually falling for the first time since neonatal ECMO was first introduced in the late 1970s. It is likely that we will recognize that the single most important advance in ventilator management will be the recognition that the solution is part of the problem and that we need to adapt our ventilator to the underlying pathophysiology of the lung rather than outmoded physiological imperatives.

Inhaled nitric oxide

As well as having a key role in the modulation of vascular tone, exogenously administered nitric oxide (NO) has been shown to be a highly selective pulmonary vasodilator. When administered by inhalation NO diffuses rapidly from the alveolus into the endothelial cell and the vascular smooth muscle where it stimulates guanylate cyclase to produce cGMP. The systemic nitrodilators currently in clinical use work by a similar mechanism but their pulmonary vasodilator effects cannot be separated from the systemic. In the case of inhaled nitric oxide (iNO), the vasodilator properties are confined to the pulmonary circulation because the marked affinity of NO for the hememoiety of hemoglobin results in its rapid binding and inactivation as soon as it crosses the alveolar capillary membrane which explains its highly selective effect on the pulmonary vascular bed.

A series of randomized control trials (RCTs) have shown that iNO improves oxygenation[7,48–51] and decreases the need for ECMO[52–54] in term and near term infants with PPHN. Although the response in terms of oxygenation may be dramatic, by no means do all infants respond. Those infants with pure right to left ductal shunting and little parenchymal lung disease would be expected to respond best while the infant with extensive pulmonary parenchymal disease as a cause of their hypoxemia (eg. meconium aspiration) may have little response. The combination of HFOV and iNO together has proved particularly effective in one RCT.[55]

An interesting alternative approach to iNO is to enhance the effect of endogenous production of NO in the vascular endothelium by blocking the inactivation of cGMP by phosphodiesterase inhibition. Two phosphodiesterase inhibitors, dipyridamole and sildenafil, have been successfully used to treat the rebound pulmonary hypertension associated with withdrawl of iNO.[56–58] Sildenafil by i.v. infusion has also been shown to be effective in infants with PPHN who have not been responsive to iNO.[59]

SURFACTANT REPLACEMENT THERAPY

Probably the most important advance in neonatal medicine in the past 30 years has been the introduction of surfactant

replacement therapy for the treatment of lung disease of prematurity. Surfactant, either used prophylactically in patients at risk for or with established lung disease of prematurity, has resulted in a reduction in mortality and in the incidence of air leak but has not made a major impact on the incidence of chronic lung disease.[60] This may be because it has not been used with an optimal ventilation strategy that minimizes ongoing lung injury. Also, there are important differences between synthetic and natural surfactants, the latter containing surfactant proteins which may have important anti-inflammatory properties.[61,62] In term and near-term infants with meconium aspiration the situation is less clear cut. These infants are not surfactant deficient but it may be inactivated by lung injury. Human studies have shown that the use of surfactant replacement therapy in this patient population is associated with decreased need for ECMO.[63,64]

VENTILATOR MANAGEMENT OF CONGENITAL DIAPHRAGMATIC HERNIA

The pre- and postoperative ventilator management of infants with CDH is one of the key factors in the improvement in survival seen over the past few years.[34–36,65] Newborn infants presenting with this anomaly have a mixture of pulmonary hypolasia, i.e. reduced alveolar number, as well as pulmonary vascular disease consisting of a reduced pulmonary vascular bed as well as a reactive and potentially reversible component due to the increased smooth muscle in the small pulmonary arterioles. The dysplastic lungs of these infants are highly susceptible to pulmonary barotrauma caused by high peak inflation pressures. The end result is hyaline membrane formation and pulmonary alveolar hemorrhage.[33] Improved survival has been noted in several centers where the focus has been on the use of low peak airway pressures with less emphasis paid to treatment of right to left shunting through the ductus arteriosus and patent foramen ovale (PFO).[34,66] Attempts to reverse this by inducing alkalosis with hyperventilation will only cause pulmonary barotrauma. Therefore the focus should be on maintaining a pre-ductal SaO_2 greater than 85% and not treating right and left shunting at the ductal level with hyperventilation. The objective for mechanical ventilation should be to maintain the PIP at $<25\,cmH_2O$ without necessarily striving to achieve a normal $PaCO_2$. It is our practice to switch to HFOV if the PIP is above $25\,cmH_2O$ on conventional ventilation as this is a less injurious mode of ventilation. The strategy with HFOV in CDH is very different to that used in other forms of neonatal lung disease. In this instance the lung is hypoplastic and not recruitable and therefore we use a mean airway pressure of no more than $14–16\,cmH_2O$. With this approach we find that HFOV is a very efficient way of maintaining normal $PaCO_2$ levels without inflicting further injury on the lung. Survival rates of >80% and decreased ECMO use have been reported by centers using this approach.[24,67] It is also our practice to obtain a cardiac echo on all CDH infants to rule out structural heart disease and to assess the degree of right to left shunting. In most infants the right ventricular pressure is elevated with either bi-directional shunting, indicating that right ventricular pressure is systemic, or pure right and left shunting in which case it is supra-systemic. iNO has been used extensively in CDH although it does not seem to be as effective as in other forms of PPHN.[52] In the event that pulmonary artery (PA) pressure is suprasystemic, prostaglandin can be infused to maintain ductal dependency and prevent right heart failure.[68–70]

POSTOPERATIVE SEDATION AND ANALGESIA

One of the most important advances in postoperative care in the past decade has been a far greater understanding of the need for analgesia and sedation in newborn infants who have had major surgery. There is now strong evidence that neonates exposed to multiple painful procedures, either during intrauterine or early in extrauterine life, exhibit acute physiological responses which are detrimental.[71–73] This has been associated with an increased physiological stress response resulting in hypertension and an increased incidence of intraventricular hemorrhage in preterm newborns. The increased hormonal and metabolic responses to major operations and to painful stimuli associated with procedures in the ICU also have the potential to increase the incidence of morbidity and mortality.[74–76] Given the limited endogenous reserves of carbohydrates, proteins, and fats in the newborn it is perhaps not surprising that in the stressed state these reserves are rapidly exhausted. There is also evidence that failure to blunt painful stimuli in the developing nervous system results in changes within the spinal cord with altered long-term sensitivity to pain.[77] There are now a number of studies which show that the use of narcotics and anesthetic drugs can blunt these responses and bring about a decrease in morbidity associated with both surgical procedures and painful interventions in the ICU.[78,79] These include reductions in catecholamine levels, lower airway pressures during mechanical ventilation, and less acute rises in blood pressure and pulmonary artery pressure.[80–83] The most commonly used narcotic agents in neonatal practice are i.v. morphine or fentanyl infusions. These are commonly combined with i.v. benzodiazepines usually in the form of midazalam or lorezepam (Table 11.4).[84] The combination of narcotics and benzodiazepams may cause hypotension when given together. Oral sucrose is effective in newborns for analgesia during minor procedures. Long-acting local anesthetic (bupivacaine), when injected into surgical wounds at the time of closure, can provide extended periods of pain relief, particularly after thoracotomies.

HEMODYNAMIC SUPPORT IN THE NEWBORN

Cardiac output is a product of heart rate × stroke volume with increases in output dependent on the ability to increase heart rate or vary stroke volume. Stroke volume in turn is influenced by three interrelated factors: (1) preload or venous return that determines end diastolic volume; (2) afterload or the impedance to left or right ventricular output;

Table 11.4 Commonly used agents for anesthesia and analgesia in newborns.

Drug	Classification	Comments	Commonly used dosages
Morphine	Narcotic	Good analgesic effect with sedation. Cumulative effect in newborns. Withdrawal effects with sustained usage	20–30 μg/kg per hour in ventilated patients
Fentanyl	Short-acting narcotic	Potent, short-acting narcotic. Commonly used for procedural sedation in ventilated patients	1–2 μg/kg per hour as a stat dose. 0.5–2 μg/kg per hour as an infusion
Midazolam	Short-acting benzodiazepine	Used as sedation either as a stat dose or by continuous infusion	1–4 μg/kg per min by continuous i.v. infusion. Stat dose 0.1–0.2 mg/kg
Lorazepam	Benzodiazepine	More prolonged effect than midazolam. Potent anticonvulsant	For seizures 0.05 mg/kg i.v.
Ketamine	Dissociative anesthetic agent. Can be given by i.m. or i.v. injection	Good analgesic properties. Used for procedural sedation/anesthesia. Sympathomimetic effect increases blood pressure	Stat dose for induction of anesthesia 1–2 mg/kg i.v.
Acetaminophen	COX inhibitor. Available as oral or rectal preparation	Useful for mild procedural pain and as an anti-pyuretic	10–15 mg/kg per dose
Sucrose	Stimulates endogenous opiods	Useful for procedural analgesia	2 mL p.o. for term infants

(3) contractility or the contractile state of the myocardial muscle, which in turn depends on its end diastolic fiber length and the speed of shortening for a given load.

In the newborn, where the myocardium is relatively immature, there is little capacity to increase stroke volume. Therefore, cardiac output is to a large part rate dependent and the neonate will primarily compensate for a fall in output by increasing its heart rate. Blood pressure reflects cardiac output poorly in this age group as this is maintained at the expense of increasing heart and vasoconstriction, until a sudden decompensation and hypotension occurs. The combination of heart rate, blood pressure, urine output, and peripheral perfusion provide a reasonably accurate estimation of cardiac output. This can be combined with serum lactate and mixed venous oxygen saturation (SvO_2) drawn from a central venous line in more critically ill newborns. In these patients measurement of central venous pressure (CVP) is particularly useful in optimizing cardiac output by the adjustment of right atrial filling pressures. Central venous access may be established through the internal jugular, subclavian, or femoral veins in the neonate, the complication rate associated with the different approaches being related to the experience and skill of the operator rather than the approach chosen.[85,86] The cannulation of the radial, posterior tibial, dorsalis pedis, or femoral arteries with a 22 or 24 GA cannula will provide reliable direct arterial pressure measurement together with access to sampling for blood gas, electrolyte, and acid–base measurement. Umbilical arterial lines are satisfactory for short-term use only due to the potential to cause renal or gut ischemia if not positioned correctly.

The initial approach to the infant with shock or low CO, indicated by tachycardia, vasoconstriction, oliguria, and hypotension, is to increase preload by volume expansion with 10–20 mL/kg of fluid either in the form of saline or colloid and then reassess the effect on the measured parameters.[87] Further boluses of fluid may be necessary. The CVP measurement may prove very useful in this context, as a guide to repeated volume increments which may have to be increased to as high as 12–14 mmHg in severe refractory shock. Failure to raise output by increasing preload is an indication to attempt to decrease afterload or increase contractility by the use of vasoactive drugs, a condition referred to as fluid refractory shock.[87]

The use of vasoactive drug therapy

In order that the correct therapeutic option is chosen when dealing with a low cardiac output state in the newborn, it is important to know what effects vasodilators and inotropes have on the circulation in this situation. Since the objective is improved tissue oxygen delivery, changes in heart rate, filling pressures and afterload, which in turn profoundly affect myocardial work and therefore oxygen consumption, should always be considered when electing to use a particular drug. While one could use a vasoconstricting agent to maintain blood pressure in an infant in low cardiac output, this would be unsuccessful in most circumstances because this could only be achieved at the expense of a greatly increased afterload, decreased tissue perfusion and oxygen delivery. The aim must be to move the depressed myocardial function curve upwards and to the left as depicted in the Starling curve (Fig. 11.1), either by increasing contractility or by reducing preload or afterload. In the case of contractility, this can be achieved by using an inotrope which may cause significant increases in heart rate, which the neonate, with its relative freedom from ischemia, is able to tolerate reasonably well. The ideal vasoactive drug would be that which increased contractility and decreased afterload with no change in heart rate, while at the same time maintaining renal and splanchnic perfusion.[88] There are a limited

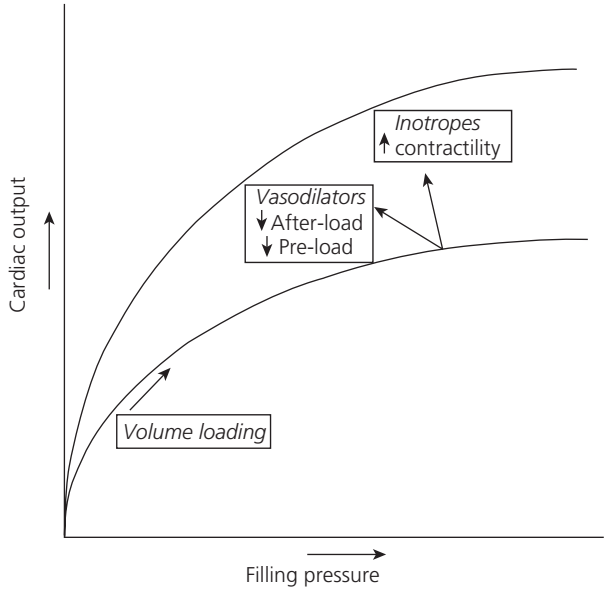

Figure 11.1 Effect of increasing right atrial filling pressures, vasodilator drugs and inotropes on cardiac output (Frank–Starling curve).

number of studies of the effect of vasoactive agents in the newborn and many of these are in premature infants or term infants after open heart surgery.

INOTROPES

Dopamine

Dopamine is an endogenous precursor of norepinephrine with sympathomimetic properties. It has been shown to be useful in the management of shock associated with cardiovascular surgery, sepsis, and severe asphyxia with demonstrable inotropic, vasoconstricting, and renal vasodilating effects. It has a well-documented range of activity with selective vasodilatory effects on cerebral, mesenteric, coronary, and renal vascular beds through stimulation of dopaminergic receptors in a dose range of 0.5–3.0 μg/kg per minute. As the dose increases from 3 to 10 μg/kg per minute it directly stimulates β_1 receptors of the myocardium causing a rise in blood pressure, CO, and heart rate, in addition to indirect stimulation through the release of norepinephrine. As the dose increases from 10 to 20 μg/kg per min, progressive α adrenergic stimulation negates the effect of β stimulation causing a rise in systemic vascular resistance (SVR) and renal vasoconstriction.

Dopamine has been shown to be an effective inotrope following cardiopulmonary bypass in children.[89,90] Studies on the effective dose in neonates have generally been anecdotal and sometimes contradictory.[91–95] Evidence has been presented for the need for high dose dopamine to achieve measurable clinical effect, yet others have shown demonstrable effects at low doses. On balance it would seem demonstrable clinical benefit can be achieved with dopamine using modest doses (<8 μg/kg per minute), with a titratible dose-response increase in effect and little likelihood of side effects. Dopamine can be expected to increase mean arterial pressure, improve echocardiographically determined indices of ventricular function, and improve urine output with a low incidence of side effects at doses <10 μg/kg per minute. Its effect on ventricular filling pressures remains uncertain. Dopamine's effect on systemic vascular resistance appears secondary to the effect on CO at doses <10 μg/kg per minute, where there will be a drop in SVR. At higher doses there will be an increase in SVR as the α effects of dopamine become predominant (Table 11.5). Limitations on the effectiveness of dopamine in this patient population were demonstrated in a study in newborn infants after the Norwood procedure where it increased heart rate and oxygen consumption without increasing oxygen delivery.[96] Different effects on renal and pulmonary blood flow have been seen in premature infants.[95,97,98]

Dobutamine

Dobutamine is a synthetic analog of dopamine with predominately β_1 effect and relatively weak β_2 and α receptor stimulating activity. In addition, it does not seem to lead to indirect stimulation through release of norepinephrine. In

Table 11.5 Vasoactive drugs used for hemodynamic support.

Drug	Site of action	Dose
Dopamine	β1 effects on myocardium peripheral α effects at high doses indirect release of noradrenaline renal vasodilation through dopamergic receptors in kidney	1–10 μ/kg per min β effects 10–20 μg/kg per min α and β effects >20 μg/kg per min α effects
Dobutamine	β1 effects on myocardium weak α and β2 effects at periphery	5–15 μg/kg per min
Epinephrine	β1 effects on myocardium β2 effects at periphery peripheral α effects	0.01–0.1 μg/kg per min
Norepinephrine	Predominantly α effects. Potent vasoconstrictor. Pressor only with minimal intropic properties	0.01–0.1 μg/kg per min
Milrinone	Phosphodiesterase inhibitor. Acts by increasing cGMP. Vasodilator and inotropic effects	0.33–1 μg/kg/min
Vasopressin	Acts on V1 receptors in the vascular bed via cAMP. No effect on heart rate	0.002–0.0004 μg/kg per min

adults at doses of 5–15 μg/kg per minute it has been shown to increase contractility, CO, MAP, improve tissue perfusion and, unlike dopamine, results in a decrease in cardiac filling pressures. Pulmonic and systemic vascular resistances uniformly fall. It therefore can be described as having afterload reducing properties in addition to its inotropic effect.

Experience of its use in children generally parallels that of the adult literature with an increase in cardiac index and MAP in a dose-dependent fashion with doses from 2 to 7.5 μg/kg per minute.[99–101] Neonatal experience has usually been in the treatment of PPHN, frequently in combination with dopamine. In a study of critically ill neonates, dobutamine up to a dose of 7.5 μg/kg per minute increased cardiac output without changing blood pressure or heart rate.[102] Comparative studies of dobutamine and dopamine in preterm infants would suggest that dopamine is more effective in raising blood pressure while dobutamine has more effect on cardiac output and blood flow.[103–107]

Epinephrine

Epinephrine is the final product of catecholamine synthesis and has been used in emergency resuscitation for a number of years. It stimulates both α and β receptors in a dose-dependent fashion; in low doses (0.05–0.1 μg/kg per minute) it affects predominately β receptors resulting in inotropic and chronotropic effects. In higher doses (0.2–1.0 μg/kg per minute) it is a potent vasoconstrictor, the α stimulation increasing MAP and diastolic pressure. This latter effect is the key to its effectiveness in resuscitation, where it can be given as a bolus i.v., endotracheally or rarely, intracardiac injection can be used.

Epinephrine is a potent inotropic agent for the newborn myocardium, its major disadvantages being tachycardia and increased SVR. Renal vasoconstriction can impair renal function and mesenteric vasoconstriction may cause bowel ischemia. Although epinephrine is not commonly used as a first choice inotropic agent, there are instances where it can be very useful when the more commonly used inotropes fail to produce an effect. In such instances we would commence an adrenaline infusion at 0.05 μg/kg per minute, increasing to 0.1 μg/kg per minute according to response, sometimes combined with vasodilator therapy. Comparative studies of epinephrine and dopamine in the treatment of hypotensive preterm infants have not demonstrated that one is superior to the other.[108–110]

VASOCONSTRICTORS

Norepinephrine and vasopressin

Norepinephrine is a potent vasoconstrictor with predominant α agonist effects. As such it is effective in raising blood pressure at the expense of raising afterload on the heart and decreasing peripheral perfusion. It therefore has no place in the routine treatment of low cardiac output. However, in vasodilated septic shock, as seen in Gram-negative sepsis, it can be effective in restoring perfusion to vital organs, the unwanted effects such as decreased splanchnic and renal perfusion notwithstanding. Its potent vasoconstrictor properties require it to be infused via a central vein to prevent skin ischemia and necrosis. The usual dose range is 0.01–0.1 μg/kg per minute. There has been an increasing interest in the vasoconstrictor effects of vasopressin in vasodilated shock in children. This acts through a catecholamine independent mechanism on the V1 receptors in the peripheral circulation. Although clinical experience in neonates is so far limited, published studies show that it increases blood pressure and urine output.[111–115] In the only randomized trial published in children with vasodilated shock, the use of arginine vasopressin (AVP) did not improve survival.[116]

Hydrocortisone in catecholamine-resistant hypotension

The use of i.v. inotropes for an extended period can result in downregulation of end organ receptors manifested by a decreasing response to escalating doses. Stress doses of steroid therapy can be effective in resensitizing β receptors and restoring the inotropic and pressor response. There are a number of published studies in term and preterm newborns demonstrating that doses of hydrocortisone of 1–2 mg/kg can be effective in treating hypotension and allows the doses of β agonist therapy to be reduced without any significant adverse effects.[117–124]

VASODILATORS

Vasodilators are thought to be of benefit in low cardiac output states through a number of mechanisms: (1) by decreasing impedance to ventricular emptying resulting in increased stroke volume and decreased end-systolic volume, (2) increasing venous capacitance which decreases venous return and therefore end-diastolic pressure; appropriate use of vasodilators will shift the heart to a more favorable Starling curve, so that there is an improved SV for a given filling pressure (Fig. 11.1), (3) a drop in filling pressure with preservation of MAP will improve coronary perfusion and thereby improved load tolerance, (4) decreased end-diastolic volume may favorably alter the compliance characteristics of the heart with less pronounced limitation to filling exerted by either ventricle on the other and on both ventricles by the pericardium.

With the newborn infant functioning at a high level of performance and limited reserve capacities as described above, acute preload or afterload increase, in addition to that imposed by postnatal adaptation, may be particularly harmful. Volume loading of the right ventricle from left to right shunts, excessive volume administration, or vasoconstriction from pharmacologic therapy may all lead to profound cardiovascular decompensation. A number of investigators have documented success with afterload reduction in conditions where inotropes have failed or have described additional benefit in function with the addition of vasodilators to inotropic therapy.[125–127]

Sodium nitroprusside

Sodium nitroprusside (SNP) is a direct acting arteriolar dilator that reduces SVR by predominately affecting resistance vessels and in addition reduces filling pressures by increasing venous capacitance. It is given by continuous i.v. infusion due to its short half-life of 1–2 minutes and is light sensitive. Its effect reverses within minutes of discontinuation. It is metabolized to thiocyanate which is excreted by the kidneys. Cyanide toxicity can potentially occur if conversion to thiocyanate is impaired with formation of cyanmethemoglobin and reduced red cell oxygen carrying capacity. Since its predominant effect is on arteriolar resistance vessels and LV afterload, there may be a reduction in MAP. Doses range from 0.5 to 5 μg/kg per minute. SNP is frequently combined with inotropic drugs, especially where high dose dopamine or adrenaline infusions are being used, in order to counteract the unwanted vasoconstrictor effects.

Phosphodiesterase inhibitors

A more recent innovation in pharmacotherapy for the management of low cardiac output has been the introduction of the phosphodiesterase inhibitors which act by blocking the breakdown of cGMP. This represents an alternative pathway for increasing myocardial performance rather than the traditional route via catecholamines, which can lose their effectiveness due to downregulation of β receptor activity. They also have important vasodilator properties. There are several studies of the effective use of phosphodiesterase inhibitors in the treatment of low cardiac output following open heart surgery in infants.[128–134] The most commonly used drug in this class is milrinone in a dose of 0.25–1 μg/kg per minute. The drug has a long half-life and its metabolism is prolonged in hepatic or renal failure.[135,136] A recent study of milrinone in preterm infants showed no difference in superior vena cava (SVC) flow at a dose of 0.2 μg/kg per minute compared with placebo.[137]

FLUID MANAGEMENT AND RENAL FUNCTION

Preserving normal fluid and electrolyte homeostasis is a more significant problem in the neonate compared with the older child, as the renal system is somewhat immature in the newborn. Glomerular filtration rate (GFR) is lower in the preterm compared with the term infant. However, the term newborn is capable of producing a dilute urine (30–50 mOsm/L) and will maintain a positive sodium balance with normal levels of sodium intake.[138] The kidney in the preterm infant, however, is inefficient at conserving sodium. On the other hand, there is also resistance to the effects of antidiuretic hormone (ADH) and the infant can only concentrate urine to 400–600 mOsm/L. The preterm neonate also has an increase in extracellular fluid volume (ECFV) compared to the term infant and this tends to rapidly expand immediately after birth.[139] Fluid balance in the neonate depends on the balance between fluid loss (evaporative, renal, and gastrointestinal tract (GIT)) and the intake required for maintaining normal homeostasis organ function and growth. When calculating normal fluid requirements in the newborn, all these factors need to be taken into consideration. Full maintenance fluid requirements for the non-ventilated term newborn start at 60 mL/kg per 24 hours in the first day of life and increase to 100–150 mL/kg per 24 hours by 5–7 days of life in the form of a dextrose–saline solution. Losses from the GIT due to nasogastric suction should be replaced with normal saline.

The stimulus of surgery, the use of anesthetic agents and narcotic drugs, positive pressure ventilation, and CPAP will all result in inhibition of ADH secretion and the failure to excrete a dilute urine. The frequent use of hypotonic i.v. solutions results in the accumulation of electrolyte free water and hyponatremia. In addition, intermittent positive pressure ventilation (IPPV) with humidification of the respiratory tract eliminates not only evaporative losses from the respiratory tract but will frequently result in a net fluid gain. For this reason it is common practice to calculate the maintenance requirements for fluid for an infant on a respirator as being 70% of normal requirements in order to prevent fluid retention. The use of hypotonic saline solutions for maintenance therapy in older children after elective surgery has been associated with cerebral edema and death from acute hyponatraemia.[140–145] Although this complication is rarely reported in newborns, frequent electrolyte measurements should be carried out and the i.v. fluid prescription adjusted accordingly.

A urine output of >1 mL/kg per hour is generally regarded as a manifestation of adequate renal function following surgical procedures in the newborn. However, a period of oliguria in the presence of normal renal function is not uncommon in the immediate postoperative period, especially where PPV is being used. Persistent oliguria or anuria, on the other hand, may be associated with renal failure due to either pre-renal, post-renal, or intrinsic renal damage.

Pre-renal failure is most frequently due to decreased renal plasma flow associated with blood or fluid loss or inadequate fluid resuscitation preoperatively. A fluid challenge of 20 mL/kg of isotonic fluid or 5% albumin will frequently result in restoration of urine output. Although critically ill newborns are frequently hypoalbuminemic and the maintenance of colloid osmotic pressure would seem to be an important factor in decreasing tissue edema, there is no evidence as to the efficacy of albumin compared with crystalloid solutions.[146–149] A further fluid bolus/boluses with or without a diuretic may be tried, depending on CVP measurement, if there is no initial response.

Intrinsic renal failure is a more serious complication and more difficult to manage. Causes include congenitally abnormal kidneys (cystic or dysplastic), prolonged intraoperative renal ischemia or vascular abnormalities of the kidney, arterial thrombosis associated with umbilical artery catheters, renal venous thrombosis secondary to dehydration, and prolonged hypotension due to sepsis.[150] Drugs such as indomethicin and aminoglycoside antibiotics can also cause intrinsic renal damage. This form of renal failure can be differentiated from pre-renal by the finding of red

cells, protein, and casts in the urine in association with high urinary sodium losses. Management of acute renal failure consists of eliminating the underlying cause if possible, restricting fluids to urine output plus insensible losses and treating hyperkalemia with dextrose infusions and potassium exchange resins. This is only likely to be a short-term solution as the fluid restriction will also entail restricted calorie intake and a cycle of catabolism with protein breakdown and weight loss.

TEMPERATURE REGULATION AND METABOLISM IN THE NEONATE

Temperature

To maintain a normal body temperature, the neonate has to balance heat loss with heat production. With a large body surface area to body weight ratio, the neonate tends to lose heat rapidly by: (1) conduction due to direct contact with cold surfaces; (2) convection by the cooling effects of air currents on exposed skin; (3) radiation to nearby objects such as an incubator wall; (4) evaporation of fluid from skin and respiratory tract. Failure to eliminate areas of heat loss result in the infant attempting to raise its heat production by metabolism of brown fat stores and glucose. The preterm infant is poikulothermic and will not defend its body temperature and is therefore particularly vulnerable to the effects of cold injury. These include acidosis, hypoglycemia, increased O_2 consumption, and weight loss.

It is therefore of great importance that the critically ill neonate be protected from the effects of cold stress following surgery. Nursing the infant in an incubator with an internal temperature of 32–36°C will eliminate conductive and convective heat losses. Radiation can be reduced by using double glazed incubators and evaporative heat losses reduced by humidification. Incubators do, however, limit access to the critically ill infant whereas the radiant warmer bed, while less efficient in conserving heat losses, does provide excellent access. Evaporative and convective heat loss may be reduced with this system by covering the infant with plastic cling film stretched between the side walls of the warmer bed.[151]

METABOLISM IN THE NEWBORN

Glucose and calcium

Glucose metabolism is not well developed in the newborn period and the critically ill neonate is liable to develop hypoglycemia at times of acute stress, particularly the preterm infant. This may be as a result of: (1) diminished glycogen stores (inadequate stores in the premature or depletion from catecholamine stimulated glycogen breakdown release in perinatal stress); (2) hyperinsulinemia in infants of diabetic mothers; (3) inadequate glucose production in small for gestational age infants. Failure to recognize and correct neonatal hypoglycemia will result in seizures and brain damage. In order to prevent this it is recommended that a minimum of 10% dextrose with saline be used in all maintenance fluid infusions in the newborn after surgery. In addition the blood sugar should be regularly measured to prevent hypoglycemia ($<$1.1 mmol/L in the preterm and $<$1.7 mmol in the term infant). Persistent hypoglycemia may require further boluses and increasing the infusion to 15% dextrose. Where the hypoglycemia is due to delay in glucose release from glycogen stores in the liver, the administration of glucagon 300 μg/kg or steroid may result in a rise in blood sugar.[152] Infants receiving high concentration dextrose infusions have increased blood insulin levels. Abrupt discontinuation of the infusion will result in rebound hypoglycemia and therefore these should be weaned gradually.

Hypocalcemia is common in the newborn period, but measurements of the total serum calcium do not accurately reflect the level of ionized calcium (Ca^{++}) in the blood. Levels of total serum Ca above 1.75 mmol/L rarely cause problems but levels below 1.5 mmol/L may result in seizures, apnea, and low cardiac output. Critically ill infants in the first 24–48 hours of life, infants of diabetic mothers, and newborns who have undergone large volume blood transfusions are all at risk for developing hypocalcemia. Calcium infusions should be given preferentially through central venous lines because of the tendency to cause intense venous irritation and damage to skin.

Fluid and electrolyte balance in the newborn

JOSEPH CHUKWU, WINIFRED A GORMAN, AND ELEANOR J MOLLOY

INTRODUCTION

Infants are born into a low humidity, gaseous environment from the liquid intrauterine world. Term and preterm neonates have different fluid requirements and electrolyte changes to older children and adults, especially at this time of rapid postnatal transition.

WATER DISTRIBUTION IN THE FETUS AND THE NEWBORN INFANT

Fetal body composition alters progressively throughout pregnancy. Throughout pregnancy the amount of protein and fat in the fetus increases. Preterm neonates have more water and they may lose 10–15% of their weight in the first week of life. At 1 kg birth weight (approximately 28 weeks' gestation) the fetus comprises about 80% of its weight as water, by full term water content is 75% and by three months of age (~5 kg) 60%.[1–3] Small for gestational age (SGA) preterm infants may have a higher proportional body water content: 90% for SGA infants versus 84% for appropriate for gestational age (AGA) infants at 25–30 weeks' gestation.[4] At 23 weeks' gestation infants are composed of 90% water comprising 60% extracellular fluid (ECF) and 30% intracellular fluid (ICF) (Fig. 12.1).

The total intracellular water content of the fetus and the newborn infant's body increases directly in proportion to cell mass. Twenty-five percent of the weight of the very immature fetus early in pregnancy is intracellular water and this increases to 35% at birth and 40% by three months of age. Body fat content increases from about 1% in the very early fetus to 15% at birth and 30% at three months of age.[1] Fat has a low water content.[1] The SGA infant with a low body fat content has a greater proportion of body weight as water than the AGA infant.

FUNCTIONAL ADJUSTMENTS TO POSTNATAL LIFE

Renal blood flow

Functional nephrons are first present in the fetus at approximately 8 weeks' gestation. Nephrons develop in a centrifugal pattern with juxtamedullary nephrons developing first. The full complement of glomeruli is present by 34 weeks' gestation. Renal blood supply arises from the aorta between T12 and L2, a relationship that remains constant between 24 and 44 weeks' gestation. As the renal arteries divide into segmental end arteries, the renal tissue in their area of distribution is very vulnerable to ischemia, thus follows the recommendation that umbilical artery catheters should not be positioned between T12 and L3.[5,6]

Renal blood flow and glomerular filtration rate (GFR) *in utero* increase gradually with gestational age. Growth of nephrons accounts for the increases in GFR in the fetus. Vascular resistance is high in the fetal kidney and restricts renal blood flow and glomerular filtration *in utero*. The proportion of cardiac output that is distributed to the kidneys during fetal life is about 2–3%.[5–7] It increases to about 6% during the first week of life and approximates 15–18% during the first month of life. In adults, the kidneys receive 20–25% of the cardiac output. The low renal blood flow during fetal life results from a high renal vascular resistance. Factors that may contribute to renal dysfunction in neonates include prematurity, medication (gentamicin, cephalosporin, non-steroidal anti-inflammatory drugs (NSAIDs), frusemide), hypoxia and excessive fluid loss.

Glomerular filtration rate

Glomerular filtration begins between 9 and 12 weeks' gestation in the human fetus and contributes to amniotic

	Preterm/fetus	Term infant	3 months old
TBW	80%	75%	60%
ICF	25%	35%	40%
ECF	55%	40%	20%
Fat	1%	15%	30%

Figure 12.1 Body fluid/fat composition at different ages: TBW, total body water; ICF, intracellular fluid; ECF, extracellular fluid.

fluid. In fetal sheep, glomerular filtration rate increases by 2.5 times during the last trimester and parallels the rise in fetal body weight and kidney weight.[8–10] At delivery there is a positive correlation between GFR and gestational age in newborn infants delivered between 27 and 43 weeks' gestation.[11]

In the first 24 hours after delivery, there is a three-fold increase in GFR in the term but not preterm infant, although there is no increase in total renal blood flow or increase in systemic blood pressure. Changes in GFR at birth may be influenced by plasma adrenaline and noradrenaline,[12,13] renin-angiotensin, prostaglandin, arginine vasopressin,[14–16] and plasma cortisol.[17] Indomethacin use in the preterm neonate has been shown to increase the resistance of the renal vascular bed, thereby decreasing renal perfusion.[18] Each of these, or a combination of these, hormones may influence glomerular filtration by decreasing glomerular vascular resistance and recruiting superficial cortical nephrons.

Water homeostasis

The diluting segment of the distal tubule and ascending limb of the loop of Henle develop relatively early in nephrogenesis. When challenged with a water load both the term and the preterm infant can dilute their urine to osmolalities to 50 and 70 mOsm/kg water. Glomerular filtration, however, is low and this limits the quantity of urine that can be excreted, even in the presence of a potent dilutional capacity. The newborn kidney of both the term and preterm infant has relatively low osmolality in the renal medulla and this limits the effectiveness of the countercurrent concentrating mechanism in the loop of Henle.[19,20] In the term infant, urine can be concentrated to a maximum of 600–700 mOsm/L, considerably less than that of 1200 mOsm/L in the older child or adult. Thus both the preterm and full-term neonate are unable to handle either fluid deprivation or overload, thus underlining the need for accurate assessment of fluid requirements.[21]

Immediately after birth a physiological acute isotonic volume contraction occurs, predominantly in the extra cellular water with the corresponding postnatal weight loss. Weight loss is greater and lasts longer in infants with less advanced gestational age.

Insensible water loss

Insensible water loss is the continuous invisible loss of water by evaporation that occurs from the skin and lung surface. Insensible water loss needs inclusion in the estimation of total fluid requirements.[22] Transepidermal water loss accounts for about two-thirds of insensible water loss while respiratory water loss accounts for one-third. Insensible water loss is greater in less mature infants.[23]

SWEATING

Sweating occurs to only a very limited extent in response to a thermal stimulus in the term infant, despite the fact that the

full complement of sweat glands is present at birth. Although even the most immature infant soon develops the ability to sweat in response to heat stress, the efficiency of sweating as a thermoregulatory process is poor.[24]

TRANSEPIDERMAL WATER LOSS

Evaporation of water from the skin surface occurs continuously by diffusion.[25,26] The quantity of water lost is determined by the relative humidity of the infant's surrounding atmosphere, particularly in the preterm infant with immature skin keratinization.

Transepidermal water loss (TEWL) is closely related to thermal balance – there is heat loss whenever water evaporates from a surface (1 g water = 0.58 kcal of heat loss). In a term baby under stable environmental conditions TEWL can be elevated, accounting for as much as 70 cal/kg per day heat loss (more than half of the caloric intake of the preterm infant). Preterm infant TEWL is greatly increased as gestational age decreases due to the large ratio of surface area to weight and the immature epidermal barrier to water. TEWL is exaggerated by postnatal trauma to the skin, for example from adhesive tape applied to the skin for attachment of monitors.

However, placing impermeable plastic sheets over and under the baby or the use of plastic bags can significantly reduce TEWL of the infant surgical patient.[27]

After birth, regardless of gestation, the skin matures and skin permeability to water falls. However, in the extremely preterm infant this maturation may be extremely slow and extracellular water loss has been shown to be higher than normal at 28 days postnatal age.[28,29] Transepidermal water loss gradually decreases over the first 7 days of life and is significantly lower in infants whose mothers had received prenatal steroids. However, Jain *et al.* failed to demonstrate any maturational effect of antenatal steroids on transepidermal loss in preterm infants.[30–32] Maximizing incubator humidity can reduce TEWL.[33] Insensible water loss in infants weighing <1 kg is reduced to <40 mL/kg per day if ambient humidity is above 90%.[34]

Respiratory water loss

Respiratory loss represents 39% of insensible water loss in term infants. Inspired air becomes fully saturated with water in the upper respiratory tract and some water is lost as this air is expired. Similarly, tachypnea increases water loss. The relative humidity of the air before inspiration also has an influence; the higher the humidity, the less water needs to be added and the less lost. Ventilated infants inspire humidified air delivered, reducing respiratory water loss by a third.[35]

FLUID AND ELECTROLYTE MANAGEMENT

Infants admitted to a neonatal intensive care unit who are unable to exclusively feed orally require careful management of fluid and electrolyte balance. Additional difficulties may occur if the infant is preterm and if, as frequently happens in babies requiring surgery, there are additional losses from the intestine or the kidneys as a result of a complex surgical problem. When planning maintenance fluid therapy for an infant, all the variables that have already been discussed that may influence fluid requirements must be taken into account. Any guidelines for fluid and electrolyte therapy must be modified to suit an individual infant's requirements. Tables 12.1 and 12.2 give some guidelines that may be used and modified appropriately.[36]

Preterm infants <1.5 kg should be commenced on total parenteral nutrition in the first few hours of life to optimize their nutrition. Further discussion of neonatal enteral and parenteral nutrition is beyond the scope of this chapter.

Table 12.1 Fluid requirement in the newborn.

	Fluid volume (mL/kg)	Fluid type
Baby nursed in incubator		
Day 1	60	10% dextrose/TPN
Day 2	80	Electrolyte solution/10% dextrose/TPN
Day 3	100	Electrolyte solution/10% dextrose/TPN
Day 4	120	Electrolyte solution/10% dextrose/TPN
Day 5	150	Electrolyte solution/10% dextrose/TPN
Baby nursed under radiant warmer		
Day 1 (5% dextrose if bwt <1500 g)	80	10% dextrose/TPN
Day 2	100	Electrolyte solution/10% dextrose/TPN
Day 3	120	Electrolyte solution/10% dextrose/TPN
Day 4	140	Electrolyte solution/10% dextrose/TPN
Day 5	150	Electrolyte solution/10% dextrose/TPN

Restricted fluids – two-thirds of normal maintenance fluids.
Very low birth weight infants frequently require even higher initial rates of fluid administration and frequent reassessment of serum electrolytes, urine output, and body weight.

Table 12.2 Maintenance electrolyte therapy.

	Per kg/day
Sodium	2–4 mmol
Potassium	1–3 mmol
Calcium	5–10 mL of 10% calcium gluconate (1.125–2.25 mmol calcium)

Increased fluid requirements may occur in the following circumstances:

- Low birth weight infants <1.5 kg. The very low birth weight infant has a very high insensible loss of fluid and thus increased requirements for free water.
- Phototherapy. Phototherapy increases insensible water loss by evaporation, thus fluid intake should be increased by 10 mL/kg per day per number of phototherapy unit light used in the infant >1.5 kg and 20 mL/kg per day per number of lights used with birth weights <1.5 kg.[37,38]
- Radiant warmer. Nursing in a radiant warmer increases insensible fluid loss by a mean of 0.94 mL/kg per hour[39] when compared with incubators. This increased water loss is not prevented by using a heat shield but may be prevented by using a plastic blanket.[39–41] Use of a humidified incubator is preferable, especially in preterm babies.
- Polyuric renal failure (especially in infants <26 weeks' gestation). Maintenance fluids will require very frequent readjustment, guided by regular monitoring of the weight and the serum electrolytes.

Maintenance fluid therapy may need to be decreased in the following circumstances:

- inappropriate ADH secretion;
- congestive heart failure;
- oliguric renal failure;
- patent ductus arteriosus.

Conservative patent ductus arteriosus (PDA) management involves fluid restriction to a total fluid intake of 120 mL/kg per day.[42] A high PDA closure rate (up to 100%) in preterm infants with PDA managed conservatively with fluid restriction (130 mL/kg per day), and adjustment of ventilation (reducing inspiration time and increasing the peak end expiratory pressure) may be achieved.[43]

In assessing the infant's water requirements, one needs to evaluate weight change, urine output, specific gravity and osmolality, serum sodium and creatinine, and blood urea and osmolality. Normal urine output is 2–4 mL/kg per hour. In the first 24 hours of life, urinary output may be very low or even absent. During recovery from a severe illness associated with fluid retention or edema, polyuria may occur. A physiological diuresis (water loss) of up to 10% of body weight occurs over the first 4–5 days of life. This diuresis has the effect of decreasing total body water content by contracting the ECF volume. It is greater in the preterm infant whose total body water content is higher than that of the term infant. This water loss occurs despite usual fluid intakes and is typically accompanied by a negative sodium balance even when sodium is provided.

High fluid intake (>170 mL/kg per day) increases the likelihood of symptomatic PDA.[44] High fluid intake and/or high sodium intake may also increase the likelihood of respiratory complications both in the short term and in the longer term by increasing the frequency of chronic lung disease.[45,46]

Sodium regulation

Maintenance of normal serum sodium (135–140 mmol/L) is principally controlled by the kidneys. The amount of sodium that can be excreted is limited by the GFR and the ability of the kidney to excrete a sodium load is diminished as compared with adults and falls progressively with decreasing gestational age.[47–49]

Preterm infants have a higher fractional sodium excretion than full-term infants.[47] Extrauterine existence accelerates tubular sodium reabsorption but not GFR, whose maturation is related to post-conceptual age. Al-Danhan *et al.* demonstrated that preterm infants <30 weeks' gestation require a minimum of 5 mmol/kg per day of sodium and those of 30–35 weeks' gestation require 4 mmol/kg per day to achieve a positive sodium balance and maintain normal serum sodium.[47,50]

Intestinal absorption of sodium in the very preterm infant is low and improves progressively with increasing gestational age.[48] Neonates undergoing intensive care may gain significant amounts of fluid and sodium from drugs, bronchial lavage, and flushing of catheters, sources that are often overlooked. Hypernatremia may occur, especially in the very low birth weight infant, and may have adverse effects.[51]

Prenatal steroids induce maturation of renal tubular function. Infants who have been exposed to prenatal steroids have an earlier diuresis and natriuresis.[30] Randomized controlled trials have shown that early sodium administration increases the risks of hypernatremia, particularly if TEWL is high and water intake is limited, and increases the risks of respiratory morbidity by impeding the normal, physiological loss of extracellular fluid. Subsequently, once nutritional intake is sufficient to support growth, the extremely preterm infant is at risk of chronic sodium depletion. At this stage, an intake of at least 4 mmol/kg per day is required, or more particularly in the absence of antenatal steroid exposure.[52–56]

Renal response to antidiuretic hormone

The human fetal pituitary secretes antidiuretic hormone (ADH) from 12 weeks' gestation onwards. Labor and delivery are associated with a surge in ADH secretion in cord blood. Both term and preterm infants are capable of an appropriate ADH response to stimuli. Although ADH levels in newborn infants are similar to adults, the antidiuretic response to ADH is blunted because a lower concentration gradient in the renal medulla lessens its effectiveness and low numbers of ADH receptors. Excess ADH can cause a drop in urine output and hyponatremia.[57,58]

Factors that result in excess or inappropriate secretion of antidiuretic hormone (SIADH) in the newborn include birth asphyxia, surgery, hypoxia, severe lung disease, positive pressure ventilation, intracranial hemorrhage, and pneumothorax. SIADH results in weight gain, hyponatremia, and oliguria. SIADH is diagnosed by documenting hyponatremia in association with low serum osmolality and high or normal urine osmolality and high urinary sodium due to continued excretion of sodium in urine despite low serum

sodium. There is usually no evidence of fluid depletion. It is also important to note that the renal, adrenal, and thyroid functions are usually normal in SIADH. Management is by fluid restriction in addition to alleviating the primary cause.[59]

Sodium balance

Sodium is not required during the first 24 hours of life, during which time urine and sodium output are low. Sodium supplementation of 2–4 mmol/kg per day should be given when weight loss of approximately 5–10% of birth weight has occurred and postnatal diuresis has occurred.

Hyponatremia, defined as $Na^+ < 130$ mmol/L, may occur in the following circumstances:

- laboratory error;
- excess antidiuretic hormone secretion, where low urinary loss of water results in dilutional hyponatremia;
- large renal tubular losses of sodium as occurs in extreme prematurity or polyuric renal failure;
- congestive heart failure with dilutional hyponatremia;
- diuretic therapy with loss of sodium via the renal tubules;
- hypoadrenalism: congenital Addison's disease, septic shock with adrenal failure, salt-wasting adrenogenital syndrome;
- maternal hyponatremia;[60]
- factitious hyponatremia as a result of hyperglycemia or hyperlipidemia;
- inadequate sodium intake in preterm infants with excessive renal sodium loses;
- excessive large intakes of free water or electrolyte-free solutions like dextrose water.

Hypernatremia, serum sodium > 145 mmol/L, may occur in the following circumstances:

- laboratory error;
- high insensible water loss which is incompletely replaced;
- high urinary water losses which are not replaced;
- maternal hypernatremia;
- deficiency of antidiuretic hormone;
- rarely, excessive administration of Na^+ in i.v. fluid flushes;
- excessive sodium bicarbonate administration in infants with metabolic acidosis.

Potassium balance

Potassium is predominantly an intracellular ion. No potassium is required on the first day of life. After this, intakes of 1–3 mmol/kg per day should replace losses and maintain a normal serum potassium of 3.5–5.8 mmol/L (Table 12.2). Potassium should be cautiously administered in infants with renal dysfunction and the very low birth weight infant whose ability to excrete potassium may be limited. Early non-oliguric hyperkalemia may occur in 30–50% of infants with birth weight < 1 kg as a result of a potassium shift from intracellular to extracellular space. Hyperkalemia will be exaggerated by hypoxia, metabolic acidosis, catabolic stress, and oliguria. The hyperkalemia may be severe enough to cause life-threatening arrhythmias.[8,61–64]

Hyperkalemia, serum $K^+ > 6$ mmol/L in a sample that is not hemolyzed, becomes concerning when > 6.5 mmol/L or if ECG changes occur. ECG changes in hyperkalemia vary from peaked T waves, as the earliest sign, to a widened QRS complex, bradycardia, tachycardia, supraventricular tachycardia (SVT), ventricular tachycardia, and ventricular fibrillation.

Hyperkalemia may occur in the following circumstances:

- laboratory error or hemolysis of blood sample;
- severe metabolic acidosis: with each 0.1 pH drop serum potassium increases by 0.6 mmol/L;
- tissue cell death with release of intracellular potassium, e.g. release of K^+ from neuronal cells and red blood cells (RBCs) post-intraventricular hemorrhage, trauma, or surgery;
- acute renal failure;
- very low birth weight in the absence of renal failure;
- very low birth weight in the absence of antenatal steroids;
- adrenal insufficiency secondary to acute adrenal failure as in sepsis/shock or congenital adrenal hyperplasia;
- severe hemolytic anemia.

MANAGEMENT OF HYPERKALEMIA

- Avoid potassium in all infusions in the first day of life.
- Infants born < 28 weeks' gestation should have serum potassium levels recorded from 12 to 48 hours of age. Blood gas analysis will identify the neonate with rising potassium levels. Laboratory measurement of serum potassium should be performed 12-hourly for the first 48–72 hours of life.
- Only blood from umbilical arterial line, peripheral arterial line, arterial stab, or free flowing venous sample should be used.
- Treatment of hyperkalemia should be commenced if serum $K^+ \geq 7$ mmol/L confirmed on a non-hemolyzed arterial/venous sample and/or ECG changes are present and serum $K^+ \leq 7$ mmol/L.
- ECG changes include tall peaked T waves, prolonged PR interval, small/absent P waves, widening of the QRS complex, asystole.

Treatments used in premature infants with non-oliguric hyperkalemia aim to decrease the arrhythmogenicity of hyperkalemia, redistribute potassium into the intracellular space, or remove potassium from the body[65] (Fig. 12.2). Sodium bicarbonate is not recommended. If acidosis is present, the underlying cause should be treated. Ion exchange resins are also not recommended. They have been shown to cause intestinal obstruction and perforation. Also, gastric masses found at autopsy were devoid of potassium, indicating that no exchange had occurred.

CAUSES OF HYPOKALEMIA

Hypokalemia, serum potassium < 3.5 mmol/L, may occur in the following circumstances:

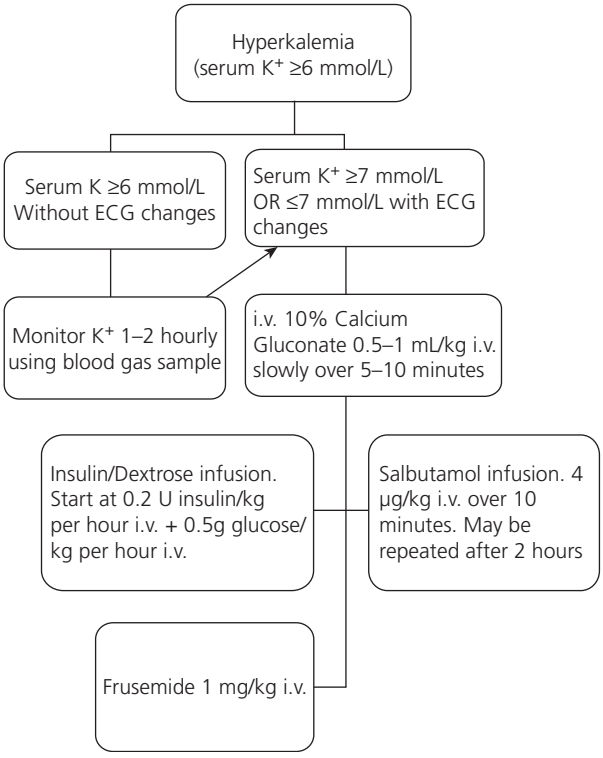

Figure 12.2 Management of hyperkalemia.

- laboratory error;
- alkalosis lowers serum potassium by shifting the potassium load intracellularly, but does not lower total body potassium;
- polyuric renal failure;
- gastrointestinal losses through vomiting or diarrhea or pooling of fluid in a 'third space', such as dilated loops with intestinal obstruction;
- diuretic therapy;
- inadequate intake;
- NG aspirate losses not replaced with appropriate fluids.

Hypokalemia predisposes to cardiac arrhythmias, paralytic ileus, urinary retention, and respiratory muscle paralysis. Thus potassium balance must be carefully monitored, taking into account the influence that pH may have on the serum potassium, in that alkalosis shifts potassium which is predominantly an intracellular ion into the cells and acidosis has the reverse effect and that both hyper- and hypokalemia will have adverse effects.

Acid–base balance

Normal values for pH are similar to those in the adult; however PCO_2 and serum bicarbonate are both slightly lower in the newborn infant than in the adult. [59,60] The lungs and the kidney both have important roles in the maintenance of acid–base balance. The lung excretes volatile acid formed during metabolism as CO_2. Respiratory failure will cause accumulation of CO_2 and respiratory acidosis.

METABOLIC ACIDOSIS

The normal kidney has a vital role in regulation of serum bicarbonate. In mature subjects serum bicarbonate is maintained at approximately 25 mmol/L, but preterm infants have a lower threshold.[66] The kidney also has an important role in the excretion of non-volatile acid (mainly sulfur containing amino acids) produced by metabolism.

Causes of metabolic acidosis

- Perinatal asphyxia.
- Severe hypotension with impaired tissue perfusion.
- Acute renal failure.
- Acute diarrhea and dehydration.
- Excess ileal loss.
- Excess protein administration, e.g. excess amino acid in parenteral nutrition.
- Inborn errors of metabolism (e.g. organic acidemia).
- Sepsis.

Acute metabolic acidosis is common in the critically ill newborn. Treatment requires management of the underlying cause. Sodium bicarbonate may be used for severe acidosis by giving a dose of 1–2 mmol/kg of 4.2% sodium bicarbonate diluted in equal volume of water. There is currently no evidence from randomized control trials to support its routine use in neonatal resuscitation. Its effect on morbidity and mortality has not been well demonstrated. There is controversy about the value of i.v. sodium bicarbonate for correction of metabolic acidosis. It is no longer recommended for resuscitation in newborn infants and although it may correct acidosis in hypotensive shocked infants, this has not been shown to result in improvement in blood pressure or perfusion.[67] Sodium bicarbonate infusion has potential side effects. Myocardial function may be depressed from the osmolar load with severe acidosis. Paradoxical intracellular acidosis may occur as well as a reduction in cerebral blood flow and increased risk of intraventricular hemorrhage. Use of sodium bicarbonate is therefore discouraged unless the infant has prolonged acidosis not responsive to other therapies including adequate ventilation.

Causes of metabolic alkalosis

Persistent vomiting causes hypochloremic alkalosis and body potassium depletion. This may occur with untreated pyloric stenosis or upper intestinal obstruction. Correction is by replacement of fluid, sodium chloride, and potassium. Rehydration and correction of depleted electrolytes will be followed by correction of the metabolic alkalosis. Chronic respiratory acidosis, as in chronic lung disease (CLD), may cause renal re-regulation of sodium bicarbonate level at a higher threshold until pH is normal. Infants with chronic hypercapnia regularly have a serum bicarbonate of greater than 30 mmol/L. Permissive hypercapnia or controlled ventilation is a strategy adopted to limit the damage done by excessive mechanical ventilation pressures or volumes to the lungs in order to decrease the incidence of CLD.[68]

Glucose homeostasis

Glucose is the most important substrate for brain metabolism and whereas ketones, glycerol, and lactate can be used, a continuous supply of glucose is essential for normal neurological function.[69,70] Fetal blood glucose is identical to that of maternal blood glucose since passive transfer of glucose occurs across the placenta.

HYPOGLYCEMIA

Immediately after delivery, blood glucose falls to ~2.5 mmol/L (45 mg/dL) in the term infant. Following delivery a combination of hormonal responses (glucagon, growth hormone, thyroxine) and oral feeds, or in their absence i.v. fluids, serve to maintain blood glucose within a normal range. There is no consensus regarding the definition of hypoglycemia in the neonate.[69,70] Blood glucose levels between 2.5 mmol/L (45 mg/dL) and 7.2 mmol/L (130 mg/dL) are accepted as being safe. Symptomatic hypoglycemia results in cyanosis, apnea, lethargy, seizures, or coma. Blood sugar values represent a continuum and there is no specific value at which brain damaging hypoglycemia will always occur.[69,71] However,' brain MRI after symptomatic neonatal hypoglycemia (median glucose level 1 mmol/L) without evidence of hypoxic-ischemic encephalopathy reveals white matter injury in 94% and neurodevelopmental impairment in 64% at 18 months.[72]

In the newborn infant requiring surgery, hypoglycemia is most commonly caused by vomiting or inadequate intake of fluids. Other contributing factors may include prematurity, septicemia, hypothermia, or hyperinsulinism as may occur in an infant of a diabetic mother. Infants with Beckwith–Wiedemann syndrome who frequently may have omphalocele, commonly have elevated blood insulin levels and severe hypoglycemia.

Blood sugar in the infant at risk should be monitored at the bedside using a bedside screening glucose analyzer. Blood sugars below 2–2.5 mmol/L should be acted upon by giving a feed or giving a bolus of i.v. 10% dextrose as appropriate for the individual infant. Significant hypoglycemia should be confirmed by laboratory blood sugar before definitive action, such as i.v. glucose being given. This is because all screening methods are not completely accurate at low blood sugar levels.

HYPERGLYCEMIA

A blood glucose > 14 mmol/L (250 mg/dL) may cause a hyperosmolar state with glucosuria, osmotic dieresis, and dehydration. This elevated plasma osmolality increases the risk of intracranial hemorrhage, at least in the infant of less than 32 weeks' gestation. Hyperglycemia most commonly occurs in the very low birth weight infant who is receiving large amounts of fluids to counteract insensible loss and whose ability to metabolize dextrose or glucose is limited. Hyperglycemia may also be due to defective islet cell processing of proinsulin, insulin resistance, and non-suppression of endogenous glucose production during continuous exogenous glucose infusion.[73,74] Infusion of small doses of insulin may be required to counteract intractable hyperglycemia.[73] Extreme low birth weight babies require a higher total dose of insulin for longer periods than low birth weight preterms. Exogenous insulin infusion partially reduces endogenous glucose production in preterm newborn infants. This treatment is efficient and safe when used with caution.[73] The use of insulin in preterm infants and prevention of hyperglycemia could also affect immune function, lipid metabolism, growth, and IGF-I generation leading to improved short-term clinical outcomes such as retinopathy of prematurity. It may also have longer-term health effects, however the outcomes of clinical trials are currently awaited.[74]

Calcium homeostasis

Calcium has a key role in many physiological processes, including activation and inhibition of enzymes, intracellular regulation of metabolic sequences, secretion and action of hormones, blood coagulation, muscle contraction, and nerve transmission. Ninety-nine percent of total body calcium is in bone, to which it gives structural support, with only about 1% in the ECF and soft tissues.[75]

Calcium is present in the extracellular fluid in three fractions: 30–50% is bound to protein, principally albumin; 5–15% is complexed with citrate, lactate, bicarbonate, and inorganic ions; and 5–15% is ionized – this is the metabolically active fraction of calcium. Calcium concentration reported as mg/dL can be converted to molar units by dividing by four (e.g. 10 mg/dL converts to 2.5 mmol/L).[36,76–78] If serum albumin is low, total serum calcium falls, but the serum level of ionized calcium is unchanged. Serum calcium could be corrected for the level of serum albumin using the formula:

$$\text{Corrected calcium} = (0.8 \times [\text{normal albumin} - \text{neonatal albumin}]) + \text{serum Ca}$$

Hydrogen ions compete with calcium for albumin binding sites. Thus acidosis increases serum ionized calcium levels without influencing total serum calcium levels. Prenatally, calcium is actively transported across the placenta from mother to fetus against a concentration gradient, which results in fetal hypercalcemia at the end of the last trimester and immediately after birth. Cord serum calcium in the full-term infant is approximately 2.75 mmol/L.[77] In healthy full term infants calcium concentrations decrease for the first 24–48 hours and reach a nadir of 1.8–2.1 mmol/L. Thereafter, calcium concentrations progressively rise to the mean values observed in older children. This transient drop in serum calcium is exaggerated in the preterm infant. Metabolic bone disease is a common feature, especially in extreme preterm infants less than 28 weeks' gestation, and results from inadequate supply of nutrients (vitamin D, calcium, and phosphate), prolonged period of total parenteral nutrition, and prolonged period of immobilization. The main features which manifest between the 10th and 16th week of life include decreased

bone mineral density and osteopenia with or without other features of rickets.

HYPOCALCEMIA

This is defined as a total serum calcium concentration <2.0 mmol/L in the term infant and <1.7 mmol/L in the preterm infant.[76] Normal serum ionized calcium in the newborn infant is 1–1.5 mmol/L.[77,78]

Causes of hypocalcemia

1. Infants of diabetic mothers
2. Asphyxia
3. Sepsis
4. DiGeorge syndrome/velocardiofacial syndrome
5. Diuretics, especially frusemide
6. Hypomagnesemia
7. Maternal hyperparathyroidism
8. Prematurity
9. Vitamin D deficiency.

Clinical manifestations

The majority of hypocalcemia is asymptomatic. The symptoms when they occur include jitteriness and seizures. An electrocardiographic Q–T_c interval longer than 0.4 seconds may occur.

Management

Early asymptomatic mild neonatal hypocalcemia does not require treatment. Infants receiving i.v. fluids should be provided with maintenance calcium gluconate. Brown and colleagues have shown that aggressive attempts at normalizing serum calcium in sick preterm infants may be ineffective and even hazardous, thus at the least in the first week of life, maintenance of serum calcium at a level of 2.0 mmol/L is adequate.[79]

Symptomatic hypocalcemia should be treated with a slow infusion of i.v. calcium gluconate [5 mL 10% calcium gluconate = 1.1 mmol = 45 mg elemental calcium]. Extreme care should always be taken when infusing calcium as extravasation can cause severe burns to the surrounding skin and subcutaneous tissue. Emergency treatment of hypocalcemia is only required if the infant is symptomatic. Symptoms include jitteriness, seizures, lethargy, poor feeding, and vomiting [bolus 1–2 mL 10% calcium gluconate i.v. (0.45 mmol = 18 mg elemental calcium) i.v. slowly]. Symptoms are uncommon at serum calcium above 1.8 mmol/L and become common at serum calcium <1.5 mmol/L. Oral calcium supplements in the form of Calcium Sandoz provides 2.7 mmol (110 mg) elemental calcium 2.5 mL (50 mg) per kg per day may be given with feeds if the infant on feeds has asymptomatic hypocalcemia, requiring treatment. Symptomatic hypocalcemia unresponsive to calcium therapy may be due to hypomagnesemia. This can be treated with 50% magnesium sulfate either intravenously or intramuscularly.[80]

PERIOPERATIVE MANAGEMENT

Preoperative fluid and electrolyte problems in the neonate

Heird and Winters have summarized the metabolic responses of the normal neonate in the first weeks of life.[82] Preoperatively, infants with abnormalities requiring surgery, especially those of the gastrointestinal tract, may have a variety of electrolyte abnormalities.[81–83] If there has been a delay in recognition of gastrointestinal obstruction and the infant has been vomiting for a period of time, he or she will be dehydrated (Table 12.3).

Upper intestinal obstruction, for example pyloric stenosis, results in loss of hydrochloric acid from the stomach, and small amounts of sodium and potassium. The kidney then conserves hydrogen ions at the expense of potassium and sodium. Bicarbonate is excreted by the kidney along with sodium and potassium and the urine pH is alkaline.

Potassium and sodium depletion occur. As loss of potassium and sodium progress, and the body stores are diminished, the kidney ceases to excrete these ions with bicarbonate. Sodium and potassium are now conserved by the kidney and hydrogen ion is lost instead causing a severe hypochloremic metabolic alkalosis. Correction must be with adequate fluid-containing sodium chloride and potassium chloride, as body stores of all these ions are depleted. Infants with lower intestinal obstruction, such as Hirschsprung's disease or other intestinal obstructive lesions, may pool large amounts of fluid and electrolytes in dilated intestinal loops; this may result in intravascular dehydration with hyponatremia, hypokalemia, and metabolic acidosis.

Neonates with necrotizing enterocolitis, peritonitis, or septic shock may have 'third space' loss of fluid into the peritoneum, pleural fluid, or interstitial tissues with resultant hypoproteinemia and marked interstitial edema. Additionally, many of these infants are ventilated, sedated, and paralyzed. Immobility resulting from paralysis will accentuate peripheral pooling of interstitial fluid. Intravascular dehydration and hypoproteinemia and hyponatremia will result.

Preoperatively, the infant's hydration should be assessed on the basis of weight, pulse, blood pressure, capillary filling time, blood urea and electrolytes and urine output, specific gravity and electrolyte content.

Table 12.3 Electrolyte composition of body fluids.

	Electrolytes (mEq/L)				
Body fluid	Na^+	K^+	Cl^-	HCO_3	pH
Gastric	70	5–15	120	0	1
Pancreas	140	5	50–100	100	9
Bile	130	5	100	40	8
Ileostomy	130	15–20	120	25–30	8
Diarrhea	50	35	40	50	>7

Adapted from Refs 77 and 78.

Intraoperative management

Careful attention to fluid and electrolyte balance intraoperatively is essential, including blood pressure, pulse, and temperature. During major procedures, intravascular lines allow blood pressure and central venous pressure monitoring. Urine output should also be measured and oxygenation and ventilation with blood gases and pulse oximetry.

Loss of fluid and heat from exposed peritoneal surfaces should be taken into account and minimized by keeping the operating room sufficiently warm. Acute blood loss should be replaced.[82]

Postoperative management

Patients who have been adequately managed pre- and intraoperatively may be well hydrated, immediately, postoperatively. If the infant had hypotension, transient renal failure with oliguria may occur and may be managed with fluid restriction and correction of electrolyte abnormalities. Inappropriate secretion of antidiuretic hormone is common and results from pain and/or ventilation, resulting in fluid retention and hyponatremia; thus care must be taken to avoid overhydration which will encourage both of these. Respiratory acidosis should be corrected by appropriate ventilation. Metabolic acidosis may occur postoperatively in the infant who is persistently hypotensive or hypoxic or who has ongoing tissue necrosis (i.e. severe necrotizing entercolitis). This must be addressed by correcting the underlying cause of acidosis and by giving sodium bicarbonate. Fluids lost through nasogastric suctioning or drainage must be replaced at regular intervals by normal saline with maintenance potassium added; if losses are from the small intestine it has been recommended that a small amount of bicarbonate is also added. Where large fluid losses occur from aspiration, calculation of the electrolyte content of these fluids may help plan replacement[80,81] (Table 12.3).

Nitrogen excretion occurs in neonates postoperatively. Thus early attention must be given to beginning parenteral nutrition in infants in whom early feeding is not foreseen. The term infant who will be fed enterally within 3 days need not be fed parenterally; however, the very low birth weight infant (<1.5 kg) who has very inadequate stores of nutrients must begin parenteral nutrition immediately.

FLUID AND ELECTROLYTE BALANCE IN SEPTIC SHOCK

Many surgical conditions predispose to sepsis and shock, including necrotizing enterocolitis, Hirschsprung's disease with enterocolitis, and volvulus. The risk of septicemia with hypotension is even higher if the infant is also preterm. Shock is a stage of acute cardiovascular dysfunction in which the delivery of oxygen and nutrients is insufficient to meet metabolic demands of the tissues. Endotoxin appears to be the common etiological factor in septic shock.[84,85]

Metabolic substrates, i.e. oxygen, glucose, and fatty acid, are available, but their utilization is impaired causing multiple organ failure. Capillary permeability increases and fluid and protein leaks into the interstitial fluid resulting in tissue edema, hypoproteinemia and a fall in intravascular fluid volume. Pulmonary hypertension, followed by marked pulmonary edema, occurs with severe respiratory distress. Myocardial depression results in decreased cardiac output.

Clinical manifestations

Neonatal bacterial septicemia may be fulminant and fatal. A high index of suspicion by the nursing and medical staff is essential. Presenting features are subtle and may be recognized only by an experienced nurse or doctor. The infant may merely appear 'off color'. Early signs of sepsis include lethargy, irritability, apnea and temperature instability, elevated C-reactive protein, and immature to total neutrophil ratio.

Management

Shock must be reversed with rapid infusion of fluid and colloid to replete the intravascular space. Normal saline at a volume of 10–20 mL/kg can be infused over 20–60 minutes.[81] Inotropic agents may be needed to increase cardiac output – dopamine improves cardiac contractility (5–20 μg/kg per minute) and in a low dose (<5 μg/kg per minute) also increases blood flow to the kidneys and the intestine; high doses have the opposite effect. Alternative drugs are dobutamine, milrinone, or isoproterenol. Patients with profound hypotension and myocardial depression may respond only to infusion of epinephrine or norepinephrine. Hydrocortisone at stress doses could be used to treat recalcitrant hypotension not responsive to full doses of inotropes and intravascular volume repletion. Administration of corticosteroids leads to rapid resolution of the hypotension without increasing the risk of spontaneous intestinal perforation, grade III–IV intraventricular hemorrhage (IVH), periventricular leukomalacia, and sepsis (bacterial or fungal).

Hyperkalemia results from oliguria and tissue catabolism; hyponatremia results from increased total body water and inappropriate ADH secretion.

ACUTE RENAL FAILURE

Acute renal failure is common in the seriously ill neonate requiring surgery. It may be prerenal as a result of severe dehydration, hypotension, abdominal distension, or sepsis. It may result from congenital severe intrinsic renal disease. It may be obstructive and result from severe obstruction in the urinary collecting system, e.g. urethral valves.[85,86]

Prerenal failure is the most common form of acute renal failure in the surgical neonate and results from a severe decrease in renal perfusion, usually as a result of profound hypotension from blood loss, sepsis, severe necrotizing

enterocolitis. or intestinal obstruction with loss of fluid into dilated intestinal loops.

Primary fascial closure of omphalocele or gastroschisis carries the risk of placing the abdominal contents under pressure which may cause a reduction in cardiac output, hypotension, bowel ischemia, venostasis, and postoperative renal failure. Limited data suggest that an intragastric pressure >20 mmHg or an increase in central venous pressure of 4 mmHg or more indicate the need of a staged repair using a pouch.[87] Additionally, newborn infants with abdominal wall defects have significantly increased fluid requirements preoperatively as major insensible water losses occur when eviscerated bowel is exposed to air and a perioperative third space is frequently associated. These conditions also favor hypovolemia, hypoperfusion of the kidney, and postoperative renal failure.

Renal vein or renal artery thrombosis, if bilateral, may be associated with acute renal failure. Treatment is by early aggressive fluid replacement until blood pressure normalizes and then by meticulous adjustment of fluid and electrolyte balance, until recovery of renal function occurs. Peritoneal dialysis may be required until renal function recovers. Recovery is associated with a polyuric phase which also requires ongoing care with replacement of large amounts of water, potassium, and sodium via the kidneys.

Renal failure due to obstruction and due to congenital malformations is often associated with severe irreversible renal diseases not compatible with normal extrauterine life. The focus of care must initially be to decide on the appropriateness of active management. Further discussion of renal failure management is outside the scope of this chapter.

CONCLUSION

Major changes in body composition and in fluid and electrolyte balance occur during the transition to extrauterine life. These changes are even more marked in the preterm infant. The newborn infant who has a disorder requiring surgery has additional possible disorders of fluid and electrolyte balance. Future research and audit of fluid management strategies are vital to prevent hypernatremia, hyperglycemia and hyponatremia, and adverse neurodevelopmental sequelae.

Nutrition

AGOSTINO PIERRO AND SIMON EATON

INTRODUCTION

The newborn infant requires nutrition not only for tissue maintenance and normal metabolism, but also for growth – a term newborn grows at a rate of 25–30 g per day over the first six months of life, so that weight has doubled by the age of five months. The newborn infant is in a 'critical epoch' of development not only for the organism as a whole, but also for the individual organs and most significantly for the brain, so a significant period of inadequate nutrition may not only affect short-term outcomes, but may also be a risk factor for the long-term menace of stunted mental and physical development. As well as providing the components necessary for increase in tissue mass, adequate provision of the nutrients required to mount an appropriate immune response is extremely important, as infection and sepsis may impair growth and neurodevelopmental outcome.[1] Hence, where indicated, early intervention with appropriate artificial nutritional support is of paramount importance.

HISTORICAL BACKGROUND

Parenteral nutrition (PN) stepped forward from numerous historical anecdotes in the 1930s with the first successful infusion of protein hydrolysates in humans,[2] followed by the first report of successful total parenteral nutrition in an infant in 1944,[3] and given a huge boost by the first placement of a catheter in the superior vena cava to deliver nutrients for prolonged periods.[4] Using this system, Dudrick and Wilmore showed that adequate growth and development could be achieved in beagle puppies and in a surgical infant.[4] Following these initial reports, Filler and co-authors reported the first series of surgical neonates with gastrointestinal abnormalities treated with long-term total parenteral nutrition.[5] During the 1970s and 1980s, significant improvements were made in the technique itself and in reduction of complications, and the last 30 years have seen considerable changes in the nutritional management of surgical neonates. Various investigators have highlighted the importance of introducing enteral nutrition (EN) as soon as possible in surgical neonates. The beneficial effects of minimal enteral feeding on the immune system, infection rate, and liver function have been elucidated.

BODY COMPOSITION

Newborn infants grow very rapidly, have higher energy expenditure, and lower caloric reserves than adults and therefore do not tolerate prolonged periods of starvation. The body composition of newborn infants is markedly different from that of adults: total body water varies from 87% of body weight at 24–25 weeks' gestation to 71% at term and 50% in adulthood (Fig. 13.1).[6] This decline in body water also reflects an increase in energy content of the body. The ratio between resting energy expenditure (in kcal/kg per day) to non-protein energy reserve (in kcal/kg) gives an

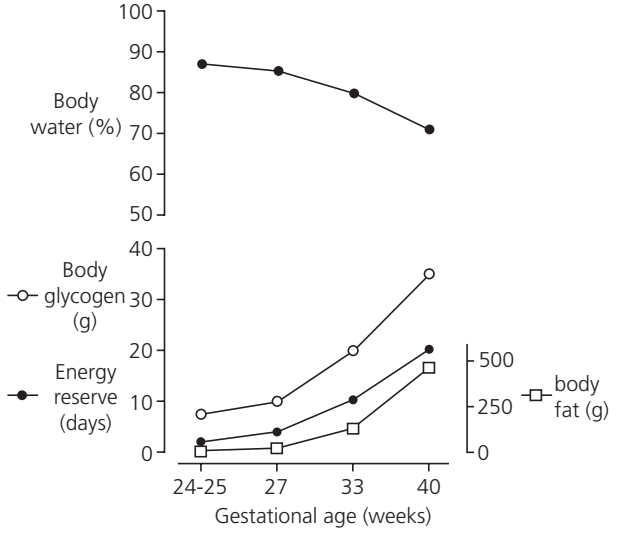

Figure 13.1 Body water and energy stores according to gestational age.

approximate estimate of the energy reserve of the infants. This is only ~2 days at 24–25 weeks' gestation, increases to ~20 days at term as glycogen and fat stores increase (Fig. 13.1)[6] and is in excess of 50 days in the adult, hence the urgent need for adequate caloric intake in very low birth weight (VLBW) and/or extremely low birth weight (ELBW) infants after birth. Early PN in VLBW infants has been shown to be beneficial,[7] although there is controversy on how 'aggressive' nutritional intervention should be in preterm infants. Full-term neonates have higher content of endogenous fat (approximately 600 g) and therefore can tolerate a few days of undernutrition.

ENERGY REQUIREMENTS OF THE NEONATE

Newborn infants have a significantly higher metabolic rate and energy requirement per unit body weight than children and adults: the total energy requirement for an extremely low birth weight (i.e. <1000 g) preterm infant fed enterally is 130–150 kcal/kg per day,[8] and that of a term infant is 100–120 kcal/kg per day, compared to 60–80 kcal/kg per day for a 10-year-old and 30–40 kcal/kg per day for a 20-year-old individual.[9–11] Of the 100–120 kcal/kg per day required by the term infant, approximately 40–70 kcal/kg per day is needed for maintenance metabolism, 50–70 kcal/kg per day for growth (tissue synthesis and energy stored), and up to 20 kcal/kg per day to cover energy losses in excreta.[12–14] Newborn infants receiving total parenteral nutrition (TPN) require fewer calories (110–120 kcal/kg per day for a preterm infant and 90–100 kcal/kg per day for a term infant[15]), due to the absence of energy losses in excreta and to the fact that energy is not required for thermoregulation when the infant is in an incubator. These data are shown diagrammatically in Fig. 13.2, but it should be stressed that energy requirements vary greatly. Several equations have been used to estimate the resting energy expenditure, and therefore the energy requirements, of infants and children. The most frequently used are those of the World Health Organization (WHO),[10] Schofield,[16] and Harris and Benedict.[17] These are based on weight, height, and/or age and are based on measurements of orally fed, healthy individuals, and thus take no account of the abnormal physiology and/or pathology of infants requiring artificial nutritional support. An equation has been developed to predict resting energy expenditure (REE) in stable surgical infants, to which the major contributing predictors are body weight, heart rate (providing an indirect measure of hemodynamic and metabolic status), and postnatal age.[18] Although adults show large increases in REE following trauma, surgery, burns, or during severe infection, this does not appear to be true for infants, although there are few studies in this area. Critically ill, post-surgical ventilated premature neonates,[19] neonates with necrotizing enterocolitis (NEC),[20] and surgical infants (with or without extracorporeal membrane oxygenation (ECMO))[21] were shown to have similar REE values to healthy neonates, whereas others have suggested that REE is increased during neonatal sepsis[22] and that REE correlates with severity of illness during sepsis in neonates.[23] Another study, examining the immediate postoperative response to neonatal surgery, found that there is a peak in REE 4 hours after surgery, which was short-lived, returning to baseline within 12–24 hours after surgery.[24] Thus, there is no clear indication that increased energy should be provided to septic or surgical neonates.[15]

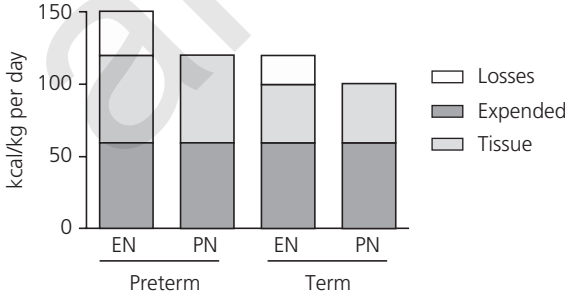

Figure 13.2 Partition of energy metabolism in preterm and term infants receiving nutrition enterally (EN) or parenterally (PN). 'Expended' includes basal metabolic rate, activity, the energy expended in laying down new tissue, and thermoregulation; 'tissue' is the amount of energy actually stored in new tissue; 'losses' include losses in stool etc. Data from: Refs 8, 9, 12, 14, 15.

Effects of operative trauma on energy metabolism

In contrast with adults, the energy requirement of infants and children undergoing major operations seems to be modified minimally by the operative trauma per se. In adults, trauma or surgery causes a brief 'ebb' period of a depressed metabolic rate followed by a 'flow phase' characterized by an increase in oxygen consumption to support the massive exchanges of substrate between organs.[25] In newborn infants major abdominal surgery causes a moderate (15%) and immediate (peak at 4 hours) elevation of oxygen consumption and resting energy expenditure and a rapid return to baseline 12–24 hours postoperatively.[24] There is no further increase in energy expenditure in the first 5–7 days following an operation.[24,26] The timing of these changes corresponds with the postoperative changes in catecholamine levels and other biochemical and endocrine parameters.[27] It has been demonstrated that the postoperative increase in energy expenditure can, at least partially, result from severe underlying acute illness, which frequently necessitates surgery (i.e. sepsis or intense inflammation, see below).[28] Interestingly, infants having a major operation after the second day of life have a significantly greater increase in resting energy expenditure than infants undergoing surgery within the first 48 hours of life. A possible explanation for this may be greater secretion of endogenous opioids in the perinatal period blunting the endocrine and metabolic responses.[27,29,30]

Resting energy expenditure is directly proportional to growth rate in healthy infants, and growth is retarded during acute metabolic stress. Studies in adult surgical patients have shown that operative stress causes marked changes in protein metabolism characterized by a postoperative increase in protein degradation, negative nitrogen balance,[31,32] and a

decrease in muscle protein synthesis.[33] However, changes in whole body protein flux, protein synthesis, amino acid oxidation, or protein degradation do not seem to occur in infants and young children undergoing major operations,[34] which led us to speculate that infants and children divert protein and energy from growth to tissue repair, thereby avoiding the overall increase in energy expenditure and catabolism seen in the adult.[20,34,35]

Effects of critical illness and sepsis on energy metabolism

Nutritional problems in infants and children requiring surgery are not unusual. The real nutritional challenge is not represented by the operation per se but by the clinical condition of the patient. Examples include intrauterine growth retardation in small for gestational age preterm infants, infants who have suffered massive intestinal resection for NEC, and infants with motility disorders of the intestine following surgery for atresia, malrotation and midgut volvulus, meconium ileus, or gastroschisis.

Nutritional integrity, particularly in the neonatal period, should be maintained regardless of the severity of the illness or organ failure due to the limited energy and protein stores in neonates. Infants and children require nutrition for maintenance of protein status as well as for growth and wound healing. One considerable challenge in pediatrics is represented by nutrition support during critical illness and sepsis. Keshen *et al.*[36] have shown that parenterally fed neonates on extracorporeal life support are in hypermetabolic and protein catabolic states. These authors recommend the provision of additional protein and non-protein calories to attenuate the net protein losses.

Sepsis is an intriguing pathological condition associated with many complex metabolic and physiological alterations.[37] Studies in adults have shown that the metabolic response to sepsis is characterized by hypermetabolism,[38] increased tissue catabolism,[38] gluconeogenesis, and hepatic release of glucose.[39] Energy is largely derived from fat, and increased protein catabolism provides precursors for enhanced hepatic gluconeogenesis.[39] However, fat mobilization is far greater than fat oxidation, implying considerable cycling[40] and, in later stages of sepsis, oxidative metabolism[41] and fat utilization may become impaired,[42] although we have shown that septic infants and children are able to oxidize considerable amounts of exogenous lipid.[43]

The existing knowledge on the metabolic response to sepsis in infants is limited. There are conflicting reports on whether critically ill infants are hypermetabolic.[21,44–49] However, most studies suggest that infants with sepsis do not become hypermetabolic[50,51](Fig. 13.3) and that septic neonates with NEC do not show any increase in whole body protein turnover, synthesis, and catabolism.[20] However, the conflicting data may reflect measurements taken at different times in infants with differing degrees of sepsis.[52]

From these studies, it is clear that the metabolic rate and hormonal response to surgery, stress, and sepsis in infants may well be different from that of adults and therefore it is not possible to adapt nutritional recommendations made for adults to the neonatal population. It is possible that neonates divert the products of protein synthesis and breakdown from growth into tissue repair. This may explain the lack of growth commonly observed in infants with critical illness or sepsis. Further studies are needed in this field to delineate the metabolic response of neonates and children to trauma and sepsis, explore the relationship between nutrition and immunity, and to design the most appropriate diet.

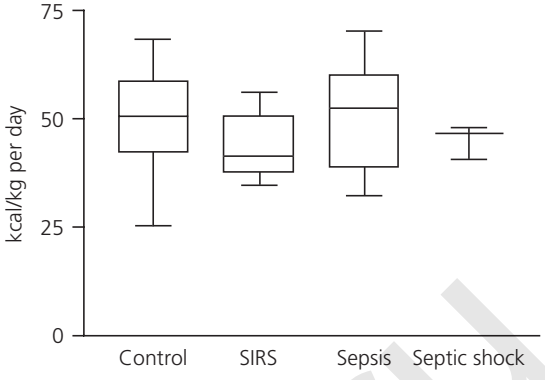

Figure 13.3 Resting energy expenditure in critically ill infants and controls. Indirect calorimetry was performed on infants and children with systemic inflammatory response syndrome (SIRS), sepsis, septic shock, and controls. Results are expressed as median, range, and interquartile range. There were no significant differences between the groups. See Ref. 50.

PARENTERAL NUTRITION

Indications

Parenteral nutrition should be utilized when enteral feeding is impossible, inadequate, or hazardous for more than 4–5 days. The most frequent indications in neonatal surgery are the intestinal obstruction due to congenital anomalies. Frequently after an operation on the gastrointestinal tract, adequate enteral feeding cannot be achieved for more than 1 week and parenteral nutrition becomes necessary. This modality of therapy has significantly improved the survival rate of newborns with gastroschisis, a condition which requires i.v. administration of nutrients for 2–3 weeks. Parenteral nutrition is also used in cases of NEC, shortbowel syndrome, gastroenterological indications, and respiratory distress.

Route of administration

As phlebitis may develop with the use of peripheral veins with solutions exceeding 600 mOsm, it is not possible to administer adequate calories peripherally for the growth of extremely low birth weight infants, and peripheral veins are only used for short-term, partial, nutritional supplementation. In neonates, the umbilical vessels can be used for provision of PN centrally, although the risk of complications increases if umbilical catheters are used for more than 5 days (arterial), or 14 days (venous).[53] Central venous catheters can

either be placed percutaneously directly in a deep vein, with subcutaneous tunneling of the extravascular part of the line, or can be a peripherally inserted central catheter (PICC). Although there has been a systematic review comparing outcomes in neonates administered PN through percutaneous central venous catheters versus peripheral cannulae, the authors concluded that there was insufficient evidence to make form recommendations.[54] For consideration of technical aspects of placement and management, the reader is directed to the ESPGHAN/ESPEN guidelines.[53]

Components of parenteral nutrition

The parenteral nutrition formulation includes carbohydrate, fat, protein, electrolytes, vitamins, trace elements, and water. The caloric needs for total parenteral nutrition are provided by carbohydrate and lipid. Protein is not used as a source of calories, since the catabolism of protein to produce energy is an uneconomic metabolic process compared to the oxidation of carbohydrate and fat which produces more energy at a lower metabolic cost. The ideal total parenteral nutrition regimen therefore should provide enough amino acids for protein turnover and tissue growth, and sufficient calories to minimize protein oxidation for energy.

FLUID REQUIREMENTS

As noted above, the proportion of body weight as water decreases with postnatal age (Fig. 13.1). In addition, the proportion of total body water which is extracellular also decreases, from 65% at 26 weeks' gestation to 40% at term, and 20% in childhood.[55] This contributes to an expected weight loss in the first days of life. Any newborn infant deprived of oral fluids will lose body fluids and electrolytes in urine, stools, sweat, and evaporative losses from the lungs and the skin. The insensible water losses from the skin are particularly high (up to 80–100 mL/kg per day) in VLBW or extremely premature infants.[55,56] This is due to the very large surface area relative to body weight, to the very thin and permeable epidermis, to reduced subcutaneous fat, and to the large proportion of total body water and extracellular water.[55] The preterm infant requires larger amounts of fluid to replace the high obligatory renal water excretion due to the limited ability to concentrate urine. In surgical newborns it is not unusual to have significant water losses from gastric drainage and gastrointestinal stoma. Phototherapy may also increase losses. In order to reduce the water losses it is important to use double walled incubators, to place the infant in relatively high humidity, to use warm humidified air via the endotracheal tube, and in premature babies to cover the body surface with an impermeable sheet. However, overhydration is potentially a problem, leading to complications such as pulmonary edema, and fluid restriction may be necessary for treatment of patent ductus arteriosus, renal insufficiency, and chronic lung disease. A meta-analysis showed that although a liberal fluid regime decreased weight loss in premature infants in the first days of life, it significantly increased the risk of mortality, and the incidence of patent ductus arteriosus and NEC.[57] Thus the recommended fluid intakes of neonates fall between 60 and 80 mL/kg per day (for premature infants on the first day of life) and 140–170 mL/kg per day (for neonates during the stable growth phase).[58] Hence, a 'one-size fits all' prescription is inappropriate, and frequent monitoring of weight, urine output, and urea and electrolytes, with reassessment of fluid prescription, should be mandatory in the first weeks of life.

ENERGY SOURCES

Carbohydrates and fat provide the main energy sources in the diet, and this is reflected by their importance as a source of calories in parenteral nutrition. Glucose is a main energy source for body cells and should be the primary energy substrate in parenteral nutrition, covering 60–70% of non-protein calories.[59] The amount of glucose that can be infused safely depends on the clinical condition and maturity of the infant, as the ability of neonates to metabolize glucose may be impaired by prematurity and low birth weight. Since (1) pancreatic islet cell function is relatively unresponsive for the first 2 weeks of neonatal life; (2) glycogen stores are limited (Fig. 13.1); (3) gluconeogenesis may be impaired; and (4) liver and peripheral tissues are relatively insensitive to insulin, premature neonates are at risk from both hypoglycemia and hyperglycemia.[60] Glucose infusion should be at least at a rate capable of maintaining blood glucose above 2.6 mmol/L, the current consensus definition of neonatal hypoglycemia.[61] As the rate of endogenous glucose metabolism in neonates is of the order of 5 mg/kg per minute, this should be considered the lowest infusion rate likely to avoid hypoglycemia.[59] As glucose tolerance increases, the rate of glucose infusion can be increased. However, carbohydrate conversion to fat (lipogenesis) occurs when glucose intake exceeds metabolic needs. The potential risks associated with this process are two-fold: accumulation of the newly synthesized fat in the liver, and aggravation of respiratory acidosis resulting from increased CO_2 production, although whether these are clinically relevant in PN-fed infants is uncertain. In addition, hyperglycemia in ELBW infants is a risk factor for late onset sepsis, mortality and the risk of developing advanced NEC.[62] A rapid increase in plasma glucose concentration precedes development of NEC,[63] and infants with established NEC have both a high prevalence of hyperglycemia and a worse outcome if hyperglycemic.[64]

Lipids provide an energy-dense (9 kcal/g of fat), isotonic alternative to glucose as an energy source for PN, which also prevents essential fatty acid deficiency and facilitates provision of fat soluble vitamins. Combined infusion of glucose and lipids confers metabolic advantages over glucose, because it lowers the metabolic rate and increases the efficiency of energy utilization.[65,66] There is a close interdependence of carbohydrate and lipid infusion rates on the one hand, and net fat deposition or oxidation on the other (Fig. 13.4). When the intake of glucose calories exceeds 18 g/kg per day (i.e. resting energy expenditure), net fat oxidation is minimal regardless of fat intake, and net fat synthesis takes place.[67] At a carbohydrate intake of 15 g/kg per day, the proportion of energy metabolism derived from fat oxidation does not

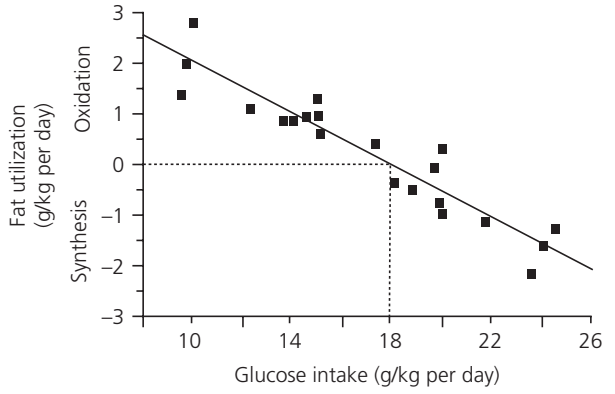

Figure 13.4 Linear relationship between glucose intake and fat utilization ($r = -0.9$; $p < 0.0001$). Lipogenesis is significant when glucose intake exceeds 18 g/kg per day. From Pierro *et al. Proc Nutr Soc* 1993; **52**: 237A with permission from the publisher, Cambridge University Press.[67]

exceed 20%, even with a fat intake as high as 6 g/kg per day. At a carbohydrate intake of 10 g/kg per day this proportion can be as high as 50%.[67] However, lipid utilization is often low and unpredictable in neonates and, consequently, lipids are usually introduced slowly, especially in premature neonates.[68]

The most commonly used fat emulsions for PN in pediatrics are based on soybean oil, in which the lipid is present as long-chain triglycerides (LCT). LCT require carnitine for their oxidation, and as decreased carnitine levels have been found in parenterally fed neonates,[69,70] supplementation has been recommended by some groups. However, carnitine levels have to fall extremely low before fat oxidation is impaired,[71] and a systematic review found no evidence to support the routine supplementation of parenterally fed neonates with carnitine[72] and although one subsequent trial found a beneficial effect of carnitine on catch-up growth,[73] others have found no significant benefits.[74,75] Medium-chain triglycerides (MCT), which do not require carnitine for their oxidation, can increase net fat oxidation without increasing metabolic rate when used to partially replace LCT.[76] Although there have been recent suggestions that MCT/LCT mixtures may improve essential fatty acid status (by protecting essential fatty acids from oxidation),[77] no randomized controlled trials (RCTs) comparing clinical outcomes between LCT and MCT/LCT in neonates are available. Although there is also interest in alternative lipid emulsions containing structured triglycerides (in which medium-chain and long-chain fatty acids are on the same triglyceride molecule), olive oil-based[78] and fish oil-based emulsions, no outcome-based RCTs in neonates on PN have been published.

AMINO ACIDS

In contrast to healthy adults who exist in a state of neutral nitrogen balance, infants need to be in positive nitrogen balance in order to achieve satisfactory growth and development. Preterm infants who are receiving glucose alone lose protein quickly (at the rate of 1–2% body protein per day), so should start to receive at least 1–1.5 g/kg per day amino acids parenterally if not receiving EN.[80] Infants are efficient at retaining nitrogen, and can retain up to 80% of the metabolizable protein intake on both oral and i.v. diets.[81] Protein metabolism, and deposition of body protein for growth, is dependent upon both protein and energy intake, so that above an energy intake of 70 kcal/kg per day, the major determinant of nitrogen retention in preterm infants is the amino acid intake.[81] The PN amino acid requirement of term newborn infants is between 2.5 and 3.0 g/kg per day, which allows for accretion of body protein.[82] Complications like azotemia, hyperammonemia, and metabolic acidosis have been described in patients receiving high levels of i.v. amino acids[83] but are rarely seen with amino acid intake of 2–3 g/kg per day.[84] In patients with severe malnutrition or with additional losses (i.e. jejunostomy, ileostomy), protein requirements are higher.[85] The nitrogen source of TPN is provided as a mixture of amino acids, and mixtures specifically formulated for neonates are available. However, the ideal amino acid composition for term and preterm infants is uncertain. As well as the amino acids usually considered essential for adult humans, histidine is considered essential for infants, and the following amino acids have all been considered 'conditionally essential' for neonates: arginine, cysteine, glutamine, taurine, and tyrosine.[86]

Cysteine is unstable in amino acid mixtures, but is central to sulfur amino acid economy and for glutathione synthesis. It is not certain whether newborn infants, especially those born prematurely, are capable of adequate rates of cysteine synthesis.[86] A meta-analysis of available trials in PN-fed neonates suggested that although cysteine supplementation may improve nitrogen balance, there were insufficient data to evaluate the risks of cysteine addition, such as metabolic acidosis.[87]

Like cysteine, glutamine is excluded from PN amino acid mixtures because of poor stability, although it can now be added as a dipeptide. Glutamine is important for the immune system and the intestine, as well as being essential as a nitrogen-carrier between organs. It has been hypothesized that glutamine supplementation to parenterally fed neonates would decrease the incidence of infection and decrease to time to full enteral feeding. Two small studies examined the effects of PN glutamine supplementation in premature infants and found decreased duration of ventilation and decreased incidence of sepsis.[88,89] However, a larger study in premature infants[90] found no benefit of glutamine supplementation. One RCT[91] in surgical infants found that parenteral glutamine supplementation had no significant effect on intestinal permeability or nitrogen balance, although this study was not powered to detect differences in clinical end points such as incidence of sepsis or duration of PN.

Arginine has also been considered conditionally essential to the neonate[86] and studies have shown low plasma arginine in infants with NEC.[92–94] Supplementation of PN, followed by EN, with arginine decreased the incidence of NEC in an RCT,[95] and recently it has been suggested that infants who have genetic polymorphisms that cause lower arginine levels have an increased susceptibility to NEC.[96]

Tyrosine synthesis from phenylalanine may be impaired in neonates,[82,86] and the measured tyrosine requirement for

neonates is much greater than is available in current neonatal amino acid mixtures, due to poor solubility.[97]

Taurine is a non-protein forming amino acid that has roles in the immune system, as an osmolyte, and in retinal and neurological function, and for bile acid conjugation.[98,99] Neonates on PN may have poor taurine status due to poor renal reabsorption, impaired activity of synthetic enzymes, and low levels of cysteine, the immediate precursor for taurine.[99] Plasma taurine status of preterm infants has now also been suggested to affect neurodevelopmental outcome.[100] Despite the lack of strong evidence from RCTs, most PN amino acid mixtures for neonates now contain taurine. This has been suggested to decrease the incidence of cholestasis in infants on PN.[101]

MINERALS, VITAMINS, AND TRACE ELEMENTS

Minerals, vitamins, and trace elements are important structurally, as cofactors, or as components of enzymes, and provision of adequate supplies is important for the growing neonate. Fe, Ca, P, and Mg should all be provided in adequate amounts for growth and development, but conversely, can cause problems if provided in excess of needs or if their metabolism is impaired. In addition, administration of adequate amounts can be problematic, because of lack of stability in solution or lack of compatibility with other components. Consequently, iron is often only supplemented in longer-term PN[102] whereas calcium and phosphate supply depends on solubility in PN mixtures.[102] Vitamins and trace elements are particularly important in maintenance of the body's antioxidant defences: vitamins C and E, selenium (for glutathione peroxidase), copper, zinc, and manganese (all for superoxide dismutases), chromium, iodine, and molybdenum can all be added to PN. However, for many of these, the precise requirements are not known. Although there is evidence that selenium supplementation may be beneficial, selenium status varies widely geographically, so global recommendations are difficult.[103] It is suggested that if the duration of PN is less than 4 weeks, of the trace elements, only zinc needs to be added.[102,104] There is little specific evidence for individual vitamin requirements, and the current recommendations are to continue with the available vitamin mixtures, which do not appear to cause toxicity or deficiency in the majority of neonates.[104,105] Free radical production and lipid peroxidation will be considered in more detail below.

Complications of parenteral nutrition

INFECTIOUS COMPLICATIONS

In spite of significant improvement in the management of PN, including the introduction of nutrition support teams, infection is still a major problem. In a recent prospective study, we found that around 50% of surgical neonates on PN have at least one suspected episode of sepsis, with around 25% of surgical neonates having at least one positive blood culture.[106] This may lead to impaired liver function,[107,108] critical illness, and removal of central venous catheters. Although catheter-borne infections, which can be reduced by rigorous precautions, are important,[109] microbial translocation from the intestine is also a significant source of infection in surgical infants of PN.[107,108] In a study on surgical neonates on PN[107] all but one episode of microbial translocation occurred in patients with elevated serum bilirubin (cholestasis). Pierro *et al.* have reported that almost half the surgical infants on PN develop abnormal flora and that all cases of septicemia were preceded by gut colonization with abnormal flora.[108] PN itself also impairs neonatal host defences[110] but minimal enteral feeding may help to prevent this.[111] Important factors in reducing the incidence of septic complications are placing i.v. catheters under strict aseptic conditions, preparing the parenteral nutrition solutions in pharmacy in aseptic conditions, and using meticulous care when the catheters are used. Sepsis should be suspected when infants on PN present clinical features of generalized inflammation including one or more of the following features: temperature instability, poor perfusion, hypotension, lethargy, tachycardia, respiratory distress, and fever. In these neonates, blood culture should be performed from the central venous line and/or from a peripheral vein.

METABOLIC COMPLICATIONS

The metabolic complications most frequently observed in newborn infants receiving PN are listed in (Box 13.1). These complications are related to inappropriate administration

Box 13.1 Metabolic complications of parenteral nutrition

Carbohydrate administration
- Hyperglycemia
- Hypoglycemia
- Fatty infiltration of the liver
- Hyperosmolarity and osmotic diuresis
- Increased CO_2 production

Protein administration
- Hyperammonemia, azotemia
- Abnormal plasma amino acid profiles
- Hepatic dysfunction
- Cholestatic jaundice

Fat administration
- Hyperlipidemia
- Fat overload syndrome
- Displacement of albumin-bound bilirubin by free fatty acids
- Peroxidation and generation of free radicals

Fluid administration
- Patent ductus arteriosus
- Pulmonary edema

Electrolyte imbalance
- Sodium, potassium, chlorine, calcium, phosphate

Trace element and vitamin deficiency

of nutrients, fluid, electrolytes, and trace elements or to the inability of the individual patient to metabolize the i.v. diet.

Hyperglycemia occurs frequently during the course of PN, particularly while the glucose concentration of the infusate is being increased, but most patients will produce adequate endogenous insulin to metabolize the carbohydrate load within hours. Hyperglycemia can also be a sign of impending infection, and has also been associated with development of NEC. The treatment of symptomatic hyperglycemia is usually reduction of the infusion rate, but exogenous insulin is sometimes given to ELBW infants with glucose intolerance.[112] Hypoglycemia usually results from sudden interruption of an infusion containing a high glucose concentration.

High doses of fat or an accidental rapid infusion of fat may lead to fat overload syndrome, characterized by an acute febrile illness with jaundice and abnormal coagulation and respiratory problems[68,113] and so lipids are usually advanced slowly, with close monitoring of triglyceride levels, especially in neonates with respiratory insufficiency or suspected infections.[68] Peroxidation in stored fat emulsions and the generation of free radicals during i.v. infusion of fat in premature infants have been reported.[114] However, the degree of free radical production is linked to the rate of lipid oxidation, as we have shown that a reduction in the carbohydrate to fat ratio in PN diet will result in increased oxidation of administered fat and a decrease in free radical-mediated lipid peroxide formation (Fig. 13.5).[115] It is interesting to note that the decrease in malondialdehyde (an index of lipid peroxidation) accompanying increased fat utilization was of a similar magnitude to that observed when the fat infusion was discontinued. Therefore, it is not necessary to discontinue the infusion of fat to reduce the production of oxygen-derived free radicals. Manipulation of the carbohydrate to fat ratio therefore may be a powerful tool in changing the metabolism of fat infusions to mitigate their toxic effects while allowing continued administration.

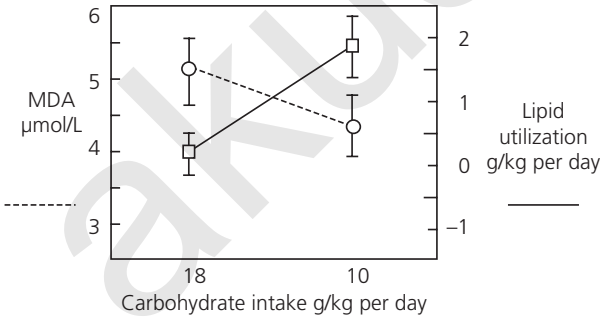

Figure 13.5 Free radical production (assessed as plasma malondialdehyde, MDA, concentration) in response to different carbohydrate contents of PN. Data redrawn from Ref. 115.

Mechanical complications

Mechanical complications related to the i.v. infusion of nutrients are not uncommon. Box 13.2 lists the mechanical complications reported in the literature. Extravasation of PN solution is a common complication of peripheral PN. Unfortunately, even a low osmolarity solution is detrimental for peripheral veins leading to inflammation and extravasation of the solution, which can cause tissue necrosis and infection. Extravasation injury is treated with occlusive dressings or hyaluronidase irrigation, but there is little evidence base for the best treatment in neonates.[116] Intravenous lines may become clogged from thrombus formation, calcium precipitates, or lipid deposition. There is disagreement on the ideal position of central venous lines (CVL) for PN in infants. Some authors advocate the atrium as the ideal position because this would give less chance of catheter dysfunction, whereas others believe that placement in the superior vena cava would reduce the risk of perforation. The current ESPGHAN/ESPEN recommendations are that the catheter tip should lie outside the atrium,[53] but because complications of either approach are very rare (albeit potentially life-threatening), there is a paucity of evidence from RCTs.

Box 13.2 Mechanical complications of parenteral nutrition

Extravasation of parenteral nutrition solution
Blockage of the central venous line
Migration of the central venous line
Breakage of the infusion line
Right atrium thrombosis
Cardiac tamponade (perforation of right atrium or vena cava)

Hepatic complications

The hepatobiliary complications related to PN remain serious and often life-threatening. The most common hepatobiliary complication of PN in neonates is cholestasis. The incidence of parenteral nutrition-associated cholestasis (PNAC) depends on the length of time on PN, so that PNAC occurs in up to 50% of infants receiving PN for at least two months.[117] Although the frequency of this complication seems to be diminishing,[118] this is probably related to the early initiation of oral feeding rather than to an improvement in the i.v. diet. The etiology of cholestatic jaundice in infants requiring PN is still unclear. However, infants requiring long-term PN still develop progressive jaundice, commonly preceded by elevation of biochemical nonspecific tests of hepatic damage, function, and excretion.

Various clinical factors are thought to contribute to the development of PNAC. These include prematurity, low birth weight, duration of PN, immature enterohepatic circulation, intestinal microflora, septicemia, failure to implement enteral nutrition, short bowel syndrome due to resection, and number of laparotomies (reviewed[119]). In addition to the effects of extremely low birth weight, and length of time on PN, infants receiving PN for either gastroschisis or jejunal

atresia seem to be at particular risk.[120] PNAC has a higher incidence in premature infants than in children and adults. This may be due to the immaturity of the biliary secretory system since bile salt pool size, synthesis, and intestinal concentration are low in premature infants in comparison with full term infants.[121] PNAC is a diagnosis of exclusion without any specific marker yet available. Therefore, infants with cholestasis (conjugated bilirubin >2.0 mg/dL) who are receiving or have received PN must have an appropriate diagnostic evaluation to exclude other causes of cholestasis, such as bacterial and viral infections, metabolic diseases (e.g. alpha-1-antitrypsin deficiency, tyrosinemia), and congenital anomalies (e.g. Alagille syndrome, biliary atresia, choledocal cyst).[122] The cholestasis is progressive unless PN is ceased and enteral feeding introduced. Hepatosplenomegaly and severe jaundice are characteristic features of the advanced disease, and portal hypertension may develop. Although PNAC resolves with time after discontinuation of PN, this is not possible in many patients with short bowel, and in these patients, cholestasis is the strongest predictor of mortality.[123]

The etiology of PNAC remains unclear. Possible causes include the toxicity of components of PN, lack of enteral feeding, continuous non-pulsatile delivery of nutrients and host factors, infection, and sepsis.[119] Risk factors are listed in Box 13.3. Most of the components of PN have been implicated in the pathogenesis of cholestasis. Hepatic damage from the components of i.v. diet may result from excessive trace element administration (e.g. aluminum and manganese), deficient amino acid administration (e.g. lack of taurine for bile acid conjugation[101]), or may be related to impurities present in PN lipid.[124,125]

The clinical care of infants and children who require PN and develop progressive jaundice represents a real challenge, compounded by this lack of knowledge. Prevention of PNAC is based on the early usage of enteral feeding and on the administration of i.v. feeding only when appropriate and necessary. In most patients the cholestasis resolves gradually as enteral feedings are initiated and PN is discontinued. It has been shown that minimal bolus enteral feeding (1 mL/kg) during PN in premature infants induces significant gallbladder contraction and after 3 days of starting minimal enteral feeds, the gallbladder volume returns to normal.[126] Unfortunately, as a consequence of gut dysfunction, enteral feeding is often not feasible. Maini *et al.*[127] suggested that cycling the PN may diminish cholestatic hepatic changes in adults. This may explain the less frequent liver disease in children receiving their PN cyclically at home. Experience with this technique in premature infants is extremely limited but encouraging.[128,129] Rebound hypoglycemia is a common complication of this approach. Modification of the PN constituents has been proposed but no prospective trial has demonstrated any benefit in reducing or changing the intake of nutrients.

Box 13.3 Patient risk factors for the development of parenteral nutrition–associated cholestasis

Age
Prematurity
Immaturity of biliary secretory system
Absence of oral/enteral intake
Septicemia
Bacterial overgrowth in the small bowel
Short bowel length
Necrotizing enterocolitis
Hypoxia
Major abdominal operations
General anesthesia

Several reports have described the attempts to use drug therapy to treat or prevent PNAC. Cholecystokinin has been administered to diminish gallbladder stasis and promote bile flow, and has been shown to be effective in preventing stasis and sludge in the gallbladder in a randomized, double-blind controlled trial in adults receiving PN.[130] However, despite promising pilot studies in neonates,[131,132] cholecystokinin was shown not to be effective in preventing PNAC in a randomized, double-blind, controlled trial in 243 neonates receiving PN.[133] Ursodeoxycholic acid can be used in infants and children on PN to correct the decreased secretion of endogenous bile acids. Ursodeoxycholic acid is non-toxic and acts as a natural bile acid after conjugation. Although ursodeoxycholic acid has shown beneficial effects in treatment of children with established PNAC, there have only been limited trials of ursodeoxycholic acid,[134] or the related compound tauroursodeoxycholic acid, in the prevention of PNAC in neonates, neither of which showed a benefit. In a multivariate analysis of the same patients enrolled in the neonatal cholecystokinin trial described above, it was suggested that the presence of taurine in the PN amino acid solution protects against the development of cholestasis.[101] However, most pediatric-specific amino acid solutions now contain taurine, and it is unknown whether supplementation with additional taurine would have any benefit. Recently, much interest has been shown in the use of fish oil-based (omega-3 containing) lipid emulsions in the prevention of PNAC. Two patients who appeared to have a reversal of cholestasis after switching from a soy-based lipid emulsion to a fish oil-based emulsion have been reported,[79] and there have been other anecdotal reports, but until an RCT is performed, the efficacy of fish oil-based emulsions is uncertain.

Cholecystectomy is the treatment of choice for patients with acute and symptomatic cholelithiasis and cholecystitis. Rintala[135] proposed laparotomy and operative cholangiography followed by biliary tract irrigation in patients with progressive cholestatic jaundice not responding to medical treatment. In some patients the hepatic disease may progress to cirrhosis, portal hypertension, and hepatic failure. Bowel lengthening procedures may help transition to EN,[136,137] whereas in those with advanced liver disease and no prospect of enteral autonomy, transplantation may be considered. Isolated liver transplantation, isolated intestinal transplantation, and liver plus intestinal transplant are all feasible in children, and although results are improving, overall outcomes are still poor and organ availability is, of course, a problem.[138]

Enteral nutrition

The energy requirement of an infant fed enterally is greater than the i.v. requirement because of the energetic cost of absorption from the gastrointestinal tract and energy lost in the stools (Fig. 13.2).

FEEDING ROUTES

Alternative feeding routes where neonates are unable to feed orally include naso-gastric or oro-gastric tubes, naso-jejunal tubes, gastrostomy tubes, or jejunostomy tubes. Gastric feeding is generally preferable to intestinal feeding because it allows for a more natural digestive process, i.e. allows action of salivary and gastric enzymes and the antibacterial action of stomach acid. In addition, gastric feeding is associated with a larger osmotic and volume tolerance and a lower frequency of diarrhea and dumping syndrome. Thus, transpyloric feeds are usually restricted to infants: (1) unable to tolerate naso- or oro-gastric feeds; (2) at increased risk of aspiration; (3) with anatomical contraindications to gastric feeds, such as microgastria. Neonates are obligatory nose breathers and therefore oro-gastric feeding may be preferable over naso-gastric feeding in preterm infants to avoid upper airway obstruction. However, naso-gastric tubes are easier to secure and may involve a lower risk of displacement. In infants requiring gastric tube feeding for extended periods (e.g. more than 6–8 weeks) it is advisable to insert a gastrostomy to decrease the negative oral stimulation of repeated insertion of nasal or oral tubes. The tube can be inserted using an open, endoscopic, or laparoscopic approach. In infants with significant gastro-esophageal reflux, fundoplication with gastrostomy tube or enterostomy tube placement is indicated.[139] In preterm infants with gastro-esophageal reflux, enteral feeding can be established via a naso-jejunal tube inserted under fluoroscopy. Naso-jejunal feeding usually minimizes the episodes of gastro-esophageal reflux and their consequences. However, it is common for these tubes to dislocate back in the stomach. Regular analysis of the pH in the aspirate is essential to monitor the correct position of the tube. Feeding jejunostomy tubes can be inserted through existing gastrostomy or directly into the jejunum via laparotomy or laparoscopy.

SELECTION OF ENTERAL FEEDS

Breast milk is the ideal feed for infants because it has specific anti-infectious activities, aids gastrointestinal maturation and neurological development. When breast milk is not available, chemically defined formulae can be used, which are designed either for term infants or specifically for preterm infants. If malabsorption is present and persists, an appropriate specific formula should be introduced. A soy-based disaccharide-free feed is used when there is disaccharide intolerance resulting in loose stools containing disaccharides. For fat malabsorption, a formula containing MCTs should be used. An elemental (free amino acids) or semi-elemental (protein hydrolysate containing di- and tri-peptides) formula may be indicated when there is severe malabsorption due to short bowel syndrome or severe mucosal damage as in NEC. Semi-elemental preparations have the advantage of a lower osmolality, are well absorbed, and have a more palatable taste. Infants recovering from NEC pose a particular problem, as malabsorption may be severe and prolonged. These infants may have had the small bowel resected, in addition to which the remaining bowel may not have healed completely by the time feeds are begun. Feeding may provoke a relapse of the necrotizing enterocolitis and feeding should therefore be introduced cautiously. For persistent severe malabsorption, a modular diet may be necessary. Glucose, amino acid, and MCT preparations are provided separately, beginning with the amino acid solution and adding the glucose and then the fats as tolerated. Minerals, trace elements, and vitamins are also added. These solutions have a high osmolality and if given too quickly may precipitate dumping syndrome, with diarrhea, abdominal cramps, and hypoglycemia. It is important therefore to start with a dilute solution and slowly increase the concentration and volume of each component. This may take several weeks and infants will need PN support during this period.

ADMINISTRATION OF ENTERAL FEEDS

Enteral feeds can be administered as boluses, continuous feeds, or a combination of the two. Bolus feeds are more physiological and are known to stimulate intestinal motility, enterohepatic circulation of bile acids, and gallbladder contraction;[140] continuous enteral feeding leads to an enlarged, non-contractile gallbladder in infants.[141] Contraction is observed immediately after resuming bolus enteral feeds and gallbladder volume returns to baseline after 5 days. Therefore, the mode of feeding has important bearings on the motility of the extrahepatic biliary tree. Bolus feeds mimic or supplement meals and are easier to administer than continuous feeds since a feeding pump is not required. Bolus feeds are usually given over 15–20 minutes and usually every 3 hours; term infants can tolerate a period of 4 hours without feeds before hypoglycemia occurs. In preterm neonates or in neonates soon after surgery, 2-hourly feeds are occasionally given. Where bolus feeds are not tolerated, for example in the presence of gastro-esophageal reflux, continuous feeds should be administered via an infusion pump over 24 hours. This modality of feeding is used in infants with gastro-esophageal reflux, delayed gastric emptying, or intestinal malabsorption. Infants with jejunal tubes should receive continuous feeds and not bolus feeds as the stomach is no longer providing a reservoir.

COMPLICATIONS OF ENTERAL TUBE FEEDING

Enteral tube feeding is associated with fewer complications than parenteral feeding. The complications can be mechanical including tube blockage, tube displacement or migration, and intestinal perforation. Although infection is less of a risk than with PN, the risk of infected enteral feeds should not be ignored.[142] Other complications involve the gastrointestinal tract. These include: gastro-esophageal reflux with aspiration pneumonia, dumping syndrome, and diarrhea. Jejunostomy

tubes inserted at laparotomy can be also associated with intestinal obstruction. The use of hyperosmolar feeds has been associated with development of NEC, dehydration and rarely, intestinal obstruction due to milk curds.[143]

In surgical infants, enteral feeding often results in vomiting, interruption of feeding, inadequate calorie intake, and rarely in NEC. In infants with congenital gastrointestinal anomalies, exclusive enteral feeding is commonly precluded for some time after surgery due to large gastric aspirate and intestinal dysmotility. Therefore, appropriate calorie intake is established initially by total PN. Supplementary enteral feeding is introduced when intestinal motility and absorption improves. The percentage of calories given enterally is gradually increased at the expense of i.v. calorie intake. This transition time from total PN to total enteral feeding could be quite long. The presence of significant gastric aspirate often induces clinicians and surgeons not to use the gut for nutrition. However, minimal enteral feeding can be implemented early in these patients even if its nutritional value is questionable. Minimal enteral feeding may be all that is required to enhance some immunological function. This is supported by studies in animals[144] and infants.[111] Shou *et al.*[144] reported that supplementation of PN with just 10% enteral calories as chew diet improved rat macrophage and splenocyte function. Okada *et al.*[111] have shown that the introduction of small volumes of enteral feed improved the impaired host bactericidal activity against coagulase-negative staphylococci and the abnormal cytokine response observed during total PN. The increase in bactericidal activity against coagulase negative staphylococci after the addition of small enteral feeds in patients on PN was significantly correlated with the duration of enteral feeding. This implies that stimulation of the gastrointestinal tract may modulate immune function in neonates and prevent bacterial infection.

Vascular access in the newborn

SEAN J BARNETT AND FREDERICK C RYCKMAN

INTRODUCTION

Although only a small fraction of all neonates require extensive resuscitation, the large number of births throughout the world ensures that adequate neonatal intensive care facilities remain on the cutting edge of technology. Advancements in monitoring, ventilatory support, vascular access, and maintenance of core body temperature have been paramount in the vast increase in the survival rates of newborns.[1] New innovations in size and materials coupled with new routes of vascular access have been paramount for neonatologists in regards to invasive monitoring, ionotropic support, and total parental nutrition. Invasive monitoring includes both continuous blood pressure measurements and also the ability to obtain arterial blood for up to the minute blood gas measurements for ventilatory support. Smaller catheter size and peripheral central routes have enabled the neonatologist to maximize the use of blood products, electrolytes, drug delivery, and nutrition, especially in those neonates that are unable to tolerate enteral nutrition for long periods of time. These new catheters now allow for smaller and sicker neonates to gain the same advantage that was once only available to larger infants within the intensive care unit.

ARTERIAL CANNULATION

Invasive access to the arterial system has been a mainstay in the monitoring of the critically ill patient for decades. Short-term arterial access has circumvented the need for numerous heel sticks or difficult arterial punctures for blood gas analysis utilized for ventilatory changes. Continuous blood pressure monitoring allows for up to the minute decision-making when using supportive vasoactive medications and can also be used to draw needed blood studies, obviating frequent venopunctures. The majority of these cannulae can be placed by percutaneous insertion techniques at the bedside.

Maintenance

Catheters within the arterial system are particularly prone to thrombosis, which guides their general care. Continuous infusion of a balanced saline solution with heparin (1 unit/mL) at a minimum of 0.5 mL/hour for all arterial lines helps to ensure patency. The type of fluid can be altered, dictated by the clinical situation. Arterial catheters are flushed with 0.5 mL of normal saline over 5 seconds after each blood draw to clear the system.

Blood pressure monitoring devices are connected by three-way stop cocks for ease of blood draws and to ensure sterility. Transducers are leveled to the phlebostatic axis (located at the fourth intercostal space and half the anterior-posterior (AP) diameter of the chest). The system is zeroed with the transducer in this position at the initial set-up, each shift change, and with position change of the transducer. The waveform can become dampened due to microthrombi, positioning, or from mechanical disturbances within the system. Once a waveform appears dampened, all connections are checked and secured, the tubing is evaluated for air within the system (this tends to blunt the actual pressure reading), and the catheter is then irrigated. The infant or catheter can be re-positioned and the limb immobilized if necessary.

Most arterial catheters in infants in our institution are sutured into place to provide stability and promote safety. Transparent dressings (Tegaderm, Opsite) are utilized facilitating inspection of the insertion site while maintaining sterility. The connections, catheter, stitches, and tubing are examined and their status documented every shift to ensure that they are intact. Intravenous fluids are changed every 24 hours and the tubing is changed every 72 hours, utilizing sterile technique. Transducers are changed every 72 hours as well. Nursing assessment of color, pulses, capillary refill, and temperature is documented every 2 hours and the position of deeper indwelling catheters (i.e. umbilical arterial catheters) is documented with x-rays following placement and as indicated.

Complications

Most complications with peripherally inserted arterial catheters arise due to thromboembolic events or vasospasm.[2,3] Treatment is prompt removal at the first sign of blanching of the distal extremities. Further treatment includes the use of heparin or tissue plasminogen activator (TPA) and in rare circumstances surgical removal of clot if extremity tissue viability is compromised. Infectious complications are rare with arterial catheters as long as appropriate measures as described above are followed.

Umbilical artery catheters have a higher risk of thromboembolism, especially when they are placed in the low lying position (L3–L5).[4] The infectious rates are similar to central venous catheter rates.[3] We tend to remove these catheters within 5 days of being placed to help prevent these issues. Studies have also shown that there is no evidence that prophylactic antibiotics are useful with these catheters.[5]

UMBILICAL ARTERY CATHETERIZATION

Cincinnati Children's Hospital Medical Center serves as the regional referral center for neonatal care for southern Ohio, Northern Kentucky, and West Virginia, and for southeast Indiana. As a referral neonatal intensive care unit with no inborn population, the majority of neonates in need of umbilical artery monitoring have had their catheters placed by a referring neonatologist in the initial nursery. There are certain situations which require this invasive type of monitoring, i.e. EXIT procedures and congenital diaphragmatic hernia patients who are either born at our facility or immediately transferred at birth. Whereas this is not a common procedure performed by most pediatric surgeons, the ability to place these catheters is a valuable tool in the invasive monitoring of the critically ill neonate.

One or both umbilical arteries may be cannulated for continuous blood pressure monitoring or for frequent arterial blood gas measurements for complex ventilator management. Resuscitation fluids and medications can be delivered via these cannulae in urgent situations but are best infused using venous access sites discussed later in this chapter.

Access technique

Catheter length should be established prior to initiating the procedure using standardized graphs, which utilize the shoulder to umbilical cord length in centimeters to estimate the position of the catheter.[6] Calculations can also be performed using birth weight (BW) to estimate the desired position of the catheter (high T6–T9, low L3–L5), such as those described by Shukla and Ferrara:[7]

$$\text{Low catheter position UA length (cm)} = \text{birth weight (kg)} + 7$$

$$\text{High catheter position UA length (cm)} = (3 \times \text{BW (kg)}) + 9$$

Since this may not be accurate in very low birth rate infants, Wright *et al.*[8] suggest using the formula UA length (cm) = (4 × BW (kg)) + 7 for those infants less than 1500 g for a high lying position. We generally attempt to place umbilical artery catheters (UACs) in the high lying position to theoretically decrease the rates of thrombosis and intestinal ischemia given previous studies.[4] In all cases, an abdominal x-ray is used to check the catheter position prior to the completion of the procedure (Fig. 14.1).

Standard umbilical catheters measure 3.5 Fr (premature) to 5 Fr (full-term) and can be purchased from various manufacturers. The infant is generally placed under a radiant warmer with the surgeon donning standard sterile equipment. The umbilical stump and surrounding abdominal skin is prepped with a surgical prep solution and the field draped. A minor instrument set including forceps, hemostats, and needle drivers is all that is needed for catheter placement. Appropriate fluids should be available to infuse into the catheter upon gaining access. We prefer to use one-quarter normal saline with heparin (1 unit/mL) to keep the line patent. The catheter should be flushed with sterile saline prior to insertion. The umbilical stump is grasped and umbilical tape is used to encircle the stump below the skin level to prevent bleeding. The stump is cut with care to leave adequate length for ease of manipulation during placement. One umbilical artery is identified, the vein is normally larger and thin walled and the arteries are small, thick walled and

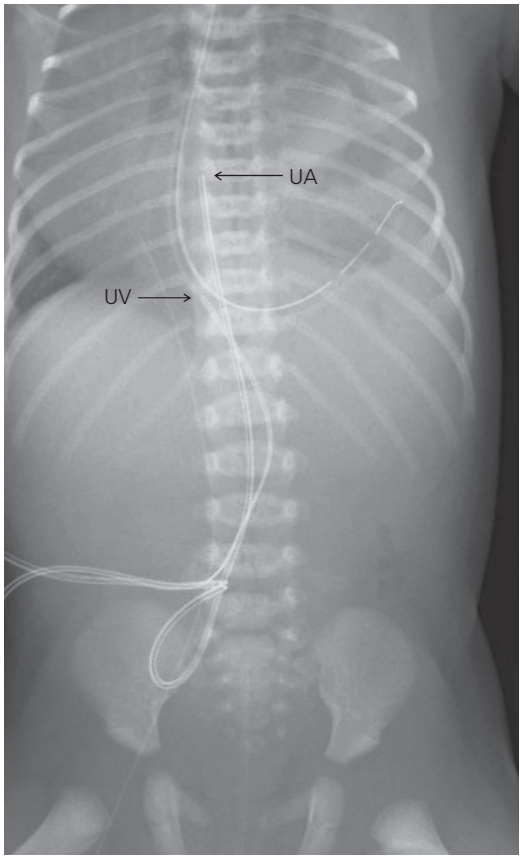

Figure 14.1 X-ray of high lying umbilical artery catheter (UA) and umbilical vein catheter (UV) in desired position.

normally are two in number, and gently dilated with either a hemostat or forceps. Either a 3.5 Fr (infants less than 2 kg) or 5 Fr (those greater than 2 kg) previously flushed catheter is then passed into the lumen with gentle traction applied to the umbilical stump. Blood return is usually encountered when the catheter enters the iliac artery. The catheter is then advanced to the desired position and secured with suture through the substance of the cord. X-rays can be used to confirm position prior to breaking sterile conditions to allow for manipulation. The desired fluids and measurement devices are then secured to the catheter by way of a three-way stopcock mechanism or manifold.

ALTERNATIVE METHOD FOR CANNULATION

At times the umbilical cord is too short or dry to allow for easy cannulation. Access to both umbilical arteries can be achieved through an infraumbilical incision and blunt dissection through the subcutaneous tissues. Once the umbilical arteries are encountered, proximal and distal control can be gained by silk or vicryl sutures. The artery can be accessed by making a transverse arteriotomy through the anterior half of the artery allowing direct catheter passage. The distal control suture is tied to secure the artery and catheter. The incision can be closed with interrupted suture and a sterile dressing applied.

RADIAL ARTERY CANNULATION

The most common site for arterial access is the radial artery. It provides a site that is ideal to access due to its consistent anatomical relationships, collateral blood flow, and this location can be easily maintained by the nursing staff. Most radial arterial lines can be placed percutaneously, which helps to maintain sterility and allows for potential re-cannualization in the future. In rare instances, a cut-down technique is required for direct access to the artery.

Access technique

Collateral circulation of the hand should always be assessed (Allen test) and documented prior to radial or ulnar artery access attempts. Blanching or cyanosis of the fingers or hand should preclude placement. The radial artery can be palpated medial to the styloid process of the radius along the proximal wrist crease. The infant's forearm is placed on an arm board with the wrist dorsiflexed approximately 30–45° (Fig. 14.2). The wrist is then prepped (betadine solution) and draped in a sterile fashion. Local anesthetic can be used but will sometimes obscure the radial pulse and is generally avoided. A 22 or 24 Fr needle catheter is inserted at approximately a 20° angle until blood can be seen within its hub. The catheter tip is then gently advanced into the vessel while removing the needle. If resistance is met, a small guidewire (Cook 0.15″ fixed core guidewire) can be passed into the catheter to aid in manipulation and to allow easier advancement. A T-piece connector and stopcock are then attached to the catheter and it is flushed to ensure patency. The arterial line is then stitched into place and dressed with a transparent dressing (Tegaderm, Opsite).

Figure 14.2 Positioning for radial arterial catheter.

If a cut-down approach is necessary, a small transverse incision can be made proximal to the joint over the point of maximal impulse. Blunt dissection is usually all that is necessary parallel to the vessel course for adequate exposure. Once exposure is obtained, proximal and distal control is secured with silk or vicyl suture ties. Once again a 22 or 24 Fr catheter is used to gain percutaneous access with gentle traction on the distal control suture. A guidewire (Cook 0.15″ fixed core guidewire) can also be useful in this setting to guide the catheter into place once blood is obtained within the hub. Backflow of arterial blood ensures successful placement. Distal vascular occlusion to prevent back bleeding is generally not necessary and the control sutures can be removed following the procedure. The skin site is then closed with interrupted sutures and the catheter is sutured into place at the skin level. The catheter is then dressed and accessed in a similar manner as earlier described.

PEDAL ARTERIAL CANNULATION

The next most commonly used sites for arterial cannulation are the posterior tibial and dorsalis pedis arteries. Once again, these sites allow for collateral blood flow and easy maintenance. Access can be obtained percutaneously or by cut-down. The anatomical relationship of the posterior tibial artery posterior to the medial mallelous provides an easy site for surgical access. Insertion techniques are similar to those described for the radial artery. The line is then immobilized in a similar manner.

AXILLARY AND FEMORAL ARTERIAL CANNULATION

These sites are generally reserved for emergent situations where peripheral arterial pulses are weak and access is unobtainable. The high risk of vasospasm and embolization

to the extremities and minimal collateral blood flow preclude their everyday use. In an urgent situation that these lines are required, they should be removed as soon as clinically possible.

Percutaneous access can be obtained via the axillary artery with the arm extended beyond the horizontal and midway through its course. A guidewire is generally not needed for this catheter placement. Access to the femoral artery can be gained below the inguinal ligament, also by percutaneous methods. Guide wires are generally used to ensure correct position within the iliac artery. They are secured in a similar manner to the peripherally placed lines.

VENOUS CANNULATION

The ability to gain venous access in newborns has been available for decades and allows neonatologists and surgeons the ability to provide consistent vascular access to deliver critical care. New catheter materials including plastic and silicone allow for small bore devices and the cannulation of the smallest of veins. Temporary peripheral access can be easily obtained in the newborn at the bedside with 24 Fr angio catheters or by umbilical vein catheterization. This access, however, is temporary and often central i.v. access is needed for long-term parental nutrition or vasoactive medication drips.

New access methods including peripheral intervenous central catheters (PICC) are now the mainstay for central venous access in the neonatal intensive care setting. The ability to insert these catheters at the bedside, coupled with decreased expense and rapid insertion times, have significantly decreased the need for both cut-down and umbilical catheter access in these babies. Opportunities still arise when a PICC line is unable to be placed, is of insufficient size to accommodate all of the needs of the patient, or emergency resuscitation dictates the need for expedited central venous access. It is imperative for the pediatric surgeon to be skilled in all these access modalities.

Maintenance

Many hospitals have established designated central line teams to manage the everyday care of central venous catheters. The neonatal intensive care unit at Cincinnati Children's Hospital Medical Center is no exception and utilizes care teams as well as the bedside nurse to provide consistent daily cares for central venous catheters.

Umbilical vein catheters are cared for in a similar manner as described earlier for umbilical artery catheters. Fluids are maintained at a minimum of 1.0 mL/h to ensure line patency. Lines are flushed in a similar manner and the length and position of the catheter is documented with x-rays after the initial placement (ideal placement is at the junction of the inferior vena cava (IVC) and the right atrium) and their length checked every shift by the bedside nurse. Connections are checked hourly and padded hemostats are available at the bedside for accidental disconnections. All fluids and tubing are changed in similar manner to UACs. Discontinuation of either the UAC or umbilical venous catheters (UVCs) is performed by the physician, nurse practitioner, or qualified bedside nurses. Only 3–5 minutes of firm pressure is needed to maintain hemostasis.

Percutaneous and tunneled catheters are maintained in a similar manner. Access to the central venous catheter (CVC) via the hub, cap, or manifold is preceded by a 30 second scrub and 30 second air dry time with 2% chlorhexidine gluconate with isopropyl alcohol (ChloraPrep). Heparin volumes for unused ports vary depending on the size of the line. We utilize the Biopatch protective disk (Ethicon) to cover and surround all insertion sites for CVCs. This disk and dressing is changed at a minimum of every 7 days or if the site appears erythematous, or the dressing is compromised. The site is cleansed with a 30 second ChloraPrep or 60 second Providone scrub. A new Biopatch and transparent dressing (Tegaderm or Opsite) is then applied after the site has completely dried. All CVCs are checked hourly and documented by the bedside nurse. Each shift the nurse documents the position of any sutures, skin integrity, redness or induration, the position of the cuff in tunneled lines, occlusiveness of the dressing, changes in the extremity, and any site pain or discomfort. Cut-down sites are maintained in a similar manner. Although uncommon, interosseous (IO) needle sets can be placed in an emergency situation but are removed within 24 hours of placement. Providone soaked gauze is placed around the insertion site and is changed every 2–3 hours or when the gauze is dry. Particular attention is paid to the hemodynamic status of the limb for any signs of compartment syndrome.

Complications

Complications associated with central lines are numerous but most can be avoided with careful placement techniques and nursing care. Pneuomothorax, chylothorax, lung injury, malposition of the line, and perforation of the vessel are but a few of the many issues that can arise during the initial placement.[9] Cardiac arrhythmias can occur due to stimulation of the endocardium in those patients whose line is placed deeper than the superior vena cava/right atrial junction. This can be avoided in most cases by using fluoroscopy when placing subclavian or jugular venous access lines. Tunneled line expulsion is very uncommon when using Dacon cuffed tunneled lines.

Neonates in particular are susceptible to thrombosis near the catheter tip of CVCs given their small vessel. Even with continuous heparin infusion, up to 30% of neonates with CVCs have some form of thrombosis detected.[10,11] Most episodes of thrombosis are asymptomatic and generally present as inability to flush or withdraw blood from the CVC. Tissue plasminogen activator (TPA) can be utilized to remove clot build-up on the catheter tip. This is usually successful and can be repeated for stable clots. Continued build-up of clot demonstrated by ultrasonography may necessitate removal of the line. One should be wary of removing lines in neonates unless the child is symptomatic due to the relative difficulty in placing and maintaining these

lines. Rarely do neonates require heparin therapy following removal.[12]

The most common complication of any central catheter is infection. Documented rates as high as 29% are seen in neonates, with smaller infants at greatest risk.[11,13] Differences in infection rates can be attributed to differences in patient populations and practice guidelines.[11] Coagulase-negative staphylococci continue to be the most common cause of central line infection and bacteremia. Numerous other bacteria, including Gram-negatives, anaerobes, and *Candida* species, can cause line infection, especially in the post-surgical neonate. Although many authors advocate treatment with antibiotics for the clearance of central line infection, removal of the foreign body (CVC) associated with the infection may be needed in refractory cases. PICC lines can be inserted as a bridge to replacement of more permanent access during antibiotic treatment of the bacteremia. Insertion site infections can generally be treated with antibiotics alone and do not require removal of the catheter unless bacteremia is documented. With careful guidelines for the placement and maintenance of these catheters, very low infection rates can be achieved.

PERIPHERALLY INSERTED CENTRAL CATHETER

The majority of centrally placed lines in our neonatal unit are PICC lines. These are quickly placed by specially trained nursing personnel, radiologists, or pediatric surgeons at the bedside with little to no sedation. The catheters are made of silicone or polyurethane and come in sizes as small as 2 Fr (Vygon Corp, Ecouen, France) (Fig. 14.3). In contrast, the smallest surgically placed lines are usually 3 Fr catheters. This small size allows for placement in neonates as small as 500 g. Although the initial experience with PICC line placement used fluoroscopy for all cases,[14] this is now generally reserved for those infants who have failed multiple attempts at bedside placement.

Access technique

Sterile technique is maintained throughout the procedure. After the appropriate site is chosen (antecubital, saphenous, or scalp veins) the catheter is flushed with heparinized saline, 2 unit/mL. The proposed length of the catheter is then measured. The site is cleansed with a surgical prep, draped sterially, and a tourniquet is applied. The introducer needle set is then inserted into the vein with return of blood flow confirming position. The catheter is then advanced through the peel-away introducer in 1 cm increments to the premeasured length (Fig. 14.3). The catheter can be flushed with normal saline to facilitate insertion. Once the desired length is reached, blood is aspirated and the line is flushed with heparinized saline. The breakaway needle is released and a securement device is placed. Steri-strips are applied and a Biopatch placed over the insertion site with a transparent dressing as a covering. A chest x-ray confirms the position of the catheter tip.

(b)

Figure 14.3 (a) 2 Fr, single lumen, PICC line (Vygon Corp). (b) Advancement of PICC line into sheath.

UMBILICAL VEIN CATHETER

The majority of UVCs are placed by neonatologists at outside facilities prior to transfer. These lines can be used for emergency medications, fluids during resuscitation, transfusions, and longer-term central access for i.v. fluids. The complications are similar to other central venous catheters but do have an increased risk of infectious complications of the liver and heart.[3] The generally accepted optimal position for UVC placement is the tip at the level of the IVC right atrial junction. Cardiac arrhythmia can occur with placement of the UVC within the heart itself and is the most common complication during insertion. Cardiac perforation with pericardial tamponade and subsequent demise has been reported with deep insertion.[15] Hepatic necrosis and portal hypertension can occur with placement into the portal system.

Access technique

The placement of the UVC catheter is similar to the previously described placement of the umbilical artery

catheter. A 3.5 or 5 Fr catheter is used to gain access to the single umbilical vein. Catheters are advanced gently usually only 1–2 cm beyond the point of blood return (generally only about 5 cm in a term infant). X-rays confirm the position of the catheter, preferably at the level of the diaphragm (Fig. 14.1). The catheter is maintained similar to the umbilical artery catheter.

Access can also be gained in emergency situations in the operating theater in the newborn by a supraumbilical incision with gentle dissection and cannulation of the ductus venosus. This site is usually only viable for a few days prior to closure.

PERCUTANOUS CANNULATION

Multiple sites can be utilized for the percutaneous introduction of central venous catheters, including the internal jugular veins, subclavian veins, and femoral veins. Although these can be placed at the bedside in extreme conditions, they are more safely placed in the operating room under general anesthesia with ultrasound or fluoroscopic guidance. The technique of ultrasound-guided placement of central venous lines is particularly effective for the internal jugular vein[16] and is a helpful technique at any age. The improved safety with this placement technique is quickly establishing this as best standard practice. We utilize fluoroscopy liberally while placing any centrally dwelling catheter in the operating room. This not only helps to confirm placement but also allows direct vision while dilating vessels and advancing catheters into the correct position with the Seldinger technique.

Access technique

Percutaneous access for central line placement is accomplished by the use of the guidewire (Seldinger) technique. The patient is placed supine on the operating table and a small towel roll or bump is placed under the infant's shoulders to extend the neck with the head midline. Both sides of the neck and chest are prepped and draped in the standard fashion. The patient is then placed in the Trendelenburg position. The two standard infant-sized Broviac catheters in our facility are the 2.7 and 4.2 Fr single lumen catheters (Bard, Salt Lake City, UT, USA). Temporary 4 Fr double lumen catheters are also available (Cook, Arrow). We prefer for the child to be at least 10 lbs before placing a double lumen catheter, given its size. Standard introducer sets contain introducer needles, guidewires, and introducer sheaths with dilators. In the central approach for internal jugular venous access, the vein lies at the apex of the sternal and clavicular heads of the sternocleidomastoid muscle. Ultrasound guidance is particularly useful in identifying the vein. Once the vein has been accessed and the guidewire placed, fluoroscopy is utilized to confirm position. A site on the chest is chosen and the catheter is tunneled from this site to the insertion site. We prefer to use live fluoroscopy to pass the dilator sheath complex over the guidewire and to measure the appropriate length of the catheter. The dilator and guidewire are then removed and the catheter is placed via the peel-away sheath and into position. The final position of the line is confirmed with fluoroscopy. Incisions are closed and a Biopatch and transparent dressing are applied. This same technique can be used for percutaneous femoral vein catheterization. Subclavian vein access can be facilitated by ultrasound guidance, but the technical considerations are more difficult given the location of the clavicle. Generally, the landmarks of the mid angle of the clavicle and the sternal notch are used for subclavian venopuncture with fluoroscopy used in a similar manner as described.

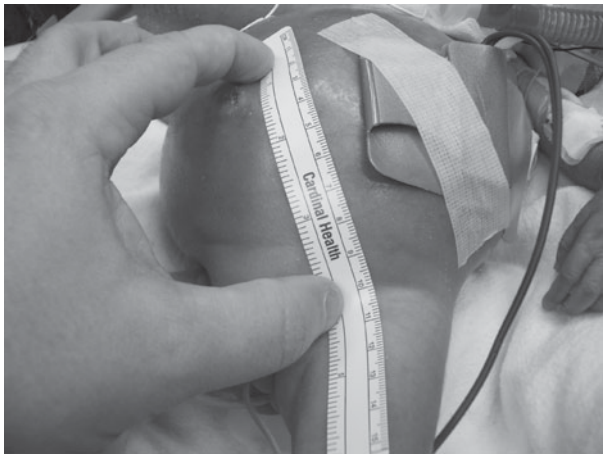
The femoral vein can also be accessed at the bedside by first using a 24 Fr angiocatheter to gain access. A small guidewire (Cook 0.15″ fixed core guidewire) passes easily through this sheath. A larger angiocath can then be placed over the wire to facilitate the larger guidewire in the temporary central line set. Abdominal x-rays can then confirm position.

PERIPHERAL VEIN CUT-DOWN

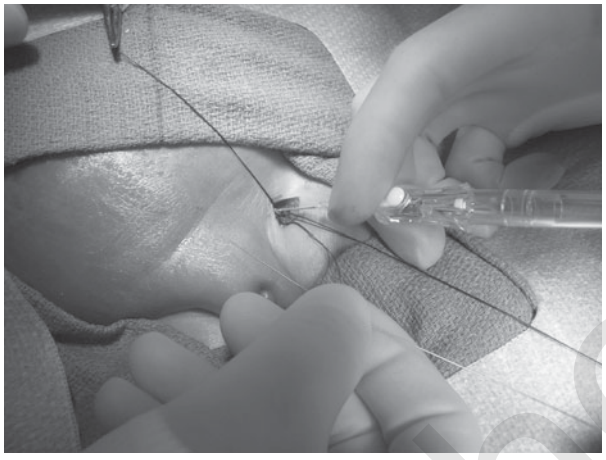
With the significant increase in PICC lines placed at our institution, we have seen a dramatic decrease in the number of peripheral vein cut-downs performed. These now seem to be reserved for those small infants where percutaneous methods are impossible. The common facial vein, external jugular vein, internal jugular vein, and saphenous vein are the most commonly used sites in our practice. With excellent nursing care and sterile technique, the infection rates are comparable to the percutaneous route of cannulation.

Access technique

The saphenous vein can be accessed at numerous points along its course. The most distal site is just superior to the medial malleolus. This site is not useful for long-term access and is not central in its location. The saphenous vein drains into the femoral vein at the level of the femoral triangle and is an easy access point for central cannulation. The infant is placed in a supine position and a rolled towel is placed under the pelvis to allow easier access. The groin is prepped and draped in the standard fashion. The length of the catheter can be measured by the length from the proposed incision to just superior to the umbilicus (iliac vein/IVC junction) (Fig. 14.4). A transverse incision is made inferior to the groin crease inferior to the inguinal ligament. Gentle dissection is carried out parallel to the expected path of the vessel with a hemostat until the saphenous vein is found. The vein is then elevated and proximal and distal control is gained with 5-0 silk ties. At least 1 cm of the vein should be exposed to allow for easy cannulation. The distal control ligature is then elevated to put tension on the vessel. A 24 Fr angiocath is then used to gain access to the vessel and is advanced as the needle is removed (Fig. 14.4). Care must be undertaken to avoid going through the back wall of the vein. A small guidewire (Cook 0.15″ fixed core guidewire) can then be advanced into the angiocath allowing a 22 Fr angiocatheter to



(a)



(b)

Figure 14.4 (a) Measurement for length of saphenous vein cut down central line. (b) Access of the saphenous vein with 24 Fr angiocath.

be placed which is large enough to accommodate the guidewire found in most 3 or 4 Fr central line kits. The catheter is then advanced and the proximal suture is tied down to secure the line and the vessel. The distal ligature can be removed or tied down if there is significant back bleeding. The incision is then closed in the usual fashion and the line site is dressed as previously described.

Similar techniques can be used for the facial vein, external jugular, and internal jugular venous cut-downs. There are numerous other devices, such as a vein pick, which can be useful if a venotomy is preferred over a percutaneous technique. Lines can also be easily tunneled with this technique if needed.

INTRAOSSEOUS DEVICES

During trauma or emergency resuscitation, the venous system may be collapsed due to hypovolemia and shock. Gaining intervenous access in these cases can be quite challenging and time consuming. A quick and easy alternative is the placement of an intraosseous device. These devices come in a multitude of sizes with the smallest available in our facility being 1.8 mm × 15 mm in length. Contraindications to their placement include fracture, absence of landmarks, infection at the proposed insertion site, and previous instrumentation of the extremity. These devices have gone through many evolutions and have a very low (<1%) complication rate.[1] The EZ-IO system (Vidacare, San Antonio, TX, USA) allows for quick and stable access even in the newborn.

Access technique

For infants between 3 and 39 kg, the small, 15 g needle system (PD) can be effectively used (Fig. 14.5). The two most common insertion sites are the proximal tibia just below the tibial tuberosity and, less commonly in infants, the humerus at the level of the humeral head. Local anesthesia can be injected at the proposed insertion site once it is prepped and draped. The needle is inserted into the driver system and the needle cap is removed. The needle and driver should be positioned at a 90° angle to the bone. The needle is then pressed into the skin until the tip touches the bone (ensure that at least 5 mm of the catheter is still visible at this point). The bone cortex is penetrated by squeezing the driver's trigger and applying gentle, steady downward pressure. Once a sudden give or pop is encountered the medullary space has been entered. The driver and stylet are removed and the catheter is flushed with at least 5 mL of normal saline. If the catheter flushes well, fluids and medications can be administered.[17] A dressing is placed around the device and changed on a PRN basis. IO devices should be removed within 24 hours to avoid complications such as osteomyelitis and compartment syndrome.

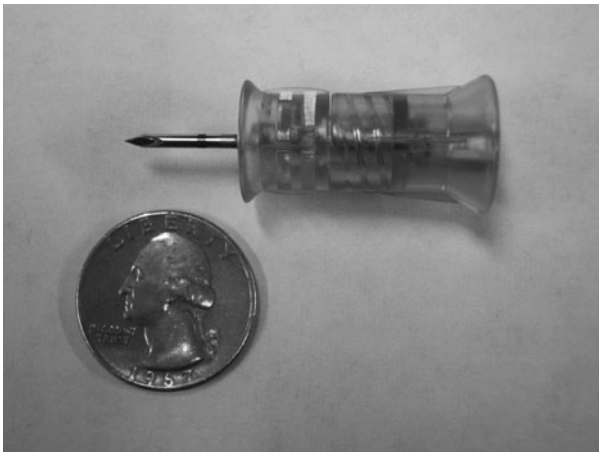


Figure 14.5 15 G intraosseous needle (Vidacare).

CONCLUSION

With smaller, critically ill neonates being managed in our intensive care units, reliable vascular access is a necessity. Improvements in techniques, miniaturization of catheters,

and development of new materials allows for stable access and improved care in premature and newborn infants. As these catheters continue to evolve, newer and safer techniques will soon follow.

Radiology in the newborn

J KELLEHER AND IAN HW ROBINSON

INTRODUCTION

During the past decade, significant developments in surgical techniques, anesthesia, and intensive care have advanced and improved the care of the sick newborn baby. All imaging modalities have reached a new higher level of sophistication and the range of invasive and interventional radiology procedures has also greatly increased. These advances have placed greater demands on pediatric radiology departments which must be well staffed, funded, and equipped to keep pace with these developments. Because of this plethora of available tests, it is essential that both conventional radiographic and high-technology imaging facilities be used efficiently and rationally. A logical sequence of investigations should be applied commencing with the simplest and least invasive, and, where possible, minimizing exposure to ionizing radiation. At all times the As Low As Reasonably Achievable (ALARA) principle should be foremost in our mind. This approach may provide the diagnosis and obviate the need for more complex, invasive, and expensive studies, even if these additional modalities are readily available. Duplication of information, obtained from these various imaging modalities, which does not improve or influence management of the patient, should be avoided.

CONVENTIONAL RADIOGRAPHY

Plain radiography is often the first and most useful study in the evaluation of the surgical neonate. Radiographic examinations should be directed to achieving the required information with the minimum of handling or disturbance while maintaining the infant's body temperature and employing measures to limit radiation exposure. Only relevant projections should be obtained in relation to the clinical problem and condition of the baby (Fig. 15.1). There is no longer a place for routine lateral chest views.

Rooms for examinations in newborns should be kept warm – around 80°F (27°C) – and the baby should be removed from the warm protective environment of the incubator for the

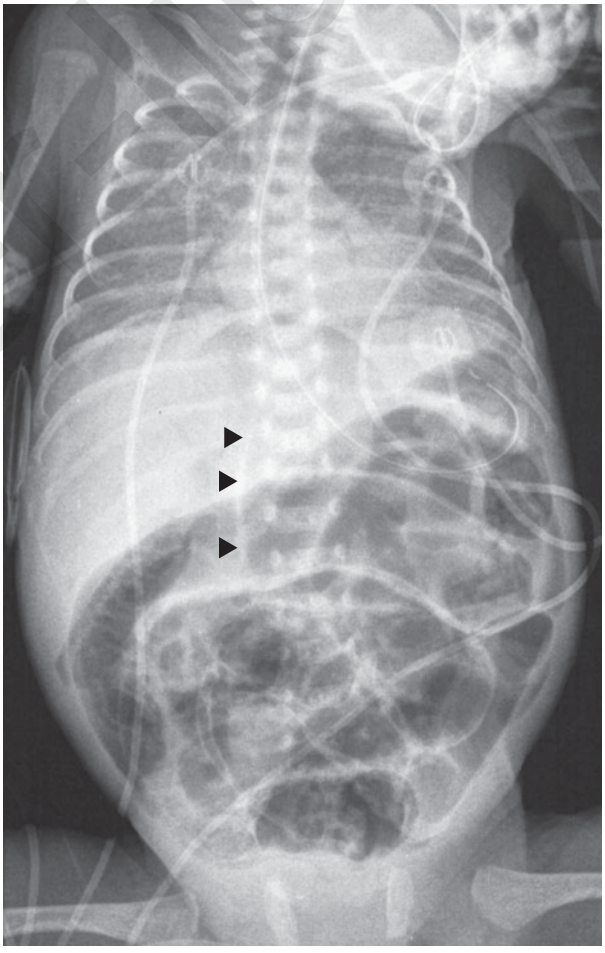

Figure 15.1 Supine chest and abdomen. Supine x-ray of the chest and abdomen in a premature neonate demonstrates abnormal increased lucency over the liver, with free intraperitoneal gas clearly outlining the falciform ligament (arrowheads). A decubitus x-ray is not required in this situation as the diagnosis of perforation is already made. Also evident is intramural gas in keeping with necrotizing enterocolitis and diffuse granular pulmonary parenchymal opacity with central air bronchograms, typical of surfactant deficiency syndrome.

shortest possible time. The use of the newer generation of 'giraffe' type incubators has greatly reduced this problem.

Measures to reduce radiation include the use of rare earth intensifying screens in the cassettes and carbon fiber table tops to give lower exposures and shorter times. High frequency generators, added beam filtration, and digital image receptors all contribute significantly to reducing the radiation burden to the infant.[1] The beam should be collimated to cover only the relevant area and gonad protection with lead shields should be used. Where repeated examination of the chest and mediastinum is anticipated, the use of thyroid shielding should be considered. Good radiographic technique is essential to produce radiographs of high quality, thus avoiding the unnecessary extra irradiation and disturbance of babies resulting from repeat exposure.[2] A sufficient number of well-trained and experienced radiographic technicians should be available to ensure that these high standards are maintained.

MOBILE EXAMINATIONS

In recent years a great increase in demand for portable radiographic examinations has occurred. The position of vascular access catheters and endotracheal tubes may need to be repeatedly checked and frequent examinations may be required in infants with severe respiratory problems on ventilation.[3] Mobile x-ray machines have become smaller, more maneuverable, and give shorter exposure times. Incubators chosen for special or intensive care baby units should be user-friendly for radiography.

Lateral decubitus views of the chest or abdomen are readily performed with a horizontal beam, leaving babies in their incubators. They can be very useful in demonstrating pneumoperitoneum and in evaluating fluid levels in bowel (Fig. 15.2). A dorsal decubitus view of the abdomen is perfectly adequate to either confirm or exclude pneumoperitoneum and is obtained without any re-positioning of the infant in the incubator (Fig. 15.3a–c). Erect views should no longer be requested or performed.

Protocols should be in place to maximize the information obtained while minimizing the disturbance and distress to

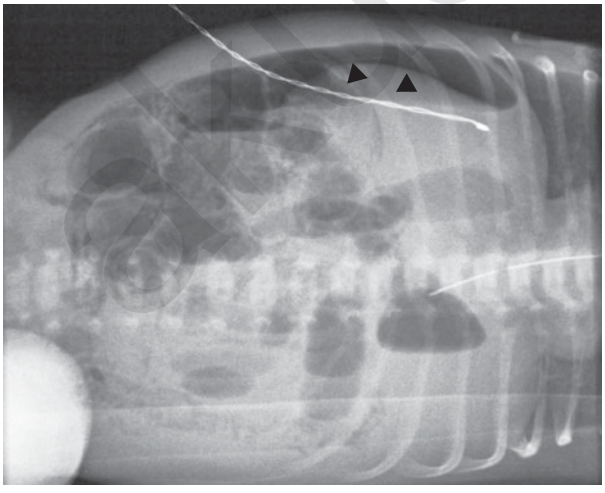

Figure 15.2 Left lateral decubitus. Decubitus x-ray in a neonate with perforated necrotizing enterocolitis. The free intraperitoneal gas rises, outlining the liver (arrowheads). Intramural gas in keeping with NEC is also demonstrated. The decubitus x-ray is also useful in the detection of air fluid levels.

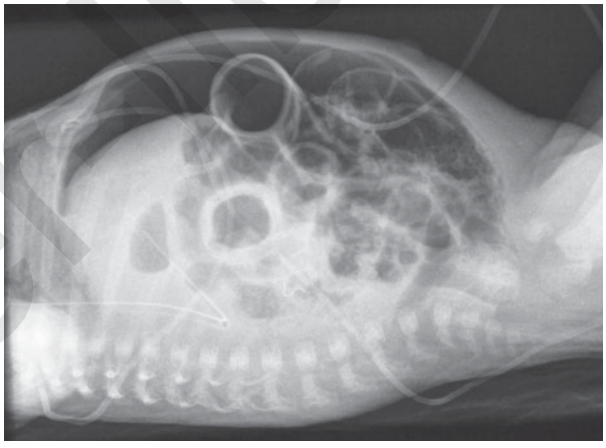
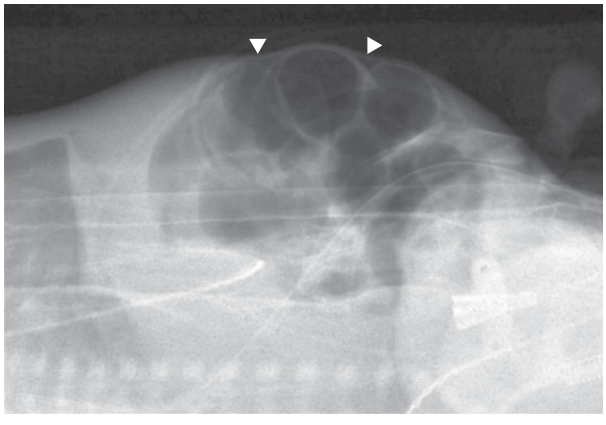
(a)



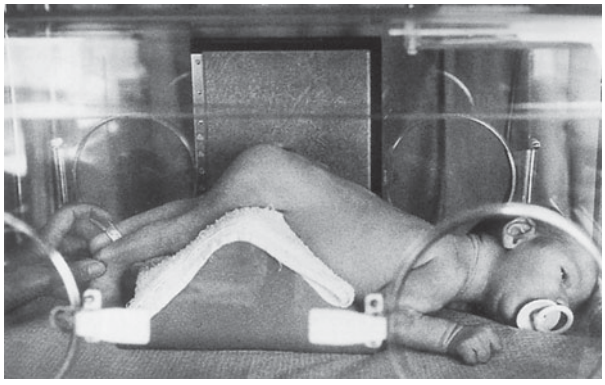
(b)



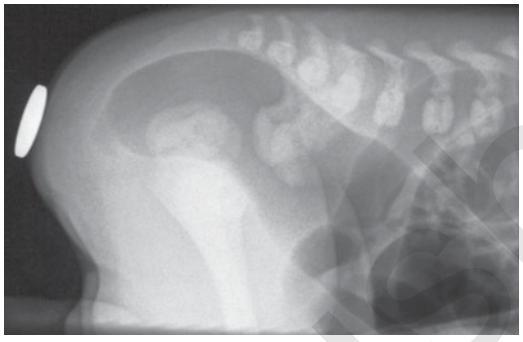
(c)

Figure 15.3 (a) Dorsal decubitus. Position of baby in incubator for horizontal beam exposure. (b) Dorsal decubitus – large amount of free gas. In the dorsal decubitus position, a large amount of free intraperitoneal gas clearly outlines the diaphragm, liver, and bowel loops. (c) Dorsal decubitus – small amount of free gas. Even small amounts of gas may be detected in the dorsal decubitus position, outlining the anterior abdominal wall and adjacent bowel as in this case, (arrowheads) or anterior to the liver.

the infant. A good example of this is that our previous practice of performing inverted lateral radiographs for anorectal anomalies has been abandoned. It is unacceptable that the baby be removed from the incubator and held upside-down by the legs while the exposure is taken. Aside from the trauma to the infant, it is difficult to obtain a good true lateral view centered at the correct level. A prone lateral view with the buttocks elevated and using a horizontal x-ray beam is a far superior technique. The baby can be left comfortably in this position for a period of time to ensure that gas outlines the distal limit of the blind rectal pouch (Fig. 15.4a,b).



(a)



(b)

Figure 15.4 (a) Lateral rectum. Newborn with imperforate anus in prone position in incubator, with buttocks elevated for lateral view with horizontal beam. (b) Lateral rectum. Lateral x-ray of the rectum demonstrating the distal limit of the rectal pouch in this child with anorectal malformation. An assessment of the sacrum can also be made.

FLUOROSCOPIC EXAMINATIONS

For investigations in neonates the fluoroscopy room should be warm, with oxygen and suction outlets readily available. A fully equipped resuscitation trolley should be at hand. Procedures should be carried out quickly but carefully. A satisfactory i.v. infusion should be ensured before commencing any invasive or interventional procedure. The radiologist should concentrate on solving the clinical problem presented and tailor the study accordingly.

Developments in computerized digital fluoroscopy in recent years have resulted in the potential for a marked reduction in radiation exposure, more rapid performance of dynamic contrast studies, and greatly improved recorded images. Digital fluoroscopy units often have the facility to provide a rapid series of exposures at up to 8/second. While this can be very useful in studies of the swallowing mechanism or of the airway, the ability to store and review a 'video-loop' is much more valuable. The use of appropriate reduced rate pulsed fluoroscopy greatly reduces radiation dose. A 'last image hold' facility allows hard-copy images to be obtained with no additional radiation. In most neonates it should be possible to screen without a 'grid', thus further reducing radiation dose and the use of magnification should be minimized. Modern installations provide image enhancement, processing and digital subtraction facilities, which are very useful in angiography.[4]

Non-ionic water soluble contrast media are used for all intravascular studies in children. Such contrast agents can also be used for gastrointestinal examinations. They permit excellent anatomic delineation and may be safely used even where leakage or obstruction is suspected. They are well tolerated even if pulmonary aspiration occurs, though some element of pulmonary edema may develop. If diluted, an iso-osmolar solution can be achieved for even greater tolerance in the airway. A good example of this is shown with a bolus injection in the upper esophagus in H-type tracheo-esophageal fistula (Fig. 15.5).

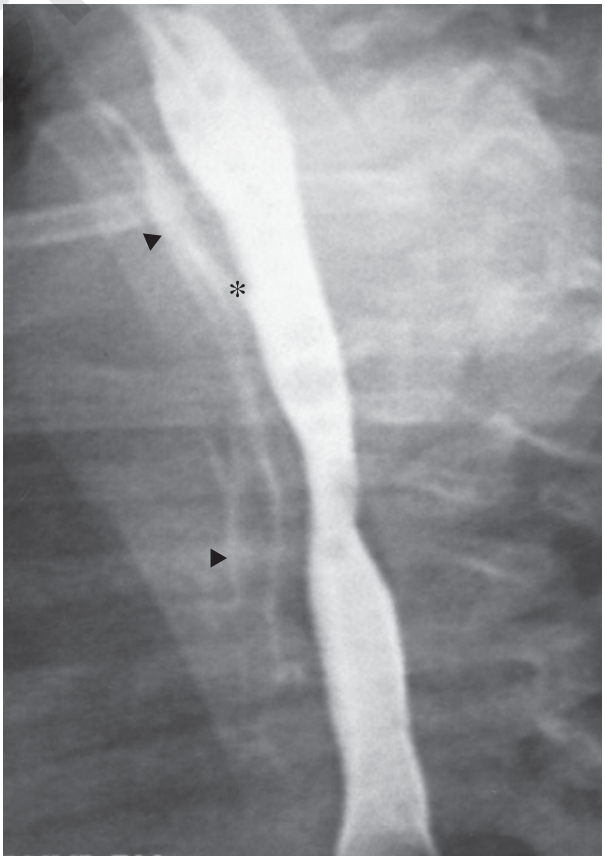


Figure 15.5 H-type tracheo-esophageal fistula. Water soluble contrast fills the esophagus and passes through an H-type fistula (asterix) into the trachea (arrowheads).

Conventional ionic contrast agents, e.g. Urografin (Bayer) 30%, are less expensive and are appropriate for micturating cystourethrography (MCUG) (Fig. 15.6). All infants should have appropriate antimicrobial cover during MCUG to reduce the risk of infection. The contrast agent should be warmed to body temperature and may be diluted with sterile water. Either a 5F or 6F feeding tube is used to catheterize the baby. In males, a steep oblique view of the urethra must be obtained during voiding to exclude the presence of posterior urethral valves. Screening time can be kept to a minimum by observing the flow of contrast from the bottle. When flow stops, the baby is usually ready to urinate.

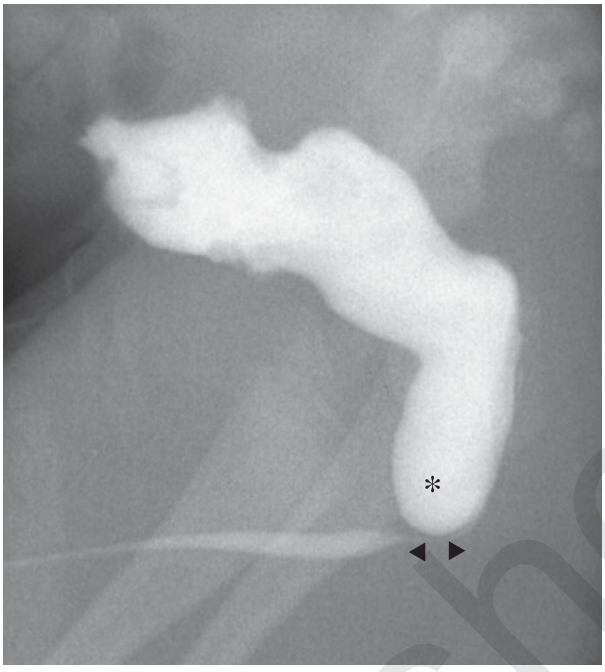

Figure 15.6 Micturating cystourethrography. Lateral image of the bladder and urethra in a male infant taken during micturition. The bladder is abnormal in contour and the posterior urethra is markedly dilated (asterix). The thin filling defect representing the membrane of the posterior urethra valve is visible (arrowheads).

ULTRASONOGRAPHY

This relatively inexpensive and widely available imaging modality has transformed neonatal diagnostic imaging. Lack of ionizing radiation, portability, and the freedom to do serial repeat studies make it especially suitable for this patient population. In premature or severely ill babies, ultrasound (US) scans can be performed satisfactorily without removing the infants from their incubators. The principles of minimal handling and maintenance of body temperature apply. Examinations should be carried out quickly and efficiently, aimed to achieve a diagnosis and not prolonged or repeated just to produce the 'perfect picture'.

Congenital structural abnormalities are being diagnosed with increasing frequency on antenatal scans. Congenital brain malformations, hydrocephalus, and spinal anomalies are easily recognized.[5] Prenatal recognition of anomalies, such as cystic adenomatoid malformation, cystic renal disease or intestinal tract obstructions, alerts the neonatologist to the need for careful postnatal evaluation.

The identification of abdominal wall defects, e.g. exomphalos and gastroschisis or of a diaphragmatic hernia on an antenatal scan, allows the delivery to be arranged in or close to a major pediatric surgical center. *Ex utero* intrapartum treatment or 'EXIT' surgery can be planned if major airway problems are detected *in utero*. Antenatal interventional techniques can be performed under US guidance, e.g. the insertion of stents or drains in obstructed urinary tracts.

Cranial US is now an indispensible facility in any department dealing with newborn patients.[6] Using real-time high frequency probes, images of excellent detail are obtained. Hydrocephalus secondary to intraventricular hemorrhage (IVH) or myelomeningocele can be accurately diagnosed and graded. Serial examinations are helpful in relation to the need for shunting. However, if the cause of the hydrocephalus is not evident, then other imaging, e.g. magnetic resonance imaging (MRI), will be necessary. One of the most important contributions of US is in the diagnosis and grading of IVH. Early diagnosis of minimal lesions can be achieved in infants at risk. The discovery of IVH can influence the decision to operate on a newborn with a congenital malformation if IVH is severe (Fig. 15.7).

There is an increasing use of ultrasound in evaluating suspected anomalies of the spinal cord in infants (Fig. 15.8). The scans can demonstrate the entire spectrum of intraspinal anatomy, both normal and abnormal, and define pathological conditions with a high degree of accuracy.[7] It may obviate the need for MRI.

Sonography plays a significant role in the investigation of mass lesions in the neck and mediastinum. It permits localization, delineation of relationships to surrounding structures, and especially differentiation of cystic from solid lesions (Fig. 15.9). Real-time sonography is very useful in evaluating phrenic nerve paralysis.

Figure 15.7 Cranial US. Coronal US image of the brain in a premature neonate. Hemorrhage is visible within both lateral ventricles (asterix). The ventricle wall is echogenic. In addition there is increased echogenicity within the periventricular parenchyma on the right, in keeping with infarction, indicating a Grade 4 intraventricular hemorrhage on this side. Note the relatively poor sulcation typical of a premature infant.

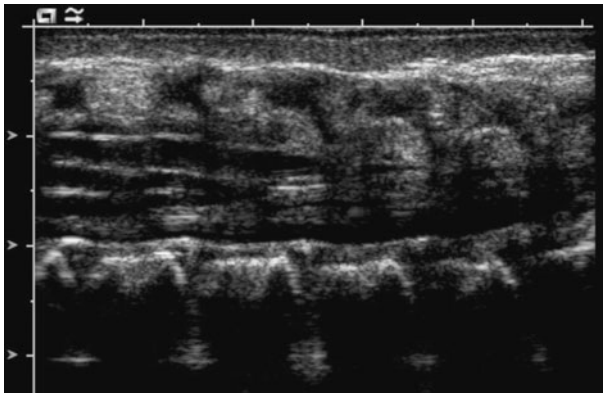

Figure 15.8 Ultrasound spine. US of the spine clearly depicts the cord, conus, and cauda equina. The position of the conus relative to the vertebral elements can be assessed and the presence or absence of spinal anomalies can be confidently determined. Spinal US is best performed before 6 weeks of age, when the relative lack of vertebral ossification allows for good visualization.

Abdominal US is very frequently carried out in the newborn to diagnose or exclude renal disease. Lesions confined to the kidneys include multicystic dysplastic kidney, polycystic disease, and hydronephrosis. The latter may be due to obstruction at pelvi-ureteric or uretero-vesical level or, in males, to the presence of posterior urethral valves. All these lesions are readily diagnosed with US, and severity of obstruction and renal damage can also be assessed. The kidneys are frequently involved in complex syndromes, e.g. VACTERL syndrome. The spectrum of renal anomalies varies from agenesis to crossed fused ectopic and duplex kidneys.

Ultrasound is well established as the optimal diagnostic tool in the routine evaluation of infantile pyloric stenosis. Whilst pyloric stenosis is rare in the first 2 weeks of life, it has been reported, and the standard US measurement criteria may not be valid in this patient population.[8]

In the evaluation of space-occupying lesions of the neonatal abdomen, US should be the first investigation. It will characterize the lesion, for example differentiating cystic from solid and identifying the organ of origin. Figure 15.10 shows the typical cystic appearance of neonatal adrenal hemorrhage. In comparison, Figure 15.11 demonstrates a solid suprarenal mass, confirmed to be neuroblastoma, stage 4S. US may give the complete diagnosis, e.g. congenital mesoblastic nephroma. Failing that, it should give a clear indication of the next logical investigation.

In neonatal jaundice, US has a key role in defining the anatomy of the biliary tract. Choledochal cyst may be diagnosed with confidence and biliary atresia excluded. It can demonstrate or exclude dilatation of the biliary duct system (Fig. 15.12). Radionuclide imaging may be complementary.

The development of Doppler, including color Doppler, has been a considerable advance with widespread application. The safe placement of vascular access lines is greatly aided by this technique. It can accurately map the vascular anatomy of abdominal masses or of arteriovenous malformations in other sites. It allows noninvasive imaging of hepatic vascular structures.

Figure 15.9 (a,b) Ultrasound neck – cystic hygroma + accompanying magnetic resonance imaging (MRI). (a) US and (b) MRI of a cystic hygroma of the neck. US and MRI are complementary modalities. US has superior spatial resolution, for example being able to detect thin septations. MRI, however, allows a more accurate assessment of the overall extent of a lesion and its relation to adjacent structures. In this example, the trachea is visible on both the US and MRI (asterix).

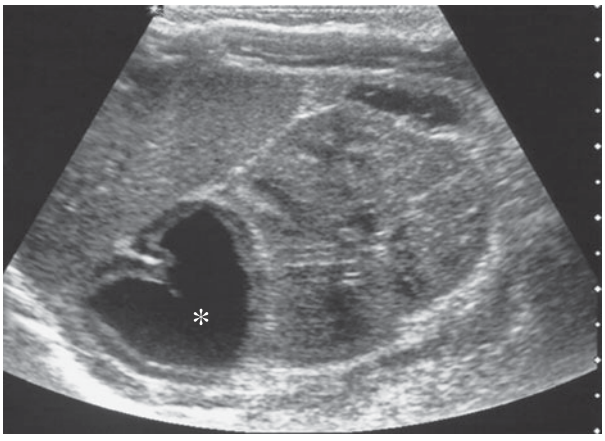

Figure 15.10 Ultrasound adrenal hemorrhage. Cystic enlargement of the adrenal gland typical of an adrenal hemorrhage (asterix). (L = liver, K = right kidney.)

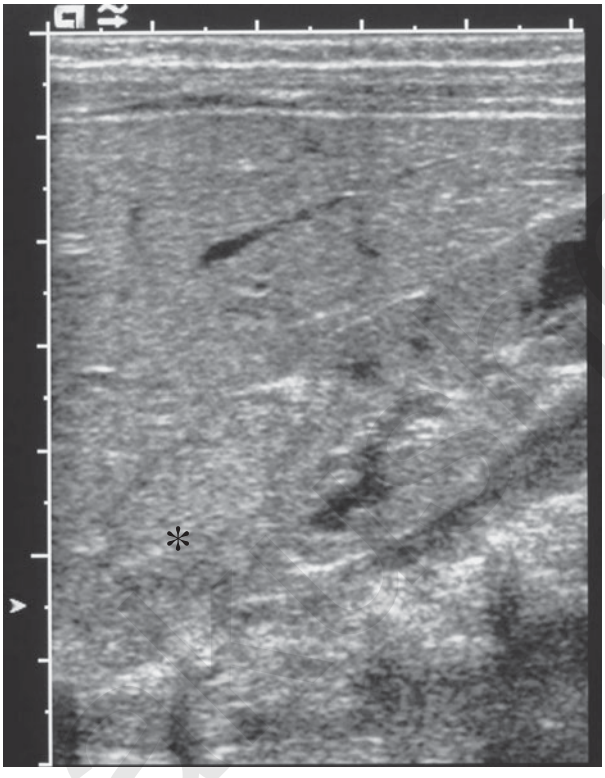

Figure 15.11 Ultrasound neuroblastoma. In contrast, this suprarenal abnormality is clearly solid, representing an adrenal mass in a child with neuroblastoma (asterix). (L = liver, K = right kidney.)

NUCLEAR MEDICINE

With the great advances in US, computed tomography (CT) and MRI, the role of radionuclide examinations is very limited in the newborn period. Functional rather than morphological studies are usually required. Total and individual renal function can be assessed, but, due to functional immaturity, imaging is less reliable than in the older infant or child. Technetium-99m labeled mercaptoacetyltriglycine (MAG 3) is used for assessment of obstruction with technetium labeled dimercaptosuccinic acid (DMSA) employed for static imaging and to demonstrate the functioning renal parenchyma. Either method will give an estimate of relative renal function. Excretory urography or IVU has no place in modern neonatal imaging.

Hepatobiliary scintigraphy is extremely useful in the investigation of neonatal jaundice where biliary atresia is a concern. The infant is given phenobarbital, 5 mg/kg per day divided into two equal doses, given for 3–5 days prior to the scan. Mebrofenin labeled with technetium-99m (Choletec) is preferred in infants because of its greater hepatic extraction. The scan will usually differentiate between biliary atresia and neonatal hepatitis (Fig. 15.13). If the biliary tract is patent, isotope should be detected in the intestine within 60 minutes.

Though uncommon, Meckel's diverticulum may present with rectal bleeding in the newborn period. It can be elegantly demonstrated on technetium pertechnetate scintigraphy (Fig. 15.14).

Isotope bone scanning can be very unreliable in the diagnosis of neonatal osteomyelitis and/or septic arthritis and is rarely employed.

Infants presenting with congenital hypothyroidism and absence of the thyroid gland from its normal location can be scanned using 99m Tc-pertechnetate, looking for an ectopic or lingual thyroid (Fig. 15.15).

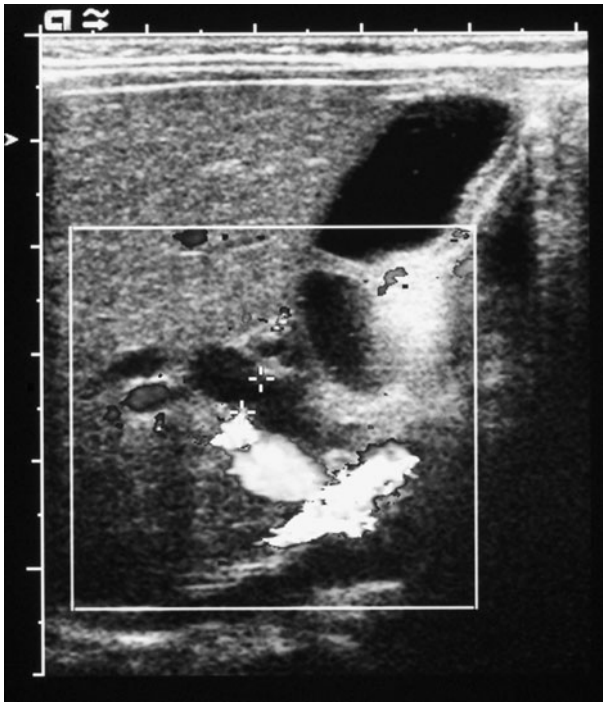

Figure 15.12 Ultrasound bile duct dilatation. US reveals dilatation of the common bile duct (calipers) in this neonate with gallstones. Color Doppler imaging is often used as in this instance to identify vascular structures separate from the bile duct.

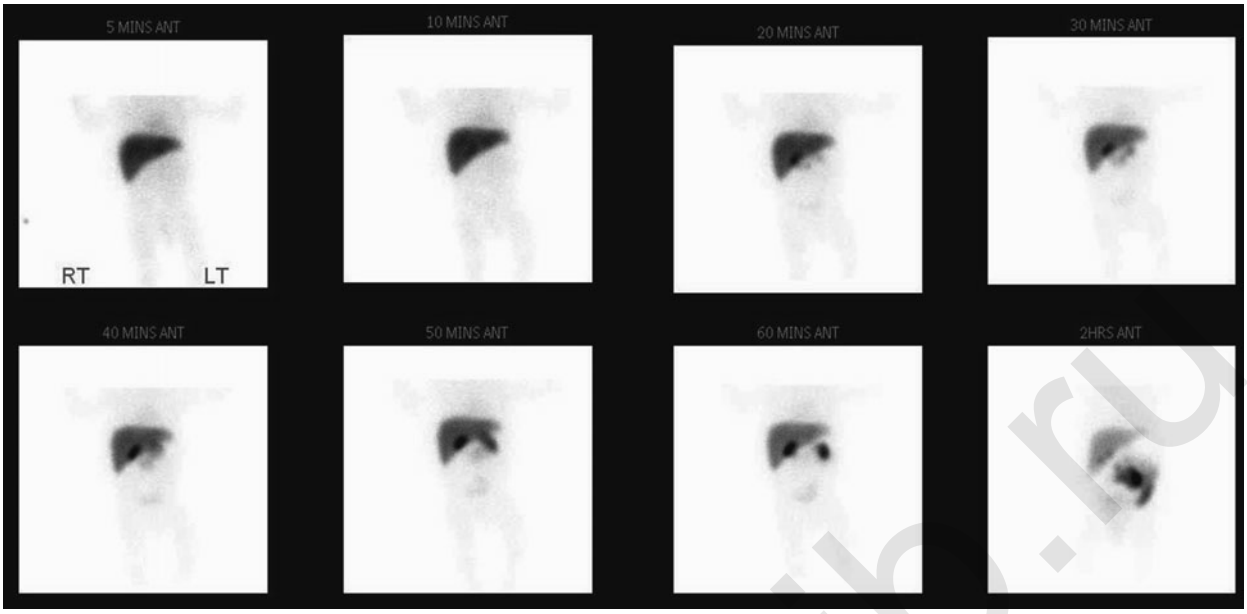

Figure 15.13 HIDA. Radioisotope rapidly appears within the liver. In this normal study, radioisotope is rapidly excreted into the gallbladder (20 min) and proximal small bowel (30 min). The delayed image at 2 hours shows radioisotope having largely passed through the liver and appearing within small bowel loops.

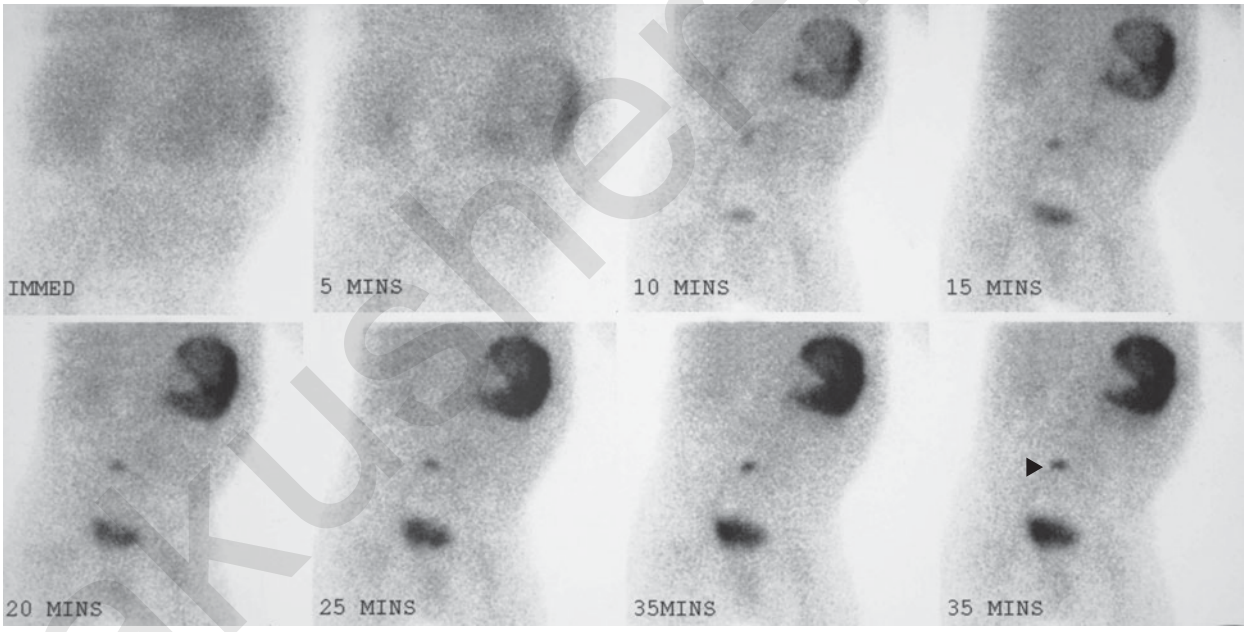

Figure 15.14 Meckel scan. Radioisotope is taken up by gastric mucosa within a Meckel's diverticulum (arrowhead). Note the normal uptake by the gastric mucosa of the stomach. Also note the normal appearance of radioisotope within the bladder, having been excreted by the kidneys.

COMPUTED TOMOGRAPHY

Computed tomography remains an established and vital imaging modality in pediatrics but has relatively limited application in the newborn where US and MRI have many advantages. While CT can be useful in evaluating structural abnormalities in the thorax, such as congenital pulmonary adenomatoid malformations (CPAM) and congenital lobar emphysema (CLE), its usefulness in evaluating the neonatal abdomen is significantly limited by the lack of intra-abdominal fat. In general, abdominal MRI is more useful than CT when US fails to provide the diagnosis. While modern multislice scanning should be available on site in any specialized pediatric unit, radiation dose remains a major concern.[9] CT should be reserved in the newborn for specific indications where other modalities provide insufficient information. These would include cranial CT scans in suspected head trauma, exclusion of intracranial calcification in congenital infection, e.g. TORCH, and assessment of bony abnormality associated with severe choanal atresia

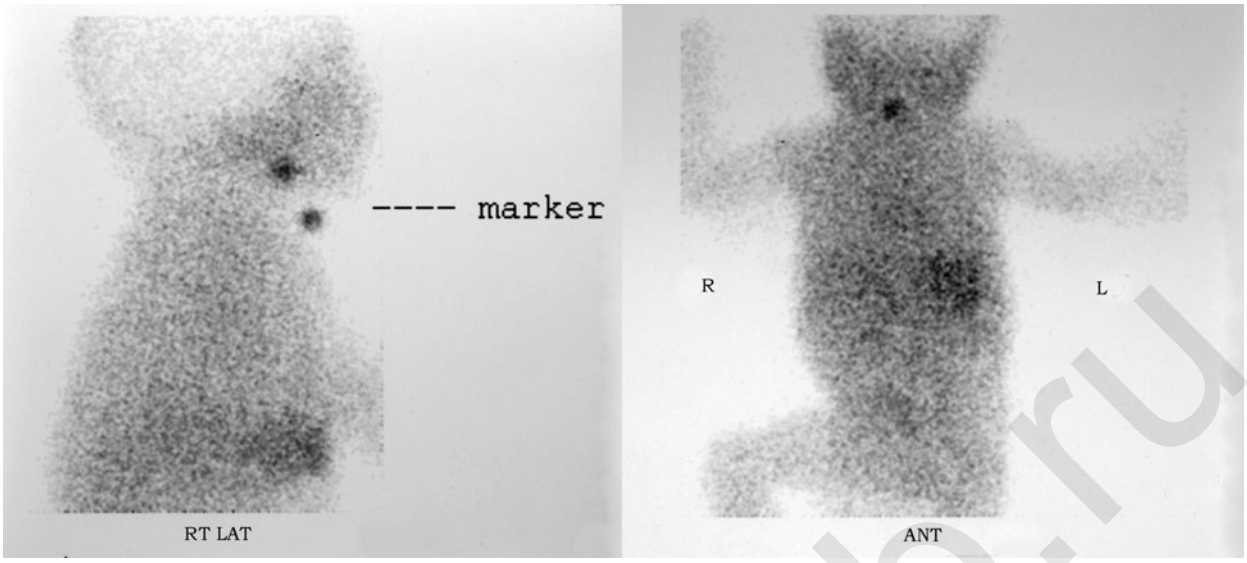

Figure 15.15 Lingual thyroid. Radioisotope accumulates within thyroid tissue which is located at the base of the tongue. Its position can be determined relative to the chin and the marker at the sternal notch. On the anteroposterior view the lingual thyroid has a rounded configuration, as opposed to the typical bilobed appearance expected of a normal thyroid gland.

(Fig. 15.16). In all instances protocols to reduce radiation dose must be in place as per the ALARA principle.[10]

MAGNETIC RESONANCE IMAGING

Increased access to MRI has transformed neonatal radiology. While US remains the mainstay of brain and spinal imaging in the neonate because of portability etc., MRI is used to clarify complex malformations and to provide vital functional and prognostic information. Hypoxic-ischemic brain injury (HIE) is a frequent and significant problem in the neonatal period. Regardless of the type of hypoxic injury, the imaging manifestations are related to the gestational maturity of the infant. Hypoxic injury to the premature brain affects primarily the germinal matrix and periventricular white matter, while in the term infant damage to the cortical tissues and basal ganglia occurs (Fig. 15.17). MRI with spectroscopy is the diagnostic modality of choice in suspected neonatal HIE.[11]

Outside of the central nervous system an increasing use of MRI is also seen. In the evaluation of mass lesions of the neck and mediastinum it offers exquisite anatomical detail. The ability to image in multiple planes facilitates surgical planning. In the abdomen, while US mostly reigns supreme, MRI is increasingly used to evaluate complex masses, to complement US in the biliary tract (MR cholangiography) and to evaluate the renal tract (MR urography). With increasing use and experience this utilization may expand but cost, availability, and motion artifacts remain a barrier, as does the requirement for sedation or anesthesia.

Over the last 25 years, advances in MRI technology have allowed safe and accurate imaging of the fetus. Fetal MR has become a useful adjunct to antenatal ultrasound.[12] It has been shown to detect sonographically occult abnormalities, and may result in changes to pregnancy management. Figure 15.18 shows MR imaging of a fetus with a large cystic hygroma of the neck. Assessment of the extent of the lesion, in particular its relationship to the airway, allowed planning for an *ex utero* intrapartum treatment ('EXIT' procedure).[13]

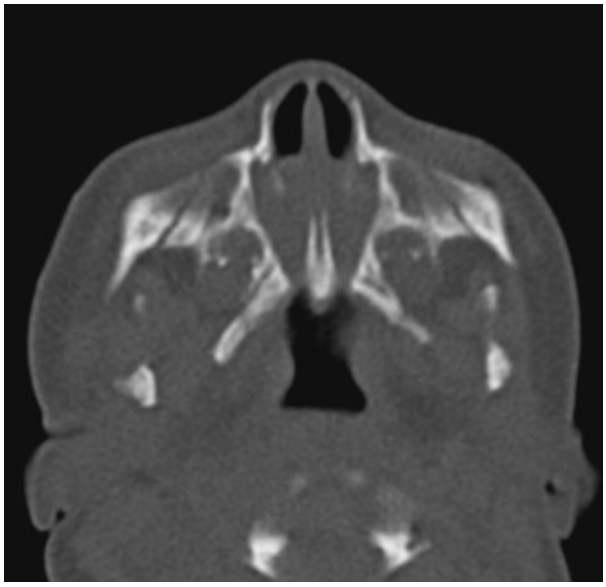

Figure 15.16 Computed tomography (CT) choanal atresia. CT is the best modality for assessing the bony narrowing of the choanae. In this case there is severe bilateral narrowing of the posterior nasal cavity in a patient with bilateral choanal atresia.

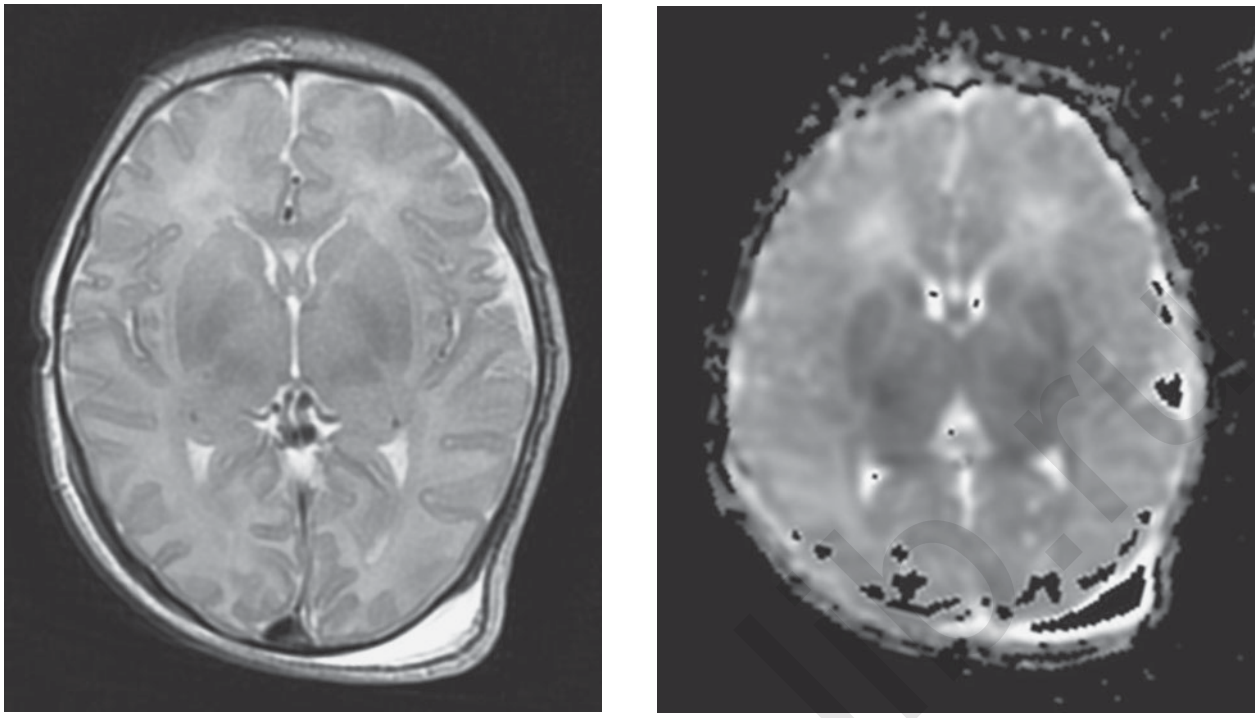

(a) (b)

Figure 15.17 (a,b) Magnetic resonance imaging hypoxic-ischemic brain injury. (a) Axial T2 and (b) adjusted diffusion coefficient (ADC) map from the diffusion-weighted imaging (DWI). Signal abnormality in the newborn is often subtle on T1 and T2 imaging, and is influenced by gestation. DWI, when performed within an appropriate timeframe, is helpful in determining the extent of abnormality. In this term infant, extensive restricted diffusion is clearly evident within the basal ganglia (low signal on the ADC) in keeping with a profound hypoxic ischemic event.

INTERVENTIONAL TECHNIQUES

There has been a dramatic increase in recent years in the number, range, and complexity of interventional procedures in pediatric as well as in adult radiology practice. Hospital stay may be shortened and patient outcome improved as these interventional procedures tend to be more cost-effective than the alternative conventional surgical approach. In the gastrointestinal tract, hydrostatic or pneumatic reduction of intussusception is a well established technique. This, however, is a rare condition in the newborn. The non-operative management of meconium ileus by Gastrografin enema is almost universal (Fig. 15.19). However, it must be remembered that complications such as volvulus, peritonitis, and perforation must be excluded before an enema is attempted. The fluoroscopy room should be warm, the infant well hydrated and a functioning i.v. line must be in place. This author advocates the use of diluted Gastrografin, one part contrast and two parts water to reduce the risks of mucosal damage. Several attempts may be made over a period of days if the infant's condition permits.

Balloon catheter dilatation of post-anastomosis esophageal strictures in neonates following repair of esophageal atresia is now established in major centers worldwide. The advantages of balloon dilatation over bougienage relate to the marked reduction in shear force with radial force mainly achieving the dilatation.

Balloon dilatation of colonic strictures complicating necrotizing enterocolitis is another, though infrequent, interventional procedure. Percutaneous gastrostomy and placement of a feeding tube in the jejunum are further useful techniques performed under fluoroscopy.

In urinary tract obstruction, percutaneous nephrostomy to relieve obstruction is widely practiced and should be performed under direct US guidance. Either a single stab technique or a modified Seldinger approach may be used and a pigtail catheter is left in place.

Percutaneous biopsy of organs or lesions under US, fluoroscopic, or CT guidance and the aspiration or drainage of abscesses or cysts are all part of the interventional radiologist's workload. The cumulative radiation burden to the infant must be borne in mind, and in general, US is the imaging modality of choice.[14]

In the very low birth weight (VLBW) infants vascular access procedures are amongst the most common indication for radiological intervention and are not without complication.[15]

CONCLUSION

The role of the imaging department and of the pediatric radiologist in the management of the neonatal patient is continuously evolving and expanding. They should be involved as an integral member of the 'team'. Frequent consultation among all carers will avoid inappropriate requests for imaging. It will prevent duplication of examinations and the accumulation of redundant information, thus helping to reduce costs. The application of appropriate imaging techniques will also have the great virtue of reducing the infant's discomfort and morbidity.

Immune system of the newborn

FIONA O'HARE, DENIS J REEN, AND ELEANOR J MOLLOY

INTRODUCTION

The first line of defense against infection is the innate immune system and activation occurs when a pathogen breaches the host's natural barriers (Fig. 16.1).[1] The innate immune system developed before the separation of vertebrates from invertebrates and is the primary immune response for most multicellular organisms.[2] It responds instantaneously to microbes and is composed of both soluble (the alternative and mannan-binding lectin pathways of the complement system, acute phase proteins, and cytokines) and cellular elements (monocytes, macrophages, neutrophils, dendritic cells, and natural killer cells). Careful modulation of the innate immune system is vital to prevent either uncontrolled microbial growth or devastating inflammatory responses with tissue injury, vascular collapse, and multiorgan failure.

Detection of invading microorganisms is mediated by pattern recognition receptors expressed on the surface of innate immune cells, which recognize structures common to many microbial pathogens and are called pathogen-associated molecular patterns (PAMPs). These include endotoxins (lipopolysaccharide: LPS), peptidoglycan, lipoteichoic acid, lipopeptides, flagellin, mannan, and viral RNA, which are essential for survival of the microorganisms and therefore do not undergo major mutations. Pattern recognition receptors have been evolutionarily conserved not to recognize any self-structure. Any receptor that bound to a self-ligand could lead to death of the organism that expressed such a receptor. Therefore, autoimmunity is prevented when the only available recognition system is the innate immune system.[3]

Several intracellular signaling pathways are activated when a PAMP binds to a pattern recognition receptor, resulting in activation of transcription factors (NF-kB, AP-1, Fos, Jun). These transcription factors control the expression of immune response genes and the release of numerous effector molecules, such as cytokines. Cytokines are chemical mediators with an essential role in orchestrating the innate and acquired immune responses to an invading pathogen.[4]

The acquired immune system has evolved relatively recently and is built upon the phylogenetically older innate immune system, by which it is controlled and assisted. The principal mediators of acquired immunity are the highly evolved lymphocytes, which express an enormous array of recombinant receptors, immunoglobulin (Ig) and T-cell receptors. They can recognize any potential pathogen with which the host may come in contact. This response takes from days to weeks to develop optimally. Newborns acquire passive immunity from their mothers by maternally derived IgG crossing the placenta. Transferable maternal immunologic memory is essential for the survival of the fetus, newborn, and infant. Moreover, the attenuation of infection by transferable maternal immunity permits microbial agents to immunize the child under optimal conditions. This provides protection for up to the first six months of life at which time neonatal acquired immunity has developed.[5]

The hygiene hypothesis states that exposure to allergens in the environment early in life reduces the risk of developing allergies by boosting immune system activity. Conversely, a relatively clean environment in early life would sway the immune system towards allergy-promoting responses. The hygiene hypothesis may explain the rising incidence of allergic diseases and facts such as the lower incidence of allergy in those living on farms or in rural areas (due possibly to more exposure to bacteria); the lower incidence of allergy in younger children of large families with three or more older siblings (due perhaps to repeated exposure to infection); and the lower incidence of asthma and wheezing in children attending day care (with more exposure to infections). The hygiene hypothesis, however, cannot explain the higher rates of allergic asthma among poor African Americans in inner city areas.[6,7]

CLINICAL OUTCOMES IN NEONATAL SEPSIS AND INFLAMMATION

Death and long-term complications are common sequelae of bacterial infections in newborns. Neonates undergoing

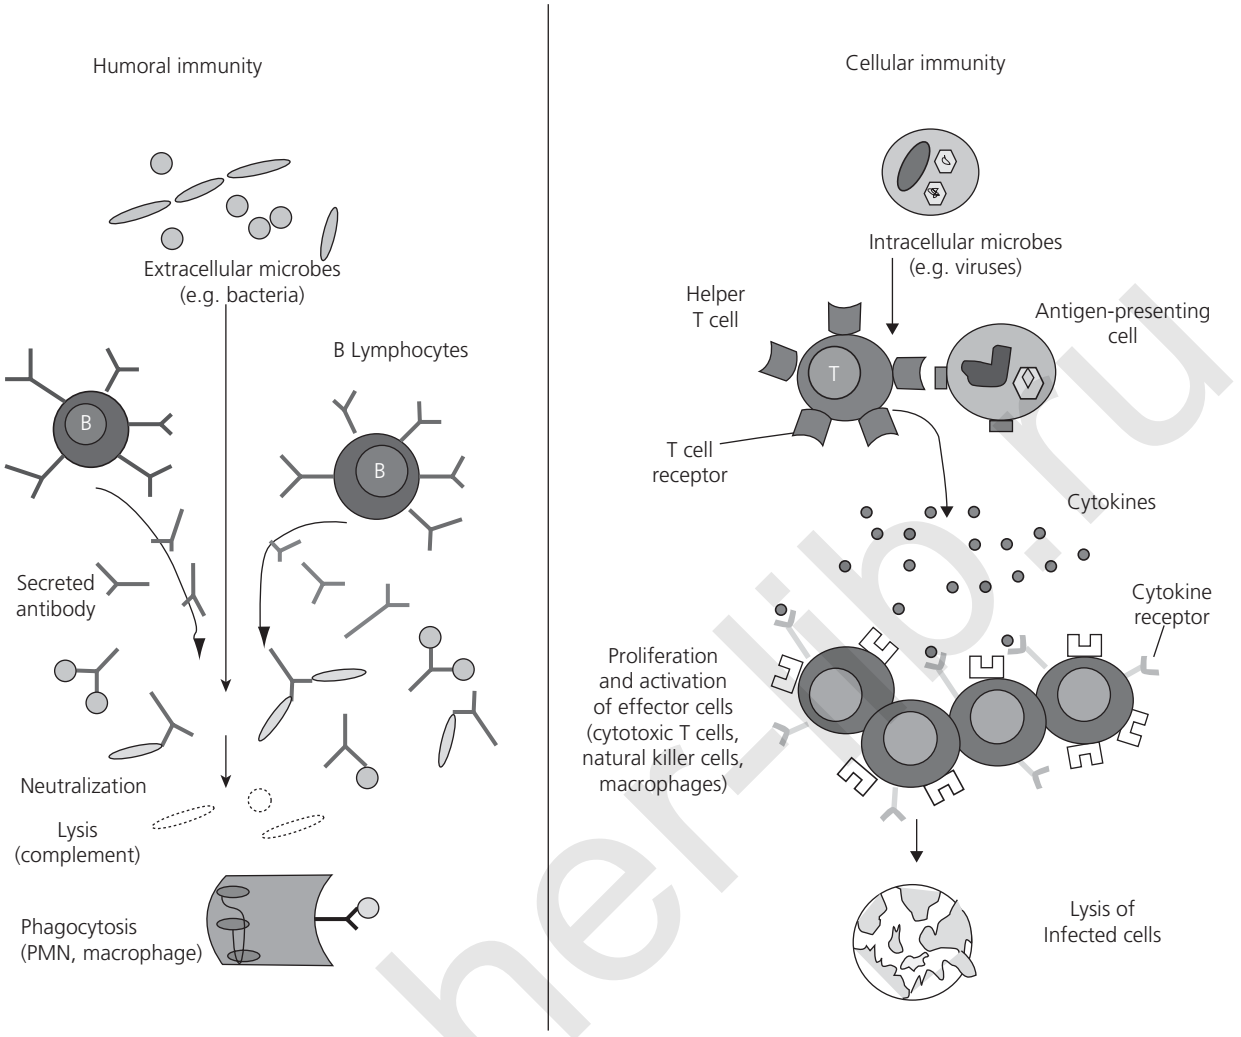

Figure 16.1 Immune function: Humoral and cellular immunity. Humoral immunity is mediated by B-lymphocytes which produce soluble antibody proteins. These antibodies can either: (1) directly neutralize extracellular microbes; or (2) activate complement, neutrophils, macrophages to kill microorganisms. Cellular immunity is mediated by T-lymphocytes. Cytotoxic T-cells directly lyse pathogens. Helper T-cells produce cytokines which stimulate other immune cells to remove microorganisms.

intensive care have infection rates of 25–50%[8,9] and mortality has not changed from 15–20% over the last 20 years. Altered bactericidal mechanisms are responsible for the increased vulnerability to sepsis in this group and mirror the pattern seen in grossly neutropenic patients.[10] Neutropenia commonly develops in neonatal sepsis in contrast to the leukocytosis in septic adults.[11] This may be mediated by a decreased neutrophil storage pool and a limited capacity for increased progenitor production in newborns, especially preterms.[12]

There is increasing evidence that sepsis and inflammation are important in the pathogenesis of perinatal brain injury. In preterm infants episodes of sepsis are associated with poorer neurodevelopmental outcomes.[13] In addition, an association between cerebral palsy and maternal peripartum infection in term infants has been well documented.[14] Elevated proinflammatory cytokines have also been demonstrated in retrospectively reviewed dried neonatal blood spots from children aged three years with cerebral palsy.[15] Activated leukocytes and infection have been implicated in the pathogenesis of neonatal brain damage.[16] Severe disruption of the blood–brain barrier in severe asphyxia may exacerbate neuronal damage[17] allowing infiltration of activated immune cells and cytokines.

NEONATAL INNATE IMMUNITY

Newborns rely on their innate immune system initially following birth as there are deficiencies in the adaptive response due to lack of previous exposure to antigens *in utero*.[7] The intrauterine environment is usually sterile and transition postnatally to the foreign antigen-rich external world starts with colonization of skin and gut with microorganisms. The fetus is considered to be immunologically naive and exists in a state of immune privilege *in utero*, to prevent rejection by the maternal immune cells. The *in utero* defense system is largely unknown although recent evidence hints at a powerful fetal system of innate immunity.[18] The

antibacterial properties of vernix caseosa, the creamy white substance covering the skin of term babies, have also been recognized and in particular the presence of antimicrobial peptides including alpha defensins[19] and inflammatory mediators.[20] Antimicrobial peptides may be an adjunctive compensatory mechanism in the neonate as adaptive immunity evolves.[21] Neonates are immune competent but with a predominant Th2 profile being geared towards immune tolerance instead of towards defense from microbial infections (Th1-skewed).[22] Th1 responses are suppressed by placental products such as progesterone, prostaglandin E2, and cytokines such as IL-4 and IL-10.[23–25]

MONOCYTES

The crucial role of monocytes/macrophages in the immune response resides in their accessory cell and immunoregulatory functions of both humoral and cellular immunity. Human cord blood contains almost three times as many monocytes as adult blood does and major changes occur in the levels of monocytes during the first few weeks of life. Newborn macrophages show poor resistance against facultative intracellular organisms. Newborn monocytes exhibit marked heterogeneity with respect to density. This heterogeneity in density is reflected in functional responses in different populations of newborn monocytes.[26] The most dense population of newborn monocytes appear to have helper function for antibody production, while suppressor function resides in the less dense populations.[27] Neonatal blood monocytes are also characterized as having a much lower frequency of class II molecular expression than adult monocytes, which may be related to the selective incapacity of neonates to secrete significant levels of IFN-γ.[28] The precise role of the monocyte in the newborn's unique susceptibility to infections with various agents remains a challenging area for future study. Dendritic cells are the primary antigen-presenting cells for optimum sensitization of naive T-cells to antigen. Newborn dendritic cells have been shown to be deficient in IL-12 (p35) expression, a key regulator of Th1-type T-cell responses.[29]

Neutrophils

The critical role of the neutrophil in host defenses against microbial infection has long suggested that defects in this particular cell type might be the cause of the increased susceptibility of the newborn to serious bacterial infections. Impaired neonatal neutrophil function at birth has also been implicated in neonatal inflammatory disorders.[11] Recent advances in our understanding of the molecular basis of cell adherence and phagocytosis have provided us with greater insight into the role of the neutrophil in the newborn's defense system. Numerous *in vitro* abnormalities include decreased chemotaxis, leukocyte adherence, bacterial killing, and depressed oxidative metabolism.[30,31] However, most of these neonatal neutrophil functions have been found in cord blood, which contains immature forms of the cells, and therefore care must be taken in interpreting some of the data. Oxidative metabolic function of cord blood monocytes, measured by chemiluminescence, has been shown to be depressed 12–36 hours after birth.[32] Cytoskeletal actin polymerization has also been shown to be altered in neonates.[33]

Decreased adherence of neonatal neutrophils may be caused, at least in part, by the decreased expression of adherence glycoproteins, or by decreased fibronectin content in the plasma membrane of neutrophils.[34] Humoral defects have also been found in neonates, which may help explain the decreased levels of chemotaxis reported in neonatal neutrophils. Such altered humoral factors include decreased levels of complement components and fibronectin.[35,36]

Neonatal neutrophils exhibit normal phagocytosis of opsonized particles as well as particles that required no opsonization. The major opsonic role of neutrophils for the uptake of antibody or complement-coated microorganisms is reflected in their expression of a number of receptors both for antibody (Fc receptors) and complement (CR receptors). In newborn cord blood, the levels of these receptors are similar to those in adult neutrophils.[37–39] The level of expression of Fc receptors is significantly more upregulated in response to *in vitro* stimuli such as f-met-leu-phe (FMLP) on adult neutrophils compared to newborn neutrophils.[33]

Neonatal neutrophils have diminished function[40] and delayed apoptosis (programmed cell death) compared with adults.[41,42] In addition, neonatal neutrophil lipopolysaccharide (LPS) responses are altered,[43,44] which may further increase susceptibility to sepsis in this population. The effects of granulocyte colony stimulating factor (GCSF) and granulocyte macrophage colony stimulating factor (GMCSF) on neonatal neutrophils is altered compared with adults, showing that GCSF may improve neutrophil survival whereas GMCSF augments function.[45]

NETs are lattices of extracellular DNA, chromatin, and antibacterial proteins that mediate extracellular killing of microorganisms and are thought to form via a unique death pathway signaled by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase-generated reactive oxygen species (ROS). Neutrophils from term and preterm infants fail to form NETs when activated by inflammatory agonists, in contrast to leukocytes from healthy adults, reflecting a deficit in extracellular bacterial killing.[46]

THE INFLAMMATORY RESPONSE SYNDROMES

One reason for the failure of anti-inflammatory strategies in patients with sepsis may be a change in the syndrome over time (Fig. 16.2). Initially, sepsis may be characterized by increases in inflammatory mediators; but as sepsis persists, there is a shift towards an anti-inflammatory immunosuppressive state.[47,48] If the initial insult is sufficiently severe, the proinflammatory response can become intense and lead to a massive systemic inflammatory response syndrome (SIRS) and disrupt homeostasis.[49] If the delay is prolonged and the resolution of inflammation is blocked, the neutrophil[50] has a very high potential for causing extreme damage to healthy

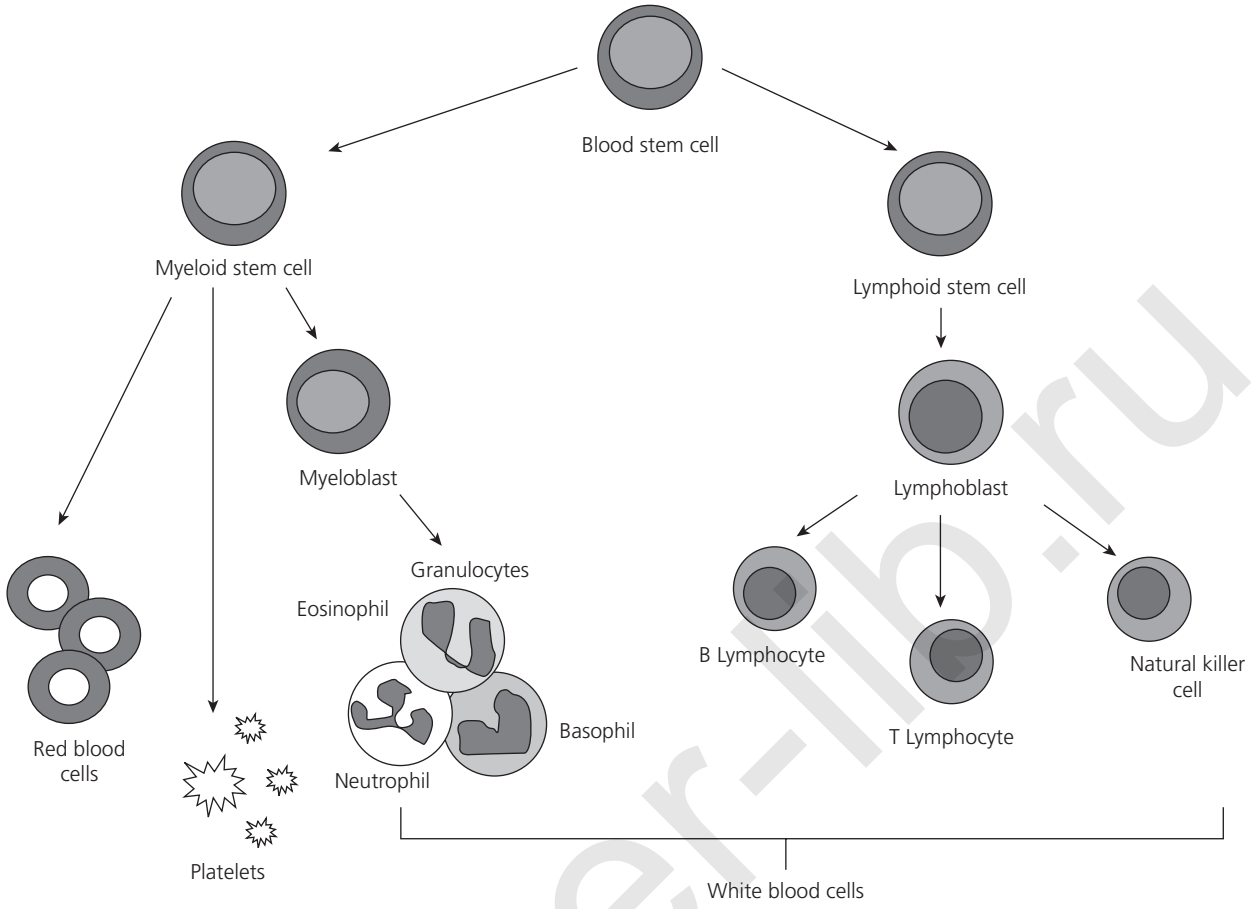

Figure 16.2 Blood cell development. Blood stem cells released from the bone marrow develop into mature blood cells over time. The blood stem cell may become a myeloid stem cell or a lymphoid stem cell. The myeloid stem can further differentiate into either red blood cells, white blood cells, or platelets. The lymphoid stem cell becomes a lymphoblast which then differentiates into one of the following lymphocyte types: B-lymphocyte, T-lymphocyte, or natural killer cell.

tissue due to the concentrated release of ROS and proteases.[51] This then forces the body to produce a massive compensatory anti-inflammatory response syndrome (CARS) that may be inappropriate and result in tissue injury. If this occurs, the body develops 'immune paralysis' and is more susceptible to infection. The final stage occurs when the overwhelming inflammation is not resolved, causing multiple organ dysfunction syndrome and death of the patient.[52] Adjunctive immunomodulatory treatments for sepsis seek to balance these responses and restore homeostasis.[52] However, discovering which inflammatory phase is dominant in the patient at a certain time point remains difficult and hinders appropriate therapeutic immunomodulation. Anti-inflammatory treatment can increase mortality. Following a cecal ligation and puncture model of sepsis in a murine model, mortality was increased in mice pretreated with interleukin receptor antagonist (IL-1ra).[53]

Fetal inflammatory responses (FIRS) and neonatal inflammatory responses (NIRS) have been described. A systemic fetal inflammatory response as determined by increased interleukin-6 is an independent risk factor for severe neonatal morbidity.[54] Preterm neonates with systemic infection have elevated IL-6, IL-10, and TNF-α concentrations. Severe infection is signified by increased IL-10/TNF-α, and IL6/IL-10 ratios. Transiently elevated IL-10 or IL-10/TNF-α levels are not invariably associated with a poor prognosis.[55]

Toll-like receptors

The Toll-like receptors (TLR) provide the critical link between microbial immune stimulants and initiation of host defense. TLR-4 is the transmembrane LPS receptor that initiates the innate immune response to common Gram-negative bacteria.[56] Neonates have an equivalent if not enhanced capacity compared with adult white-blood cell TLR-mediated response to support Th17- and Th2-type immunity, which promotes defense against extracellular pathogens. However, neonates have a reduced Th1-type response, which promotes defense against intracellular pathogens.[57] TLR-4, TLR-2, and CD14 have been shown to be increased on neonatal immune cells and cytokine release is decreased to a greater extent than adults with TLR-4 antagonists.[58] During infections, pathogens bind to TLR-4 and CD14 receptors and induce cytokine release, leading to inflammation. Neonatal IL-10 and TNF-α release depends on LPS binding, not only to CD14/TLR-4 but also to CD14

associated with another TLR.[58] There is a differential expression of TLR-2 but not TLR-4 in the course of neonatal sepsis.[59] Although decreased levels of MyD88 have been described in neonatal monocytes in response to LPS,[60] there have been few studies on neonatal neutrophils. Wynn *et al.* have recently demonstrated improved survival following polymicrobial sepsis induced by TLR-4 agonist pretreatment which enhanced peritoneal neutrophil recruitment with increased oxidative burst production.[61] Similarly, TLR-7/8 agonism also enhanced peritoneal neutrophil recruitment with increased phagocytic ability. However, these outcomes were independent of the adaptive immune system and type I interferon signaling.[61] Labour upregulates TLR-2 and TLR-4 on cord blood monocytes at the protein level suggesting that labor may be immunologically beneficial to normal newborns.[62] Augmenting innate immune function using TLR signaling may be a potential future adjunctive therapy in neonatal sepsis.

MUCOSAL IMMUNITY, HUMAN MILK, AND NECROTIZING ENTEROCOLITIS

Although the intestinal tract of the fetus is considered to be sterile, recent studies suggest that many preterm infants are exposed to microbes found in the amniotic fluid, even without a history of rupture of membranes or culture-positive chorioamnionitis.[63] Infants are colonized during vaginal delivery and subsequent breastfeeding with maternal vaginal and fecal flora. The fecal microbial profile of infants delivered vaginally versus Cesarean section showed no colonization with *Bacteroides* sp. before two months of age in infants in the latter group, and *Bacteroides* colonization that was half that of vaginally delivered infants by six months of age.[64] The common use of antibiotics, type of feeding (human milk versus formula), mode of delivery (vaginal versus Cesarean section), decreased maternal–infant direct skin contact, and various manipulations in the neonatal intensive care unit (e.g. nursing in an incubator versus under radiant warmers) have the potential to alter the intestinal microbiota.[65] In response to pathogenic intestinal microbiota, proinflammatory cytokines can increase barrier permeability, facilitating bacterial translocation with elaboration of the SIRS and multiple organ failure.[66]

Necrotizing enterocolitis (NEC) is one of the most devastating diseases in newborns. It is associated with loss of gut integrity and immune dysfunction. NEC is also characterized by exaggerated TLR-4 signaling and decreased enterocyte proliferation through unknown mechanisms.[67] Delayed bacterial commensal gut colonization is common in preterm infants in intensive care and tends to render bacterial species virulent. This abnormally upregulates TLR-4 and is associated with activation of NF-κ-B, promoting the transcription of genes for inflammation, and increased concentrations of inducible nitric oxide synthase, another potent proinflammatory regulator.[68] Increased intestinal expression of TLRs (especially TLR-2 and -4) and cytokines precedes histological injury in the experimental NEC.[69]

There is a dose-related association of human milk feeding with a reduction of risk of NEC or death after the first 2 weeks of life among extremely low birth weight infants.[70] Human milk influences neonatal microbial recognition by modulating TLR-mediated responses specifically and differentially.[71] Fresh human milk contains many immunoprotective factors, such as Ig, lactoferrin, neutrophils, lymphocytes, lysozyme, and PAF acetylhydrolase (which inhibits PAF). Human milk is also believed to promote intestinal colonization with *Lactobacillus*. The efficacy of banked human milk is less clear because freezing and pasteurization reduce the cellular components and Igs.[66]

NEONATAL ADAPTIVE IMMUNE RESPONSE

The adaptive immune system consists of B-cells, T-cells, and their products. T-cells or lymphocyte clones each bear a unique T-cell receptor (TCR) which recognizes peptides, derived from foreign or self proteins, bound in a molecular complex to the major histocompatibility complex (MHC) proteins on the surface of other cells. T-cells are divided into subsets based on their expression of different proteins which are assigned cluster differentiation (CD) numbers. Killer T-cells express CD8 and are important to kill virally infected cells. Helper T-cells express CD4 and orchestrate the overall immune response by secreting cytokines and providing co-stimulatory signals to $CD8^+$ cells and B-cells.

The basis of an adequate immune response resides in the capacity of individual cells of the immune system to recognize and react to the myriad antigens in the environment. The hemopoietic system of pluripotent stem cells is the source of all the major cell types, which are involved in the immune response. These cells include various lymphocyte subsets, macrophages, natural killer cells, monocytes, and polymorphonuclear leukocytes. These cells are involved in a complex regulatory network of cell interactions which constitute an immune response, and whose function is to eliminate both self-aberrant molecules and cells, as well as to protect the host from microbial attack (Fig. 16.3).

Lymphocyte development occurs along two distinct pathways leading to the production of the two major lymphocyte

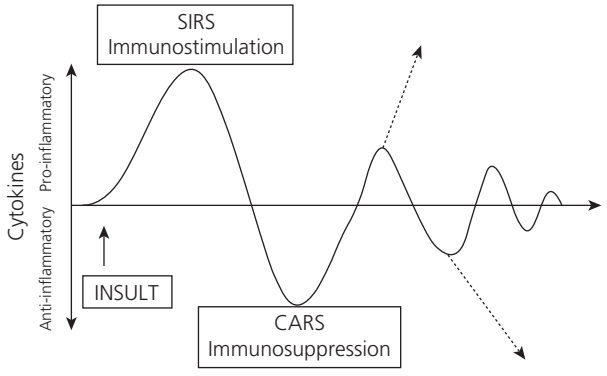

Figure 16.3 Pro-v anti-inflammatory responses. These responses eventually balance to produce homeostasis and recovery. If one or other response predominates it may increase morbidity and mortality. CARS, compensatory anti-inflammatory response syndrome; SIRS, systemic inflammatory response syndrome.

populations, T-cells and B-cells, which have very different biological effector functions. The thymus is the site of development of T-cells, which are responsible for the range of effector functions collectively termed cell-mediated immunity. Cell-mediated immunity ranges from the release of soluble factors such as cytokines, which regulate the activity of all cells of the immune system, to direct cytopathic effect of cytotoxic lymphocytes on viruses or tumor cells. B-lymphocytes, on the other hand, have a more restricted effector function, confined to the synthesis and secretion of humoral antibodies in each of the Ig classes, IgG, A, M, D, and E. More recently, B-lymphocytes have been shown to be capable of presenting antigen to T-cells.[72] In man, the site of synthesis of B-lymphocytes is the bone marrow.

The different regulatory and effector functions mediated by cells of the immune system represent the capabilities of populations of cells that can be recognized by the presence of different patterns of expression of cell-surface antigens. The availability of monoclonal antibody reagents for the recognition of lineage, differentiation stage, activation phase, and effector function of different cell types has contributed enormously to our understanding of the extent of heterogeneity of different cell types within the immune system. This heterogeneity of cell types forms the basis for an international leukocyte typing classification system, utilizing monoclonal antibodies which recognize specific cell-surface markers in order to define individual leukocyte subsets.[73] The more widely used CD antigens, for classifying immune effector cell types, are described in Table 16.1.

It is now well established that T-lymphocytes do not recognize native antigen on any pathogen, but rather a processed form of the antigen, in association with self MHCs, class I (HLA-A,B,C) or class II (HLA-DR/Ia) molecules.[74,75] This important processing of foreign antigen is carried out by one of a group of antigen-presenting cells which include macrophages, dendritic cells, Kupffer cells, and some B-cells. The proper functioning of these accessory cells is therefore as central to an adequate immune response as that of specific effector cells, such as the T-lymphocytes. When antigen becomes localized and processed by the antigen-presenting cell (APC), the complex interaction of APC, T-cells, and B-cells begins, which eventually leads to specific immunological memory, both of T-cells and B-cells as well as to antibody production. Although B-cells can be directly activated by antigen, under experimental conditions, concomitant activation of T-cells is required for the clonal expansion of antigen-specific B-cells, leading to the generation of long-lived memory B-cells and Ig-secreting plasma cells.[76,77]

Table 16.1 Cell surface antigens which identify leukocyte subtypes in the newborn.

Antigen	Function
T-cells	
CD2	LFA-3 receptor (adhesion)
CD3	Associated with cell receptor
CD4	Class II and HIV receptor
CD5	Co-stimulatory
CD7	Unknown
CD8	Class I receptor
B-cells	
CD19	Signal transduction
CD20	Unknown
CD21	C3d and EBV receptor (CR2)
CD72	Ligand for CD5
NK-cells	
CD16	IgG receptor (FcRIII)
CD56	Isoform of N-CAM
CD94	Unknown
Myeloid/monocytic cells	
C14	Unknown
C15	Unknown
CD32	IgG receptor (FcRII)
CD35	C3b receptor (CRI)

T-cell responses

Several studies in the literature have questioned the stage of maturity of circulating lymphocytes in the newborn. Some parameters of T-cell function in cord blood, however, have been shown to be normal or similar to those of healthy older children. These include the quantity and proportion of T-lymphocytes,[78] lymphocyte response to mitogens,[79] and production of certain cytokines such as IL-2.[80] However, other newborn cellular immune functions have been reported to be depressed. These include PHA-induced cytotoxicity, lymphotoxin production, as well as reduced cAMP levels.[81–83] The overall characteristic that distinguishes newborn T-cells from other T-cells at different stages of development is that they are recent thymic emigrants, not long after exiting the thymus.

Lymphocyte phenotype

There has been a reported incidence of up to 25% of cord blood lymphocytes co-expressing both CD4 helper T-cell and CD8 suppressor T-cell surface markers.[84] Cells of this double positive phenotype are common in the thymus, where they are considered to be the precursors of mature helper and suppressor T-cells. However, more recently, using more sensitive flow cytometry-based analytical techniques, workers investigating cord blood samples failed to detect the presence of doubly labeled CD4/CD8-labeled cells.[85] Other markers of an immature phenotype of newborn T-cells have been described. The CD38 antigen, which is a marker of immature thymus-derived T-cells, as well as activated lymphocytes, is present in the majority of newborn cord blood lymphocytes.[86] This thymocyte-like membrane phenotype can be modulated by the influence of thymic hormones *in vitro*.[87] In addition to the presence of CD38 thymocyte-associated antigen, human cord blood contains T-cells of the unusual phenotype which include peanut agglutinin-positive/CD8-positive as well as some CD3-positive CD1a-positive lymphocytes.[88] Like CD38, CD1a is a marker present on early thymocytes.[88] CD1a-positive cells are especially present in

preterm and antenatally stressed infants.[89] While the neonate has adequate numbers of CD4 helper T-cells, cord blood T-cells are deficient in their ability to provide help for antibody production, probably at the level of altered cytokine production.[90,91] The cellular basis for this functional defect is reflected in other phenotypic markers of functional activity. More than 90% of cord blood T-cells carry the $CD45RA^+$ 'virgin' cell phenotype marker, compared with 50% of adult T-cells which express $CD45RA^+$.[92] In contrast, less than 10% of cord blood lymphocytes express the CD45RA 'memory' T-cell marker compared to a 50% level of expression in adult T-cells.[93] This major imbalance in the ratio of $CD45RA^+$/CD45RA, CD4-positive T-cells in the newborn compared to adults may help explain some of the functional differences of newborn cells compared to adult lymphocytes. Regulatory factors contributing to the differences in functional activity and the different phenotypic profiles of newborn T-cells compared to adults require further investigation in order to arrive at a fuller understanding of the mechanisms involved.

B-cell responses

The newborn's capacity to produce antibody is significantly reduced, both quantitatively and qualitatively, compared to that of an adult. Newborn B-lymphocytes poorly differentiate into Ig-producing cells.[94,95] The mechanisms controlling this aspect of B-cell immunocompetence in the newborn are unknown. Many studies have focused on the ability of cord blood lymphocytes to terminally differentiate into IgG-, IgA-, and IgM-producing plasma cells in response to mitogens. However, a delay occurs in B-cell differentiation, resulting in decreased production of plasma cells, markedly diminishing the secretion of antibody, and restriction of secreted antibody to IgM isotype.[96] Cord blood B-lymphocytes, unlike adult B-cells, are usually unable to differentiate into Ig plaque-forming cells when cultured with pokeweed mitogen alone, or with killed *Staphylococcus aureas* Cowan 1 alone.[97] However, it appears that these two stimuli can act synergistically to induce a significant *in vitro* plaque-forming cell response in cord blood B-cells.

The relative inadequacy of IgG and IgA antibody synthesis cannot be attributed to the lack of precursor B-cells, since lymphocytes bearing these Ig classes on the surface are present in the fetus and on cord blood B-cells.[98,99] The impaired capacity to undergo IgG or IgA synthesis has been attributed to immaturity of cord blood B-cells, since their activation by polyclonal activators, like pokeweed mitogen, lipopolysaccharide, or Epstein–Barr virus, generally results in moderate or reduced levels of IgM synthesis with no IgA, IgG, or IgE production.[95] However, the question of T-cell immaturity as a significant factor in the restricted imunoglobulin isotype production of cord blood B-cells has to be taken into account.[100,101] Cord blood mononuclear cells produce normal levels of IgE *in vitro*, when cultured in the presence of IL-4, indicating that the B-cells are mature in their capacity to switch to IgE-producing cells.[100] The defect observed may be associated with the failure of cord blood T-cells to produce detectable levels of IL-4, which has been shown to be responsible for induction of IgE synthesis, both *in vitro* and *in vivo*.[101] An inadequacy of newborn T-cell help for plasma cell isotype switching to IgG and IgA Ig-producing cells is also suggested by the observation that IgG and IgA antibody responses are more dependent upon T-cell help than are IgM responses. In a series of experiments, co-culturing adult T-cells and newborn T-cells with adult or newborn B-cells, the addition of adult T-cells greatly enhanced the pokeweed mitogen-driven responses of newborn mononuclear cells, which included IgG and IgA responses.[102,103] Cord blood T-cells, however, did not show augmentation of B-cell differentiation when co-cultured with non-T-cells from adults. These data, looked at collectively, would indicate that deficient T-cell function, as well as possible deficiencies of B-cell function, exist in the newborn. The defect in Ig production may also be contributed to, of course, by suppressor T-cell activity of newborn lymphocytes or even by enhanced suppressor activity of newborn monocytes. The newborn also possesses a major population of CD5-positive[102] B-cells, which are only commonly found in patients with autoimmune diseases. It appears that these cells, in the newborn, uniquely express the activation antigens 4F2 and CD25.[104] The significance of these activated CD5-positive B-lymphocytes is, however, unclear. A particular function of these cells is the production of natural polyspecific autoantibodies.[105] A possible role for these cells in the newborn may therefore be the influencing of emerging B-cell specificities. Preterm infants are susceptible to viral infection and this is associated with impaired Toll-like receptor-3 and -7 expression on γδ cells compared with term babies and they failed to optimize cytokine production in response to coincident TCR and TLR agonists.[106]

IMMUNOGLOBULINS

The presence of physiological hypogammaglobulinemia has been noted by several investigators in preterm and term infants. Neonates have low levels of IgA and IgM immunoglobulins because of the poor ability of these Ig classes to cross the placenta.[107] Furthermore, all IgG sub-classes are not equally transferred across the placenta, especially the IgG2 and IgG_4 sub-class levels, which are therefore also relatively low in the newborn.[54] The neonate is consequently very susceptible to pyogenic bacterial infections since most of the antibodies that opsonize capsular polysaccharide antigens of pyogenic bacteria are contained in the IgG2 sub-class and IgM immunoglobulin subfraction. Neonates, even during overwhelming sepsis, do not produce type-specific antibodies.[57,108] This impairment in antibody production appears to be secondary to the defect in the differentiation of B-lymphocytes into Ig-secreting plasma cells and T-lymphocyte-mediated facilitation of antibody synthesis. There is a marked limitation in infant antibody responses to most bacterial capsular polysaccharides.[109] This limitation prevents successful infant immunization with Hib polysaccharide vaccines,[110] which fortunately can be circumvented by use of conjugate vaccines shown to be immunogenic in infants.[111]

CYTOKINES

Among the major molecular components of the immune system are the Igs, cytokines, and proteins of the acute phase response and complement system. The term 'cytokine' is used to describe a group of peptides with potent immunoregulatory effects, which are produced and utilized by individual cells of the immune system to communicate with each other and to control the environment in which they operate. A description of some of the major characterized cytokines is listed in Table 16.2.

Present evidence suggests that cytokines are of immense importance in controlling both local and systemic immune responses, inflammation, and the regulation of hematopoiesis.[112,113] Their most important function appears to be at local level, modulating the behavior of adjacent cells in a paracrine fashion,[113] or the cells that secrete them, in an autocrine fashion.[114] In addition, especially in the case of TNF-α, IL-1, and IL-6, cytokines may affect endocrine-like activity on distant organs or tissues.[115] Cytokines have important biological activity which can be of major clinical benefit, such as stimulation of antimicrobial function, promotion of wound healing, and myelostimulation.[116,117] With such diverse biological function, an exaggerated or prolonged secretion of these peptides may be detrimental for the host. Specifically, aberrant secretion of cytokines, such as TNF-α and IL-1, are thought to be responsible for the hemodynamic changes in the host during septic shock and in cachexia of chronic disease.[118,119] The availability of recombinant DNA techniques to produce cytokines in almost unlimited quantities, and the production of specific antagonists such as soluble cytokine receptors and IL-1 receptor antagonists, are leading to new and exciting therapeutic potential for these molecules.

Table 16.2 Cytokines.

Name	Principal cellular source	Principal cellular target
IL-1α + β	Macrophages, fibroblasts, endothelial cells	Thymocytes, endothelial cells, neutrophils, T-cells, B-cells
IL-2	T-cells	T-cells, B-cells
IL-3	T-cells	Multipotential stem cells
IL-4	T helper cells	T-cells, B-cells, mast cells, macrophages
IL-5	T helper cells	B-cells, eosinophils
IL-6	Fibroblasts	B-cells, fibroblasts, hepatocytes
IL-7	Stromal cells	B-cells
IL-8	Macrophages	Neutrophils
IL-10	T-cells, activated monocytes	T-cell subsets, macrophages
IL-12	Macrophages	T-cells, NK cells
IL-13	T helper cells	B-cells
TNF-α	Macrophages, fibroblasts	Many cells type
TNF-β	T-cells	Many cells type
IFN-α	Macrophages, fibroblasts	Many cells type
IFN-β	Fibroblasts	Many cells type
IFN-γ	T-cells, NK cells	Macrophages, T-cells, B-cells
TGF-β	T-cells, macrophages, platelets	Many cell types
GM-CSF	T-cells, endothelial cells	Multipotential stem cells

Chronic lung disease may be associated with impairment in the transition from the innate immune response mediated by neutrophils to the adaptive immune response mediated by T-lymphocytes. Of 1062 extremely low birth weight infants in the Neonatal Research Network of the National Institute of Child Health and Human Development, 606 infants developed chronic lung disease or died. On the basis of results from all models combined, bronchopulmonary dysplasia/death was associated with higher concentrations of interleukin 1β, 6, 8, and 10 and interferon γ and lower concentrations of interleukin 17, regulated on activation, normal T-cell expressed and secreted, and tumor necrosis factor β.[120]

IMMUNOMODULATATION

Neonates, especially those preterm, are particularly vulnerable to sepsis. Transplacental transfer of Igs from the mother to the fetus occurs after 32 weeks of gestation and endogenous production commences at a few months of age. Administration of i.v. Ig provides IgG that can bind to cell surface receptors, provide opsonic activity, activate complement, promote antibody-dependent cytotoxicity, and improve neutrophilic chemoluminescence. Term neonates have low type-specific antibody and opsonin deficiencies.[39,121,122] Preterm neonates also have severe hypogammaglobulinemia[123] and deficient complement activity.[124,125]

Theoretically infectious morbidity and morbidity could be reduced by the administration of i.v. immunoglobulin (IVIg). Meta-analysis of small trials has suggested that IVIg may reduce the rate of neonatal death but the Cochrane review could not recommend routine use of prophylaxis against nosocomial infections or for treatment in proven or suspected infection.[126,127] The International Neonatal Immunotherapy Study (INIS) is an international multicenter randomized controlled trial studying the use of non-specific IVIg in addition to antibiotics in babies with suspected or proven sepsis. This study is designed to confirm or refute the hypothesis that IVIg reduces the rate of mortality and major morbidity and results are awaited.[128]

COLONY STIMULATING FACTORS

Neonates often become neutropenic when septic and therefore the use of GCSF and GMCSF have been studied on this population. The Cochrane meta-analysis of trials has found no significant improvement in outcome when colony stimulating factors (CSFs) were used for prophylaxis or treatment of sepsis.[129]

The PROGRAMS Multicenter RCT of Prophylactic GMCSF to Reduce Systemic Sepsis in Preterm Neonates included 280 infants <31 weeks. When GMCSF 10 μg/kg per day was administered prophylactically for 5 days, neutrophil counts were higher on days 3–12 than controls. There were no significant differences in sepsis-free survival in infants who are neutropenic at recruitment, the number of infants experiencing one or more episodes of culture-positive sepsis or survival to discharge. GMCSF rapidly corrected neutropenia in preterm, growth-restricted neonates. Prophylactic GMCSF and correction of neutropenia, even when severe, did not reduce sepsis or all cause mortality.[130] Kuhn *et al.* recently described a multicenter, randomized, double-blind, placebo-controlled trial of the prophylactic use of GCSF in neutropenic preterm infants <32 weeks ($n=200$) and found no differences in survival free of confirmed infection for 4 weeks after treatment with either rG-CSF (10 mg/kg per day) or placebo for 3 days.[131] However, activated leukocytes may mediate neonatal brain injury.[16] GMCSF stimulates neonatal neutrophil activation, unlike GCSF, and both prolong neutrophil survival.[45] Therefore, the two-year developmental outcomes of the PROGRAMS trial will be awaited with interest. In addition, a randomized controlled trail of CSF use in infants with sepsis is needed to address the use of these agents in neonates.

APC (drotrecogin alfa activated) decreased death from any cause in patients with sepsis (absolute reduction in RR 6.1%) and there was one additional life saved for every 16 patients treated. There was a decrease in coagulopathy: D-dimers and inflammation:IL-6[132] RESOLVE (REsearching severe Sepsis and Organ dysfunction in children: a gLobal perspectiVE) trial evaluated sepsis for safety, pharmacokinetics, and pharmacodynamics of drotrecogin alfa (activated) in children with severe sepsis.[133] The patients studied were from term newborn to 18 years with similar pharmacokinetic profiles, effects on D-dimer levels, other coagulation parameters, and bleeding rates to PROWESS, although there was more Gram-negative sepsis.

PREBIOTICS AND PROBIOTICS

Prebiotics are unique oligosaccharides that are not absorbed but facilitate colonization by probiotic organisms (bifidobacteria and lactic acid-producing bacteria). Use of probiotics has been shown to decrease the duration and severity of rotavirus-induced diarrhea, allergies to cow milk protein, atopic dermatitis, and some inflammatory intestinal diseases. A relative reduction in the risk of NEC, late-onset sepsis, and mortality has been demonstrated with probiotics (*B. infantis*, *Streptococcus thermophilus*, and *B. bifidus* in one study and *Lactobacillus acidophilus* and *B. infantis* in another).[134,135] A multicenter, double-blind, randomized, controlled trial of the probiotics *B. bifidus* and *L. acidophilus* showed a lower incidence of NEC in the study group than controls but sepsis was more frequent,[136] although this difference was not significant on multivariate analyses and none of the affected patients developed sepsis with organisms used as probiotics. There are persistent concerns about the use of probiotics in immunosuppressed infants as there have been reports of preterm infants who had short gut syndrome developing *Lactobacillus* bacteremia while receiving this probiotic bacterium.[137] In adults, another multicenter, double-blind, randomized, controlled trial of probiotics to reduce infections in pancreatitis showed a more than two-fold increase in mortality and no reduction in infections.[138] In addition to these immediate concerns about sepsis, the long-term effects of the use of probiotics, especially in preterm infants in terms of immune modulation in later life, development of immune disorders (such as insulin resistance, diabetes, obesity, and cancer), and neurodevelopmental outcomes are not known.

IMMUNE DEFICIENCY DISEASES IN THE NEWBORN

Although there are many forms of primary immunodeficiency in the newborn there are several well-described clinical conditions, two of which we will mention in this chapter. DiGeorge's syndrome (DGS) usually involves a hemizygous microdeletion in the chromosome 22q11.2 region characterized by the triad of conotruncal cardiac anomaly, thymic hypoplasia, and hypocalcemia. The syndrome encompasses a broad spectrum of congenital defects that have varying degrees of severity, especially in the degree of immunodeficiency, and the incidence is one in 4000 births. Only $<1\%$ of patients have severe immunodeficiency but early identification is essential to prevent and treat life-threatening infections and to plan for immune reconstitution. Immunodeficient DGS patients present with profoundly decreased T-cell numbers ($<50/mm^3$), depressed T-cell function (as measured by lymphocyte proliferation assays, such as with mitogens), and often concomitantly low Ig levels. These patients are at high risk for the development of disseminated and life-threatening infections with organisms that require an intact cell-mediated immune system for eradication, such as cytomegalovirus, adenovirus, or *Pneumocystis jiroveci* (formerly *P. carinii*). Graft-versus-host disease also may be found due to transplacental transfer and engraftment of maternal T-cells, leading to the typical rash and diarrhea seen in other forms of graft-versus-host disease.[139]

Severe combined immunodeficiency (SCID) is a primary immune deficiency with a severe defect in both the T- and B-lymphocyte systems, resulting in serious infections within the first few months of life. Newborn screening for severe combined immunodeficiency is advancing toward pilot trials as early diagnosis improves outcomes and facilitates bone marrow transplantation.[140] Persistent lymphopenia or leukopenia and recurrent infections in neonates warrant further investigation and immunology and infectious diseases involvement.

CONCLUSION

In fetal and neonatal life, many aspects of the immune system are different to older children and adults. The molecular and cellular basis for these abnormalities, while partially explained by many of the observations described in this chapter, remains

relatively unclear. The prospects for more specific and selective immunological intervention as part of the treatment of the immunocompromised neonate undergoing surgery will benefit enormously from ongoing research into the biological basis of immuno-incompetence of the newborn.

Designing new drugs to neutralize microbial products or block their interaction with specific receptor on immune cells is an attractive concept.[141] Potential targets include LPS binding protein, CD14, TLR-4, and MD-2 for Gram-negative sepsis, and CD14, TLR-2, and TLR-6 for Gram-positive sepsis. Monoclonal antibodies against CD14 are being evaluated in phase II studies. Several intracellular signaling molecules, such as MyD88 and mitogen-activated protein kinase, are other possible therapeutic targets. However, inactivating molecules that are pivotal to innate immunity can be harmful, as shown by the increased sensitivity to bacterial sepsis in mice with mutations of the Tlr4 gene.[142] Careful selection of patients with severe infections associated with a high probability of death will therefore be essential.

Neonatal sepsis

JAMES PIERCE, TRACY GRIKSCHEIT, AND HENRI FORD

INTRODUCTION

Neonatal sepsis remains one of the most common and potentially preventable causes of mortality and long-term morbidity in the world. A recent study by the Neonatal Research Network of the National Institute of Child Health and Human Development (NICHD) demonstrated that compared with uninfected infants, those who develop infections in the neonatal period were significantly more likely to have adverse neurodevelopmental outcomes at follow-up. These include cerebral palsy, poor vision, delayed psychomotor development, low Bayley Scales of Infant Development II scores on the mental development index, as well as impaired head growth, a known predictor of poor neurodevelopmental outcome.[1] Similarly, a four-fold increase in the incidence of cerebral palsy was reported in a British cohort,[2] and poor neurodevelopmental outcomes were noted in a large American cohort[3] following neonatal infections.

DEFINITIONS AND CLINICAL FEATURES OF SEPSIS

Sepsis is characterized by an invasive microbial infection and a resulting systemic inflammatory response. Classically, sepsis was described in the adult patient with a Gram-negative infection who subsequently developed fever, hypotension with poor tissue perfusion, and ultimately multiple organ failure. Subsequently, bench and clinical research demonstrated that a number of initial insults, including significant infection, toxin exposure, severe tissue necrosis, and open burn wounds, were capable of inducing these signs and symptoms. Therefore, the term systemic inflammatory response syndrome (SIRS) was introduced to describe this constellation of symptoms. A number of pro-inflammatory as well as regulatory (or anti-inflammatory) cytokines and hormones have been identified in association with the SIRS response. Investigators have grouped various patterns of cytokine response with specific clinical signs and symptoms. Thus, in addition to SIRS, the concept of a compensatory anti-inflammatory response syndrome (CARS) or a mixed anti-inflammatory response syndrome (MARS)[4,5] has also evolved (Fig. 17.1).[6]

Sepsis is defined as the presence of a SIRS response coupled with a causative infection. Historically, group B streptococci (GBS) and associated SIRS accounted for the majority of admissions to the neonatal intensive care unit for sepsis (see Table 17.1).[7,8] Subsequent implementation of perinatal antibiotic therapy has drastically reduced the number of GBS infections; nevertheless, GBS and *Escherichia coli* remain common pathogens in neonates. This is in stark contrast to *Pseudomonas*, *Klebsiella*, and *Bacteroides*, which are significantly more common in the pediatric and adult age groups. In addition, systemic fungal infections, particularly *Candidiasis*, have become increasingly prevalent in the neonatal population.[9,10] Thus, a discussion of sepsis in the neonate – from epidemiology to outcome – cannot be separated from the epidemiology of neonatal infections.[11,12]

Sepsis neonatorum is the presence of systemic symptoms in the setting of an identified microbial infection. Because neonates have a relatively immature immune system and their intestinal microbial flora continues to evolve during the first weeks of life, defining criteria that appropriately identify sepsis and serious bacterial infections in this age group remains challenging. Furthermore, as the phenotype of the neonate's immune system changes rapidly, criteria must take into consideration immunologic differences in preterm, term, or older infants. Therefore, a list of the clinical features of sepsis must reflect both corrected gestational age and chronologic age. There are multiple criteria for defining or diagnosing sepsis. Clinicians can apply these criteria to determine if sepsis is likely, guide subsequent workup and antibiotic therapy, or document the presence of sepsis for outcome analysis (see Table 17.2 for comparison of different sepsis criteria). One of the important early criteria, for example, is the Rochester Criteria.[13,14] These criteria predict serious bacterial infection and high risk of sepsis in a population of healthy term infants, less than three months of age. However, the Rochester criteria neither effectively

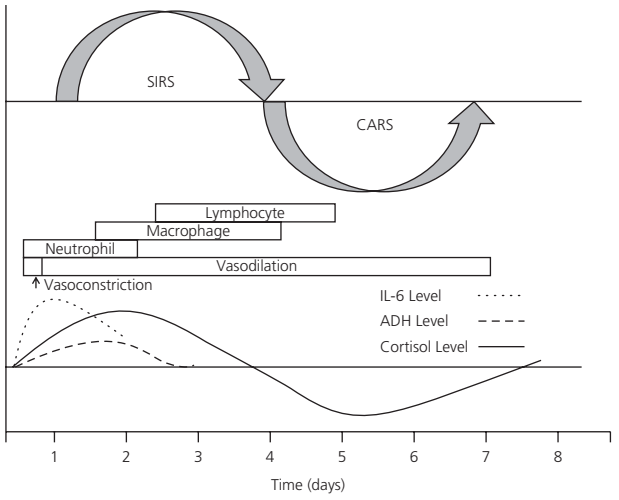

Figure 17.1 Following onset of sepsis, there are predictable phases of systemic inflammatory response syndrome (SIRS) and compensatory anti-inflammatory response syndrome (CARS). This figure is not meant to be comprehensive, but representative of several of the most well-understood components of each phase.

Table 17.1 Major events in the changing epidemiology of bacterial sepsis in the neonatal intensive care unit.

Changing epidemiology of neonatal sepsis	
1930–40s	Majority of infections were Gram-positive cocci
1950s	Balanced frequency of *S. aureus*, *E. coli*
1960s	Rising incidence of group B *Strep*, ongoing *E. coli*
1970s	Peak of group B *Strep*
1980s	Coagulase-negative *Staph* surpassed *Strep*, *S. aureus*, *E. coli*
1990s	Rising incidence of nosocomial infections: CNS and *Candida* sp.
2000s	Multidrug resistant infection

define sepsis nor assist in the management of complicated perinatal or preterm infants.[15] Pediatric criteria,[11] developed from large-scale pediatric databases to parallel adult criteria, are useful in defining sepsis for outcome analysis but lack characteristics that make them applicable to the neonatal population. In addition, some criteria are strictly biochemical[16] rather than clinical, in contrast to the more classic 'Bone' criteria.[17,18] Table 17.2 shows a useful list of criteria that help define the sepsis syndrome in the neonate.[17,19–22]

EPIDEMIOLOGY AND RISK FACTORS

Recent studies have shown an increased incidence of sepsis in the United States[23] and in the world.[24–26] Martin and colleagues reported an 8.7% increase annually in the overall incidence of sepsis between 1979 and 2000.[27] Indeed, a national survey of nearly 1.6 million hospitalized children, ages 19 years or younger, revealed 42 364 cases of sepsis per year.[28]

Overall, bacterial sepsis affects approximately 32 000 infants annually, or 1–8 cases per 1000 live births. Nursery-acquired sepsis has a national incidence of 1.4% and NICU-acquired sepsis ranges from 5 to 30%, depending on the level of acuity of the unit. Well-established independent risk factors for infections can be divided into genetic, prenatal, perinatal, and postnatal causes. In the prenatal period, the presence of maternal–fetal infection, the need for invasive procedures, low maternal age, multiparity, and group B strep colonization have been identified as putative risk factors for sepsis.[29] Perinatal risk factors include prolonged (greater than 12 hours) internal monitoring, documented chorioamnionitis and endometritis, premature and prolonged rupture of membranes,[30] low birth weight, low gestational age, and presence of existing comorbidities.[31,32] Postnatal need for procedures or indwelling catheters, prolonged hospitalization, and overcrowded nurseries have been associated with

Table 17.2 Criteria for diagnosing sepsis in critically ill neonates and children.

Physiologic criteria	Laboratory criteria	Biochemical criteria
Fever (rectal temperature $>38^{\circ}C$), hypothermia ($<35^{\circ}C$), or increased temperature variability in isolette	White blood cell count $>12\,000$ cell/cc or <4000 cell/cc	Elevated C-reactive protein (>3 mg/cc with physiologic symptoms, >10 mg/cc without symptoms)
Tachycardia (heart rate >95th percentile for age)	Bandemia ($>10\%$ bands)	Elevated interleukin >44.4 pg/mL
Tachypnea (respiratory rate >95th percentile for age) or increasing frequency of apneic events with bradycardia	Ratio of immature to total neutrophils (>0.2 for infection, >0.8 for bone marrow depletion)	Elevated procalcitin (PCT >6.1 ng/mL)
Hypotension (mean arterial blood pressure <5th percentile for age)	Thrombocytopenia ($<50\,000$ per cc)	Elevated lipopolysaccharide protein (LBP >25 μg)
Poor peripheral perfusion (delayed capillary refill or central-peripheral temperature disparity)	Metabolic acidosis (pH <7.25 or base excess <-5)	
Oliguria (urine output <1 mL/kg per hour after day of life 1)	Elevated lactate (>4 mmol/cc)	
Poor feeding		

an increased risk of sepsis.[12,33] There is increasing evidence for a genetic,[34] proteomic,[35] and phenotypic role in neonatal sepsis. Consistent with this observation, male gender and African-American ethnicity are independent risk factors for neonatal sepsis.

According to current terminology, preterm neonates are defined as those born before 37 0/7 weeks' gestation and late preterm neonates are those born between 34 0/7 and 36 6/7 weeks (Table 17.3).[36] Extreme prematurity refers to neonates at the limits of viability, specifically between 23 0/7 weeks and 27 0/7 weeks' gestation.[37]

Birth weight is defined relative to gestational age. In particular, an infant is considered small for gestational age if he/she is less than the 10th percentile in weight in an age-matched cohort; by contrast, an infant is large for gestational age if he/she is above the 90th percentile for weight. As birth weight is an independent risk factor for a number of outcomes, including neonatal sepsis, age-matched birth weight is a confounding variable. Thus, definitions for non-age-matched birth weight exist as well. Any newborn less than 2500 g is considered to have low birth weight (Table 17.4). A newborn less than 1500 g is categorized as very low birth weight, while any infant weighing less than 1000 g is considered to be extremely low birth weight. Unfortunately, neither small for gestational age, nor low birth weight captures an additional important variable – the trajectory of intrauterine weight gain. A trajectory of normal weight gain for a small for gestational age fetus is significantly less concerning than a sudden change in the trajectory of weight gain for an appropriate weight fetus. Falling off an intrauterine growth curve can indicate either primary placental insufficiency or increased fetal demand due to maternal–fetal infection.

The NICHD Neonatal Research Network defines early-onset sepsis as a culture-positive systemic infection that occurs within 72 hours of birth, while late-onset sepsis presents after 72 hours from birth (Table 17.4).[38] As a result, infants who develop early-onset sepsis consist of those delivered during active, invasive maternal–fetal infections, and those delivered without significant maternal–fetal infections but exposed to either subclinical uterine infection or maternal vaginal flora.

In recent years, several perinatal study groups have identified maternal and fetal infectious processes as being clinically significant to the fetus and a major cause of preterm delivery.[39] Microbial invasion is evident in up to 40% of preterm neonates' fetal membranes and, similar to sepsis, asymptomatic histologic chorioamnionitis is associated with poor neurodevelopmental outcome.[40] This process has both direct invasive infection and maternal–fetal-systemic effects and has appropriately been termed fetal inflammatory response syndrome (see Fig. 17.2).[41–44] Given that pathologic evaluation of fetal membranes is not always performed and final pathologic results are often not available at tertiary neonatal units, many meconium aspiration and other peripartum sepsis events may represent an underdiagnosed group of peripartum sepsis events. Indeed, respiratory distress syndrome,[45] preterm necrotizing enterocolitis,[44] long-term pulmonary,[43] and neurologic[46] outcome have all been shown to correlate with the presence of invasive infection and cord hypercytokinemia. In brief, early or prolonged rupture of membranes and ongoing vaginitis are associated with higher rates of funisitis and chorioamnionitis. These findings are more common in preterm neonates and the incidence of chorioamnionitis increases sharply with earlier gestational age (from 10% in late preterm neonates to as high as 60% in extreme prematurity). Several maternal biomarkers, including the vaginal presence of fetal fibronectin, have also been associated with increased early onset infection.[47] Appropriate use of antibiotics has been shown to reduce neonatal sepsis secondary to GBS from 78 to 47%, and overall sepsis from 4 to 1.2%.[48]

Early-onset sepsis peaks in the first 24 hours of life (85% of overall cases), and declines in frequency over the next 48 hours. As a result, early-onset sepsis is believed to be related to peripartum events, particularly transplacental infection or

Table 17.3 Rates of early-onset and late-onset sepsis by gestational age at birth.

	Extreme preterm (23–27 weeks, %)	Preterm (<37 weeks, %)	Late preterm (34–36 weeks, %)	Term (>37 weeks, %)
Early-onset sepsis (<72 hours)	Not reported by gestational age	0.56	0.44	0.02–0.35
Late-onset sepsis (>72 hours)	22–48	16	6.3	1.4

Table 17.4 Rates of early-onset and late-onset sepsis by birth weight. This table does not take into account large for gestational age (greatest 10th percentile).

	Extremely low birth weight (<1000 g)	Very low birth weight (1000–1500 g)	Low birth weight (1500–2500 g)	Appropriate birth weight (>2500 g)
Early-onset sepsis (<72 hours)	Not reported by weight	0.19–0.59%	Not reported by weight	0.12–0.66%
Late-onset sepsis (>72 hours)	22–33% mean (38% 750–1000 g, 48% 500–750 g)	16–22% mean (7% 1250–1500 g, 18% 1000–1250 g)	5–16%	1.4–5.6%

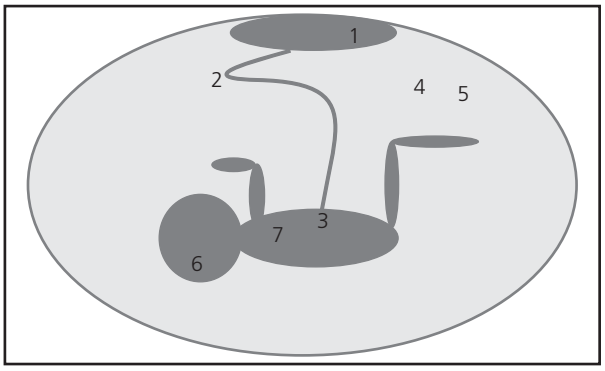

Figure 17.2 Components of fetal inflammatory response syndrome (FIRS) and ascending maternal–fetal infection; not all are present nor is the order of presentation required. 1 – Infection and inflammation of the placenta (chorioamnionitis), 2 – Ascending vasculitis and infection of the umbilical cord (funisitis), 3 – Presence of inflammatory cytokines in the fetal circulation, 4 – Presence of inflammatory cytokines in the amniotic fluid, 5 – Presence of bacteria in the amniotic fluid, 6 – End organ dysfunction and damage due to cytokinemia, including altered blood–brain barrier, 7 – End organ dysfunction and damage due to cytokinemia, including changes in alveolar cellular development and surfactant production.

ascending maternal infection. By contrast, late-onset sepsis, which occurs after the first 72 hours, is almost entirely due to an environmentally acquired (nosocomial) infection. It is important to recognize, however, that some neonatal intensive care units – particularly those referral centers that accept outborn neonates – do have some term and late-preterm neonates with community-acquired infections.

Since the implementation of screening for, and treatment of group B Strep with antibiotics, rates of GBS infection have fallen. The rate of infection, which was estimated at 0.51 cases per 1000 births in the 1990s, is currently around 0.40 cases per 1000 births.[49] Although perinatal practices continue to reduce GBS sepsis, rising Gram-negative resistance to ampicillin is evident.[50] The long-term significance is unclear as it may result in exchanging one infection for another and may require a significant change in the early empiric treatment of suspected sepsis.

Late-onset sepsis, predominantly of nosocomial origin, accounts for the majority of cases of neonatal sepsis. There has been a shift towards rising ampicillin resistant Gram-negative infections. Additionally, candidal infection, which had been rising, may recently have reached its peak with the institution of fluconazole prophylaxis.[51,52] The remainder of late-onset sepsis is predominantly associated with indwelling devices, including central venous catheters, endotracheal tubes, and urinary catheters (see Table 17.5).[53]

Two issues that have recently become more important are the rising incidence of resistant organisms (discussed below) and the management of suspected and culture-confirmed meningitis. Despite relatively high incidences of meningitis following bacteremia, practice surveys and retrospective analyses have shown that there is significant practice variation regarding performance of lumbar puncture for diagnosis of meningitis and management of duration of therapy.[54] While a full discussion of meningitis is beyond the scope of this chapter, it has become increasingly clear that lumbar punctures should be performed more frequently than currently and repeat lumbar punctures to confirm sterilization of the meninges are necessary.[38,48,55]

Table 17.5 National surveillance and rates of nosocomial infection in neonatal intensive care units.

Type of nosocomial infection	PPN (%)	NNIS (%)
BSI/1000 CVC/day	Not reported	8.6
<1000 g	12.8	9.1
>1500 g	4.7	4.1
VAP/1000 Vent-day	Not reported	2.5
<1000 g	4.9	1.5
>1500 g	1.1	1.4
Overall PNA/1000 pt-day	12.9	Not reported
UTI/1000 pt-day	8.6	Not reported

BSI, Blood stream infection; CVC, central venous catheter, PNA, pneumonia; UTI, urinary tract infection; VAP, ventilator associated pneumonia.

PATHOPHYSIOLOGY OF SEPSIS

There are two necessary criteria for the establishment of an invasive infection: significant bacterial virulence and failure of the host defense system. Bacterial virulence factors include ability to adhere to epithelia, invade through the basement membrane into host tissues, and evade the host defense mechanisms. The process of microbial adhesion depends on bacterial fimbriae or pili, which bind to the common peptide sequence Arg-Gly-Asp found in fibronectin, collagen, and other host structural proteins. After adhering, high affinity receptors bind to cellular integrins to promote internalization or invasion.[56] Bacteria then use a number of different enzymes and toxins to neutralize intracellular, cell-mediated, and humoral host responses. These include hyaluronidase, collagenase, lecithinase, and proteinases, as well as exotoxins capable of inhibition of neutrophil and phagocyte function.[57]

The neonatal immune system is profoundly different from that of pediatric patients.[58] While it still consists of both innate and adaptive components, and generates both humoral and cellular responses, the infant's immune system is immature and the transition between fetal and extrauterine life represents a transient period of relative immunosuppression (Fig. 17.3). The humoral innate system at birth lacks significant opsonin function,[59] and complement levels decrease after birth and reach their nadir at 3 weeks. Normal complement levels and opsonization do not occur until approximately six months.[60] The adaptive humoral system is dependent on maternal production of antibodies as infant B-cells have not yet been exposed to a significant antigen load. During the peripartum period placental transfer provides a lopsided supply of maternal antibodies – excellent for antitoxins but poor for enteric somatic antibodies (O antigen).[61] Postpartum antibodies are delivered through maternal colostrum and milk. They reflect primarily the maternal response

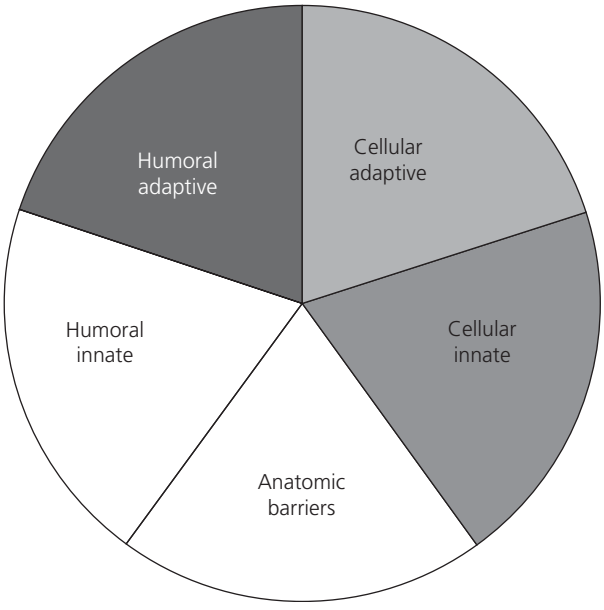

Figure 17.3 The five components of neonatal host defense against pathogens: anatomic barriers including skin and mucosa, innate and adaptive humoral response, and innate and adaptive cell-mediated response.

to gastrointestinal antigenic exposure and thus do not confer protection against NICU pathogens.[61] Cellular innate and adaptive defense mechanisms are present as early as 13 weeks of gestation.[62] However, significant production of leukocytes does not occur until nearly the 30th week, and innate cells like neutrophils continue to represent only 20–30% of the adult pool.[62] Although lymphocytes account for the majority of the leukocyte population at this age, the adaptive immune response remains qualitatively immature until significant antigen exposure leads to development of an appropriately mature helper T-cell population. Only then will T-cell mediated cytotoxicity and B-cell antibody production begin to increase.[63]

Several deficiencies exist in non-immunologic neonatal host defenses as well. External anatomic barriers such as the skin suffer from immaturity or fragility, which results in skin breaks due to injuries during delivery and invasive procedures in the nursery.[64] The gastrointestinal mucosal barrier is also immature and gut colonization with commensal bacteria occurs in several waves before the normal distribution of microflora is achieved.[65] Finally, internal barriers, particularly the meninges and the blood–brain barrier, are immature and allow active translocation of bacteria to normally sterile areas during bacteremia.[54]

Management

Given the profound morbidity and mortality associated with neonatal sepsis, best practice management should begin with prevention. There are two principal targeted approaches to prevent or reduce early-onset sepsis. The first centers on the prenatal and peripartum management of the maternal–fetal unit. The second approach focuses on active management of early postpartum newborns based on their risk profile. Both perinatal and postpartum studies indicate that term neonates without any risk factors do not require systemic antibiotic prophylaxis. Unfortunately, there are no good data on term neonates with risk factors for sepsis.[66] Furthermore, given the significant improvement in perinatal care over the last two decades, the epidemiology of early-onset sepsis has changed greatly.[9,67] Current recommendations from the Centers for Disease Control for intrapartum therapy are penicillin G or ampicillin at loading doses and then every 4 hours until delivery.[68] Postnatal ampicillin should be administered to the neonate every 4–6 hours for moderate to high risk newborns.[69,70] Due to the increase in Gram-negative sepsis, particularly *E. coli*, several postnatal protocols have been developed including the additional administration of an aminoglycoside such as gentamicin or third generation cephalosporin like cefotaxime.[71]

A significant effort has also been made toward prevention of late-onset sepsis in the hospital nursery. Although aggressive skin care, including 3% hexachlorophene bathing, can significantly reduce *S. aureus* and other Gram-positive cocci colonization, the significant skin permeability of the neonate leads to absorption and associated neurotoxicity.[72] The World Health Organization recommends dry skin care in developed countries and antiseptic use in developing countries,[73] although many centers routinely apply small amounts of antimicrobials to the umbilicus and circumcision sites. Indeed, a recent randomized controlled trial investigating umbilical cord care demonstrated superiority and safety of chlorhexidine powder to dry care.[74] Additionally, prevention of colonization and infection in nurseries requires adequate space and personnel. Recommendations of space range from 36 to 100 square feet and nurse to patient ratio of 1:4 to 1:1, depending on acuity. Although good outcome studies of individual interventions are not possible due to power restrictions, quality assurance and intervention bundle studies indicate that combined implementation of infection control techniques reduces the risk of nosocomial infections. This includes frequent hand hygiene, gowns and gloves, care of invasive devices, sterilization of equipment, and epidemic control techniques.[75,76] Despite the success of these environmental techniques, several well-designed Cochrane reviews failed to produce evidence in favor of prophylactic systemic antibiotics in ventilated newborn infants[77] or neonates with central venous[78] or umbilical catheters.[79]

The cornerstone of treatment of established sepsis is combining source control with adequate antibiotic coverage. As described above, early-onset sepsis is caused by ascending or transplacental transmission of infection. Source control consists of clamping and cutting the umbilical cord. Late-onset sepsis, on the other hand, is most commonly related to indwelling vascular catheter-related sepsis, ventilator-associated pneumonias, and urinary tract infections. When considering source control, it is important to consider alternative forms of therapy. These include prompt removal of umbilical catheters, placement of peripherally inserted central catheters, and surgically placed tunneled lines. Similarly, extubation to noninvasive positive pressure ventilator support (such as continuous positive airway pressure) or patient positioning for ventilator associated pneumonias[80,81]

and early removal of indwelling urinary catheters should be considered if possible. However, the systemic inflammatory response syndrome and multi-organ dysfunction often make these maneuvers impossible.

Selection of initial antibiotic therapy can be difficult. The epidemiology of early-onset sepsis continues to change rapidly, and while a penicillin and aminoglycoside appear to be optimal peripartum therapy, integration of individual unit antibiograms and ongoing surveillance are necessary for treating late-onset sepsis. Furthermore, decreasing Gram-negative and Gram-positive sepsis has led to a commensurate rise in anaerobic, fungal, and viral sepsis. There is inadequate evidence from randomized trials to support any particular antibiotic regimen in the initial treatment of suspected late-onset sepsis in the newborn.[82] Although variations on penicillins (such as anti-pseudomonal penicillins or beta-lactamase inhibitors) and low cross resistance between aminoglycosides help individual units develop broad-spectrum strategies, increasing rates of methicillin-resistant *Staphylococcus aureus* (MRSA) and multidrug-resistant Gram-negative infections make optimal broad-spectrum coverage a moving target. Increasingly, initial therapy includes vancomycin in units highly colonized with MRSA as well as an antifungal agent due to the increased incidence of *Candida* spp. sepsis as well.[83] Indeed, there are randomized controlled trials that support prophylactic,[84] initial, and completion antifungal therapy.[85,86]

Once culture proven sepsis has been documented, it is safe and appropriate to narrow the spectrum of initial antibiotic therapy. The challenge of culture-directed therapy in neonatal sepsis, however, is the optimal duration of treatment. Only one small randomized trial investigated 7-day versus 14-day duration of antibiotics for neonatal sepsis.[87] Unfortunately, small sample size and heterogeneity of enrolled neonates precluded statistical significance. Several randomized clinical trials[88] have examined optimal duration of treatment for meningitis with similar limitations. Indeed, the greatest challenge is the lack of good criteria for response to therapy, as many neonates may appear minimally symptomatic despite positive blood cultures and permeable meninges. For this reason, repeat cultures to ensure site control are mandatory, and antibiotic therapy is often carried on for several days following clearance of cultures and disappearance of symptoms. Although C-reactive protein emerged nearly a decade ago as a useful biomarker of the response to sepsis,[89] subsequent investigation failed to produce a consistent or reproducible pattern to determine those infections that respond to therapy.[90] The negative predictive value of C-reactive protein is significantly more useful than its positive predictive value.[91] No prospective randomized trials exist in neonates regarding the utility of biomarkers in guiding duration of antibiotic therapy. Thus, current practice is to repeat cultures and laboratory values to ensure clearance of bacteremia and then continuing antibiotic therapy specifically tailored for the offending microorganisms for a minimum of 5 days for neonates without central venous catheter, 10 days for infants with indwelling central venous catheters, and up to 2 weeks for documented meningitis. Nevertheless, as more experience with screening and management with biomarkers in neonatal sepsis accumulate, well-powered randomized controlled trials regarding duration of tailored antibiotic therapy will be required.

Because sepsis often leads to shock, adequate resuscitation is imperative in the management of sepsis. Significant improvement in the morbidity and mortality of adult and pediatric sepsis has been achieved through goal-directed resuscitation (see Fig. 17.4).[92] Unfortunately, the 'goal' of resuscitation is not as clear in the neonatal population as it is in adults.[93] At birth, newborns carry a 'backpack' of extra salt and water to carry them through transition.[12] During transition and early life, many hemodynamic parameters such as blood pressure do not have clear 'normal' values.[94] In addition, immature cardiovascular and endocrine systems may blunt the appropriate stress response in newborns, making vasopressor, inotrope, calcium, and hormone replacement necessary.[95] Finally, aggressive fluid resuscitation is associated with a significant risk of reopening the ductus arteriosus and potentially worsening perfusion.[96] Nevertheless, fluid resuscitation, vasopressor use, calcium replacement, and endocrine replacement are key components of the therapeutic armamentarium for achieving adequate tissue perfusion.[97,98]

There are no validated clinical signs of shock or poor tissue perfusion without end organ damage. Clinical signs include urine output, blood pressure, heart rate, color, capillary refill, and central-peripheral temperature discrepancy. Though frequently assessed for management, studies have demonstrated no association between blood pressure and tissue perfusion[99] and weak association between color,[100] capillary refill,[101] and tissue perfusion. Significantly decreased tissue perfusion has several measurable laboratory and biochemical effects on the neonate. In particular, metabolic acidosis, base deficit, and serum lactate can be utilized as markers of poor perfusion.[102] Therefore, improvement in these laboratory markers along with urine output can be used as putative 'goals' for resuscitation.

The first approach to resuscitation should consider volume expansion (Fig. 17.5), remembering that most hypotensive neonates have a normal circulating blood volume. During transition from fetal to extrauterine circulation, evidence suggests that excessive volume resuscitation is associated with bronchopulmonary dysplasia,[103] intraventricular hemorrhage,[104] and reopening or persistence of the ductus arteriosus. Late-onset sepsis in the neonate receiving chronic diuretic therapy requires adequate fluid resuscitation. Therefore, while the surviving sepsis guidelines indicate pediatric patients can be strongly recommended to receive 60 mL/kg within 15 minutes, a more appropriate empiric choice in neonates appears to be incremental 10–20 mL/kg boluses with low threshold for vasopressor use.[95]

The most commonly studied and prescribed adrenergic medications include dopamine, dobutamine, and epinephrine. In addition, milrinone is a frequently used phosphodiesterase inhibitor. Due to the differing proportions of alpha- and beta-adrenergic receptors in the neonate, there has been significant skepticism regarding the utility of alpha-specific medications such as phenylephrine or norepinephrine, although they are used routinely in older patients. Nevertheless, a recent prospective trial evaluating norepinephrine demonstrated improved tissue perfusion and

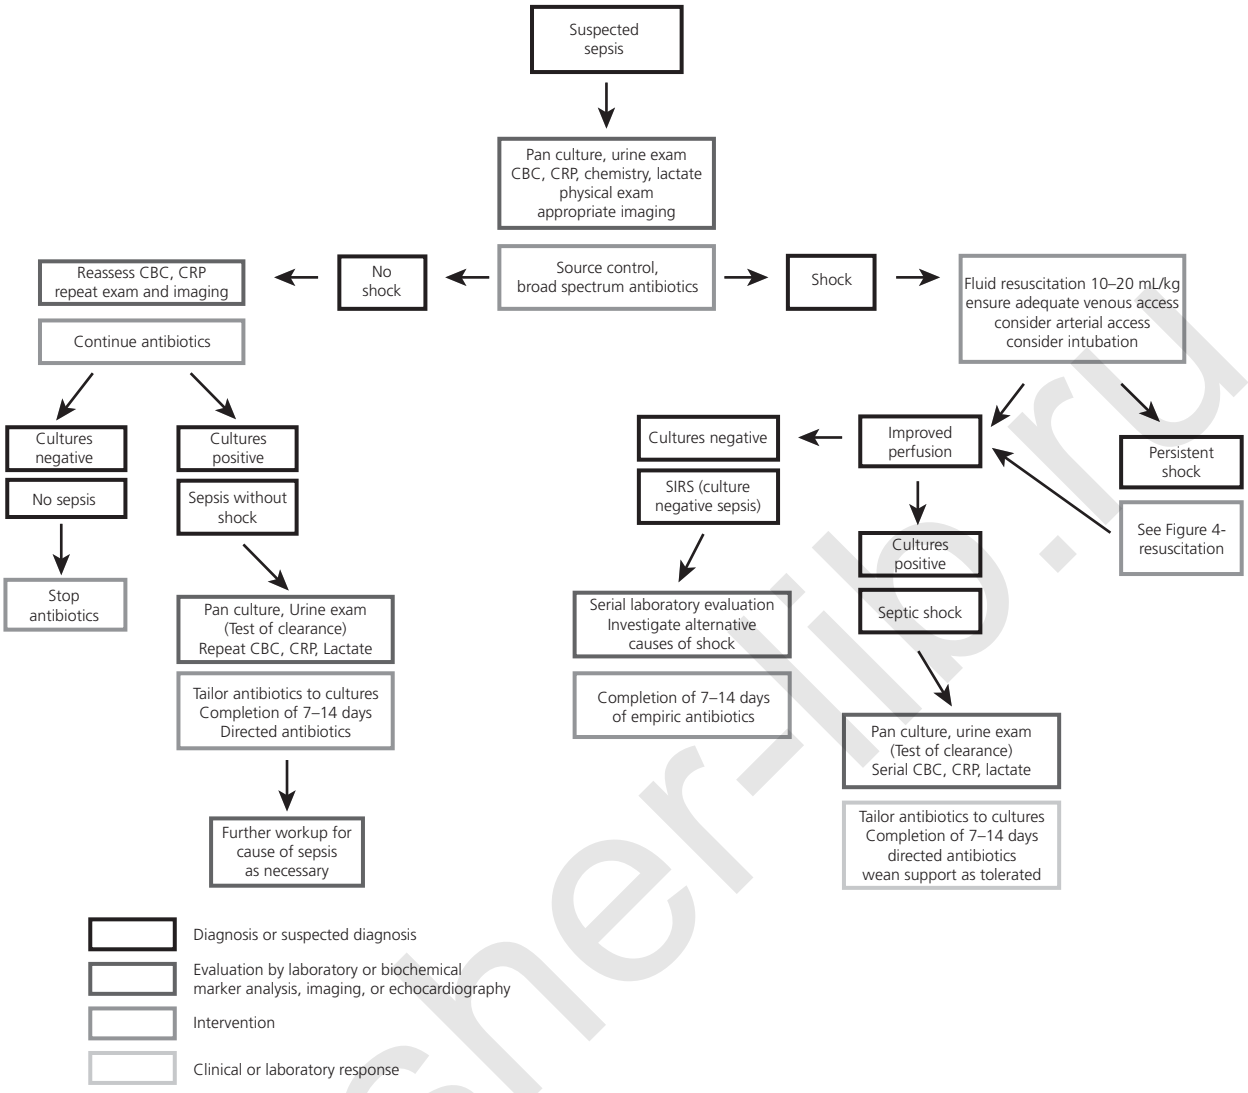

Figure 17.4 Algorithm for management of sepsis.

relative safety in the neonate with shock refractory to fluid and classic vasopressors.[105] Similarly, several reports of neonatal use of vasopressin agonists in refractory shock and post cardiopulmonary bypass stun suggest vasopressin[106] and terlipressin[107] also appear to be effective and relatively safe. Nonetheless, current neonatal guidelines generally favor dopamine over dobutamine as an initial choice of vasopressor, and epinephrine as a rescue medication for dopamine-refractory shock, despite ongoing debate about the optimal pressor for different types of shock.[95] Because neonatal sarcomeres are immature, sarcoplasmic calcium stores are significantly less;[108] this results in a profound dependence on serum calcium for successful contractility of the myocardium and tone of the arteriolar vascular tree. Calcium chloride infusions, along with various forms of calcium replacement, have been strongly advocated in the pediatric and anesthesia communities,[109] but safety and i.v. access issues have not been studied in the setting of calcium infusion for septic shock. Nevertheless, most units prefer to add calcium to i.v. fluid and parenteral nutrition, as well as i.v. calcium boluses to maintain calcium in the normal range.

Recent evidence supports endocrine replacement therapy in the setting of neonatal shock refractory to vasopressor treatment.[110] Although there is inadequate evidence to support empiric corticosteroid use,[111,112] measurement of serum cortisol concentrations and absolute and relative adrenal insufficiency can identify neonates who will benefit from hydrocortisone replacement therapy.[113] Corticosteroids have two main classes of effects: genomic and non-genomic. Late effects, such as alterations in IL-2 production and secretion, are due to changes in leukocyte gene regulation. Early non-genomic effects, on the other hand, are responsible for the efficacy of endocrine replacement in shock. In particular, corticosteroids lead, in a non-genomic, rapid fashion, to the prevention of endocytosis of adrenergic receptors and downregulation of secondary messenger systems that lead to tachyphylaxis to both autologous and extrinsically infused adrenergic vasopressors.[110] Successful response to hydrocortisone therapy generally is immediate (minutes to hours)[114] and requires replacement of stress dose cortisol levels only, or hydrocortisone 1 mg/kg every 6 hours. There are currently no evidence-based guidelines on weaning

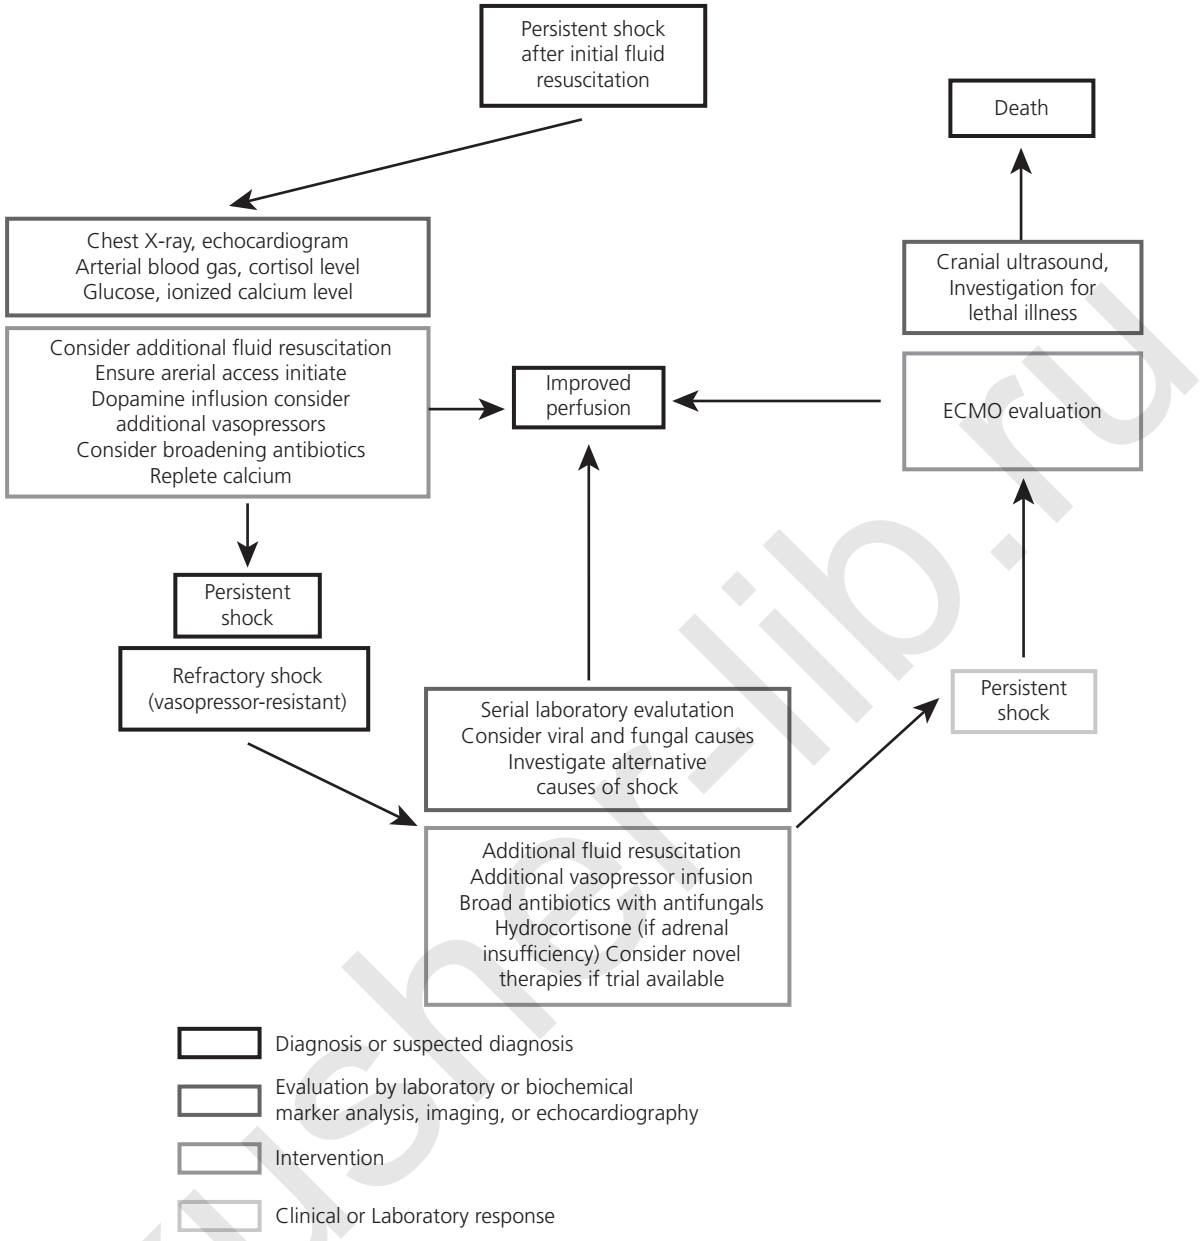

Figure 17.5 Algorithm for management of shock.

hydrocortisone.[115] Of note, extracorporeal membrane oxygenation (ECMO) is a very effective tool for providing cardiopulmonary support for refractory shock in neonatal sepsis.[116–118] A full discussion of ECMO is beyond the scope of this chapter.

Several new therapies have been developed for the management of neonatal sepsis. Polyclonal intravenous immunoglobulin (IVIg), known to be effective in inflammatory neurologic and rheumatologic disorders, has long been hypothesized to be effective in reducing the risk of, and complications from infections. Nondiscriminate use of IVIg in the neonatal population has had anecdotal success, but several clinical trials have failed to demonstrate a benefit in the morbidity and mortality of neonatal sepsis.[119] Restricting IVIg to preterm or low birth weight infants, although successful in reducing the risk of culture proven sepsis by 3%, also failed to demonstrate a benefit in decreasing morbidity or mortality.[120] The heterogeneity of these populations, however, may have obscured the benefit of IVIg in the subset of very low birth weight neonates. Because prior IVIg trials did demonstrate safety, a well-powered randomized, double-blinded, placebo-controlled trial is currently being conducted to examine efficacy in the treatment of neonatal sepsis.[121] In addition to polyclonal immunoglobulin, monoclonal antibodies against several specific targets are currently being studied. Unfortunately, only anti-staphylococcal antibodies have been extensively investigated. They have been found to be safe but did not result in any significant improvement in outcome.[122] Oral immunoglobulins have also been administered in an attempt to mimic breast milk, however, they did not reduce the risk of developing necrotizing enterocolitis or mortality.[123] Secretory IgA, one

of the active components of breast milk, has not yet been evaluated. Several additional interventions, including pentoxyfilline,[124] recombinant activated protein C,[125] and colony stimulating factors,[126] are still awaiting adequate clinical trials before they can be added to our armamentarium.

MULTIDRUG-RESISTANT AND OPPORTUNISTIC INFECTION

Management of systemic infections or sepsis in general has become increasingly challenging because of the emergence of multiple antibiotic-resistant bacteria.[127] Two molecular patterns of antibiotic resistance have been described. First, epidemic outbreaks of drug-resistant infections occur following introduction of new organisms to a nursery. Such outbreaks propagate due to environmental crowding and lapses in inter-patient infection control strategies.[128] In many cases, these epidemics begin with a health-care worker, fomite, or visitor, although molecular genotyping suggests that community-acquired infections may also be transmitted vertically (up to 20% of MRSA).[129] Alternatively, drug resistance can be driven by institutional antibiotic strategies, as has been shown with GBS prophylaxis.[50] Administration of newer broad-spectrum antibiotics can lead to abnormal colonization with saprophytes and yeast, resulting in invasive opportunistic infections.[130]

MRSA is the most common antibiotic-resistant organism in the neonatal intensive care unit and a major cause of neonatal morbidity and mortality.[131] Several molecular phenotypes of community-acquired and nosocomial MRSA make it particularly virulent.[132] A recent National Nosocomial Infections Surveillance System (NNIS) report indicated a more than 300% increase in neonatal MRSA infections between 1995 and 2004, with nearly 59% of *S. aureus* isolates being classified as MRSA.[133] In 2008, 432 MRSA-negative mothers delivered a cohort of term newborns who subsequently developed 11 MRSA infections within 4–23 days of birth.[134] Amazingly, molecular analysis of these MRSA isolated demonstrated hospital patterns of methicillin resistance. With an increasing awareness of endemic and epidemic patterns of neonatal MRSA infection, attention must be paid to prevention of nosocomial spread and containment of outbreaks of MRSA.[135] Countries such as the Netherlands, which apply very aggressive containment procedures, consistently have MRSA rates significantly lower than less aggressive countries such as the USA.[48,136] In brief, infection control bundling should include three components: prevention, management of outbreaks, and quality assurance. While individual preventive interventions such as wearing gloves would be difficult to assess, it is possible to decrease horizontal transmission of infection by bundling of proper hand hygiene, gowns, gloves, masks, with provision of adequate isolette space, isolation of patient care equipment, and screening of infants to detect MRSA and vancomycin-resistant enterococcus (VRE) colonization. Furthermore, it is very effective during outbreaks to isolate or cohort both patients and health-care staff (especially nurses), culture environmental sources in response to a cluster of colonization or infection, and investigate all outbreaks with molecular analysis (pulsed-field gel electrophoresis or a comparable tool) to assess the relatedness of strains found in NICU patients, health-care workers, and the environment. The major challenge is the implementation of patient care practices designed to prevent horizontal transmission of infection and contain outbreaks, rather than the development of new antibiotics.[137]

VRE, like MRSA, is also on the rise. In a predictable fashion, VRE begins to appear after a significant increase in vancomycin use for endemic and epidemic MRSA. Although the pediatric prevention network has not yet published estimates, the CDC-NNIS reported a 12% rate of VRE in *Enterococcus* isolates from neonatal intensive care units compared to 28.5% in all ICUs up until 2004.[138] Two subsequent studies[139,140] demonstrated epidemic clusters of VRE that could be traced to an original hospital site. Much like MRSA, it is the implementation of infection control practices, rather than the introduction of newer antibiotics, that will likely reduce the burden of VRE disease.[137]

Unlike MRSA and VRE, which propagate in epidemic-type outbreaks, prophylactic administration of beta-lactam antibiotics for GBS has resulted in a significant increase in extended-spectrum beta-lactamase (ESBL) producing Gram-negative organisms.[141] Several reports regarding neonatal epidemiologic trends of ESBL *Klebsiella*,[142] *E. coli*,[143] *Serratia*,[144] and *Enterobacter*[145] have demonstrated this pattern as well. More data are required before risk factors and outcomes for ESBL Gram-negative organisms can be effectively assessed. Nevertheless, adjustment of empiric therapy for suspected sepsis in nurseries and neonatal intensive care units with high rates of ESBL Gram-negative organisms has generally been effective.[146]

In addition to inducing multidrug-resistant organisms as described above, broad-spectrum antibiotics also foster the development of opportunistic or unusual infections in the host. This situation is best exemplified by the explosion of invasive candidal infections during the past 20 years.[147] Despite an expanding antifungal armamentarium, chemotherapeutic options work slowly and mortality remains high once fungal infection occurs. Thus, prevention remains the keystone to minimizing fungal sepsis.[148,149] Similarly, bacterial opportunistic infections have been on the rise as well. *Acinetobacter*, a saprophyte with significant natural drug resistance patterns previously unique to burn units, has already appeared in several neonatal intensive care units.[150–152] Saprophytic infections are a marker for significant use of antibiotics and critical illness. Unfortunately, because most of these Gram-negative soil bacteria are nearly pan-resistant, the associated sepsis is often lethal despite aggressive therapy. In this situation, complete containment with unit sterilization following patient loss is the only available mechanism to protect other patients.[153,154]

CONCLUSION

Neonatal sepsis continues to be a major cause of long-term morbidity and mortality. Each advance in the prevention, identification, and therapy of sepsis produces a shift in the

epidemiology and bacteriology of the disease. Thus, the development of systems-based practice organizations has become one of the most important advances during the last 50 years. The World Health Organization and various national organizations such as the National Nosocomial Infections Surveillance System provide ongoing surveillance for the changing epidemiology of early- and late-onset sepsis. Ongoing design of well-organized trials looking at optimizing prenatal and perinatal care, along with future development of trials to investigate prophylactic measures for late-onset sepsis, however, will continue to change the bacteriology of sepsis neonatorum. Hopefully, completion of several large trials investigating novel sepsis therapies and alternative methods of resuscitation of neonatal septic shock will increase the armamentarium available for combating the new distributions of infections. In the meantime, continued hand hygiene, proper neonatal environment design, and early intervention for suspected sepsis will remain the standard of care for minimizing neonatal infections and improving outcomes.

Hematological problems in the neonate

OWEN P SMITH

INTRODUCTION

The neonatal period is a time of rapid flux and hematological problems that present during this period as a result of a genetic defect, immaturity, or stress and present a major diagnostic and therapeutic challenge to the neonatologist and hematologist alike. The recent explosion in molecular biological techniques has allowed the elucidation of the molecular and cellular mechanisms that give rise to the disorders of platelets, coagulation proteins, and red cells that present in the newborn. Because of the space allotted it is hoped that this chapter will give the reader a broad understanding and appreciation of the major hematological disorders seen in the neonatal period, especially those involving platelets and clotting proteins.

PLATELETS

The normal range of the platelet count is similar in fetal life to that seen in adulthood, being in the range of 150×10^9/L to 400×10^9/L. Neonatal thrombocytopenia, defined as a blood platelet count of below 150×10^9/L is common, with a reported frequency to approximate 0.9% in unselected newborns, and 40% in infants in intensive care units.[1–3] The differential diagnosis of thrombocytopenia in the neonatal period is similar to thrombocytopenia in older children with a number of exceptions that include the inherited thrombocytopenia group and those that arise due to pathophysiological events unique to the antenatal and perinatal periods. It is important to remember to confirm that the low platelet count is genuine by careful inspection of the blood sample and smear before initiating further investigations. Once established, the approach to the diagnosis of the thrombocytopenia should be tailored to the individual infant and mother. For example, assessment of the child's general well-being is very important as healthy neonates usually have an immune or an inherited etiology, whereas the presence of lymphadenopathy, hepatosplenomegaly, mass lesions, hemangiomas, bruits, and congenital anomalies will point towards a totally different spectrum of causes. It should also be emphasized that obtaining a detailed maternal history to include bleeding problems, pre-eclampsia, and drug ingestion in the present and past pregnancies and any history of viral infections or connective tissue disease will save time and indeed unnecessary investigations. The causes of thrombocytopenia are divided into two broad categories; inherited thrombocytopenia and congenital thrombocytopenia

INHERITED THROMBOCYTOPENIA

The inherited thrombocytopenias comprise a group of platelet formation abnormalities in which platelet numbers are reduced. In the vast majority of patients the platelet count is only mild to moderately reduced (50×10^9/L and 100×10^9/L) and therefore, significant spontaneous hemorrhage tends not to be problematical. There are however, a small number of notable exceptions where spontaneous bleeding is a prominent clinical feature of the syndrome. These include Wiskott–Aldrich syndrome, amegakaryocytic thrombocytopenia, and thrombocytopenia with absent radii where the platelet count is usually very low and in the Bernard–Soulier and Chediak–Higashi syndromes where there is also a marked platelet dysfunction.[4] Immune-mediated thrombocytopenia is a major differential diagnosis in children with low platelet counts and, therefore, making the correct diagnosis of these conditions is important as it usually prevents the useless and potentially dangerous prescribing of immunosuppressants such as corticosteroids.[4,5]

Bernard–Soulier syndrome

Bernard–Soulier syndrome (BSS) is the best characterized inherited thrombocytopenia which has in association, an abnormal platelet function. Typically, there is moderate to severe thrombocytopenia, a prolonged bleeding time and

platelet morphology usually reveals 'giant' forms. BSS is inherited as an autosomal recessive manner with the underlying molecular defects due to quantitative or qualitative defects in platelet membrane receptors.

Pseudo-von Willebrand's disease

Pseudo-von Willebrand's disease (pseudo-vWD) is an autosomal dominant disorder characterized by mild intermittent thrombocytopenia, mild bleeding, absence of high molecular weight von Willebrand factor (vWf) multimers, and increased ristocetin-induced platelet aggregation. It can be differentiated from type 2B von Willebrand's disease (vWd), where the mutation resides in the vWf protein by spontaneous aggregation of the patient's platelets with normal plasma[4].

Type 2B vWd

This subtype of vWd is clinically and biochemically very similar to pseudo-vWd. Type 2B is usually diagnosed by the increased platelet agglutination induced by low concentrations of ristocetin.[4]

Montreal platelet syndrome

This syndrome is characterized by thrombocytopenia, large platelets, spontaneous platelet aggregation, and a reduced response to thrombin-induced aggregation. It can be distinguished from BSS by its autosomal dominant inheritance and a normal platelet agglutinability response to ristocetin.[4]

Gray platelet syndrome

This is an extremely rare autosomally inherited syndrome characterized by a markedly reduced platelet alpha-granule content but normal dense-bodies and lysosomes. Other features include a prolonged skin bleeding time, morphologically large platelets, and highly variable platelet aggregation profiles. The thrombocytopenia and bleeding symptoms are usually mild.[4,6]

Paris–Trousseau syndrome

This is a recently described autosomal dominant syndrome comprising mild thrombocytopenia, a moderate hemorrhagic tendency, giant alpha-granules in a subpopulation of platelets, bone marrow micromegakaryocytes with enhanced megakaryocyte apoptosis, and a deletion of the distal part of chromosome 11 at position 11q23 (del (11)(q23.3;qter)).[4,6]

Wiskott–Aldrich syndrome

Wiskott–Aldrich syndrome (WAS) is inherited as an X-linked recessive trait and is characterized by eczema, microthrombocytopenia, and combined immunodeficiency. It is often fatal by the early teens due to infection, lymphoreticular malignancy, or bleeding. Hemorrhagic events in this syndrome are common during the first two years of life and the reason for this is multifactorial.[4,6]

WISKOTT–ALDRICH SYNDROME VARIANTS (X-LINKED THROMBOCYTOPENIA)

This is a heterogeneous group of thrombocytopenic disorders with X-linked inheritance. The thrombocytopenia is usually less severe in WAS variants and requires no treatment.[4,6]

OCULOCUTANEOUS ALBINISM – HERMANSKY–PUDLAK AND CHEDIAK–HIGASHI SYNDROMES

Oculocutaneous albinism denotes a group of inherited disorders characterized by reduced or absent pigmentation of the skin, hair, and eyes. While the majority of these patients have an isolated platelet storage pool defect, in some an accompanying low platelet count can occur.[4,6]

Hermansky–Pudlak syndrome is an autosomal recessive disorder with the classic triad of oculocutaneous albinism (tyrosinase-positive), platelet dense-body or combined dense-body and alpha-granule storage pool deficiency, and depositions of ceroid-like material in the monocyte–macrophage system. The bleeding tendency is usually mild (related to the storage pool defect and not thrombocytopenia, as the latter is not a feature syndrome), however, excessive bleeding following tooth extractions and tonsillectomy is the rule.[4,6]

The features of Chediak–Higashi syndrome include partial oculocutaneous albinism, the presence of giant granules in all granule-containing cells, neutropenia, peripheral neuropathy, and platelet storage pool deficiency which usually involves the dense-bodies. Thrombocytopenia usually occurs during the accelerated phase of the disease which involves the development of pancytopenia, hepatosplenomegaly, lymphadenopathy, and extensive tissue infiltration with lymphoid cells.[4,6]

May–Hegglin anomaly

This is an autosomal dominant disorder, characterized by giant platelets, variable thrombocytopenia, and Dohle-like inclusions within granulocytic cells including monocytes. Platelet function has been reported to be normal in some and impaired in others.[4]

Alport variants

Alport syndrome is associated with the findings of sensorineural deafness (usually high tone deafness), hematuria, cataracts, and progressive renal failure. The disorder is a

heterogeneous group with the majority having autosomal dominant inheritance. Many variants of Alport syndrome have been described, the three associated with thrombocytopenia include Epstein's syndrome, Fechtner syndrome, and Sebastian platelet syndrome.[4]

INHERITED BONE MARROW FAILURE SYNDROMES

Thrombocytopenia with absent radii

Thrombocytopenia with absent radii (TAR) is a rare, autosomal recessive disorder that is usually diagnosed at birth as the vast majority of these patients are thrombocytopenic and have the pathognomonic physical sign of bilateral absent radii. Other skeletal abnormalities involving the ulnae, fingers, and lower limbs are also seen but are much less common. TAR differs from Fanconi anemia in several ways: the absent radii are accompanied by the presence of thumbs, the thrombocytopenia is the only cytopenia, there is absence of spontaneous or clastogenic stress-induced chromosomal breakage, and evolution to aplastic anemia and leukemia have not been reported.[4,7] The majority of children with TAR have recurrent significant bleeding episodes in the first six months of life.[4,7] Intracerebral and gastrointestinal hemorrhage are the usual causes of mortality with previously one in four of these children dying by four years of age. The majority of these deaths however, occur in the first year of life. The mainstay of treatment is judicious use of single donor platelet concentrates aiming to keep the platelet count above 20×10^9/L, especially in the first year of life as this is the time of maximum morbidity and mortality.[4,7]

Amegakaryocytic thrombocytopenia

Amegakaryocytic thrombocytopenia (AMEGA) is an extremely rare disorder of infancy and early childhood. The thrombocytopenia is nonimmune, usually severe, and early bone marrow examination shows a normal karyotype, absent or greatly reduced numbers of megakaryocytes. Platelet transfusions are the main therapeutic intervention from diagnosis.[7]

Fanconi anemia

Fanconi anemia (FA) is a premalignant disorder, inherited as an autosomal recessive trait, with genetic heterogeneity and a gene frequency of about one in 600. Thrombocytopenia is usually the first cytopenia to appear but rarely in the neonatal period.[7]

Trisomy syndromes

Moderately severe thrombocytopenia is seen in some cases of trisomy-18 syndrome, trisomy-13 syndrome and, to a lesser extent, in trisomy 21. Both trisomy 13 and 18 are usually diagnosed at birth as the associated abnormalities are usually quite striking. The majority of these cases die in the neonatal period from non-hemorrhagic sequelae.[4]

CONGENITAL THROMBOCYTOPENIA

Congenital thrombocytopenia is defined as a low platelet count at birth not resulting from the association of a specific gene defect and accounts for the majority cases of neonatal thrombocytopenia. Thrombocytopenia is a common finding in sick neonates, however, and since the introduction of automated cell counters it is now considered a relatively common (approximately 1%) finding in apparently normal infants.[8] In the vast majority of cases the thrombocytopenia results from increased platelet destruction which can arise by several mechanisms, the majority of which are not known.

Immune thrombocytopenia

Immune-mediated thrombocytopenia is usually seen in term babies that are clinically well and may be responsible for one-third of cases of thrombocytopenia seen in the general neonate population.[9] There are two broad groups of conditions, those mediated by an alloimmune mechanism and those with associated autoimmune phenomena.

Neonatal alloimmune thrombocytopenia

Neonatal alloimmune thrombocytopenia (NAIT) arises following maternal sensitization to paternal antigens present on fetal platelets. It occurs in approximately one in 1500 to one in 2000 births, with the mother having a normal platelet count and a negative history for bleeding.[9] The maternal alloantibody produced does not react with the mother's platelets but crosses the placenta and destroys fetal platelets. NAIT typically presents as an isolated severe thrombocytopenia in an otherwise healthy child at birth. Severe thrombocytopenia may be present early in gestation and at least 20% of cases suffer intracranial hemorrhage.[8] Widespread petechial hemorrhage is present in more than 90% of cases, while cephalohematomata, hematuria, and gastrointestinal bleeding occur in a significantly smaller number of children.[1,4,9] Typically, the platelet count spontaneously returns into the normal range within 3 weeks after birth. The mainstay of treatment for affected infants is washed, irradiated, maternal platelet concentrates.

Maternal autoimmune thrombocytopenia

Autoimmune thrombocytopenia (AIT) is due to the passive transfer of autoantibodies from mothers with isolated immune thrombocytopenic purpura (ITP), or it may be seen in association with conditions that have immune dysregulatory features such as maternal systemic lupus

erythematosus, hypothyroidism, and lymphoproliferative states.[9] Approximately one in 10 000 pregnancies are complicated by maternal ITP. The risk of significant infant morbidity and mortality is minimal, as the infant platelet count is rarely less than 50×10^9/L, intracerebral hemorrhage (ICH) rarely if ever happens and when it does occur it is not related to birth trauma.[9]

Intrauterine infections (TORCH syndromes)

Intrauterine viral infections rarely produce severe thrombocytopenia ($< 20 \times 10^9$/L) and therefore, therapeutic intervention in the form of platelet concentrate and/or antiviral therapy are only indicated when there is active bleeding or surgical intervention is being considered.[10] In the vast majority of cases the platelet count returns into the normal range within 2–4 weeks after birth but may persist to four months of age.

Giant hemangioma syndrome (Kasabach–Merritt syndrome)

Kasabach–Merritt syndrome (KMS) is the association of giant cavernous hemangiomata and disseminated intravascular coagulopathy. The consumptive coagulopathy which is seen in approximately 25% of cases of KMS is usually low grade and compensated. However, acceleration into the fulminant form, which is characterized by hypofibrinogenemia, raised D-dimers, red cell microangiopathy, and severe thrombocytopenia, is not uncommon. Fortunately, spontaneous regression of these tumors occurs in the majority of patients.

The vascular tumors associated with KMS are usually kaposiform hemangioendotheliomas (KHE) and not the more usual infantile hemangiomas that are seen in early childhood. The KHE lesions tend to affect males and females equally, have a predilection for the trunk, retroperitoneum, proximal extremities, and less frequently the cervicofacial region. Like other tumors, whether benign or malignant, KHE is dependent on the formation of new blood vessels from pre-existing vasculature (angiogenesis) and this complex process is regulated by several proangiogenic (e.g. vascular endothelial growth factor) and anti-angiogenic molecules (e.g. endostatin). Because of their large size and infiltrative nature, complications such as hemorrhage from consumptive coagulopathy, airway obstruction, and congestive cardiac failure are not uncommon in a small subset of these patients and surgical resection or embolization may not be an option. Over the past three decades medical intervention for these potentially life-threatening lesions has included the use of corticosteroids as a single agent or in combination with vincristine and/or interferon-α together with the judicious use of plasma and clotting factor concentrates with variable responses. More recently, because of their role in tumor growth, there has been a move to target the platelet by using antiplatelet agents and withholding of platelet concentrate infusions, even in those patients who have significant thrombocytopenia and are coagulopathic.[4]

Hypercoagulable states

Consumptive thrombocytopenia, mainly secondary to disseminated intravascular coagulation (DIC) following thrombin generation, can be the first manifestation of an acquired or inherited hypercoagulable state.[11]

MISCELLANEOUS CONDITIONS

Other associations of neonatal thrombocytopenia include maternal pre-eclampsia, maternal use of drugs, disseminated intravascular coagulation, primary microangiopathic hemolytic anemias, including hemolytic uremic syndrome, transient abnormal myelopoiesis (TAM) associated with Down syndrome, hemophagocytic lymphohistiocytosis, osteopetrosis, congenital leukemia, metastatic neuroblastoma.

COAGULATION PROTEINS

Plasma levels of many of the hemostatic coagulation factors are lower in newborns than in older children and adults.[12–15] At the end of gestation, a healthy normal newborn should have approximately half the adult values of the vitamin K-dependent coagulant factors (factors II, VII, IX, and X) and contact factors (factors XII and XI, prekalikreinin, and high molecular weight kininogen).[12–15] In preterm infants these levels are even lower. The natural anticoagulants, antithrombin and protein S, are also approximately 50% at term with a similar relationship to gestational age.[12–15] The plasma levels of the procoagulant co-factors, factor V and factor VIII, and fibrinogen are the same in term infants as is in adults. Like the coagulation system the fibrinolytic system is also physiologically immature in the neonate.[12–15]

Inherited bleeding disorders

Hemophilia A (factor VIII deficiency) is the second most common inherited bleeding disorder in man with a frequency of approximately 1:5000 male births.[16] Hemophilia B or factor IX deficiency is approximately one-sixth as common as that of hemophilia A. When there is a family history of hemophilia, newborns are usually picked up early as the condition is usually suspected. However, one-third to one-half of all individuals with hemophilia A and B arise from the *de novo* mutations and it may be some time before a firm diagnosis is made as a significant number of these children will be seen in the general pediatric setting.[16] Hemophilia has a worldwide distribution, and affects all racial groups. Hemophilia A and B are clinically indistinguishable. In the severe form the phenotype is characterized by bleeding into the joints and soft tissues. Both the factor VIII and factor IX genes were cloned over 15 years ago and as a result recombinant factor VIII and factor IX are the treatment of choice.[16]

Hemorrhagic complications in moderate and severe hemophilia A and B may become obvious after birth, especially if the child is circumcised. Severity and type of bleeding is related to the absolute level of circulating plasma VIII:C. A minimal effective level for hemostasis is about 25–30% for hemophilia A and 20–25% for hemophilia B. Those with severe deficiency (less than l%) usually experience repeated and often spontaneous hemorrhages. While muscular skeletal bleeding is by far the most common clinical event, other spontaneous hemorrhagic manifestations frequently occur and may be life threatening. Successful treatment in acute or potentially acute (pre-surgery) bleeding is usually achieved with adequate and prompt factor replacement therapy. The level of factor concentrate required to achieve adequate hemostasis will depend on the type of bleeding.[16]

Other coagulation factor deficiencies

Deficiencies of all coagulation factors have been described. However, it should be remembered that the number of patients with hemophilia A greatly outnumber all of these put together. Common features to these rarer forms of coagulation factor deficiencies have variable bleeding and autosomal recessive inheritance.[16,17]

ACQUIRED BLEEDING DISORDERS

The acquired coagulation disorders are far more common than the inherited disorders and are usually associated with multiple coagulation factor deficiencies.

HEMOPHAGOCYTIC LYMPHOHYSTIOCYTOSIS

Hemophagocytic lymphohystiocytosis (HLH) is a rare autosomal recessive disorder of infancy and childhood that manifests as a hyperinflammatory state resulting from an abnormal proliferation of activated lymphocytes and histiocytes (tissue macrophages). The classic clinical features include fever, hepatosplenomegaly, cytopenias, hypertriglyceridemia, hypofibrinogenemia, hyperferritinemia, lymphadenopathy, skin rash, jaundice, and edema. Although it can occur in all age groups, neonatal-onset HLH is said to be rare, however it should be noted that the classic pentad of fever, big liver and spleen, together with low fibrinogen and high triglycerides, may not all be present and hence mutational analyses for UNC13D and perforin gene should be performed in neonates suspected of having HLH. Early recognition and treatment is necessary to prevent disease progression. Remission can be achieved with the use of etoposide-based chemotherapy regimens in conjunction with immune modulating medications such as ciclosporin A, corticosteroids, and antithymocyte globulin. The only definitive cure, however, is allogeneic hematopoietic stem cell transplantation.

VITAMIN K

Vitamin K is crucial for the function of procoagulant factors II, VII, IX, and X and the natural anticoagulants protein C and protein S. Vitamin K itself is recycled and when this process is blocked, as with warfarin administration, these vitamin K-dependent factors are not produced in adequate amounts.[16,18]

HEMORRHAGIC DISEASE OF THE NEWBORN

This syndrome usually occurs on the second to fourth day of life as a result of decreased synthesis of vitamin K-dependent factors. The etiology of vitamin K deficiency in newborns is multifactorial to include reduction of vitamin K stored in the fetus and neonate, functional immaturity of the liver, lack of bacterial synthesis of vitamin K in the gut, and low amounts of vitamin K in breast milk.[16,18] Most neonates now are given vitamin K at birth. Exceptions to the rule are those children with known glucose 6-phosphate dehydrogenase (G6PD) deficiency in the family as a significant number of these patients will develop frank hemolysis. In those children who present with frank bleeding, vitamin K and infusions of fresh frozen plasma (FFP) can be given to arrest the blood loss.

LIVER DISEASE

The coagulopathy associated with liver disease is complex, involving reduced synthesis of vitamin K-dependent procoagulant factors, non-vitamin K-dependent procoagulant factors, structually abnormal coagulation proteins, and reduced amount of natural anticoagulants.[19] A significant number of these patients are also vitamin K deficient because of an associated malabsorption. It should also be noted that these patients are usually thrombocytopenic and even though the platelets do circulate, they are usually dysfunctional. Correcting the coagulopathy usually involves replacement of vitamin K, addition of fresh frozen plasma and, when volume restriction is imperative, then factor concentrates such as factor VII concentrate, and prothromplex concentrate can be given along with platelets and 1-deamino-8-D-arginine vasopressin (DDAVP).[19]

CARDIOPULMONARY BYPASS

The coagulopathy associated with cardiopulmonary bypass is multifactorial involving activation of the contact pathway, fibrinolytic pathway, tissue factor pathway, and platelets; also these children have significant platelet function defects.[16]

CONGENITAL HEART DISEASE

A significant number of children with congenital heart disease will have coagulation defects. It should be remembered, however, that in children with cyanotic heart disease with associated polycythemia, the elevation in prothrombin time (PT)/activated partial thromboplastic time (APTT) may be spurious, i.e. may be secondary to a sampling defect as there will be an alteration in the plasma anticoagulant ratio, especially when the hematocrit is greater than 60%.[16]

VON WILLEBRAND'S DISEASE

von Willebrand's disease is the most common inherited bleeding disorder in man with a gene prevalence of approximately 1% of the population.[16] There is significant phenotypic heterogeneity even among members of the same family. The majority of individuals have type 1 vWd with type 3 vWd being seen in 1–2 per million of the population. Bleeding tends to be predominantly mucocutaneous, so called 'wet purpura', the most common type being epistaxis, easy bruising, gum bleeding following tooth brushing and, in adolescent girls, heavy menses. Bleeding into joints is rare and typically only seen in individuals with severe type 3 disease where the circulating plasma FVIII levels are usually around 2%.

The main objective of treatment is to correct the two laboratory hallmarks of the disease, namely, the prolonged bleeding time, and the low FVIII level.[16] As most patients have a quantitative defect it is possible to stimulate endogenous release with i.v. DDAVP. While this treatment is inexpensive and infection-free, it does have a number of rare side effects, notably, hyponatremia and seizures, especially in very young children. Failure to respond occurs in approximately 10–15% of patients, and in those who do not respond a significant number become refractory when the drug is given over an extended period of time (tachyphylaxis).[16]

Thrombotic states

The fetus and neonate are less efficient in generating thrombin and thus thrombotic disease in early childhood is rare and when seen is either secondary to an acquired prothrombotic state or indeed the child has inherited gene defects predisposing to clot formation.[12–15,20] When it does occur in childhood it can be fatal or associated with several sequelae such as amputation, organ dysfunction, and post-phlebitic syndrome.[20] The peak incidence for these thrombotic events is undoubtedly the neonatal period where the use of indwelling catheters in the tertiary care pediatrics is almost the norm.[20]

Acquired states

CENTRAL VENOUS CATHETER DEVICES

Central venous catheter devices have revolutionized the intensive care management of neonates requiring indwelling vein or artery catheterization. Unfortunately, thrombosis related to their placement continues to be a therapeutically challenging complication in terms of diagnosis, prophylaxis against thrombosis, and also treatment of established thrombosis within the catheter. Once clot formation occurs, the catheter may be salvaged using either/or antithrombotic or antifibrinolytic agents, however, it should always be remembered that these therapeutics pose special risks in the neonatal age group. It should be remembered that, although very uncommon, death from venous thromboembolic disease in young children does occur. Therefore, early detection of such thrombotic events and adequate treatment are absolutely mandatory in this group of children.

RENAL ARTERY AND VEIN THROMBOSIS

Renal artery thrombosis, especially in the neonatal period, is commonly associated with umbilical artery indwelling on umbilical artery catheters.[20] It may be difficult to diagnose and hypertension and heart failure may be the presenting clinical features. There is usually extension of the thrombus to other vascular beds such as the aorta. Its incidence can be as high as one in six neonates and factors that can reduce its incidence include prophylactic anticoagulants, using a smaller size catheter, and also concentration of fluids infused.[20] Both medical and surgical approaches have been used with variable outcome. Renal vein thrombosis is more common than renal arterial thrombosis in the newborn period. It is associated with birth asphyxia, dehydration, hypotension, cyanotic heart disease, polycythemia, and babies born to diabetic mothers. The most common presenting features are flank swelling followed by hematuria, microscopic hematuria, renal dysfunction, and thrombocytopenia. Usually ultrasound will reveal renal enlargement with or without evidence of venous thrombosis. The use of anticoagulants and thrombolytic agents in this condition continue to be evaluated.[20] Survival rates in babies are as high as 80% and renal status after recovery ranges from normal function to renal atrophy, hypertension, and chronic renal failure.

ACQUIRED PROTEIN C/S DEFICIENCY

Purpura fulminans is a term to describe an acute, often lethal, syndrome of DIC and purpuric skin.[21] Inherited and acquired abnormalities of the protein C pathway, especially protein C deficiency, are mainly responsible for the majority of patients with this clinical syndrome.[21–23] The treatment of choice is protein C replacement.

ACQUIRED ANTITHROMBIN DEFICIENCY

Acquired deficiencies of antithrombin have been associated with a large number of diseases, which in turn have an increased rate of venous and arterial thrombosis. Antithrombin concentrates are available and are the treatment of choice during the acute phase of the disease.[20]

MISCELLANEOUS CONDITIONS

Other associations of neonatal thrombosis include necrotizing enterocolitis, respiratory distress syndrome, heparin-induced thrombocytopenia/thrombosis syndrome (extremely rare in neonates), antiphosolipid antibodies and lupus anticoagulant, extracorporeal membrane oxygenation (ECMO), hemolytic uraemic syndrome, and birth asphyxia.[20]

Inherited thrombotic states

Genetic defects within the protein C pathway account for the majority of cases of inherited thrombophilia.[23]

PROTEIN C AND PROTEIN S DEFICIENCY

Hereditary protein C (PC) and protein S (PS) deficiency (homozygosity or compound heterozygosity) are associated with a high venous thromboembolic risk at birth or in the first few months of life. The first clinical manifestation is usually skin purpura, mainly affecting extremities and in some cases massive large vessel thrombosis can also be a presenting feature. Optimum therapy involves factor replacement (PC concentrate in PC deficiency or fresh frozen plasma in PS deficiency) and heparin in the acute phase and oral anticoagulation in the long term.[23]

ANTITHROMBIN III DEFICIENCY

Reducing functional defects are also associated with a high risk of venous thromboembolic disease. The homozygous state is extremely rare and appears to be incompatible with life. Presentations of antithrombin deficiency in neonates include myocardial infarction at birth, aortic thrombosis, saggital sinus thrombosis, and cerebral thrombosis.[20]

OTHER INHERITED THROMBOPHILIAS

Several other inherited gene defects have been associated with increased propensity to clot formation, the most common being activated protein C resistance (APCR) and factor V^{R506Q}/factor V Leiden, factor II gene variant (prothrombin^{G20210A}), and hyperhomocysteinemia.[20]

Management

The indications for use of anticoagulants in infants and children have changed dramatically over the past 20 years with major advances in tertiary pediatric care such as ECMO, cardiopulmonary bypass, hemodialysis, and the use of intra-arterial and i.v. indwelling catheters.[20,24,25] The choice of anticoagulant is dependent upon the duration of anticoagulation and therefore in the acute phase heparins, either unfractionated or low molecular weight forms are used, while in the longer term oral anticoagulants are the treatment of choice. In more specific disease states, such as inherited or acquired PC or antithrombin deficiencies, factor concentrate replacement as an adjuvant hemostatic support is used more and more. It should be remembered that because the hemostatic system in infancy and throughout childhood is constantly maturing, the anticoagulant effects of unfractionated heparin and warfarin are not predictable and therefore are deemed age dependent.

ANEMIA

There is a gradual decrease in hemoglobin (Hb) level following birth and throughout the first two months. This is termed 'physiological anemia' and it is a direct consequence of changes in red cell production reflecting the increase in oxygenation with adaptation to pulmonary respiration, together with redistribution of blood flow following birth and changes in red cell production.[26] When the level of Hb is below the 'physiological anemic' range then a pathological neonatal anemia is present.[26] While the majority of cases of anemia occurring in the neonatal period are acquired, a number of inherited disorders that involve genes, defects of hemoglobin, red cell membrane, and enzymes also present during this period.[27] Anemia, whether it be acquired or inherited, may present as an incidental finding on a blood count performed for other reasons, with nonspecific signs of pallor, tachypnea and/or tachycardia, failure to thrive, jaundice, splenomegaly, or bleeding. If the anemia is due to a hemolytic process, the jaundice is almost always present.

Acquired anemia

ALLOIMMUNE HEMOLYTIC ANEMIA

Hemolytic disease of the newborn (HDN) is caused by transplacental passage of maternal alloantibodies.[27] The most common allo-antibodies causing severe hemolytic disease of the newborn are: anti-D, anti-c, and anti-Kell which produce hemolysis in fetuses which carry the D, c, and Kell antigens, respectively.[27] The alloantibodies are acquired either as a result of blood transfusion prior to or during pregnancy or as a result of alloimmunization during the pregnancy itself. Alloimmunization due to anti-D affects around 1200 pregnancies per year and causes at least 50 deaths every year in the UK.[27] HDN is usually diagnosed by testing the blood group of the mother and baby together with the presence of maternal alloantibodies and a positive Coomb's test. If HDN is due to Rhesus antibodies the number of circulating nucleated red cells is often very high and thrombocytopenia may be present in those severely affected. In HDN due to ABO incompatibility the Hb is often normal and the nucleated red cell count is rarely elevated; however, there are very large numbers of spherocytes, in contrast to a relative paucity of spherocytes in Rhesus disease.

AUTOIMMUNE HEMOLYTIC ANEMIA

This is a very uncommon cause of neonatal anemia and it arises when autoantibodies produced in the mother are directed against fetal red cell antigens causing hemolysis in a similar fashion to neonatal thrombocytopenia secondary to AIT.[27]

INFANTILE PYKNOCYTOSIS

This transient acquired disorder typically presents with jaundice, mild hepatosplenomegaly, and anemia in a term baby within a few days or weeks of birth.[27] It is not an uncommon cause of moderate anemia in the first few weeks of life in term infants. The cause is unknown but some cases appear to be due to selenium deficiency. The Hb may fall as low as 4 g/dL and many neonates require one or two red cell

transfusions before the condition resolves spontaneously around 4–6 weeks of age.[27]

BLOOD LOSS

Anemia due to blood loss is the most common cause of neonatal anemia in preterm infants. In most cases this is iatrogenic and due to frequent blood sampling. In term infants, blood loss is also not an uncommon cause of anemia and is often occult. This is the most common cause of otherwise unexplained neonatal anemia. Blood loss may occur before or around delivery due to feto-maternal hemorrhage or to twin–twin transfusion; it may occur as a result of bleeding from a ruptured cord or abnormal placenta, or there may be bleeding into the baby.

ANEMIA OF PREMATURITY

Almost all preterm infants have anemia, the etiology of which is usually multifactorial with reduced red cell lifespan and inappropriately low erythropoietin production being the most important contributing factors.[28–31] The best approach is prevention. While blood transfusion is usually carried out especially in babies of less than 28 weeks' gestation or those requiring prolonged mechanical ventilation, the amount of allogeneic red cell exposure can be significantly reduced by reducing blood tests in the child, give folate and iron to all preterms, appropriate use of erythropoietin, and compliance with peer-reviewed transfusion guidelines.

APPROACH TO MANAGEMENT

Only severe or moderate neonatal anemia should be treated with blood transfusion and this decision is made on clinical grounds as well as the Hb in accordance with peer-reviewed guidelines.[31] HDN always resolves, albeit it may take one to two months and in the first couple of weeks of life the hemolytic process may be so brisk that the high bilirubin necessitates phototherapy to prevent kernicterus. Blood transfusion may also be required for infantile pyknocytosis and for neonatal anemia due to blood loss.

Inherited anemia

As stated above, if the anemia is due to a hemolytic process the jaundice is almost always present. When the hemolytic process is secondary to a red cell membrane disorder then jaundice is usually accompanied by mild to moderate splenomegaly. Jaundice is also frequently seen in neonates with inherited red cell enzyme deficiencies, however in G6PD deficiency anemia is not usually present and the hyperbilirubinemia is thought to be most likely of hepatic origin. Most of the hemoglobinopathies, apart from alpha-thalassemia major and hemoglobin-H (HbH) disease, do not cause neonatal jaundice.[27]

RED CELL MEMBRANE DEFECTS

These can be difficult to diagnose in the neonatal period, especially in the case of the most common type, hereditary spherocytosis (HS) where the classic blood film morphology of numerous spherocytes is indistinguishable from that seen in ABO incompatibility. Spherocytes are also seen in the neonatal period with consumptive coagulopathy, birth asphyxia, and when there was significant placental insufficiency. A positive family history of HS is usually the best piece of additional information that is needed to make the diagnosis as osmotic fragility testing in this age group is not reliable and should be postponed until the child is between six and 12 months of age. Hereditary elliptocytosis is straightforward to diagnose from peripheral red cell morphology.

HEMOGLOBINOPATHIES

As globin chain synthesis is in a state of flux between late fetal life and following birth, diagnosing hemoglobinopathy is fraught with difficulty in the neonatal period.

The hemoglobinopathies that cause neonatal anemia include α-thalassemia major (Hb Barts hydrops fetalis) and HbH disease. In sickle cell syndromes the Hb is normal.

RED CELL ENZYME DEFICIENCIES

These usually are straightforward to diagnose in the neonatal period. A G6PD assay should be performed in any cases of prolonged or severe jaundice unless there is an obvious alternative cause. Pyruvate kinase deficiency is also diagnosed by assaying red cell enzyme levels; PK assays should be performed in cases of unexplained hydrops, those with hemolytic anemia of unknown cause, and where there is a family history.

MISCELLANEOUS

Other inherited conditions that can present as anemia in the neonatal period include Diamond–Blackfan anemia,[32] Pearson's syndrome,[33] congenital dyserythopoietic anemia,[34] Aase syndrome,[35] and osteopetrosis.[27]

Genetics in neonatal surgical practice

ANDREW GREEN

NATURE AND STRUCTURE OF A GENE

Genetics is traditionally defined as the science of biologic variation, and has been a scientific discipline for over 100 years. Human genetics makes up a large part of the field of genetics, but the principal laws of genetics are universal, and apply equally to all species, including humans. Mendel's studies in the 19th century were originally felt to have no relevance to humans, and it is only in retrospect that their importance can be seen. Many of the principles of genetics were discovered through the study of smaller organisms, such as bacteria, yeast, and fruit flies. The basic genetic mechanisms of cell division, development, and differentiation happen in the same way in widely divergent species. Therefore it is impossible to look at human genetics in isolation, and there are large amounts of information from lower species which have bearing on human disorders. The study of the genetics of small organisms has had a profound impact on our understanding of human development, and of how human diseases develop. It is likely that such basic science will continue to contribute significantly to the understanding of human genetic disease. This chapter will attempt to outline the basic elements of genetics, describe the types of genetic tests now available to help in neonatal diagnosis, and give an approach to the diagnosis of congenital abnormalities.

The basic unit of inheritance for any species is the gene. The original concept of a gene arose long before the relationship between genes and nucleic acids was ever understood. A gene was considered to be a stable heritable element, which conferred a particular property or phenotype onto an individual organism. This element was passed on to subsequent generations of a particular species, and the nature of the phenotype varied according to the nature of the gene. The concept of dominant and recessive traits, which will be discussed later, was derived from studies of inheritance patterns, long before the molecular basis of the gene was understood.

A gene can also be considered in another way, as a specific length of deoxyribonucleic acid (DNA), which encodes a particular function, in most cases the synthesis of a protein. This also is a stable heritable unit. Each cell in an organism, regardless of its function, has the entire set of genes for that particular organism, but only a proportion of those genes will be active. DNA is found in the nucleus of every cell of an organism as a double helix (Fig. 19.1).

Each strand of the double helix has a backbone of alternating phosphate and deoxyribose sugar molecules, with the sugars attached to the 5′ and 3′ hydroxyl groups of the phosphate group. Attached to the sugar molecule, lying

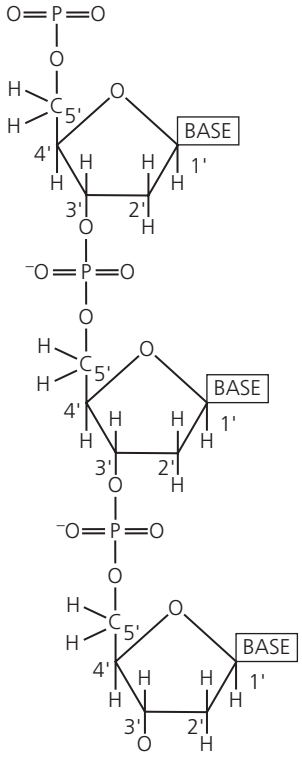

Figure 19.1 Structure of a DNA chain. The deoxyribose and phosphate residues are linked to form the sugar-phosphate backbone of DNA.

within the helix, is one of four nitrogen-containing nucleic acid bases. Two of these bases, adenine (A) and guanine (G), are purines, and two are the smaller pyrimidines cytosine (C) and thymine (T). The A and T bases pair together by hydrogen bonding, and the G and C bases similarly pair by hydrogen bonds (Fig. 19.2). The two strands of the double helix are held together by paired A-T or G-C bases of opposite strands of the double helix. The DNA strand can be read in only one direction from 5′ (left hand) to 3′ (right hand). The two strands of DNA are complementary to each other, and the sequence of one strand can be predicted from its opposite. If one strand reads 5′-CAGCGTA-3′, then the opposite strand must read 5′-TACGCTG-3′. The double-stranded sequence would then be written as follows:

5′-CAGCGTA-3′
3′-GTCGCAT-5′

The simplicity of the double helix structure allows for several important functions for DNA.

First, huge amounts of information can be stored in the strand of DNA. If a molecule of DNA is one million bases long, then there are $4^{1\,000\,000}$ possible sequences for that stretch of DNA. A genome is the complete DNA sequence of an organism. In humans, the estimated genome size is 3×10^9 base pairs (bp). The human genome contains a huge amount of coded information, of which as yet only a small part is known.

Second, the double helix provides a framework for DNA replication. One strand of DNA acts as a template for the synthesis of a new strand of DNA. The double helix unwinds, allowing DNA replication enzymes access to the template strand of DNA. The replication system builds a new strand of DNA based on the template. The new double helix formed as a result will contain one original strand, and a newly synthesized complementary second strand. This is the basic mechanism of DNA replication in all species.

Third, the double helix provides a basis for repair of damaged DNA. A damaged base can be replaced, knowing its complementary base is present on the opposite strand. Damage to the sugar-phosphate backbone can also be repaired using the opposite strand as a template.

Figure 19.2 Double-helix structure of DNA. The double helix of deoxyribose and phosphate molecules is held together by paired purine and pyrimidine bonds.

DECODING THE INFORMATION IN DNA

About 90% of the DNA in the human genome does not code for any specific property. Only about 10% of the genome actually contains coding information in the form of a gene. In simple terms, the genetic code in DNA is transcribed into a molecule called messenger RNA (mRNA). The mRNA is then translated into a protein, which carries out the function encoded by the specific DNA.

A gene has several distinct elements (Fig. 19.3). The major part of the gene is divided into coding regions, called exons, and non-coding regions called introns. Just before (5′) the first exon, there is a promoter which indicates where transcription of a gene should start. There can be several promoters for one gene, and different promoters can be used according to the tissue in which the gene is being expressed, in other words the promoter is tissue specific. Further 5′ of the promoter, there can also be enhancers or suppressors, which can increase or decrease the level of transcription of the gene. Not all of the mRNA will code for protein, as some exons will code for mRNA that does not directly encode protein. These areas, known as untranslated regions, can be either at the start (5′) or the end (3′) of the mRNA.

To express the DNA code, mRNA is used. There are several different types of RNA, but mRNA is the most important in decoding DNA. There are three differences between RNA and DNA. First, the sugar backbone of RNA contains ribose rather than deoxyribose. Second, mRNA exists as a single strand, and remains more unstable. Third, in RNA the base uracil (U) is used instead of thymine (T), whereas the other three nucleic acids remain the same.

The DNA code in most genes is expressed as a protein, which is a peptide made of the building blocks of individual amino acids. Each amino acid is coded for by a sequence of three DNA bases, known as a codon. For some amino acids, there is more than one codon (see Table 19.1). A long series of DNA codons in a gene will thus code for an entire protein. The mRNA codons coding for amino acids are identical to DNA codons, with the substitution of U for T. There is a tightly controlled mechanism for the generation of protein from a DNA template.

To decode a gene into protein, the DNA is first transcribed into mRNA. A strand (the 'sense' strand) of the DNA double helix is used by the enzyme RNA polymerase to synthesize a complementary strand of mRNA. Transcription of mRNA starts from the 5′ end of the first exon of the

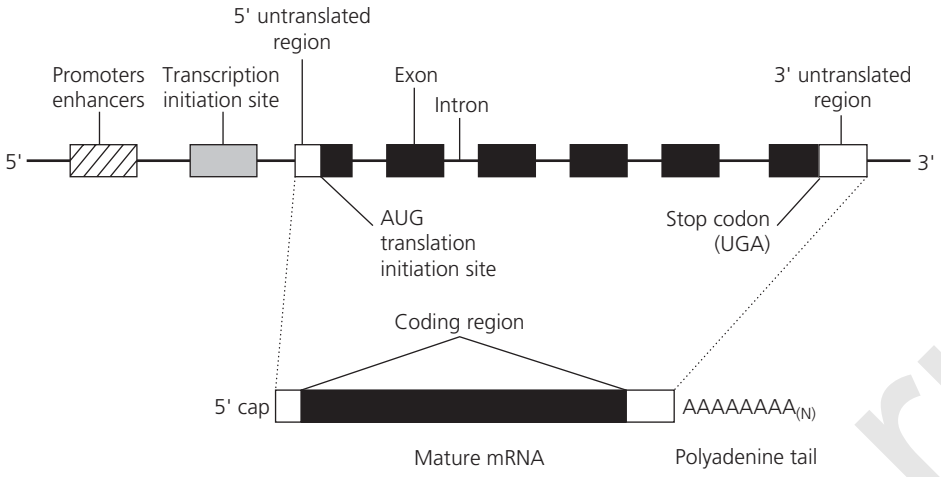

Figure 19.3 An idealized gene.

Table 19.1 The genetic code.

	GUA Val	GCA Ala	GAA Glu	GGA Gly	A
	GUG Val	GCG Ala	GAG Glu	GGG Gly	G

gene, until the end of the most 3′ exon. The intervening introns are initially included and the first molecule is known as pre-mRNA. The intronic RNA sequences are spliced out, and a 3′ polyadenine tail is added, producing mature mRNA. The mature mRNA is then transferred from the nucleus to the ribosome to be used as a template for the production of protein. The mature mRNA has both 5′ and 3′ untranslated regions.

Protein synthesis does not begin at the 5′ end of the mRNA, but at the first 5′ AUG codon, which codes for the amino acid methionine. Protein translation stops at the first truncation codon (usually UGA) thereafter (Fig. 19.3). In the ribosome, amino acid-specific RNA molecules, called transfer RNAs (tRNA), bind a free molecule of their specific amino acid. The binding is carried out by an anti-codon in the tRNA, which is complementary to the mRNA that codes for that specific amino acid. Using its anti-codon, the tRNA binds the specific mRNA codon for its amino acid. By complex machinery, the amino acid is then added to a growing peptide chain which will eventually form the mature protein (Fig. 19.4). The 5′ end of the mRNA corresponds to the NH_2 (amino terminus) of the protein, and the 3′ end of the mRNA corresponds to the COOH (carboxyl terminus) of the protein. Many proteins in higher species are modified after translation by the addition of phosphate or lipid groups.

CHROMOSOMES AND CELL DIVISION

The first coiling of DNA is in the form of the double helix. However, there are subsequent higher orders of coiling and packaging of DNA. The first order gives a loop of about 146 bp in size, wound around a histone protein. The complex is known as a nucleosome. The highest order of coiling of a large DNA molecule, with its associated histones and other proteins, is known as a chromosome.

A chromosome consists of one very long double helix of DNA, containing very many genes in millions of base pairs. Humans are diploid, that is to say they have two copies of every chromosome. The normal human chromosome complement is 46, made up of 22 pairs of autosomes (non-sex chromosomes) and two sex chromosomes, either X and Y in a male, or two X chromosomes in a female. Each member of a pair of autosomes contains the same genetic information. The pair of X chromosomes in a female will contain the same genetic information, but X and Y chromosomes in a male only have a small amount of genes in common. A normal human metaphase karyotype is shown in Figure 19.5.

When cells divide, the genetic content must also be duplicated so that the daughter cells have the correct genetic material. Most cell division occurs as mitosis, where one cell divides to give two cells genetically identical to that parent.

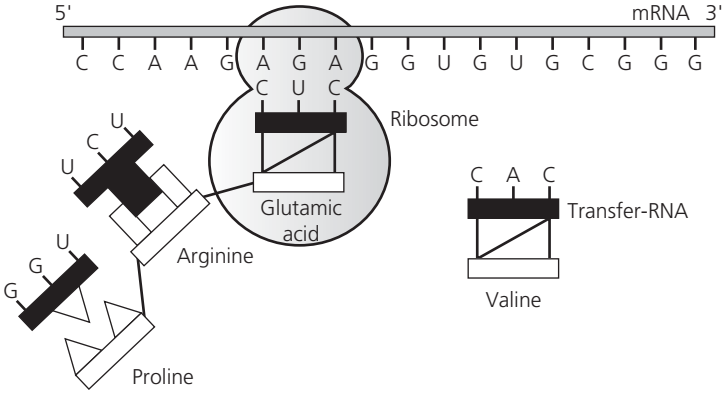

Figure 19.4 Diagram of protein synthesis from mRNA.

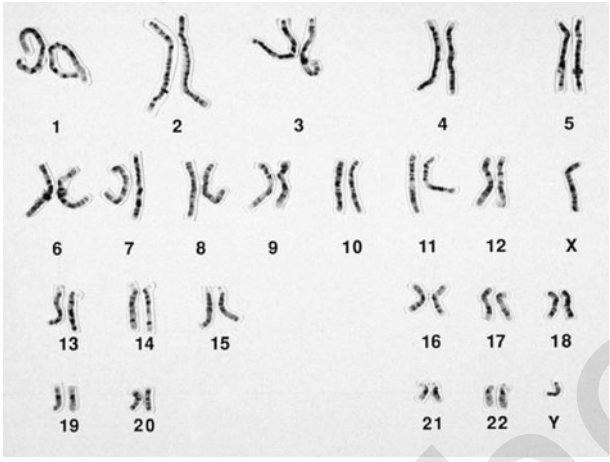

Figure 19.5 A normal male karyotype.

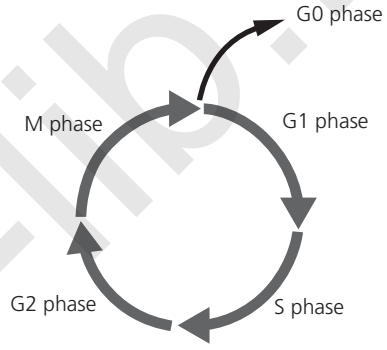

Figure 19.6 Cell cycle.

This is the process which allows the formation of a complete human being from one fertilized embryo, and is also the process by which the cells of many organs are constantly renewed. Mitosis is one short period during a carefully programmed cell cycle (Fig. 19.6). After mitosis, the cell may enter a resting phase (G_0), or go on to divide again (G1). A cell in G1 will then go on to synthesize new DNA as described earlier (S phase). There is then a second gap phase (G2) followed by mitosis (M).

Prior to mitosis the cell can be said to be in interphase, during which the chromosomes are very elongated. Just before mitosis, in S phase, the chromosomes are duplicated, and begin to condense as two (sister) chromatids per chromosome. This condensation phase is known as prophase. In the next phase, metaphase, the condensed chromatids line up along the plane of the cell, and spindle fibers develop between the centromeres (narrow waist of each chromatid), and the polar centrioles. Standard analysis of human chromosomes is carried out in metaphase. The chromatids separate, starting from each centromere, and pass to the new daughter cell, in the step called anaphase. By the telophase, the chromatids have reached to opposite poles of the dividing cell, and division completes.

Meiosis is the form of division required to form gametes (sperm or oocyte). Gametes are haploid, with only one of each chromosome, 23 chromosomes in the case of humans. This allows the formation of a new diploid organism from two haploid gametes. Meiosis occurs in two stages: meiosis I and meiosis II. The first phase of meiosis I, prophase I, is similar to that in mitosis, with the appearance of two condensed chromatids which have duplicated. At this stage, crossing over of genetic material from one chromatid to another can occur. It is estimated that about 1–2 crossovers occurs per chromosome in each meiosis. This introduces further genetic diversity, ensuring that the inherited chromosomes are different from the chromosomes of the parent. Metaphase I then occurs, where chromatids do not separate, but go to the opposite ends of the cell in anaphase I and telophase I. The cells at this stage are still diploid.

The second meiotic division then occurs, where chromatids condense again in prophase II, and line up along the axis of the dividing cell in metaphase II. The chromatids then separate, passing to opposite ends of the cell in anaphase II. The new cells are then haploid, with 23 chromosomes, and the chromatids elongate into thin strands in telophase II.

CHROMOSOME ANALYSIS

To examine chromosomes from a patient (a karyotype), dividing cells in culture must be examined. These cells are usually lymphocytes, amniotic fluid cells, or fibroblasts. Cells

are arrested in the metaphase stage of mitosis, and stained in such a way that the chromosomes are easily visualized. The usual technique used is G-banding (using a Giemsa stain), which gives a characteristic positive and negative banding pattern to each chromosome. Each chromosome has a constriction, called a centromere, dividing the chromosome into a short arm (p) and a long arm (q). Each arm has a number of prominent bands, which can then be subdivided into smaller bands. The gene for the ABO blood group is localized to chromosome 9q34. The gene thus lies in the fourth sub-band from the centromere (q34) of the third band from the centromere (q34) on the long arm (q34) of chromosome 9 (9q34).

Chromosome abnormalities can broadly be classified into abnormalities of chromosome number, or a rearrangement of a normal number of chromosomes. The critical issue in most cases for determining the significance of a chromosome abnormality is whether the abnormality gives rise to an excess or deficiency of the normal diploid state (aneuploidy).

Abnormalities of chromosome number are relatively common, but many are not recognized, as they may result in the early loss of a pregnancy. Triploidy (69 chromosomes) and tetraploidy (92 chromosomes) are relatively common causes of early pregnancy loss. Trisomy, the presence of a single extra chromosome (47 chromosomes), is also a common cause of miscarriage. Specific trisomies can give rise to an affected neonate, the most common being trisomy 21 (Down syndrome), trisomy 13 (Patau's syndrome) and trisomy 18 (Edwards' syndrome). All these trisomies usually occur as a result of autosomal non-dysjunction in meiotic division of the oocyte. In non-dysjunction, the specific chromatids fail to separate, resulting in an extra chromosome in one oocyte, and no chromosome in the opposite gamete. A fertilized embryo from the oocyte with an extra chromosome will therefore be trisomic. The fertilized oocyte with an absent chromosome will be monosomic, and be lost as an early miscarriage. Non-dysjunction tends to occur more frequently with increasing maternal age. Non-dysjunction can occur in the male germline, but rarely produces viable offspring.

There are numerous types of chromosome rearrangements, the most common of which are shown in Figure 19.7. Pericentric and paracentric chromosome inversions are usually balanced, and inherited without any phenotypic effect. Paracentric inversions are usually associated with a low risk of producing a liveborn unbalanced karyotype, but pericentric inversions may carry a higher risk. Insertions, duplications, deletions, isochromosomes, and ring chromosomes are all usually aneuploid and associated with significant clinical abnormalities. Reciprocal translocations occur where there is exchange of genetic material from one arm of a chromosome in return for genetic material from a different chromosome. Reciprocal translocations are usually balanced, without any clinical effect, but may carry a risk of having a child with problems due to an unbalanced karyotype.

Another type of translocation occurs between the acrocentric chromosomes (13–15, 21 and 22), where there is no appreciable coding material on a very small short (p) arm. This is known as a Robertsonian translocation. Robertsonian translocations are one of the most common human chromosome translocations, and in the balanced form have no clinical effect. A Robertsonian translocation involving chromosomes 14 and 21 is shown in Figure 19.8. Those who carry a Robertsonian translocation involving chromosome 21 may be at significantly higher risk of having a child with Down syndrome as an unbalanced product of the translocation. The same applies to a lesser extent for those carrying a

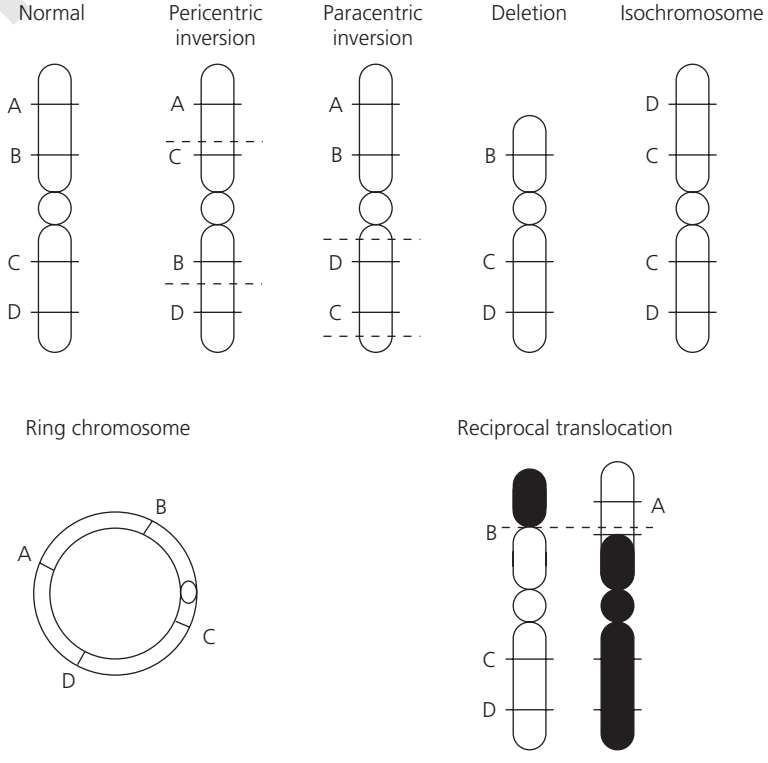

Figure 19.7 Different types of chromosome anomaly. A–D represent notional chromosomal loci.

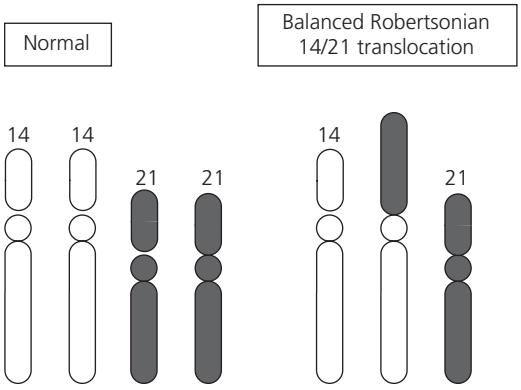

Figure 19.8 Robertsonian translocation.

Robertsonian translocation involving chromosome 13, and a subsequent risk of a child with Patau's syndrome.

The nomenclature for reporting a chromosome analysis is strict, and needs to be read carefully. A karyotype is reported initially as the number of chromosomes, regardless of whether those chromosomes are normal or not. The sex chromosomes are then described. If there is no further abnormality, the report is then complete. Any further abnormality is added after the sex chromosomes. A normal male karyotype is thus 46,XY. A male with non-dysjunctional Down syndrome will have the karyotype 47,XY,+ 21, an extra unattached chromosome 21. A male with Down syndrome due to a Robertsonian translocation between chromosomes 14 and 21 will have the karyotype 46,XY,t(14;21), and his carrier mother will have a karyotype 45,XX,t(14;21).

A standard laboratory chromosome analysis will be performed on G-banded chromosomes, which will detect many common and less common chromosome abnormalities, and in most cases no further laboratory work is required. However, recombinant DNA technology has allowed new techniques for chromosome analysis, based on the hybridization of fluorescently labeled fragments of DNA to the DNA of chromosomes, prepared in a standard fashion, immobilized on a glass slide. The slides can then be visualized by eye using a fluorescent microscope, or indirectly by generating an image of the hybridization on computer. This technique is known as fluorescent *in situ* hybridization (FISH). The information which can be gained from this technique depends on the origin of the fragments of DNA hybridized to the chromosome preparation. Labeled whole chromosome 'paints', consisting of DNA exclusively from one chromosome, are now commercially available. For example, whole chromosome paints can be used to identify the origin of extra chromosomal material which cannot be identified using G-banding techniques. Whole chromosome paints are also helpful in determining the origin of subtle complex translocations. It is also now technically possible to use a chromosome 21 paint on uncultured cells in interphase, to look for trisomy 21. A cell would show three fluorescent nuclear dots, representing three chromosomes 21, as opposed to two in the normal situation.

Fluorescently labeled small DNA fragments, corresponding to 40–50 kb of DNA from a specific chromosomal region, can also be hybridized to metaphase chromosomes. Chromosomal deletions which cannot be detected within the resolution of conventional cytogenetic analysis can be detected by the FISH method. A normal karyotype will give two hybridization signals: one from the same part of each chromosome. A karyotype containing a submicroscopic chromosomal deletion involving the segment of the chromosome corresponding to the 50 kb DNA fragment will only give one hybridization signal. An example would be the submicroscopic deletion of chromosome 22q11 which occurs in most cases of the Di George spectrum, which can only be seen by FISH analysis of chromosomes.

GENOMIC ARRAY ANALYSIS

A new technological development is the ability to immobilize thousands, and more recently millions, of distinct recognizable pieces of DNA on slides of silicone or glass as ordered microarrays, colloquially known as DNA microchips. This genomic array technology can permit analysis of thousands of individual loci simultaneously, and gives chromosome analysis at a resolution at least 100 times greater than conventional G-banded chromosome analysis. Genomic array technology will identify pathogenic chromosomal anomalies in 20–25% of infants in whom no underlying diagnosis had been identified previously. There is a drawback in that genomic array technology will often find genetic variants of unknown significance, and the current understanding of the role of such variants in disease pathogenesis is limited. Genomic array technology is now becoming available in an increasing number of diagnostic cytogenetic laboratories. Genomic array technology is likely to replace standard G-banded chromosome analysis for a wide variety of indications over the next few years.

PATTERNS OF INHERITANCE

Single-gene disorders have one of three principal modes of inheritance: autosomal dominant, autosomal recessive, and X-linked recessive. Other rare forms of inheritance include X-linked dominant, and mitochondrial disorders, as well as disorders due to abnormalities of genetic imprinting. Disorders caused by inheritance of unstable elements of DNA are now increasingly being recognized (see Other forms of inheritance).

Autosomal dominant inheritance

Autosomal dominant disorders are characterized by vertical transmission from parent to child, and the hallmark of these conditions is male-to-male transmission of the disease (Fig. 19.9).

Those affected with an autosomal dominant disorder have an alteration in one or other copy of their two genes responsible for that condition. Each child of a person with an autosomal dominant disorder has a 50:50 chance of inheriting the gene responsible for the condition from its parent.

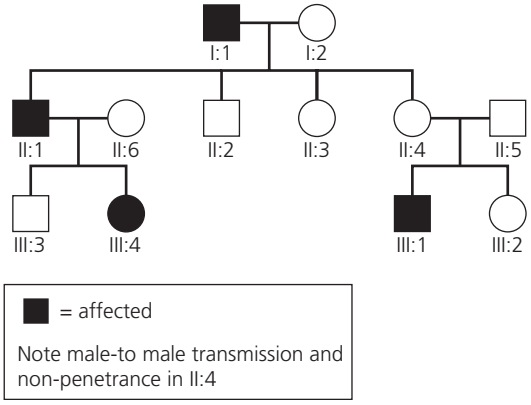

Figure 19.9 Autosomal dominant inheritance.

There are many examples of autosomal dominant disorders, including neurofibromatosis 1 and 2, familial adenomatous polyposis coli, myotonic dystrophy, and Huntington's disease. There can often be variability in both expression and penetrance of autosomal dominant disorders. For example, neurofibromatosis 1, an autosomal dominant condition, will almost always manifest in someone who has an altered neurofibromatosis 1 gene. This means that the condition has almost complete penetrance. However, different people can manifest the condition in different ways, with some people showing mild skin lesions, and others with severe intracerebral complications. This means that the expression or expressivity of the condition is very variable. In contrast, only 80% of those who have a single altered gene for the rare hereditary form of retinoblastoma will actually develop an eye tumor. The penetrance in this situation is 80%, but the expression of the altered gene is consistent, as manifested by a retinoblastoma.

Autosomal dominant disorders are not commonly seen in neonatal surgical practice. A list of the more frequent conditions is outlined in Table 19.2.

Table 19.2 Autosomal dominant disorders in neonatal surgical practice.

System affected	Condition
Gastrointestinal	Hirschsprung's disease (some cases)
	Beckwith–Wiedemann syndrome with exomphalos (some cases)
	Pyloric stenosis (some cases)
Genitourinary	Vesico-ureteric reflux
Skeletal	Stickler's syndrome
	Most craniosynostosis syndromes
	Achondroplasia
	Osteogenesis imperfecta
	Limb reduction defects (some cases)
Cardiac	Holt-Oram syndrome
	Noonan's syndrome
	22q11 microdeletion syndrome
Other	Retinoblastoma

Autosomal recessive inheritance

When a child is diagnosed with an autosomal recessive disorder, then both copies of a particular gene responsible for the condition are altered. Both its parents are therefore carriers for that condition, with one normal and one altered gene. Two of the child's four grandparents are also carriers, and it is likely that many of the child's relatives are also unknowingly carriers (Fig. 19.10). In most cases, being a carrier for an autosomal recessive condition has no effect on that person.

When both parents are carriers for an alteration in the same gene, then there is a 25% or one in four chance for each of their children to be affected by the condition. The risk of a healthy carrier sibling of having a child with the same condition depends on the chances of that sibling's partner also being a carrier. A child of a person with an autosomal recessive disorder will automatically be a carrier. The child's chances of being affected will depend upon whether its unaffected parent is a carrier for an alteration in the same gene.

Autosomal recessive disorders are commonly encountered in neonatal practice, and the nature of the disorder depends on the population being seen. Each regional population has its own recessive disorder, where the frequency of carriers for that disorder is highest. For instance, cystic fibrosis is a very common autosomal recessive disorder in Western Europe, whereas sickle cell anemia is the most common autosomal recessive disorder in West Africa. Common examples of autosomal recessive conditions include cystic fibrosis, sickle cell anemia, several of the mucopolysaccharidoses, beta-thalassemia, spinal muscular atrophy, and congenital adrenal hyperplasia (Table 19.3). Prenatal diagnosis is available for many of these conditions.

X-linked recessive inheritance

In X-linked recessive inheritance, the condition affects almost exclusively males, and females can be carriers (Fig. 19.11). The classic examples of such conditions are hemophilia A and B, Duchenne and Becker muscular dystrophy, and Hunter syndrome.

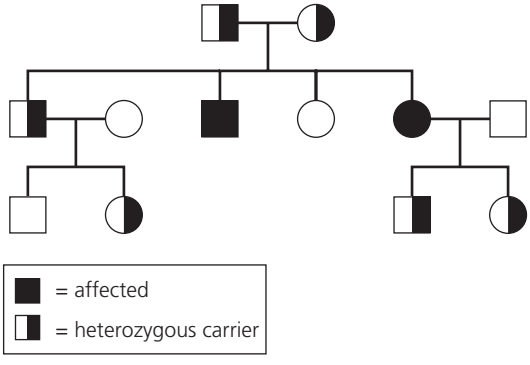

Figure 19.10 Autosomal recessive inheritance.

Table 19.3 Autosomal recessive disorders in neonatal surgical practice.

System affected	Condition
Metabolic	Cystic fibrosis
	α-1-antitrypsin deficiency
Skeletal	Short-rib polydactyly syndrome
	Jeune's syndrome
	Robert's syndrome
Genitourinary	Infantile polycystic kidneys
	Meckel–Gruber syndrome
Endocrine	Congenital adrenal hyperplasia

The daughters of a man with an X-linked recessive condition are all obligate carriers. The sons of a man with an X-linked condition are all normal, as they inherit his Y chromosome, and not his X chromosome. When a woman is a carrier of an X-linked condition, each of her sons has a 50:50 chance of being affected, and each of her daughters has a 50:50 chance of being a carrier. There can be a relatively high mutation rate for some X-linked recessive conditions, and affected boys may not have any family history of the condition. About one-third of cases of boys with Duchenne muscular dystrophy occur as a result of new mutations. Prenatal diagnosis is available for a wide range of X-linked recessive diseases. The more common X-linked disorders in neonatal practice are shown in Table 19.4.

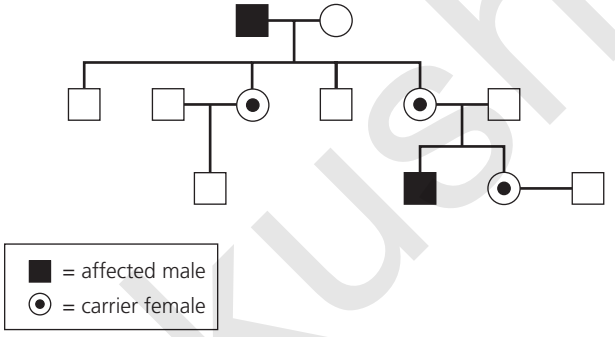

Figure 19.11 X-linked recessive inheritance.

Table 19.4 X-linked recessive disorders in neonatal surgical practice.

System affected	Condition
Neurological	Hydrocephalus with aqueduct stenosis (some cases)
Hematological	Hemophilia
Skeletal	Amelogenesis imperfect
Endocrine	Androgen insensitivity syndrome
Metabolic	Adrenoleukodystrophy

Polygenic inheritance

Many congenital conditions do not have a clear mode of inheritance, and can be classed as polygenic or oligogenic, where a disease may arise as a result of the effects of several genes. A good example is cleft lip and palate, which usually occurs in the absence of a family history. However, monozygotic twins have a high concordance for cleft palate, suggesting a genetic influence. A similar model applies to the genetics of neural tube defects, which arise as a result of the combination of several environmental and genetic factors.

Other forms of inheritance

There are also much rarer forms of inheritance, including X-linked dominant, which can be hard to tell apart from autosomal dominant, except that females will be more mildly affected, and there is no male-to-male transmission. An example of an X-linked dominant condition is hypophosphatemic rickets.

Mitochondrially inherited diseases show a very unusual pattern of inheritance. Most of the proteins in the mitochondria are encoded for by nuclear genes, but the mitochondria also contain their own small genome of 18 kb, with many copies per cell. The mitochondrial genome replicates independently and far more frequently than the nuclear genome. Several important mitochondrial proteins are encoded by the mitochondrial genome. Mitochondria are only inherited via oocytes, and not sperm. Therefore, where a gene alteration is in the mitochondrial genome, it will pass exclusively down the female line, but both males and females can be affected. The children of an affected male will not inherit his mitochondrial gene alteration. Children with mitochondrial disorders can present with many varied symptoms, including myoclonic seizures, acute acidoses, muscle weakness, deafness, or diabetes. A number of point mutations and deletions in the mitochondrial genome have been described in patients with a wide variety of conditions, including MELAS (myoclonic epilepsy with lactic acidosis and stroke-like episodes) or MERRF (myoclonic epilepsy with ragged red fibers on muscle biopsy). To complicate matters further, Leber's hereditary ophthalmopathy is a mitochondrially inherited condition, with a characteristic mitochondrial mutation, but the expression appears to have an X-linked recessive influence.

Some conditions show a phenomenon known as genetic imprinting. An imprinted gene has been marked during meiosis, to indicate the parent from which it comes. For some genes, it appears to be important not only to inherit two copies of that gene, but to inherit one from each parent. Some genes may be silenced, depending upon which parent has passed on that gene. A good example is the presence of a small deletion of chromosome 15q, which has a different effect, depending upon which chromosome 15 is deleted. If the deletion occurs on the chromosome inherited from a child's normal father, the child will develop Prader–Willi syndrome. If the deletion occurs on the chromosome inherited from a child's normal mother, the child will develop a completely different clinical condition, Angelman's syndrome. The genes

in this area of chromosome 15 are therefore imprinted. In addition, if a child has two maternal copies of chromosome 15 (maternal disomy), but no paternal copy, he or she will also develop Prader–Willi syndrome. Other conditions which show imprinting effects include Russell–Silver syndrome, Beckwith–Wiedemann syndrome, and the rare condition of transient neonatal diabetes mellitus.

A new molecular mechanism for genetic disease has been described, of inherited unstable triplet repeat expansions. At least nine different conditions are caused by this phenomenon. In one of these genes, a normal person has a stable number of a repetitive element of three bases of DNA (for example 20 copies of a CAG repeat) in a particular gene. In that case the gene functions normally and the children of that person have the same number of repeats in their gene. An affected person has an increased number of repeats (say 100 copies) in that gene, and the affected children of that person have more serious disease, with perhaps 200 repeats in the gene. The molecular genetic findings appear to be the genetic correlate of the phenomenon of anticipation, where a condition appears to worsen from generation to generation. The most extreme example is that of congenital myotonic dystrophy, where a minimally affected mother can have a profoundly affected infant. In this case, there is a small repeat expansion of say 150 repeats in the mother, increasing to many hundreds of repeats in her affected infant.

This molecular mechanism is responsible for Fragile X syndrome, Huntington's disease, Friedreich's ataxia, several forms of spinocerebellar ataxia, and probably several other conditions.

MOLECULAR GENETIC ANALYSIS FOR SINGLE-GENE DISORDERS

Laboratory tests for single-gene disorders have been available for a considerable amount of time. Hemoglobin electrophoresis for sickle cell anemia and thalassemia, and enzyme assays for Tay–Sachs' disease, are very effective in resolving clinical issues in individual families. However, an increasing number of specific DNA-based tests can now be used in diagnosis and prediction of single-gene disorders.

The two major techniques used in molecular genetic analysis are the polymerase chain reaction (PCR) and Southern blotting techniques. PCR is a technique which allows amplification of a specific genetic region in large quantities from a small amount of DNA template (Fig. 19.12). The DNA sequence of the region to be amplified must be known, so that synthetic pieces of single-stranded DNA (oligonucleotide primers) corresponding to the region can be designed and manufactured. The oligonucleotide primers are added in great excess to the DNA template, along with a thermostable DNA polymerase, and free nucleotides (A,C,T,G). The mixture is heated up to cause the two strands of template DNA to separate, and then cooled. As the DNA cools, the oligonucleotides bind to the template sequence, and are extended by the polymerase. A new copy of the template DNA is thus produced. The cycle is repeated 30–40 times, with an exponential increase in the amount of the target sequence.

DNA generated by PCR can be used in many different ways to detect an abnormality in the sequence. If the test is aimed at detecting a known sequence abnormally, such as the common three base pair deletion on the cystic fibrosis gene Phe508del, the PCR product can be analyzed using mutation-specific oligonucleotide primers, or a DNA restriction enzyme test. If the search is for an unknown DNA mutation, such as those seen in hereditary breast and ovarian cancer, then many pieces of DNA generated by PCR from the patient can have their sequence analyzed using a semi-automated DNA analyzer.

Southern blotting is a more protracted procedure involving the digestion of a relatively large amount of DNA by a restriction enzyme. The digested DNA is then electrophoresed through an agarose gel, giving a smear of DNA of different sizes. The DNA is then transferred (blotted) and fixed to a membrane. The fixed DNA is then hybridized to a labeled DNA probe specific for the gene to be analyzed, and the specific sizes of DNA to which the probe binds allows determination of the 'genotype' (Fig. 19.13). This test is often superseded by PCR technology.

There are different degrees to which molecular genetic tests can contribute to clinical diagnosis. Some specific molecular genetic tests can be used to detect a known pathogenic DNA mutation, and give a diagnosis, even without any knowledge of the patient's clinical status. For instance, the PCR detection of the Phe508del deletion in both copies of a person's cystic fibrosis (CFTR) gene immediately gives a diagnosis of cystic fibrosis. Such direct mutation tests are possible where both the gene responsible for a condition has been isolated, and specific pathogenic mutations have been identified. Similarly, a PCR test detects a deletion of exons seven and eight in both alleles of a gene called SMN on chromosome 5q in almost all children with spinal muscular atrophy. Southern blot analysis of DNA from infants with congenital myotonic dystrophy shows a very large expansion in a triplet repeat DNA sequence in the myotonin kinase gene

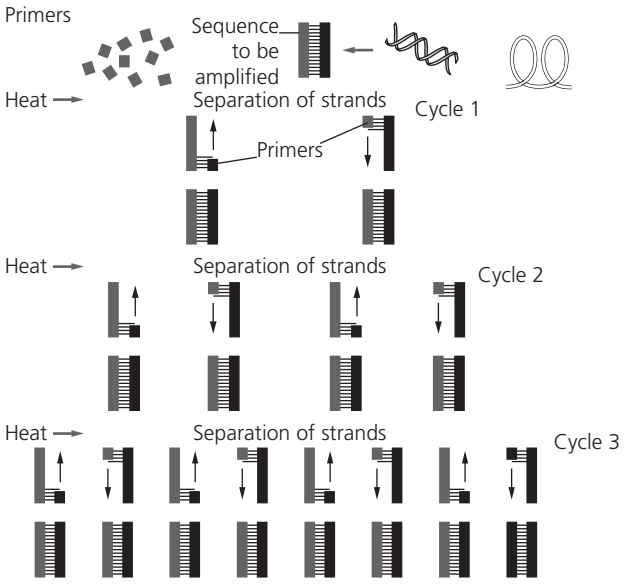

Figure 19.12 Polymerase chain reaction (PCR).

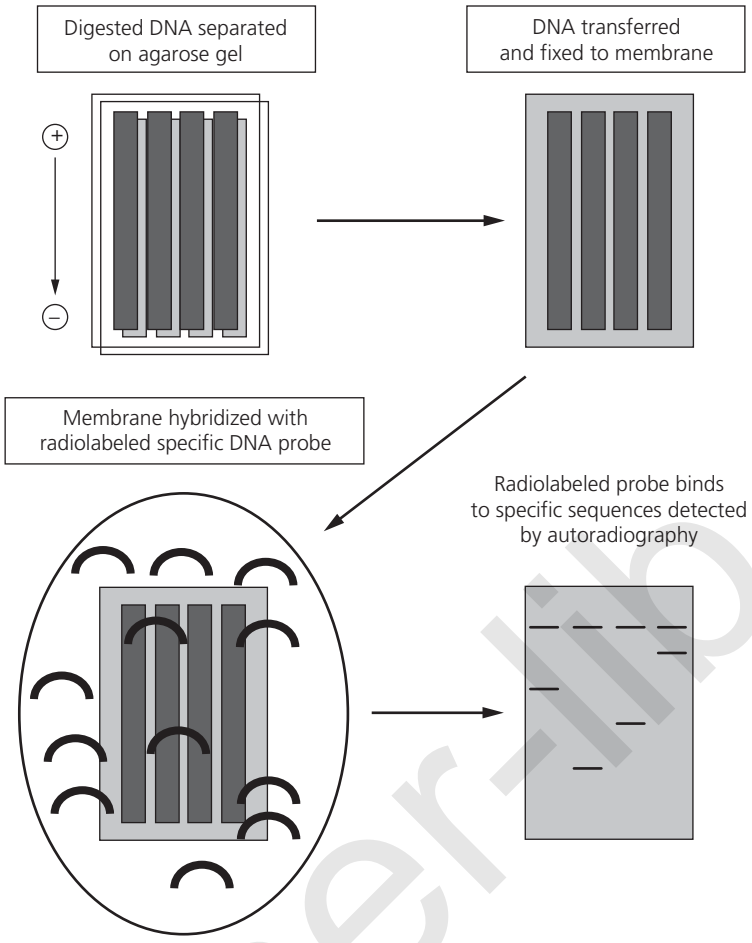

Figure 19.13 Southern blotting and hybridization.

on chromosome 19, as described earlier under Other forms of inheritance.

In other cases, molecular genetic diagnosis can point towards a diagnosis, without confirming it. For instance, the presence of a single Phe508del CFTR gene mutation in a child with a history suggestive of cystic fibrosis increases the likelihood of the child being affected.

In some cases, where either a gene is not known, or very few gene mutations have been identified in a known gene, gene tracking studies can be performed in a family to predict whether a person in that family is affected. This is known as linkage analysis. Such a study requires careful clinical examination of several family members, to establish whether they are affected or unaffected. Where their clinical status is clear, DNA samples are then obtained.

Gene tracking analysis in the family uses the property of normal variation in a gene between different people. Some genetic areas show wide variation between individuals, and a DNA marker from such an area, which can detect many variations, is described as being polymorphic. Each variant of a polymorphic marker is known as an allele. There are now thousands of polymorphic markers covering most of the human genome, and such markers can be found very close to most known genes. There are several types of polymorphic DNA markers, including markers characterized by different numbers of specific DNA-cutting enzymes recognition sites or restriction fragment length polymorphisms (RFLPs). Other markers detect the variation in number of anonymous elements of repetitive DNA and are called microsatellites or minisatellites.

If the two alleles of a polymorphic marker can be distinguished to discriminate between the two copies of that particular chromosome from where the marker comes, then the marker is informative in that individual. Where a gene location is known but the actual gene has yet to be found, the alleles of informative markers which lie on either side of the gene will be inherited along with each copy of the gene in question. This can be used to predict a child's clinical status.

If one set of alleles is found in the affected members of the family, but not in those unaffected, then the presence or absence of these alleles in the at-risk individual can be used to predict their chances of being affected. An example of linkage analysis for an autosomal recessive disorder is shown in Fig. 19.14. This form of linkage analysis is often used in families with X-linked recessive conditions such as Duchenne muscular dystrophy, to predict whether a woman is a carrier. Such linkage analysis can also be used in prenatal diagnosis.

Of its nature, linkage analysis is more prone to error than direct mutation testing. This can be due to difficulties in assessing a person's clinical status, and because of the possibility of recombination between the polymorphic

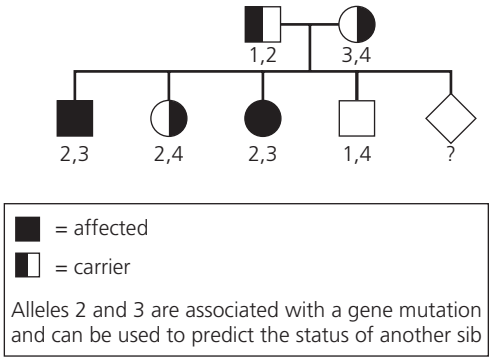

Figure 19.14 Linkage analysis in an autosomal recessive disorder using an intragenic polymorphic marker.

markers. However, with the rapid advances in molecular genetics, many more mutations are being found in many different genes, and linkage analysis is often superseded by direct mutation testing.

The rapid advances in genetic technology will alter how genetic testing will be used in clinical diagnosis. Present DNA sequencing technology allows analysis of several thousand DNA bases over a period of weeks. New short high density oligonucleotide DNA sequencing technology, called collectively next generation sequencing, can now permit the analysis of millions of DNA bases over a much shorter period of time. With this technology, many genes can be analyzed in a short clinically relevant period of time at reasonable cost. Thus in children with specific sets of malformations, direct sequencing of multiple genes in a short period of time will soon be available to provide rapid clinical information for clinicians and families.

A CLINICAL GENETIC APPROACH TO DIAGNOSIS OF MALFORMATION SYNDROMES

Definitions

One child in 40 (2.5%) is born with a significant congenital anomaly and 20–25% of perinatal and childhood mortality is accounted for by congenital anomalies. Only a small number of these anomalies will occur as part of a specific genetic syndrome. A list of common congenital anomalies and approximate birth incidence is shown in Table 19.5.

Awareness of the possibility of a genetic or syndromal association for anomalies is very important for management of the patient, and for advising the whole family. A distinction has also to be drawn between several different forms of abnormality, with appropriate definitions.

A 'disruption' can be defined as an anomaly which is caused by an interference in the structure of a normally developing organ. A good example would be the digital constrictions and amputations caused by amniotic bands.

A 'deformation' can be defined as an anomaly which is caused by an external interference in the structure of a normally developing organ. An example would be talipes equinovarus caused by chronic oligohydramnios, perhaps from an amniotic leak.

Table 19.5 Examples of major congenital anomalies.

Type	Birth incidence (per 1000 births)
Cardiovascular	10
Ventricular septal defect	2.5
Atrial septal defect	1
Patent ductus arteriosus	1
Fallot's tetralogy	1
Central nervous system	10
Anencephaly	1
Hydrocephalus	1
Microcephaly	1
Lumbosacral spina bifida	2
Gastrointestinal	4
Cleft lip/palate	1.5
Diaphragmatic hernia	0.5
Esophageal atresia	0.3
Imperforate anus	0.2
Limb	2
Transverse amputation	0.2
Urogenital	4
Bilateral renal agenesis	2
Polycystic kidneys (infantile)	0.02
Bladder extrophy	0.03

A 'malformation' can be defined as an anomaly which is caused by an intrinsic failure in the normal development of an organ. Common examples would be congenital heart disease, cleft lip and palate, and neural tube defects.

A 'dysplasia' is an abnormal organization of cells in a tissue, often specific to a particular tissue. For example, achondroplasia is a skeletal dysplasia caused by a mutation in the FGFR3 gene. Most dysplasias are single-gene disorders.

A 'sequence' can be defined as a group of anomalies which arise due to one single event. An example would be Potter's sequence. Potter's sequence (Fig. 19.15) is the group of anomalies consisting of pulmonary hypoplasia, oligohydramnios, talipes, cleft palate, and hypertelorism. All of these anomalies arise as a result of the failure of urine production in the fetus. The cause of Potter's syndrome and failure of urine production could be posterior urethral valves, dysplastic or cystic kidneys, or renal agenesis, all of which can have genetic, non-genetic, or chromosomal origins. Pierre Robin sequence is the grouping of cleft palate, micrognathia, and glossoptosis, which can have at least 30 different causes. A sequence therefore does not have a specific cause or inheritance pattern.

An 'association' can be defined as a clustering of anomalies, which is not a sequence, and which occurs more frequently than by chance, but has no prior assumption about causation. A good example is the association of VATER (vertebral anomalies, anal abnormalities, tracheo-esophageal fistula, and radial or renal anomalies). There is no clear cause for VATER, although it can rarely occur in people with chromosome 22q11 microdeletions, and can also rarely be mimicked by Fanconi's anemia.

A 'syndrome' is a description of a group of symptoms and signs, and a pattern of anomalies, where there is often a

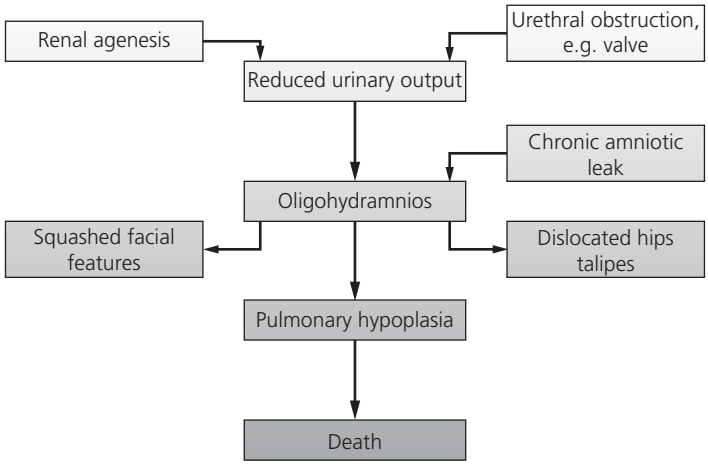

Figure 19.15 Potter's sequence.

known cause or an assumption about causation. The looser definition of 'syndrome' to describe an anomaly should be avoided. The term can include chromosomal disorders such as Down syndrome, or single-gene disorders such as van der Woude syndrome, which can cause cleft lip and palate with lower lip pits.

An approach to diagnosis

When a child is born with a congenital anomaly, several particular aspects of the history need to be explored. A good family history must be taken, with reference not only to a history of the same anomaly, but other anomalies as well. A family history must include documentation of pregnancy losses, stillbirths, and neonatal deaths. Any history of potential teratogens in the pregnancy should be looked for, considering the likely embryological timing of the anomaly. Teratogens can include medications, recreational drugs, maternal diabetes, and prolonged maternal hyperthermia.

If a child has one congenital anomaly, a very careful examination should be carried out to check for any other more subtle abnormalities or for dysmorphic facial features, e.g. to check for hydrocephalus in an infant with a spinal meningomyelocele. If there is more than one malformation or significant dysmorphology, a chromosomal analysis should be requested, as chromosomal aneuploidy is a well-recognized cause of multiple malformations. A clinical genetic opinion should also be sought, as a clinical geneticist can often help greatly in achieving a diagnosis, as well as in counseling parents about the likelihood of recurrence of similar problems in other family members.

A diagnostic approach to congenital anomalies is outlined in Figure 19.16. Deformations and disruptions need to be excluded first. If the pattern of malformations fits into a well-described sequence, then a cause for that sequence should be sought. If the anomalies do not fit into a sequence, then a syndrome or association diagnosis should be attempted. If a syndrome diagnosis is achieved, it is important to remember that syndromes can be caused by chromosomal disorders, single-gene (monogenic) disorders, or by environmental agents (teratogens).

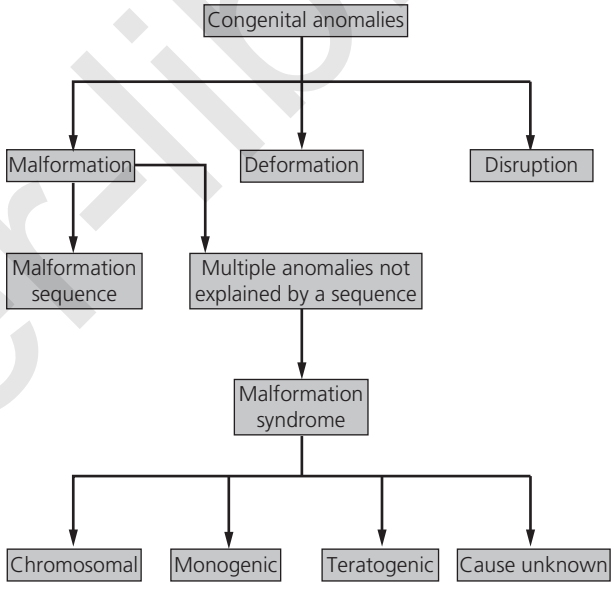

Figure 19.16 A diagnostic approach to congenital anomalies.

Table 19.6 Causes of congenital anomalies.

Type	Relative frequency (%)
Genetic	
Chromosomal	6
Single gene	7.5
Multifactorial/polygenic	20–30
Environmental	
Drugs, infections, maternal illness	5–10
Unknown	50
Total	100

The majority of congenital anomalies have a polygenic or multifactorial origin, and most are isolated (non-syndromal). The causes of congenital abnormalities are outlined in Table 19.6, and it is important to note that about 50% do not have a clear cause. Nonetheless, parents and families want

an explanation as to the origin of their child's anomaly, and it is therefore worthwhile to pursue a diagnosis wherever possible.

This chapter is an introduction to the concepts and principles of genetics in neonatal surgical practice. It is not intended to be a comprehensive review of syndromes. Further information can be obtained from the bibliography later, and from many Internet sources.

GLOSSARY

3-prime Distal end of a gene, as indicated by the bond at the 3rd hydroxyl group of the deoxyribose sugar

5-prime Proximal end of a gene, as indicated by the bond at the 3rd hydroxyl group of the deoxyribose sugar

Acrocentric A chromosome with effectively only a long arm – chromosomes 13,14,15,21, and 22

Allele A genetic variation of a gene or DNA marker

Aneuploidy An excess or deficiency of chromosomal material

Anti-codon An element of transfer RNA which binds a specific amino acid

Autosomal dominant Inheritance pattern characterized by transmission through several generations, male-to-male transmission, and a 50:50 risk to the children of any affected person.

Autosomal recessive Inheritance pattern characterized by several affected members of the same generation, with carrier parents and a 1:4 recurrence risk where both parents are carriers

Base pair Unit of double-stranded DNA

Centromere Element of chromosome involved in chromosome replication, found as a constriction in the chromosome

Chromatid Condensed chromosome found just before mitosis

Codon Three base pair element of DNA encoding an amino acid

Diploid A complement of two copies of each chromosome per cell

DNA marker A piece of DNA corresponding to a specific gene or chromosomal segment

Enhancers Elements of DNA which are involved in increasing gene transcription

Exon A part of a gene which is transcribed into mRNA

Expression The way in which a gene fault manifests clinically

FISH Fluorescent *in situ* hybridization – a new and powerful technique for studying specific chromosomes or regions of chromosomes

Gamete A germ cell – sperm or oocyte

Genetic imprinting The marking of a gene according to which parent has passed the gene to its child

Haploid A complement of one copy of each chromosome per cell (as in sperm or oocyte)

Haplotype A pattern of alleles of DNA markers representing one of the two copies of a chromosomal region

Histone A DNA-binding protein important in chromosomal folding

Interphase Phase of mitosis in which the chromosomes are very elongated

Intron The part of a gene between the exons which is not transcribed into mRNA

Isochromosome An abnormal chromosome made up of two long or two short arms of a normal chromosome

Karyotype An analysis of the chromosome complement of a cell type

Linkage analysis The use of polymorphic DNA markers to perform gene tracking studies within a family

Meiosis The process of cell division to give haploid germ cells

Metaphase Phase of mitosis in which the chromosomes are very condensed and easier to analyze

Microsatellite marker A DNA marker which detects variation in number of an anonymous small repetitive element of DNA

Minisatellite marker A DNA marker which detects variation in number of an anonymous medium repetitive element of DNA

Mitosis The normal process of cell division to give two diploid copies of a cell

Non-dysjunction A failure of meiosis, giving two copies of a chromosome in one gamete, and no copy of a chromosome in the other gamete

Nucleosome The combination of a histone and its bound DNA

Oligonucleotide primers Small lengths of synthetic single-stranded DNA of a specific sequence

Paracentric inversion A rearrangement of chromosomal material within one arm of a chromosome

PCR Polymerase chain reaction – a method of generating large amounts of specific DNA from a small amount of target sequence

Penetrance The number of people known to carry a gene mutation who manifest the condition

Pericentric inversion A rearrangement of chromosomal material around the centromere of a chromosome

Promoter Element of a gene which is necessary to activate gene transcription

Prophase Phase of the cell cycle where condensation of the chromosomes occurs, just before metaphase

Reciprocal translocation Exchange of chromosomal segments between different chromosomes

Restriction enzyme An enzyme which cuts double-stranded DNA at a specific unique short DNA sequence

Restriction fragment length polymorphism A genetic variation between two copies of the same gene, where one gene may have one copy of a restriction enzyme recognition site, and the other has two copies. This variation can be detected using PCR or Southern blotting

Ribosome Area of the cell where mRNA is converted into protein

Ring chromosome An abnormal chromosome in which the tips of the long and short arms have fused

Robertsonian translocation A fusion of two acrocentric chromosomes

Southern blotting A process of immobilizing DNA to nylon membrane for genetic analysis

Suppressor A DNA element which reduces the expression of a gene

Telophase The last phase of mitosis

Telomere The end of a chromosome

Transcription The process of converting DNA into mRNA

Translation The production of protein from a DNA sequence

Triploidy Three of each chromosome, i.e. 69 chromosomes in man

Trisomy One extra chromosome, i.e. 47 chromosomes in man

X-linked recessive Inheritance characterized by affected males in several generations, and by female carriers

Ethical considerations in newborn surgery

JACQUELINE J GLOVER AND DONNA A CANIANO

INTRODUCTION

In caring for the extremely premature neonate with surgical disease or the infant with multiple, life-threatening congenital anomalies, pediatric surgeons often encounter difficult ethical decisions about the use of advanced, life-sustaining treatments and operative interventions. The imperative to utilize new technology is tempered with concerns about quality of life, informed parental decision making, and access to scarce medical resources. Pediatric surgeons, families, and communities ask the difficult ethical question: 'We can do this particular intervention, but, should we?' This chapter provides the pediatric surgeon with ethical guidelines to utilize in clinical situations in which therapeutic decisions contain uncertainty or conflict and the next steps in the management of an infant that pose challenges for the parents and physicians.

DEFINING THE BEST INTERESTS STANDARD

Since neonates and infants cannot make decisions about the appropriate use of technology based on their own personal values, the central ethical question is framed in pediatrics as, 'What is in the best interests of this infant?' An answer requires a unique and complex ethical framework that combines a concern for who makes the decision and what decision is appropriate.

In the United States, parents are presumed to be the appropriate decision makers for their infants,[1] but they are not unqualified decision makers. Parents and pediatric surgeons must work together to make decisions that are in the 'best interests' of infants.[2,3] The term 'best interests' is meant to capture a balancing of the benefits and burdens to this infant of a particular intervention.[4]

In the mainstream medical culture in the US, the term 'best interests' was developed to focus attention on the need to assess the benefits and burdens of treatment for a particular infant from the infant's perspective. In an effort to be as objective as possible, only the direct pain and suffering associated with an infant's condition and/or proposed treatment was to be considered in conjunction with the benefit of continued life. The standard was proposed as a very strict one, regarding treatment as beneficial and in the infant's best interest unless the infant was dying, the treatment was medically contraindicated, or continued life would be worse for the infant than an early death. A central feature of this narrow understanding of best interests includes its child-centeredness, understood to mean the exclusion from consideration of the negative effects of an impaired infant's life on other persons, including parents, siblings, and society.

A second key feature is its emphasis on the infant's concrete experience of burden in the form of pain and suffering. In addition to the difficulties associated with assessing the burdens experienced by an infant, a narrow best interests standard cannot be applied to neonates and infants with neurological deficits so severe as to exclude the possibility of experience of any sort. Infants who are not responsive to outside stimuli, for example, cannot experience pain and therefore cannot be burdened in the same way as conscious infants.

Some ethicists have appropriately pointed out that absence of pain is not the only morally relevant feature.[5] A 'relational potential' standard is necessary to augment a best interests standard. It is not morally obligatory to sustain life without any capacity for human relationship, even though life is not burdensome per se. Just as the presence of pain unable to be relieved can preclude the attainment of those basic human goods that make life worth living, so the absence of fundamental human capacity can render a life devoid of the same basic human goods.[6]

For the last few decades, the best interests standard has enjoyed prominence in pediatric ethics in the US, although its limitations have also been clearly articulated. Critics argue that an infant's interests are unknowable, that an interests appeal can yield counterintuitive results, and others' interests also deserve consideration.[7] For those who favor a best interests standard, it is a way to focus attention on the patient as the primary loyalty of the health care professional, to

maximize benefit to the patient,[8] to insure that the lives of the disabled are not undervalued, and to guarantee that justice in the form of principles of nondiscrimination are applied.[5] However, reliance on a narrow best interests standard fails to take into account other moral features that are a necessary part of ethical decision making in pediatrics. The term has been used to oversimplify a distressingly complex set of moral problems. The more one can render an ethical decision unidimensional, and the more factors one can exclude from consideration beforehand, the easier the choice becomes.[6]

An expanded understanding of best interests must take into consideration several competing ethical values. One value is respect for family autonomy or self-determination. Families ought to have the freedom to make important choices about family welfare independent of others. It is not so much that families have a right to make important decisions for their infants, as it is that families have the responsibility to make decisions and provide the necessary financial and other types of support. Families are an essential unit of care that are both valuable in themselves, and instrumentally valuable to meet the social goal of caring for children. Since families are presumed to love their children and desire to do what is best for them, they have a unique claim to the decision-making role. Also, families have to live with the consequences of the health care decisions that are made.[9]

In a very real sense, the families interests are linked with the interests of the neonate or infant.[10] An attempt to starkly separate infant and family interests is artificial and diminishes rather than enhances an understanding of the infant's well-being. One can understand how the best interests standard developed in the context of imperiled newborns, where there is great uncertainty and no one has a longstanding relationship with the infant. The objectivity sought is comprehensible only because the infant is a stranger to all. Yet even in the case of newborns, most authors agree that parents should be the primary decision makers.[11] If family interests were irrelevant, it would be difficult to make sense of such a presumption. Given this presumption in favor of parental decision making, and the fact that most infants are not strangers to their parents, a best interests standard would be better understood to include a more comprehensive understanding of a child-centered decision, one made by a family whose daily lives involve the love and care of their infant.

Additionally, the search for the 'best' interests of the infant apart from the family has several negative consequences. First of all, it can antagonize parents and turn all parties into adversaries. It can also cut off discussion and planning rather than improve it. Families may not feel free to discuss difficulties, and important needs may go unmet. Rather than search for some artificial 'best' interest, all parties should acknowledge the complex goal of promoting the infant's well-being and the necessary interdependence of families in that endeavor. To exclude the family in a concept of child-centeredness is to reduce the infant to only a physiological organism and well-being to pathophysiological function.

Another value that is in tension with respect for family decision making is respect for professional integrity. Since 'best interests' also contains an important focus on the uniquely medical interests of the infant, professional judgment plays an important role in describing and evaluating the benefits and burdens of health care interventions.[12] Pediatric surgeons have independent obligations to the infants who are their patients, to promote their well-being and protect them from harm. They have a professional obligation to promote life and quality of life, and to avoid such harms as killing, premature death, pain and suffering. Yet even based on so-called medical facts, decisions are a complex amalgam of what the infant's alternative futures will be like, how likely it is that these futures can be gained, and what the infant has to endure to get there. An infant's present interests in being free from undue burdens must be weighed against all future interests.[13]

A third important value is that of justice as nondiscrimination.[5] How do we understand the interests of a child in himself or herself, independent of how others may value him or her? What does society owe its children as a matter of justice? Infants do not only belong to their families, but they also are members of their community. Communities have an obligation to protect the most vulnerable among them, especially if they are vulnerable to the neglect and abuse of their families. All infants deserve a certain level of health care, independent of what their families might choose for them.

The principle of justice also has another important component that is in direct conflict with the highly individualistic interpretation of 'best interests'. In fact, a 'best interests' standard is an attempt to narrowly focus decisions on the patient him/herself and to avoid greater issues of the just distribution of health care resources, but this is impossible. Families and communities struggle to consider what they owe each child, but also to consider what is fair for this child and all children together. Resources of time, effort, services, and money are limited within families and communities. Each must consider the impact of choices on the availability of resources for others. There is no doubt that questions of distributive justice are among the most difficult ethical issues that families, professionals, and communities must face, but they will never be resolved if they are simply ignored in the decision-making process. The authors agree that allocation decisions are best made at levels other than at the bedside, as in the formulation of insurance plans and governmental policies, but these corporate allocation decisions will always have implications for bedside care, and must not be ignored.

An expanded 'best interests' standard is an attempt to balance the benefits and burdens of a health care intervention according to the values of the parents, pediatric surgeons, and the larger society. It should be clear that the model described represents its application in the dominant medical culture in the US. First, other cultures and countries may have a different understanding of what constitutes family and necessarily include others besides parents. Perhaps others, such as family elders, are the persons designated as decision makers. Second, this particular model is based on Western notions of the importance of informed consent and respect for the autonomy (self-determination) of the patient, and the family in the case of pediatrics. In other cultures and countries, families may not see their role as decision makers at all, but only in terms of doing what the doctor orders. Also, other cultures

and countries may emphasize other core values such as responsibility to the larger family and community rather than autonomy (self-determination). Finally, the model described presumes a certain access to technology that is primarily available in developed nations. A concern for quality of life is different in developed nations where the issue may be the result of technology that is able to save life of diminished quality, as opposed to developing nations where diminished quality of life may be primarily a consequence of inadequate access to basic health care services.

APPLYING THE BEST INTERESTS STANDARD

How does the best interests standard work in practice? It must be remembered that the term is just a place holder for a complex structure of values that must themselves be interpreted and applied. It is not possible to use the label 'best interests' and expect it to do the moral work for us. It is always necessary to discuss the particular benefits and burdens of an intervention, according to the evaluations of all the parties involved. No one party has a privileged view of the best interests of the infant.

Consider for example, an infant born with an intestinal atresia. There are no associated anomalies and the infant cannot survive without operative correction. The pediatric surgeon recommends surgery to the parents because surgery would be in the best interests of their infant. The pediatric surgeon means by the use of the term, that the possible benefits to the infant (life, restoration of function, reduction of pain and suffering) outweigh the possible burdens (time in the hospital away from family, risk of death associated with anesthesia, pain and suffering associated with testing and interventions, and risk of compromised function). The calculation of best interests is based on the infant's diagnosis, prognosis, available treatment options, and the likelihood of their success. The anomaly is fatal without intervention, and the surgery is relatively low risk with a high likelihood of success. The pediatric surgeon wishes to preserve professional integrity by fulfilling the ethical obligations to promote the infant's welfare by saving the infant's life and restoring function, and protecting the infant from harm. The pediatric surgeon is acting upon the values of what it means to be a 'good physician'.

Most parents would agree that surgery for an intestinal atresia is in the best interests of their infant. Out of their values to be 'good parents,' they strive to promote their infant's welfare and cope with the burdens placed on their infant and upon themselves. Most parents would agree that the outcome is good (life and restored function), and the surgery has a high likelihood of success with minimum burden (surgery, recovery time, and associated costs). Parents who refused such surgery in the US would most likely be accused of medical neglect, and the power of the state would most likely be used to insure that the infant received the necessary care.

In other situations, a pediatric surgeon and parents may agree that stopping life-sustaining treatment would be in the best interests of a particular infant. For example, consider the case of a 23-week-old infant weighing 600 g who develops necrotizing enterocolitis (NEC). Following an operation that leaves 15 cm of jejunoileum, the infant develops a grade IV intraventricular hemorrhage, worsening lung disease, renal failure, and ongoing sepsis. In this case, the mortality rate of the condition is very high, and the infant's quality of life is affected by the associated neurological, renal, and pulmonary complications. A pediatric surgeon and parents would be justified in withdrawing life support and instituting comfort care for this infant. It could be argued that it would be inappropriate to subject this already vulnerable infant, with little or no potential to interact with the environment, to the substantial burdens of life-sustaining technology for devastating bowel disease and compromised pulmonary and renal function. None of the treatments for devastating bowel disease, such as further surgery, the use of total parenteral nutrition (TPN), or a bowel transplant, would improve the infant's neurological condition. With little or no opportunity to experience things such as pleasure or comfort that we regard as benefits, inflicting pain or separation from family could be viewed as disproportionally burdensome or not necessary according to a relational potential standard.

Although most health care professionals and parents would agree that further interventions are not in this infant's best interests, some parents would disagree and insist that 'everything possible be done'. In the US, it is a very difficult matter both ethically and legally to stop life-sustaining treatment over the objections of the parents.[14] Conflict resolution depends on a trusting relationship between the pediatric surgeon and the family. The family must be able to trust the pediatric surgeon so that they can rely on the pediatric surgeon's judgment. This trust begins with the pediatric surgeon's honesty: the commitment to disclose all relevant information, to insure that families understand what is being said and to respond to the questions and concerns of the family. Pediatric surgeons must also be compassionate, feeling for the infant and with the family as they endure this critical illness. The family needs to know not only that the pediatric surgeon cares for and about them and their infant, but that the pediatric surgeon will not abandon them on this difficult journey. It is vital in these so-called 'futility' cases, to understand just what the family means when they say 'everything possible is being done'. The conflict may be a matter of misunderstanding the diagnosis and prognosis and such false expectations can be often corrected with open, ongoing communication. However, sometimes there is a real conflict between the values of the pediatric surgeon, the entire neonatal healthcare team, and the values of the family.[14–17]

Because families may differ in how they make value judgments about what constitutes an acceptable quality of life for their infants, it is essential to be able to elicit information about values and preferences from families. The authors have found the following questions useful. The questions are intended as subject guides only; each clinician must translate the questions into his or her own style:

1. What is your understanding of your baby's current condition?
2. How has your baby's illness affected your family?

3. What is most important in the care of your baby?
4. What do you fear the most? What would you like to avoid?
5. What are your family's sources of strength and support?

GUIDELINES FOR ETHICAL DECISION MAKING

Ethical dilemmas most often arise when parents and pediatric surgeons disagree about what constitutes an acceptable quality of life or what constitutes the best interest of the infant. Whose judgment should prevail?

Pediatric surgeons can help insure that their ethical judgments are reliable through the application of an organized process.[18] There are multiple versions available in the ethics literature, but they generally all contain the following components:

1. Identify the decision makers. Are the parents involved? Are there non-parental legal guardians? Do the parents have the capacity to make a decision? Who are the involved clinicians?
2. Gather the relevant medical facts. What is the diagnosis? What is the prognosis? Are additional tests necessary for further clarification? Is there necessary information to be gathered from other clinicians?
3. Solicit value data from all involved parties. Do conflicts exist among the values of the parents, other family members, and the physicians? Has the basis for the conflict been identified?
4. Define the available treatment options. With each option, what is the likelihood of cure or amelioration? What are the risks of an adverse effect? What is a minimum level of professionally acceptable treatment?
5. Evaluate possible treatment options and make a recommendation. Justify your choice according to the values of various parties.
6. Achieve a consensus resolution. Have all parties articulated their viewpoint? Would more factual information help to resolve any disputes? Would a mediator (ethics consultant, ethics committee, or other trusted third party) be helpful?

Most of the time, ethical conflicts between pediatric surgeons and parents can be resolved with further communication, negotiation, and accommodation, but sometimes the conflict is so severe that the pediatric surgeons should consider appealing to an outside resource such as an ethics committee or withdrawing from the case based on conscientious objections.

The threshold is high for involving the courts in a decision about surgery for a neonate or infant. Pediatric surgeons should invoke the power of the state to secure treatment for an infant only when that treatment is universally regarded as beneficial and the appropriate standard of care, making parental refusal equivalent to medical neglect, as in the previously cited case of the infant with an intestinal atresia.[19] The classic case for court intervention involves treatment for a life-threatening condition in which the benefits are substantial and the burdens minimal, such as court-ordered blood transfusions for pediatric patients.[20] Courts are also not the appropriate venue when parents demand treatments that the pediatric surgeon regards as not being in the best interests of the infant. Conflicts are resolved best at the bedside among the parties who know the infant and the circumstances, and those who will live with the consequences of the decision.

BEST INTERESTS AND CLINICAL RESEARCH

The best interest standard with its balancing of benefits and harms for individual patients and their families rests on the assumption of good information about the best proven surgical care in a shared decision-making process. Good information relies on clinical research to validate the best approach, and in the current environment of cost containment, to validate the approach that brings the best outcome with the least costs, including financial costs. There is strong support for a professional and ethical obligation of pediatric surgeons to be involved in clinical research. According to the Committee on Pediatric Research of the American Academy of Pediatrics, all subspecialists, including surgeons, should be encouraged and supported to pursue research activities.[21] The needs of newborns are unique and cannot be extrapolated from other research involving older children and/or adults.

However, there are barriers to participation in research for pediatric surgeons as well as for parents and their newborns. Caniano has noted elsewhere 'that surgery, in contrast to other areas in medicine, has been historically free to develop new operations and treatments without the stringent requirements of animal testing and rigorous, prospective multi-institutional clinical trials in humans. The boundaries are often blurred between an operation that should be evaluated by a clinical trial before it is recommended for general implementation and an operation that is considered to be a refinement of an accepted procedure, and therefore not needing rigorous testing.'[22] Other barriers include a misunderstanding of the meaning of 'equipoise', a concept necessary for the ethical conduct of research.[23] Equipoise requires that the researcher believe that one surgery or treatment is no better or worse than another or even the use of placebo, because there is no evidence supporting one over the other. Surgeons treating critically ill newborns are often in a position of rescue and believe that doing something, even if it is not proven, is better than doing nothing and better than enrolling a newborn in a trial where they may not get the proposed treatment.[24]

Even though there is support for this obligation of pediatric surgeons, and even patients, to be involved in research, there may be great hesitation because of the obvious vulnerability of the family and the infant.[25,26] Researchers struggle to apply the standard of best interests by expanding the evidence base for pediatric practice for future patients on the one hand, while also protecting the vulnerable patients in their care on the other hand. It is quite difficult to obtain parental permission that is informed and voluntary under conditions of duress and within a short therapeutic window.[26]

It is also very difficult to balance the risks and potential benefits of the research itself.[26] Research standards in both the US and Europe state that any child should only be enrolled in research when it is absolutely necessary to answer an important scientific question.[26] An important issue in both the US and Europe involves whether and how pediatric research has to provide benefit to the participating children. In the US, children can be involved in research that offers no direct benefit, but only if the risks of participation are minimal. Children may also participate in research that involves a minor increase over minimal risk, but only if there is a reasonable expectation of future benefit to those with the same condition.[27] Research guidelines from the Ethics Working Group of the Confederation of European Specialists in Paediatrics (CESP) state that 'Children should not be involved in research that serves only scientific interests and does not provide any benefit to them.'[28] In a discussion of the ethical principles and legal requirements for pediatric research in the EU, Pinxten and colleagues state, '... the principle of beneficence requires that biomedical interventions contribute to the welfare of these persons (in research). This can be achieved in two ways. First, biomedical interventions can generate benefits in the research subjects themselves. Second, the drawbacks of biomedical interventions can be balanced with a newly generated benefit, either directly to the minor research subject or to another beneficiary.'[29] A requirement for direct benefit has serious implications for the selection of control groups and research designs that include a placebo. For the regulations in the US, determining what counts as minimal risk, or a minor increase over minimal risk, is very complex.[30] If protecting children in research is not to be translated into excluding children from research, special protections must be put in place.

In general, what are the requirements for ethical research? Emanuel and colleagues have proposed seven requirements for determining whether a research trail is ethical.[31]

1. Social or scientific value
2. Scientific validity
3. Fair subject selection
4. Favorable risk-benefit ratio
5. Independent review
6. Informed consent
7. Respect for potential and enrolled subjects.

Because of the special vulnerabilities of children, and especially newborns, three procedures have been proposed to improve protection of pediatric research participants.[27]

1. Pediatric data and safety monitoring committees
2. Robust assent processes
3. Decision monitoring that could verify the 'informed' nature of the consent.

A final issue for consideration is what special protections should be in place for research in developing countries, as an increasing amount of research is, in fact, multinational. Emanuel and colleagues have proposed an eighth principle – Collaborative Partnership – to be added to the seven requirements listed above.[32] This principle emphasizes the need to develop partnerships among researchers, makers of health policies, and communities. It recognizes the importance of respecting the community's values, culture, traditions, and social practices, and, perhaps most importantly, this principle seeks to ensure that the recruited participants and communities receive benefits from the conduct and results of the research. Raising the issue of research in developing countries also raises the more general question of the role of culture in decision making in practice, as well as in research.

ROLE OF CULTURE IN DECISION MAKING

The ethical concept of best interests that has been articulated is largely dependent upon the authors' own experiences in the medical culture in the US. Some of the most difficult ethical issues that the authors have personally faced involve a conflict between this Western medical notion of best interests and families making decisions for their infants from other cultures. The following case illustrates how culture may affect parental decisions and the patient–physician relationship.

Case study

MS is a 25-day-old infant born at 26 weeks' gestation, weighing 650 g. He was stable on 50% oxygen and minimal ventilatory settings. He was on continuous feedings using a premature formula. At 25 days of age the infant developed acute abdominal distention, intolerance to feedings, and bloody stools. Urgent consultation with the pediatric surgeon was requested. A radiograph showed diffuse pneumatosis. He was mottled, acidotic, and hypotensive. His laboratory values showed a white blood cell count of 2000, hemoglobin of 7 g/dL, and a platelet count of 6000. He received packed red cells and platelets. Blood cultures were drawn and he was started on triple antibiotics. The parents agreed to bedside peritoneal drainage. After 12 hours, MS remained clinically unstable and the pediatric surgeon advised laparotomy. The parents refused the operation.

MS's parents are from Nigeria and are in the US on student visas. They have two other healthy children, aged three and five. They plan to return to their native country in six months. Both parents visit daily and are concerned about their son. Both the father and mother speak English, but the father's English is slightly better than the mother's. Sometimes the father has to translate information for the mother and translate the mother's statements for the doctors. They ask appropriate questions and seem to understand their son's medical condition, prognosis, and alternatives for treatment. They desire that their son live, but are strongly opposed to TPN, especially since this technology is not available in their village in Nigeria.

They acknowledge that MS is gravely ill and are accepting of his probable death. They say that they agreed to the use of all the previous medical technology because they thought it would save their son's life, but a life dependent on medical

technology is too burdensome. They were expecting that their son would be able to live normally once he got out of the hospital. The parents explain that they have a strong faith in God, and God will decide if their son lives or dies and they will accept whatever happens. They believe that it is not in their power to alter God's will by the continued use of technology to support a life 'that was not meant to be' and that if the boy is not able to eat like a normal infant, then it is better that he go to God. They are supported in this belief by their Nigerian minister and congregation. They have clearly stated their intention to return to Nigeria where life-sustaining technology, such as TPN and specialized nutritional formulas, are unavailable. In addition, they will not have access to pediatric specialists when they return to their native country, and worry about how they will secure medical and surgical care for an infant with a poorly functioning intestine and other chronic disabilities. What should the pediatric surgeon do?

Some may be tempted to resolve this conflict in a very legalistic fashion dependent on Western notions of medical neglect and their attendant professional obligations to turn to the courts for proper resolution. Simply stated, 'You are in the USA – our cultural norms get to override your cultural norms.' In that sense, this case is no different from any other case that raises the issue of the limits of parental discretion in medical decision making. A narrow best interests standard would seem to require overriding the parents' decision and forcing the operation. According to informed medical judgment, the infant will most likely die without the surgery, while there is a reasonable probability that the infant's life can be saved by resection of the diseased bowel. To say that the infant is better off dead is to substantially undervalue the lives of persons with disabilities, including this infant. Some would argue that this case is similar to the case of the infant with an imperforate anus or an infant needing a blood transfusion. To allow this family to choose non-treatment would violate the principle of justice as nondiscrimination.

However, there is something particularly compelling about such cases that call participants to value and respect cultural differences. Both the parents and pediatric surgeons are struggling to fulfill their role-specific obligations to be good parents and good physicians, but they literally see their roles quite differently. It is culture that provides the 'lens' for each of us to view the world. One definition of culture states:

> Culture is a set of guidelines (both explicit and implicit) which individuals inherit as members of a particular society, and which tells them how to view the world, how to experience it emotionally, and how to behave in it in relation to other people, to supernatural forces or gods, and to the natural environment. It also provides them with a way of transmitting symbols, language, art, and ritual. To some extent, culture can be seen as an inherited 'lens', through which individuals perceive and understand the world that they inhabit, and learn how to live within it. Growing up within any society is a form of enculturation, whereby the individual slowly acquires the cultural 'lens' of that society. Without such a shared perception of the world, both the cohesion and the continuity of any human group would be impossible.[33]

It seems obvious from this definition that there is no way to talk about best interests from outside a cultural perspective. All of our discussion, then, is in some sense cross-cultural. The narrow explication of best interests represents the perspective of the US, and perhaps predominantly the powerful status of its medical and legal culture.

A Nigerian anthropologist commenting on this case might point out that the US has several unique cultural features. People in the US tend to think that there is nothing worse than death – at least for a child or young person. Children are to be viewed as little adults – as individuals first and then only secondarily as members of a family or community, essentially independent of their families rather than dependent. Their right to grow up and to ultimately make their own choices is primary. US culture is very action oriented: when in doubt – act. The US is also obsessed by the development and perceived power of technology. Technology and knowledge are primary goods.

However, the central question is not really whether or not we have a cultural perspective, but whether we can judge some perspectives as better than others. This raises the difficult ethical question of cultural relativity. Cultural relativity refers to the following claims: (1) all moral judgments are relative to the culture in which they arise; (2) moral judgments across cultures are significantly different; and (3) there is no way to rank moral judgments across cultures.[34]

The well-respected physician–ethicist, Edmund Pellegrino, accepts that culture is essential in the context of medical and ethical decisions, but that there are also features of human beings as human beings according to which we can judge among cultures.[35] It can be argued that there are some universal features that all cultures either should or would accept. An example would be that moral communities must allow democratic processes and cannot be oppressive.[36] The philosopher, Sara Ruddick, identifies three universal maternal interests that are applicable regardless of the particular form they take in a culture. These maternal interests include: (1) preservation; (2) growth; and (3) acceptability.[37] Other ethicists identify universal moral principles that underlie our commitments to be tolerant of cultural diversity.[38,39] Without some principle of respect for persons, for example, there would be no reason to prefer tolerance of cultural differences.

A cultural perspective is particularly important to ethical theorists, who support the inclusion of context and relationship in an ethical analysis, and to those of us working in clinical settings. As Carl Elliot writes:

> Ethical concepts are tied to a society's customs, manners, tradition, institutions – all of the concepts that structure and inform the ways in which a member of that society deals with the world. When we forget this, we are in danger of leaving this world of genuine moral experience for the world of moral fiction – a simplified, hypothetical creation less suited for practical difficulties than for intellectual convenience.[40]

The authors wish to support an ethical analysis that includes culture as an important feature, but also acknowledges

the role of the application of universal ethical principles. Like Pellegrino, the authors accept that there are some ethical principles that apply to all humans based on their humanity. Culture is necessary to understand what these principles mean and how they are applied with respect to each of the parties in the conflict. It is possible to be respectful of cultural differences and at the same time acknowledge that there are limits. What remains critical is the perceived degree of harm; some cultural practices may constitute violations of fundamental human rights.[41] It is useful to return to the above case and apply the process for ethical decision making, with special attention to its cross-cultural features.

The ethical question in this case is: what should the pediatric surgeon do for MS? What role should culture play in the deliberations?

The family in this case clearly value their son's life and his quality of life. They also value the impact of this infant's life on their other children, the life of the family as a whole, and their plans to return to their native country. They accepted the initial use of technology in the care of their premature son, in the hope that it would deliver a 'normal' infant, free of future dependence on medical technology. They are clear that for them, in a cultural and religious sense, a life dependent on TPN, specialized nutritional feedings, and the prospect of bowel transplantation is unacceptable.

For the pediatric surgeon and the other members of the health care team, the preservation of this infant's life is a goal, but the quality of his life is also a consideration. The laparotomy will allow the pediatric surgeon to assess the severity of the NEC, the amount of diseased bowel, and the prognosis for MS to have functional intestine without the need for prolonged TPN.

There are basically three options available in this situation. First, the pediatric surgeon can go forward with all the care that it takes to save this infant's life. This would include surgery, the use of TPN for as long as necessary, and all efforts to preserve the life of MS, including the possibility for bowel transplantation. This would more than likely include going to court to force the parents to consent to the operation and having a guardian appointed to make medical decisions for MS. This option could result in the permanent loss of parental rights and placement of the infant in the care of the state. In the second option, the pediatric surgeon performs the operation in the hope that there is sufficient residual bowel without the need for long-term TPN and bowel transplantation. If there were clearly not enough viable bowel, MS would be provided with comfort care and allowed to die. If there were sufficient residual bowel, care would proceed as appropriate. A difficulty arises if there is a questionable amount of bowel and a trial of TPN would seem to be appropriate. The pediatric surgeon could resect the diseased bowel and proceed with a trial of TPN, discontinuing the use of TPN when it is clear that the bowel is not going to function normally. The third option is not to perform the operation. The infant could be maintained on current levels of support to see whether his bowel will heal on its own, or a comfort care plan could be initiated that would allow the infant to die sooner rather than prolonging the dying process.

The authors think that the first option is outside the range of moral justification and should not be recommended. The infant is critically ill with a disease that carries high rates of mortality and morbidity. Non-treatment for MS does not rise to the standard of medical neglect. The strongest argument for insisting on treatment rests on the claim that this infant is a member of the community, not only a member of his family. If families will not or cannot take proper care of their children, then we will step in to do so, but who is this 'we'? If there is no such community support, or insofar as the broader community fails in this responsibility, then the community's claim on the family's choice is diminished.

In this case, the Nigerian community (here or in Nigeria) does not make demands on the parents' choice. They do not see themselves as able, or obligated, to provide these services to MS. But in what sense is MS and his family a member of the US community? An argument can be made that they are community members by virtue of their residence, yet they are planning to return to Nigeria. The argument that treatment must be forced because of community obligations seems diminished by their departure. We will not be around to provide the support we claim is necessary, but will we provide the necessary support even if they stay? Is it possible for them to stay? Our community claims also seem diminished insofar as the family's student visa is not renewed, or access to health and social services is limited based on their foreign status. To claim that we are discharging our community obligations only by saving the child's life, seems to greatly distort the notion of community.

A final consideration needs to be mentioned. Couldn't we discharge our community responsibility by keeping the child here and placing him up for adoption? Then he certainly would become a full member of our community and the concerns raised earlier would no longer apply. Such an action could clearly state that we believe the only appropriate parental choice is to try and save the infant's life. To choose anything else is to act as bad parents who should be replaced. Yet are they really bad parents? Such a judgment clearly raises serious concerns about cultural norms of parenting, and fails to take culture into consideration. From the parent's cultural perspective, good parents would not choose surgery and neither would good physicians. This is not standard of care in Nigeria.

How should culture figure into the deliberations of the pediatric surgeon? It obviously cannot simply be ignored in a grand act of medical and parental imperialism. Also, we should not pay lip service to cultural perspectives, accepting the unusual and exotic only when it also fits into our own value framework. For example, this family could make the choice based on their cultural values only if there were a much higher mortality rate associated with the infant's condition. Finally, respect for different cultures cannot simply be some kind of ultimate trump. Automatically deferring to any choices based on cultural differences is to ignore the central values of our own culture. Ironically, it would be a violation of respect for cultural diversity in that our own cultural values are ignored. An attempt at negotiation and compromise is to be preferred.

The authors think that the pediatric surgeon should recommend surgery under the second scenario, saving the

infant if possible, letting the infant die if appropriate, and negotiating a trial of TPN if necessary. But if this is not acceptable to the parents, the pediatric surgeon should respect the parents' decision not to have surgery and proceed with a plan of care aimed at keeping the infant comfortable until he either improves or dies. A decision by a pediatric surgeon to conscientiously withdraw from this patient's care out of concern for his or her own central values should be respected.

The second option is supported by the health care professionals' and the family's values. Surgery could save the infant's life, which all parties value, but it would do so under conditions of a quality of life that are acceptable to the family. Some health care professionals may have problems with this option if a trial of TPN is necessary. It is difficult to establish how long a trial of TPN should last. This difficult negotiation must consider what is medically feasible and also acceptable to the family. Also, many believe that there is a distinction between decisions not to start treatments (withholding) and decisions to stop treatments (withdrawing). Although this distinction is psychologically powerful, it is not ethically or legally valid in the US.[41] If health care professionals and parents have sufficient justification based on the balance of benefits and burdens not to start a treatment, then they have the same justification to stop a treatment once begun. There is a hidden danger in maintaining this distinction between not starting and stopping medical and surgical treatments. Sometimes trials of therapy are not initiated when they are appropriate out of fear that the therapy cannot be stopped once it has begun.

Others argue that the provision of nutrition and hydration is different than other medical interventions, such as ventilators and dialysis, which are 'extraordinary' and ethically can be withheld or withdrawn. According to this view, the provision of nutrition and hydration is ordinary and is always morally required. The attempt to classify categories of interventions independent of their application to the care of an individual patient is misguided. So-called 'ordinary' treatments, such as antibiotics and the medical provision of hydration and nutrition, can be disproportionally burdensome to certain infants and may be ethically forgone (withheld or withdrawn).[42,43] Many physicians and parents have particular values around the importance of feeding, regarding feeding tubes and TPN as morally equivalent to bottle or breast feeding an infant or to sharing a meal. Yet the provision of TPN is not readily comparable to feeding an infant or to a shared family meal. There are important differences. When hydration and nutrition are provided through medical means, they must be assessed according to the same principles used to evaluate any medical intervention. Decisions must be based on a careful evaluation of the proportionality of the possible benefits and burdens. For this family, TPN is not only burdensome because of the risk of frequent infections and the likelihood of progressive liver disease, but because of what feeding through technology means in their culture, and the financial and social burdens to the entire family. The health care team in the US cannot allocate this family's scarce resources for them, or for their country of origin.

SUMMARY

The best interests standard is a complex amalgam of the values of pediatric surgeons, families, and broader societies. As health care itself becomes increasingly multicultural and international, the need for cross-cultural ethical dialogue increases. There are no ultimate trump cards, just a genuine need for what one philosopher calls 'communitarian perspectivalism.'[34] Any healthy, growing and self-renewing culture continually subjects itself to self-evaluation and evaluation by others. In this regard, the authors wish to point to the need for greater attention to the value of justice in the provision of health care around the globe. This chapter represents a tendency to look at the developed nations and evaluate the issue of not providing the most that can be done. This is obviously an ethical problem for the rich. What about the bigger ethical problem of not providing the basic minimum to infants everywhere – the ethical problem of not providing what poor parents want for their children and cannot afford? Certainly ethical dialogue needs to include what children around the globe are owed as a matter of justice – of fundamental human rights. Access to global health care resources is a problem that affects all persons. The contribution of the medical marketplace to the disproportionate allocation of health care that exists cannot be ignored. Medicine must take responsibility for the emphasis on expanding new technologies in the market rather than meeting basic public health needs, and the disproportionate burden it may place on the economies of developing nations or nations committed to universal access to health care. A global cross-cultural perspective is essential to help expand the concept of 'best interests' to include a necessary public health focus.

Minimal invasive neonatal surgery

RICHARD KEIJZER, OLIVER J MUENSTERER, AND KEITH E GEORGESON

INTRODUCTION

The first reports on minimal invasive surgery in adults were published by gynecologists and stem from the first half of last century. By then, it was mainly used for diagnostic procedures, due to the limitations in visualization and instrumentation. When chip cameras were introduced in the late 1980s, the surgeon and assistant were able to watch a screen and perform surgery at the same time, instead of holding a telescope and looking through a lens close to the patient. This, and the development of better endosurgical instruments, enabled surgeons to perform a variety of laparoscopic procedures including appendectomies, cholecystectomies, fundoplications, and more advanced operations. However, due to the lack of instruments, endoscopes, and trocars of appropriate size, the acceptance of minimal invasive surgery in the pediatric population in general, let alone in neonates, took longer than in adults. Recently, the development of smaller, shorter, and more durable instruments along with improved optical equipment has allowed pediatric surgeons to perform more complex endosurgical procedures in young children and newborns.[1]

This chapter reviews the current practice of minimal invasive neonatal surgery and reflects upon potential future developments in this field.

THORACOSCOPY

The first experience with thoracoscopic procedures in children was published 30 years ago.[2] Biopsies of pulmonary lesions, both primary and metastatic in origin, are the most frequently performed thoracoscopic surgical procedure in children (reviewed in Ref. 3). However, with the advancement of experience and, again, better equipment, more sophisticated procedures such as pulmonary resections and the repair of esophageal atresia with or without tracheoesophageal fistula have been embraced by the pediatric surgical community. Compared to open thoracotomy, the potential advantages of a thoracoscopic approach are the muscle-sparing nature of the procedure, decreased risk of nerve injury, and less secondary scoliosis in the long term.[4]

Physiology and anesthetic considerations

The introduction of automatic carbon dioxide (CO_2) insufflation in the early 1960s created the necessary working domain during endoscopic surgical procedures. In most thoracoscopic cases, gentle insufflation of CO_2 to a maximum pressure of 4–5 mmHg using a low flow of 1 L/min compresses the lung enough to grant access to most structures in the chest. Single-lung ventilation, which is more easily established and used in adult thoracoscopy, is rarely necessary in young children and neonates. In neonates, methods for single lung ventilation are very limited, since the smallest size double-lumen tube available cannot be used in children under 30 kg. In those cases where single lung ventilation is desired, a small Fogarty catheter has been placed into the ipsilateral main stem bronchus and gently inflated, blocking gas exchange to that lung.[5] Excellent communication between the surgeon and anesthetist is mandatory, as the establishment of an artificial capnothorax may change physiologic parameters. If anticipated, a higher endtidal CO_2 can be overcome by increasing the ventilatory rate, and decreased venous return can be counteracted by appropriate volume replacement.[6] Although described in adults, the development of CO_2 embolism is extremely rare in the pediatric population.

Diagnostic thoracoscopy and biopsy or resection of pulmonary lesions

Improvement in the resolution of diagnostic imaging techniques, such as computed tomography (CT) scanning and magnetic resonance imaging (MRI), along with the capability to produce multiplanar reconstructions in any three-dimensional plane, has made thoracoscopy almost obsolete for the mere assessment of intrathoracic anatomy. However,

the good visualization and excellent access to almost all intrathoracic lesions has resulted in the replacement of most open lung biopsies by the thoracoscopic technique. In fact, thoracoscopic lung biopsy and the resection of pulmonary lesions are the most commonly performed thoracoscopic operations in neonates. In many cases, small pulmonary lesions are easily identified and isolated from the rest of the lung using a Roeder loop (Endoloop, Ethicon San Angelo, TX, USA). After placing the suture tightly around the base of the lesion, the tissue is excised sharply peripheral to the loop and retrieved through one of the trocar sites. In children above 10 kg, a stapler can be used to transect the lung central to the lesion. Larger pulmonary lesions, such as congenital cystadenomatoid malformations and congenital lobar emphysema, should be resected by respecting the lobar or segmental anatomy. Most of the time, this entails identifying the proprietary vessels and bronchus to the affected part of the lung, and using a vessel sealing device such as the endoscopic Ligasure (Covidien, Dublin, Ireland) or Enseal (Ethicon, Cincinnati, OH, USA) to divide the vessels.[4] The bronchus can be stapled, sutured, or clipped. The authors usually leave a chest tube in place through one of the trocar sites for 24 hours after the procedure, although others do not.

Mediastinum

The thoracoscopic approach to mediastinal masses such as esophageal duplication cysts, bronchogenic cysts, and extralobar sequestrations is very useful for several reasons. Visualization of adjacent anatomical structures is usually excellent due to magnification of the video image (Fig. 21.1). Furthermore, the anatomy of the mediastinum is usually well defined, and some lesions tend to be well vascularized.

During esophageal duplication cyst resection, opening of the esophagus is common since the cyst and the esophagus

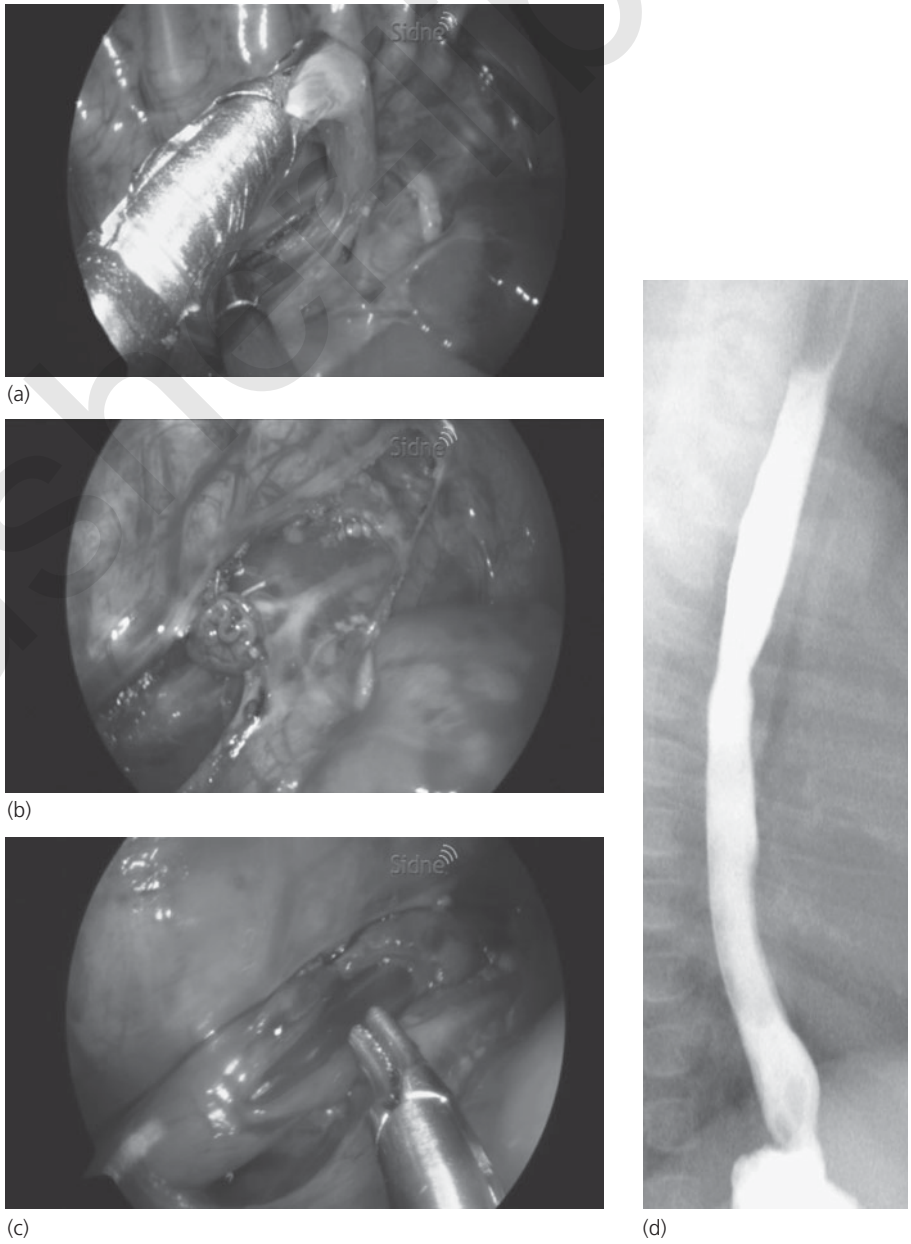

Figure 21.1 Repair of esophageal atresia with distal tracheo-esophageal fistula. The fistula is identified, dissected (a), ligated, and divided (b). Subsequently, the anastomosis is performed over an orogastric tube (c). Postoperative results are generally excellent and comparable to those of the open technique (d).

often share a common wall. Therefore, the esophageal defect should be closed or reinforced using interrupted absorbable sutures. A dilator or endoscope can be placed inside the esophagus to decrease the risk of esophageal injury.

Closure of patent ductus arteriosus and aortopexy

The first reports on thoracoscopic closure of patent ductus arteriosus (PDA) originate from the early 1990s.[7] Improvement in technique and instruments has made it possible to safely perform closure of a PDA thoracoscopically in neonates with a birth weight as low as 1500 g. However, potential complications with the thoracoscopic approach and the safety and excellent outcome of open PDA ligation have prevented both the thoracoscopic and interventional approaches from being universally accepted.

Tracheomalacia, an intrinsic weakness of the tracheal wall causing the airways to collapse during expiration, is usually a benign, self-limiting condition that improves as the infant matures. In some cases, especially when associated with other intrathoracic lesions such as esophageal atresia, the gas exchange is compromised and the tracheomalacia should be treated with an aortopexy. It is important to rule out a vascular cause for the patient's stridor (such as a vascular ring or sling) by esophagram or angiography. Once all other causes are ruled out, a thoracoscopic aortopexy can be performed using triangular position of the camera and instruments in the anterior mid- and anterior axillary lines. The surgeon generally uses three interrupted sutures to pexy the aorta to the sternum.[8]

Esophageal atresia

Thoracoscopic repair of tracheo-esophageal fistula and esophageal atresia is considered one of the most technically demanding minimal invasive procedures in pediatric surgery due to the limited domain inside the neonatal thorax, and the technical difficulty of making a good and trustworthy anastomosis between the proximal pouch and the distal fistula. Consequently, complications observed following thoracoscopic repair are often related to the anastomosis, such as anastomotic leakage and stricture.[9] In contrast, advocates of the thoracoscopic approach acclaim the excellent visualization of the anatomy and warn against the long-term disadvantages of repair using a thoracotomy, such as asymmetry of the chest wall, scoliosis, or a winged scapula as the consequence of nerve injury.[10] To date, however, both techniques have not been compared against each other in a randomized clinical trial, (RCT) and therefore, the question of which technique is superior remains to be answered. Since the learning curve of the thoracoscopic repair is considered to be lengthy, this type of study may be difficult to complete.

For esophageal atresia and fistula repair, echocardiography is used to determine whether there is a right- or left-sided aorta. The esophagus is approached from the contralateral side. The patient is positioned in a lateral decubitus position, slightly prone, to allow gravitational retraction of the lungs away from the posterior mediastinum. Three triangulated trocars are used, with an additional access site if needed for retraction. In most cases, the Azygos vein is divided, and the pleura is opened over the fistula. The fistula is suture-ligated or clipped, both ends of the esophagus are mobilized just enough to facilitate the anastomosis, and the anastomosis is performed (Fig. 21.1a–d).

Congenital diaphragmatic hernia

In contrast to tracheal-esophageal fistula repair, repair of congenital diaphragmatic hernia (CDH) (most frequently Bochdalek hernias) has gained more popularity among pediatric surgeons during the past few years. Whereas the first reports of both laparoscopic and thoracoscopic repairs were mainly anecdotal and described the procedure in older infants and children, the indication for thoracoscopic repair has shifted to symptomatic CDHs in newborns.[11] Even repair of the diaphragmatic defect using a patch has been well described with good results.[12] Most likely, the positive outcomes in the latest studies reflect the completion of learning curves by those pediatric surgeons who perform the procedure frequently. Again, at present, no RCT has compared the classic repair via a laparotomy against the minimal invasive thoracoscopic approach. Outcomes of such an RCT might be difficult to compare, since congenital diaphragmatic hernia is such a heterogeneous, complex disease. Due to the associated persistent pulmonary hypertension and pulmonary hypoplasia, many logical outcome measures to test the superiority of either technique, such as ventilation days or length of stay, will be mainly influenced by the degree of any associated conditions.

The thoracoscopic approach is generally preferred over a purely laparoscopic repair of CDH. In some cases, we have used simultaneous thoracoscopic and laparoscopic cameras to aid with the anatomic reduction of the viscera, and to rule out injury to the intra-abdominal organs during suturing. The patient is positioned in a contralateral decubitus position, and an axillary triangulated trocar configuration is used. The most lateral suture often has the most tension, and a transcostal suture placed through a small stab incision through the lower chest is helpful in facilitating a complete and secure closure of the defect. Figure 21.2 illustrates a standard diaphragmatic hernia repair.

LAPAROSCOPY

Physiology of pneumoperitoneum

While CO_2 insufflation into the thorax may be associated with considerable changes to the physiology, CO_2 insufflation to establish a capnoperitoneum is often very well tolerated by most neonatal patients. Still, the pressures and flows should be kept at the minimum necessary to guarantee adequate working space and visualization. In neonates, we generally

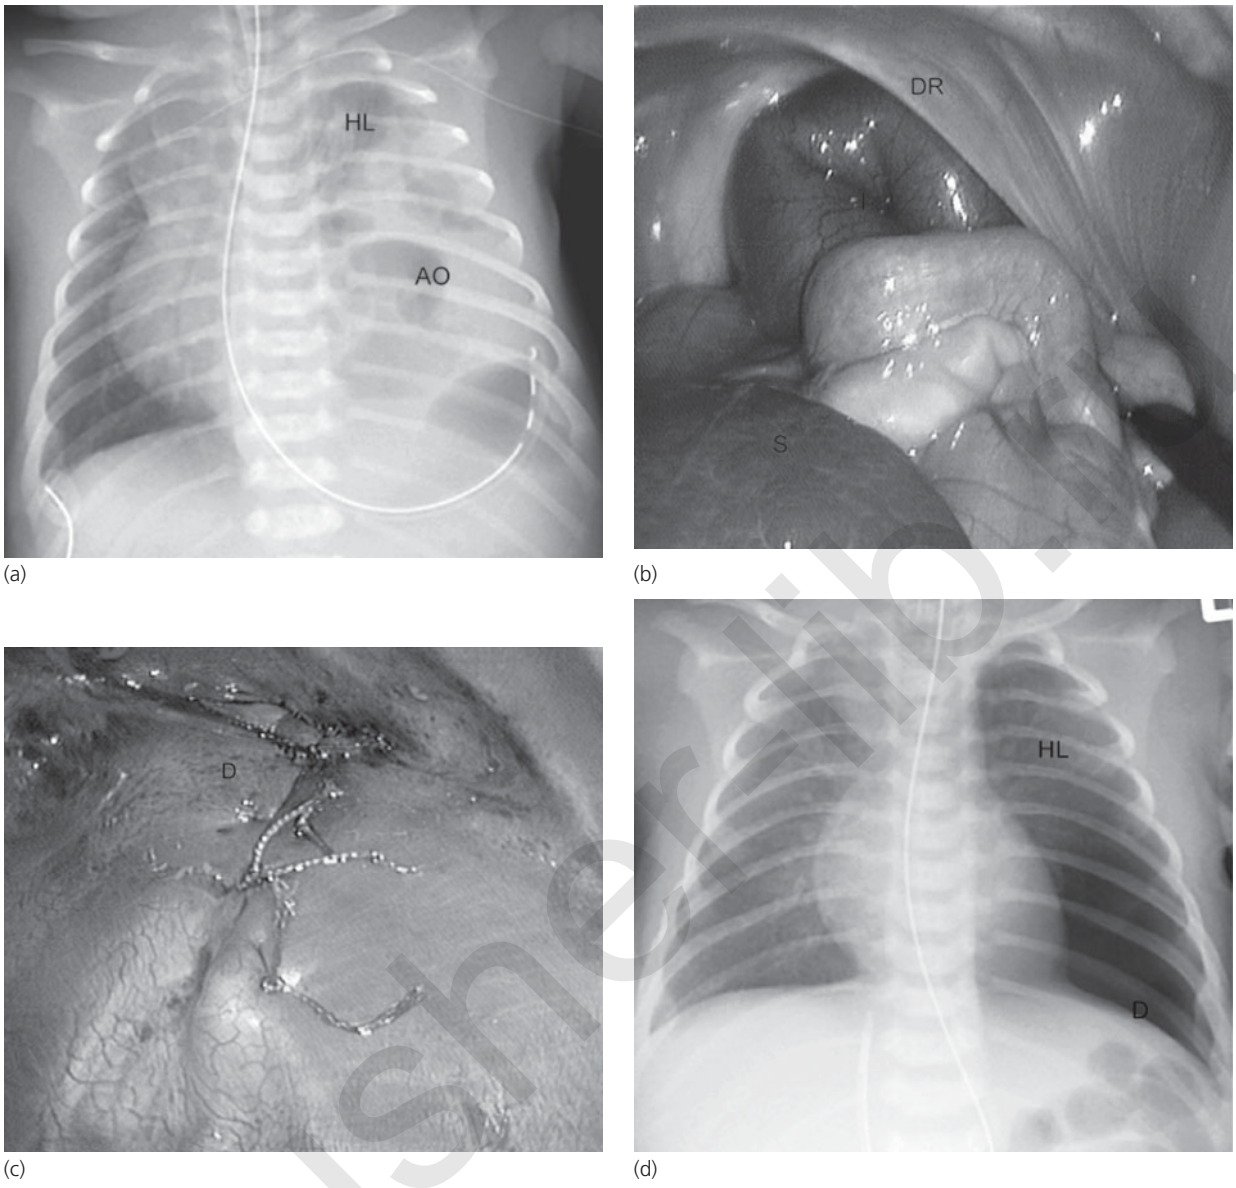

Figure 21.2 Closure of congenital diaphragmatic hernia (CDH): Preoperative chest x-ray of an infant with left-sided CDH (a). Thoracoscopic intraoperative view looking down on the abdominal organs (intestines and spleen) that herniated through the diaphragmatic defect into the thorax (b). Diaphragmatic defect has been closed using interrupted sutures (c). Postoperative chest x-ray. Note the hypoplastic lung in the top of the thorax and the reconstructed dome of the diaphragm (d). AO: abdominal organs; D: diaphragm; DR: diaphragmatic rim; HL: hypoplastic lung; I: intestines; S: spleen.

use pressures of 6–8 mmHg and flows between 1 and 2 L/min. Furthermore, the insufflated CO_2 may be absorbed into the bloodstream of neonates more readily, mainly due to smaller diffusion barriers and an increased peritoneal absorptive surface area in comparison to body weight. Subsequently, hypercapnia and respiratory acidosis may result and can usually be overcome by increasing minute ventilation during the laparoscopic procedure.[6]

Potential negative side effects of increased intra-abdominal pressure include compression of the inferior caval vein resulting in a decrease in the venous return, as well as upward displacement of the paralyzed diaphragm. This can result in pulmonary atelectasis that may only become clinically relevant after resumption of spontaneous breathing. Some of these patients may require prolonged positive pressure ventilation in order to recruit the collapsed pulmonary alveoli.

Abdominal access

There is no evidence that either the Veress needle technique or the Hasson technique is safest for initial access to the abdomen in children. As long as one adheres to the basic principles of safe insertion, damage to intra-abdominal contents, including the large vessels, is rare. As in adults, abdominal access for laparoscopic procedures is usually obtained through the umbilicus. The umbilicus might be a

potential source of infection if the umbilical cord has recently separated. Some surgeons therefore prefer a circumbilical incision instead. Following the installation of local anesthetic, and after vertically incising the skin in the umbilical scar, we prefer to enter the abdomen using the naturally occurring small umbilical hernia defect to place a 5 mm radially expanding trocar. Reusable trocars can subsequently be inserted safely under direct vision where required. When placing the trocars, the surgeon should keep the triangulation principle in mind: left hand instrument, camera and right hand instrument should form a triangle with the target organ in one axis with the surgeon and the camera.

Dislodgement of the trocars can be a major problem and nuisance during laparoscopic surgery in neonates and small children.[13] To prevent this, we place radially expanding 5 mm trocars through small incisions that hold them in place. Non-expanding trocars are secured in place using a red rubber cuff around the shaft of the trocar, secured to the skin with a silk stitch. If necessary, the trocar can then be moved in and out relative to the cuff using a mosquito clamp.

Pyloromyotomy

Laparoscopic pyloromyotomy is one of the few laparoscopic operations that have recently been demonstrated in a large multicenter RCT to be superior to the open classical approach.[14] The conclusion of the hallmark study by Hall *et al.* was that both open and laparoscopic pyloromyotomy are safe, but that time to achieve full enteral feeding was better in the laparoscopic group. The authors therefore recommend laparoscopic pyloromyotomy in centers with suitable laparoscopic experience. Interestingly, this trial was stopped by the data monitoring and ethics committee because of significant treatment benefit in the laparoscopy group at interim analysis.

Another prospective randomized trial concluded that the laparoscopic approach does not affect the length of recovery or complication rate.[15] However, the laparoscopic operation was associated with less pain and fewer episodes of emesis. In addition, the authors mentioned the cosmetic benefit of the laparoscopic approach, when compared to a right upper quadrant incision.

Although the laparoscopic approach is associated with a considerable learning curve[16] that may have resulted in more incomplete pyloromyotomies in the first published patients series, recent RCTs have failed to show a difference in this regard. In summary, advantages of laparoscopic versus open pyloromyotomy appear to result in less postoperative discomfort, a faster recovery, shorter length of stay, and better cosmesis. Recently, a single-incision laparoscopic approach has been described.[17]

Gastrostomy

Gastrostomy placement to provide either total or supplemental nutrition is a common procedure in infants and children. In many centers, gastroenterologists (sometimes in close collaboration with the pediatric surgeons) perform most of these feeding tube placements using the percutaneous endoscopic gastrostomy tube. The procedure combines flexible esophagogastroscopy with percutaneous puncture of the stomach to place a gastrostomy tube that can later be replaced by a gastrostomy button device. However, the percutaneous endoscopic technique has significant drawbacks and a relatively high complication rate, including bowel perforation. Therefore, we prefer a laparoscopic, single-incision technique for gastrostomy tube placement that was developed in our center in 1993.[18,19] This procedure allows visualization of the stomach and abdominal wall during the entire procedure, avoiding injury to adjacent viscera. It also permits primary placement of a gastrostomy button device, which is generally preferred by the caregivers.

Fundoplication

The laparoscopic Nissen fundoplication quickly gained popularity for treatment of symptomatic gastro-esophageal reflux disease (GERD). Good intraoperative visibility of the hiatus, excellent postoperative cosmesis, less pain, and reduced length of stay, as well as good efficacy combined with a low morbidity and mortality, has made this operation the standard of care. In our practice, indications for a laparoscopic Nissen fundoplication are failure of medical therapy for GERD and inability to tolerate gastric bolus feeds, either via the orogastric route or through an existing gastrostomy. The laparoscopic technique for gastrostomy placement described above assures that it is in a good location on the anterior aspect of the stomach, close to the greater curvature, and about two-thirds down from the fundus to the antrum. In such cases, a later laparoscopic fundoplication is easily achieved if necessary.

Generally, we perform a 360° wrap around the lower esophagus and gastro-esophageal junction with minimal dissection of the hiatus, as this has been shown to decrease failure rate.

Endorectal pull-through

Following a biopsy proven diagnosis of Hirschsprung's disease, a primary one-stage laparoscopic endorectal pull-through in the neonatal period is currently considered the standard of care by most pediatric surgeons.[20] Naturally, significant comorbidities or severe enterocolitis should be absent in this circumstance. The procedure is performed using three to four small abdominal ports, either in a triangular configuration or through the same skin incision in the umbilicus for a single-incision approach.[21] The transition zone is estimated by its morphology and laparoscopic seromuscular biopsies are obtained. In patients with a rectosigmoid colon transition zone, the intra-abdominal portion of the aganglionic bowel is devascularized using a hook electrocautery. In patients with longer segments of aganglionic colon, a pedicle preserving the marginal artery is fashioned as far proximal as necessary to bring the colon pedicle down without tension to form the neorectum. The rectal mobilization is performed transanally using an endorectal sleeve technique. The anastomosis is performed transanally 0.5 cm above the dentate line. Successful

techniques for performing laparoscopy-assisted Duhamel and Swenson pull-through procedures have also been reported in neonates. The laparoscopic-assisted endorectal pull-through has several advantages over a purely perineal approach. For one, the transition zone is histologically proven before the diseased bowel is resected. Furthermore, mobilizing the colon helps preserve a normal anorectal angle, which is important for later continence.

Using similar principles, a minimal invasive technique for the correction of intermediate and high anorectal malformations (ARMs) has been developed in our institution, namely the laparoscopically assisted anorectoplasty (LAARP). Taking maximal advantage of the good visualization of the pelvic musculature from the inside using the laparoscope, the distal colon and fistula are dissected and divided. An expanding trocar is then placed through the muscle complex, which is identified using the electric nerve stimulator. Placement of the trocar is further aided by transillumination of the endoscope's light.[22] In comparative studies, functionality and continence for both the perineal and laparoscopic operation are comparable.[23]

Malrotation

Incomplete rotation or malrotation of the intestines results in a malposition and non-fixation of the duodenum and terminal ileum and this situation predisposes the patient to midgut volvulus. Principles of the laparoscopic approach are similar to the open and include counterclockwise derotation of the intestines in case of a volvulus and release of the Ladd's bands starting distal to the pylorus and continuing distally until the mesenteric stalk is widened and the whole duodenum as well as the jejunum are located on the right side and the cecum is allowed to fall over to the left side of the abdomen.[24] This operation is usually performed with an incidental appendectomy as described by Ladd.

Duodenal atresia

Smaller laparoscopic surgical instruments have enabled pediatric surgeons to perform more sophisticated laparoscopic procedures, such as duodenal atresia repair. First reports of successful laparoscopic duodenal atresia repair were published at the beginning of this century. Using intracorporeal suturing, a diamond-shaped anastomosis is performed similar to the open approach to open duodenal atresia repair. We prefer to use a running suture for the back wall, and interrupted sutures in the front. Only a few small case series have been published so far, and a number of complications have been described. Therefore, this procedure should be reserved for very experienced pediatric endosurgeons and a low threshold for conversion in our view is warranted.

Billiary pathology

A large series of laparoscopic choledochal cyst excisions have been published in the literature, with excellent results comparable to the open approach. The surgical principles

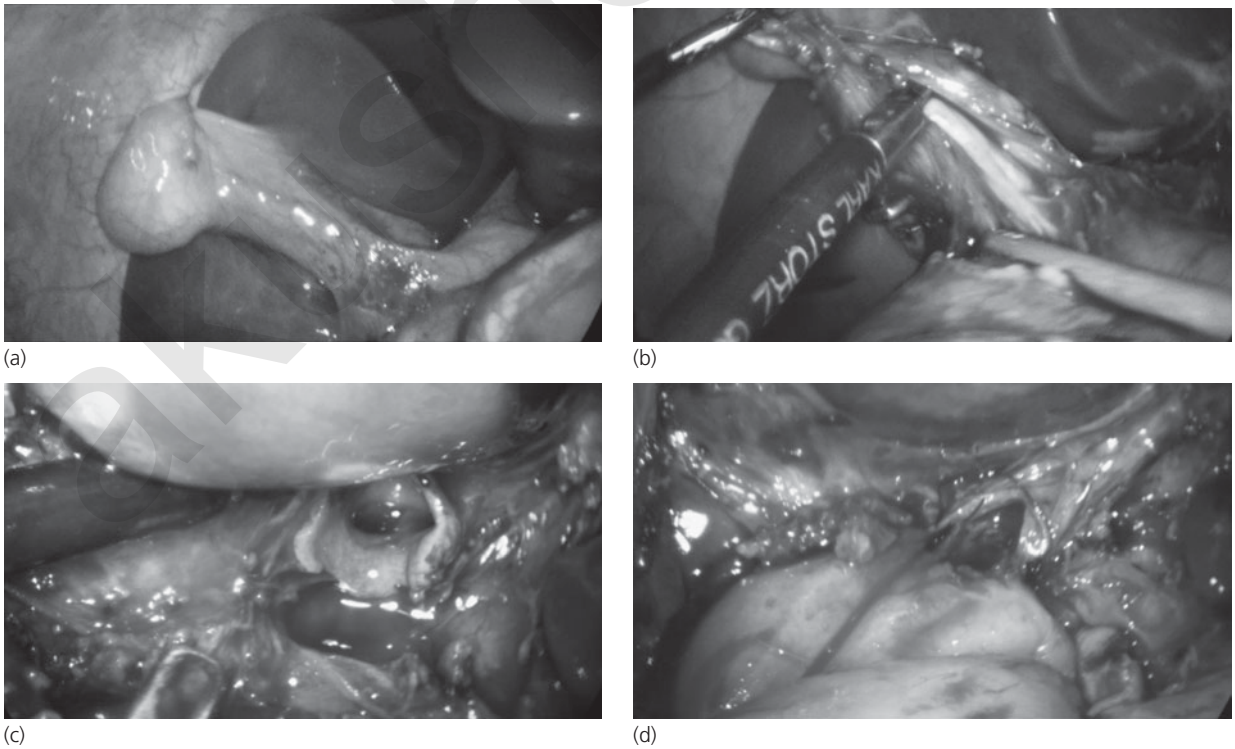

Figure 21.3 Resection of type 1 choledochal cyst: The gallbladder is restricted by a transabdominal suture, exposing the common bile duct below (a). The common bile duct is transected proximally (b) and then the cyst itself is resected (c). After creation of a Roux-en-Y limb, an enterobilliary anastomosis is performed (d).

are equivalent to those of the open procedure. Retraction of the gallbladder using a transabdominal suture in the right upper quadrant aids with the dissection. After resection of the cyst, a Roux-en-Y loop of bowel is created either intracorporeally or by exteriorizing the proximal small bowel through the umbilical incision. The anastomosis between the Roux-loop and the proximal common bile duct is performed using an intracorporeal suturing technique (Fig. 21.3a–d).

Although laparoscopic and robot-assisted Kasai procedures have been performed and reported, the higher failure rate has been reported compared to the open operation.[25] The reason for these findings is still unclear. In a sentinel vote at the 2007 IPEG meeting in Buenos Aires, the attending endoscopic pediatric surgeons agreed to perform minimally invasive Kasai operations only in well-controlled study protocols until more information is available.

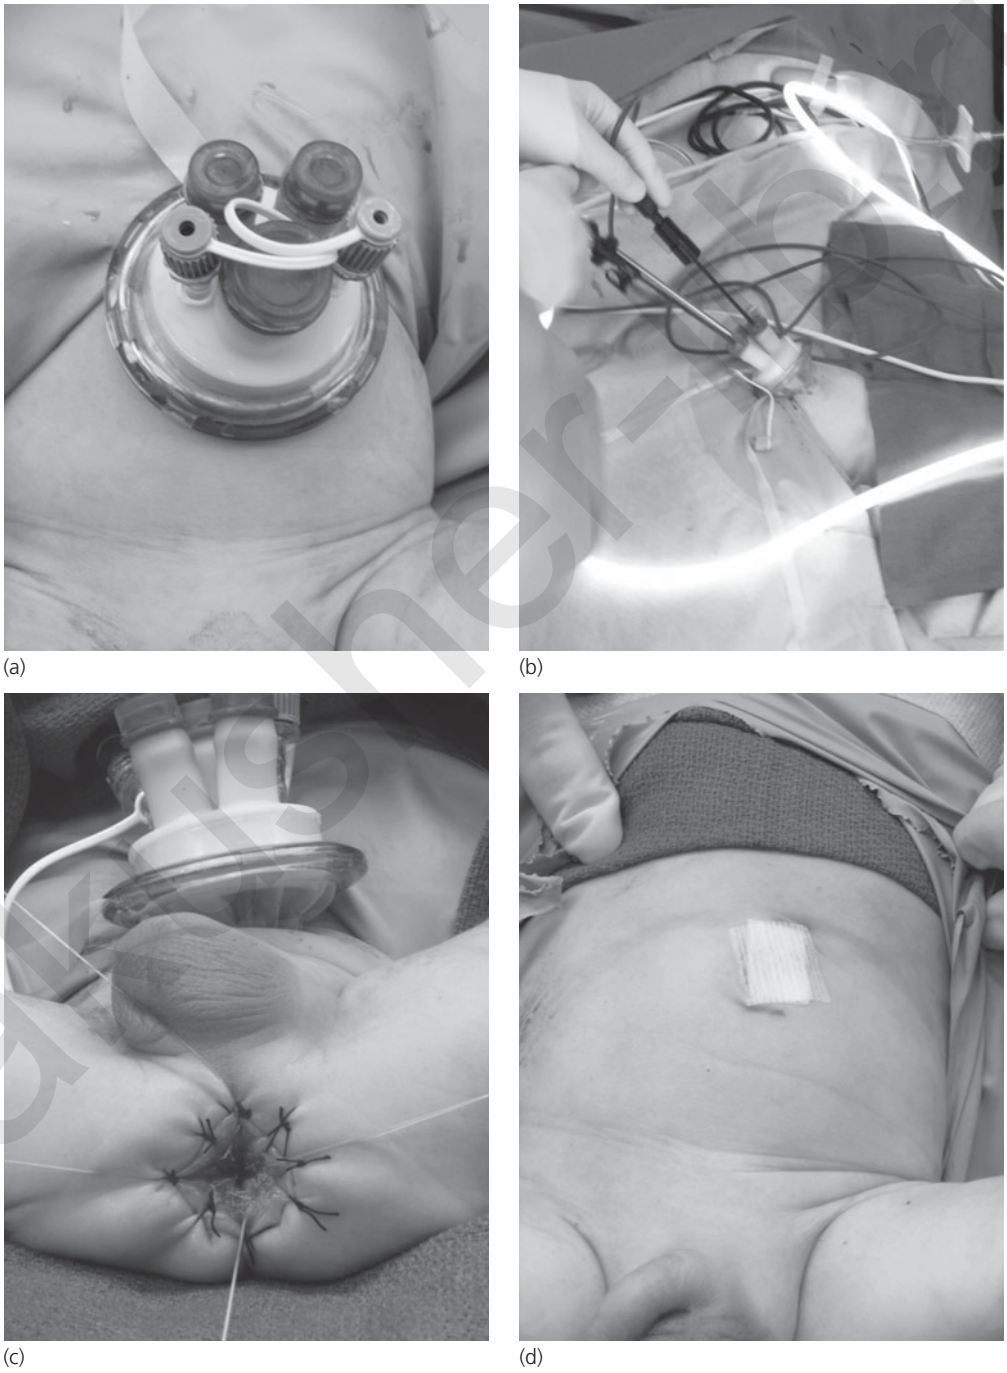

Figure 21.4 Single incision pediatric endoscopic surgery (SIPES) endorectal pull-through for Hirschsprung's disease. Single incision port introduced through the umbilicus (a). Intra-abdominal phase of operation via the umbilical port (b). Peri-anal phase of operation while umbilical port is still *in situ* (c). Umbilical incision leaves hardly any scar after surgery (d).

Pelvic pathology

With the improvement of prenatal ultrasound screening, pediatric surgeons see more neonates with enlarged ovarian cysts these days. In general, cysts with a complicated or complex ultrasound pattern, and those over 4 cm in diameter that do not resolve spontaneously after several weeks of life, warrant surgical exploration.[26] This is preferably done using laparoscopy. Serum AFP and beta-HCG levels should be checked preoperatively, and sound oncologic principles should be applied during surgery. Benign simple cysts may be drained by needle aspiration to facilitate removal through a trocar site. All other lesions can be resected in an endoscopic retrieval bag through the umbilicus or a separate, Pfannenstiel-type suprapubic incision.

Another pelvic pathology that can benefit from a laparoscopically assisted intra-pelvic or intra-abdominal dissection is the resection of a sacrococcygeal teratoma.[27,28] More than 50% of the tumors have such an intra-corporeal portion of the tumor and dissection can be facilitated by the magnified view of the laparoscope. Control of the presacral veins can be achieved laparoscopically and the intra-abdominal portion of the tumor can be mobilized off surrounding structures. Again, strict observance of oncologic principles is mandatory.

Future directions

In a period of only less than 20 years, minimal invasive surgery has become a major part of the practice of many pediatric surgeons. Many open procedures have been replaced or supplemented by comparable or even better minimal invasive procedures. It is hard to imagine that new developments in the field, such as natural orifice translumenal endoscopic surgery (NOTES) or single incision pediatric endosurgery (SIPES), are going to bring the same revolutionary advancement to general pediatric surgery as laparoscopic and thoracoscopic surgery have done. Although the first large series of NOTES procedures (cholecystectomies through the vagina) in adults have been published recently, NOTES is still suffering from the technological difficulty of perfect closure of the access organ that is used as the natural orifice.

In contrast, SIPES is slowly gaining more popularity, and series on several operations such as appendectomies, cholecystectomies, splenectomies, and pyloromyotomies have been published.[17,21,29–34] Introducing the camera and work instruments through the umbilicus, occasionally supplemented by a 2 mm percutaneous grasper in another location, we have been able to safely perform over 300 such procedures, including appendectomies, Nissen fundoplications, cholecystectomies, splenectomies, pyloromyotomies, and endorectal pull-throughs for Hirschsprung's disease (Fig. 21.4). However, our experience demonstrates that the procedures are more technically demanding because of the loss of triangulation, instrument clashing, and limited visualization. RCTs testing SIPES versus laparoscopic surgery in terms of complications, postoperative recovery, length of stay, and postoperative pain should be awaited before this technically more demanding technique can be recommended universally.

CONCLUSION

Minimal invasive neonatal surgery has become an established tool in the palette of the modern pediatric surgeon. Although the number of RCTs testing this relatively new approach is low, more and more publications are showing the benefit of the minimal invasive approach with regards to postoperative recovery, pain, and cosmesis. Whereas costs of minimal invasive surgery have always been a concern, the equipment has become less expensive over the past few years. In fact, when costs are considered on a macro-economical scale, shorter length of stay after a minimal invasive procedure may level or offset the balance in favor of minimal-invasive surgery. Eventually, it is likely that most intra-cavitary surgical conditions in neonates will be corrected using these techniques.

Fetal surgery

SHINJIRO HIROSE AND MICHAEL R HARRISON

INTRODUCTION

This chapter is an overview of fetal intervention. In reality, birth defects have a long and interesting history. As Samuel Taylor Coleridge said, 'The history of man for the nine months preceding his birth would be far more interesting and have events of far greater moment than all three-score and ten years that follow'. In this chapter, we will present general principles of fetal surgery, methods of fetal access, diseases that are amenable to fetal intervention, and a brief discussion of the future.

The impetus to try to help the fetus came from two sources. First, are the obstetricians, perinatologists, and prenatal diagnosticians who developed the technical tools that allow detection before birth. They could see the problems and say 'why don't we fix them?' Second were the pediatricians who were seeing newborn infants with terrible problems which looked as though they were not fixable unless they were treated earlier. When these two groups got together, things started to happen.

GENERAL PRINCIPLES

Fetal intervention is complicated by not only the risk to the unborn patient, but by risk to the mother as well. Our heaviest responsibility is to the mother and her family. It is obvious that she is really an innocent bystander in the calculation of risk and benefit for her baby.

In her capacity, the mother stands nothing to gain in terms of health benefits from fetal surgery, yet she undergoes significant risk or morbidity in fetal surgery. To date, there have been no reported maternal deaths due to fetal surgery, although significant short-term maternal morbidity has been reported.[1] Complications include endotracheal intubation, blood transfusion, premature rupture of membranes, chorio-amniotic separation, chorioamnionitis, and placental abruption. In this light, fetal surgery is considered only if there is a severe, life-threatening or debilitating anomaly in the fetus that has been thoroughly investigated in animal models, and has been shown to be improved by fetal surgery.

Initially, fetal surgical experiments were carried out in a variety of animal models: rat, rabbit, sheep, and non-human primate. In these experiments, it was shown that *in utero* surgery could be performed safely and was subsequently attempted in humans. The first open fetal surgical procedure was performed at the University of California, San Francisco (UCSF) and was reported in 1982.[1] Since that time, we have performed over 380 fetal interventions over the past 27 years with no maternal mortalities. The main morbidity has been and remains preterm labor and premature delivery with gestational ages at delivery following fetal surgery ranging from 25 to 35 weeks.[2] Notably, after review, subsequent fertility following fetal intervention has been good.

A crucial component contributing to the success of a fetal treatment program is a multidisciplinary approach, utilizing the skills of various specialists working in concert. At UCSF, all fetal referrals are discussed at a large, open weekly meeting at which the patients are discussed, imaging studies are reviewed, and a consensus is reached regarding workup and treatment. This group consists of perinatologists, anesthesiologists, neonatologists, cardiologists, radiologists, geneticists, and pediatric surgeons. In addition, specific subspecialists are involved for certain cases, such as pediatric neurosurgeons for fetal myelomeningocele repair. The weekly discussion not only covers medical and surgical aspects of the patients' care, but also includes the ethical and social aspects of each case. Finally, a special institutional fetal treatment oversight committee reviews all fetal interventions on a monthly basis. This group serves as a quality control mechanism as well as an ethical review.

FETAL ACCESS

There are three general methods of accessing the fetus: percutaneously, with ultrasound guidance; minimally invasive fetoscopically; and open hysterotomy. In all three methods, preoperative and intraoperative ultrasound is

crucial in order to define the anomaly or anomalies, to delineate the placental anatomy, determine the position of the fetus, detect the presence of maternal blood vessels, and to monitor the fetal heart rate during the procedure. In percutaneous and fetoscopic procedures, ultrasound is of particular importance because of the lack of direct exposure of the fetus and uterus.

Maternal positioning is usually supine, with the left side down to minimize compression of the vena cava by the gravid uterus. Anesthesia is either spinal or general, depending on the nature and duration of the intervention. Fetal anesthesia is given when operating directly on the fetus. This is given as an intramuscular injection of opiate and non-depolarizing neuromuscular blocking agent.

Ultrasound-guided, percutaneous procedures are performed via small skin incisions in the maternal skin. These procedures require real-time ultrasound, as the only visualization of the fetal and maternal anatomy is via ultrasound images.[3] Through this type of access, catheters and shunts can be deployed in the fetus, draining cystic structures or ascites or pleural fluid into the amniotic space. In addition, using the same access technique, radio frequency ablation (RFA) probes can be deployed into the amniotic space in order to treat various twin gestational complications. The needles used to place catheters as well as the RFA device are approximately 1.5–2 mm in diameter, resulting in minimal morbidity to the mother during these procedures.[4,5]

Fetoscopic or 'FETENDO' procedures are generally performed via a 3 mm fetoscope, or less frequently, via standard 3 and 5 mm laparoscopic ports. For many fetoscopic procedures, the 3 mm fetoscope with its 1 mm working channel is sufficient to perform interventions on the fetus. For these procedures, it is important to identify a 'window' in the uterus that is devoid of placenta in order to reduce the risk of maternal bleeding, placental abruption, and fetal morbidity. When using the fetoscope, we can usually identify an access point on the mother's abdominal wall and use a 3 mm skin incision and access the uterus without a maternal laparotomy. When using multiple ports and more standard laparoscopic instruments, we prefer to perform a maternal laparotomy and direct uterine closure. Occasionally, the amniotic fluid is not clear enough for a good image via the small endoscopes. In these cases, we perform amnio-exchange, using warmed crystalloid solutions in order to clear the operative view.

Open fetal procedures require general anesthesia and a combination of preoperative indomethacin and high MAC inhalational agents in order to maintain uterine relaxation.[6–8] The incision is a low, transverse incision with a vertical or transverse fascial incision, depending on the exposure needed. Preoperative and intraoperative ultrasound is again crucial in order to avoid the placenta. Specific uterine staplers with absorbable staples were developed specifically for fetal surgery and allow for a hemostatic hysterotomy with minimal blood loss. Fetal monitoring is via ultrasound and continuous pulse oximetry. The uterus is stabilized within the maternal abdomen and herniation of the uterus is avoided to reduce tension on the uterine blood vessels. In addition, fetal exposure is limited to the specific body part in question. The majority of the fetus is left inside the uterus, and great care is taken not to handle or stretch the umbilical cord as this can cause fetal ischemia due to injury or vasospasm. After the fetal procedure is completed, the fetus is returned to the uterus, fluid is replaced, and the uterus is closed in multiple layers, using absorbable sutures. Postoperatively, the mother and fetus are monitored continuously for uterine contractions and heart rate, respectively. Often, the uterus is irritable and contractions require control with tocolytic regimens. Notably, open fetal surgery requires lifelong Cesarean section for future pregnancies due to the potential for uterine rupture in subsequent births.

Complications can occur after all types of fetal access. Bleeding can originate from the fetus, the placenta, the uterine wall, or the maternal abdominal wall. The uterine vessels are specifically avoided and identified with ultrasound to minimize bleeding. Premature rupture of membranes and preterm labor remain the main problem and limiting factor following fetal surgery. This complication is contributed to by inadequate membrane closure, chorioamnionitis, chorioamniotic separation, and uterine contractions.

ANOMALIES AMENABLE TO FETAL SURGERY

Congenital diaphragmatic hernia

Despite advances in neonatal methods of respiratory support, survival for children born with congenital diaphragmatic hernia (CDH) remains at only 60–70% throughout the United States. Additionally, survival for all fetuses diagnosed with CDH may be as low as 20–27% due to *in utero* demise or death of infants with unrecognized CDH.[9–11] We have theorized that *in utero* intervention may allow increased antenatal lung growth and increased pulmonary function and survival postnatally and have studied fetal lung development extensively.[12,13] In a fetal lamb model, compression of the lungs during the last trimester, either with an intra-thoracic balloon or by creation of a diaphragmatic hernia, results in fatal pulmonary hypoplasia. In addition, removal of the compressing lesion allows the lung to grow and develop sufficiently to permit survival at birth.[14]

Fetal surgery for CDH initially involved *in utero* diaphragmatic hernia repair. Analysis of this initial group of patients proved that open fetal surgery for CDH was feasible, but did not show an increase in survival.[15] However, the subset of fetuses with severe lung hypoplasia continues to have poor prognosis and are identifiable prenatally by ultrasound and magnetic resonance imaging (MRI). The factors associated with poor outcome that can be assessed prenatally by ultrasonography are: (1) the presence of liver herniation into the chest; and (2) a low lung-to-head ratio (LHR). In our experience, survival was 100% in fetuses with CDH without liver herniation and 56% in fetuses with CDH with liver herniation into the chest. The LHR is calculated as the area of the contralateral lung at the level of the cardiac atria divided by the head circumference. This LHR value has been shown to correlate in a statistically significant fashion with survival: 100% survival with an LHR greater than 1.35, 61% survival with an LHR between 0.6 and 1.35, and 0% survival

with an LHR less than 0.6.[16] Ultrasound is also critical in identifying other anomalies associated with CDH, particularly cardiac anomalies as those portend extremely poor prognosis. Magnetic resonance volumetric imaging of the lung for CDH is a promising modality for prognostic purposes.[17]

Over the last 20 years, we have been able to stratify risk for fetuses with CDH. Over this same time period, extensive animal studies and observation in fetuses born with congenital high airway obstruction have proven that lung growth may be driven by tracheal obstruction or occlusion leading to pressurized fluid accumulating in the airway. This has led to the study of lung distension by tracheal occlusion.[18,19] Our group has focused on *in utero* tracheal occlusion as a method of augmenting lung growth in fetuses with CDH. Our preliminary study examined the effect of extrinsic tracheal occlusion by the placement of an obstructing clip *in utero* using both open and FETENDO techniques.[20,21] We found in a small number of patients that survival was increased in the FETENDO but not the open group as compared to the control group, which consisted of patients undergoing standard postnatal care. This led to an NIH-funded trial comparing *in utero* tracheal occlusion using FETENDO to standard postnatal care using minimal access techniques for fetuses diagnosed with severe left-sided CDH and no other detectable anomalies. Results of the trial showed survival of 75% with no difference between the tracheal occlusion group and the standard postnatal care group. The survival in the postnatal care group was considerably greater than as compared to historical controls.[22] Although this study did not demonstrate a difference in survival between the prenatal intervention group and the postnatal one, the results of this trial demonstrate the tremendous importance of proper randomized controlled trials for novel fetal surgical procedures.

Refinement of tracheal occlusion techniques have progressed from tracheal clipping to percutaneous, fetoscopic placement of a detachable, intratracheal balloon. Animal studies demonstrated complete occlusion with this technique, and it has now become the current method of choice for fetal tracheal occlusion. Further data regarding tracheal occlusion have suggested that temporary, short-term reversible tracheal occlusion may be preferable to longer duration occlusion. Animal models of tracheal occlusion have demonstrated that long-term tracheal occlusion can be deleterious to type II pneumocytes: the cells that secrete surfactant, and that this effect is not seen in shorter durations of tracheal occlusion. In addition, other studies demonstrated the efficacy of short-term, reversible tracheal occlusion on lung growth in animals. A recent report from Cannie *et al.* demonstrated improved lung volumes following temporary balloon tracheal occlusion in human fetuses. In 36 of 40 patients, the tracheal balloon was removed prenatally, limiting the duration of occlusion. In this group of patients, improved lung growth was associated with improved postnatal survival.[23] Finally, reversal of tracheal occlusion requires a second maternal and fetal intervention for the removal of the fetal intratracheal balloon; however, it obviated the need for an *ex utero* intrapartum treatment (EXIT) procedure at birth for these patients. The EXIT procedure is a controlled surgical delivery method for these fetuses and was initially developed to reverse tracheal occlusion in this cohort of patients. After reversal of tracheal occlusion, standard delivery plans are possible for these patients with CDH.[24,25]

Based on these data, as part of an FDA-sponsored trial, our group is currently offering reversible, fetal tracheal occlusion for fetuses with liver herniation in the chest and lung to head ratio of less than 1.0, as these patients continue to have greater than 60% mortality. We perform the initial procedure between 24 and 26 weeks' gestation, and remove the balloon between 32 and 34 weeks.

Tumors

In general, fetal tumors are rare. When they do occur, most are benign. However, if they become large enough to either impede venous return to the heart or create high output heart failure via arteriovenous shunts, they can cause non-immune hydrops in the fetus. Hydropic changes include polyhydramnios, placentomegaly, fetal skin, and scalp edema, and pleural, pericardial, and peritoneal fluid accumulation. Left untreated, fetal hydrops is nearly always fatal.[26,27] The two most common prenatally diagnosed tumors that cause non-immune hydrops are congenital cystic adenomatoid malformation (CCAM) and sacrococcygeal teratoma (SCT).

Congenital cystic adenomatoid malformations

Congenital cystic adenomatoid malformations are pulmonary lesions with a broad range of clinical presentations. They are characterized by an overgrowth of respiratory bronchioles with the formation of cysts of various sizes. Classification of CCAM has classically been based on pathologic findings regarding the size of the cysts.[28–31] Most fetuses diagnosed with a CCAM *in utero* develop normally, and can be monitored with serial ultrasound studies. These asymptomatic patients can undergo standard, postnatal resection. A small percentage of patients with a prenatal diagnosis of CCAM will develop non-immune hydrops.[30,31] Various measurements have been developed in order to predict which fetuses are at risk for developing hydrops. The most accepted measurement is the CCAM volume ratio (CVR), defined as the product of the three longest measurements on ultrasound, multiplied by the constant 0.52, divided by the head circumference. In a recent paper, Crombleholme *et al.* identified a CVR 1.6 as a cut-off for an increased likelihood of developing hydrops.[32]

Interestingly, CCAMs that are predominantly microcystic have a more predictable course than the macrocystic ones. Microcystic CCAMs undergo steady growth and tend to plateau at 26–28 weeks' gestation. In contrast, macrocystic CCAMs can have abrupt enlargements in size due to rapid fluid accumulation in a large cyst. For these reasons, patients with microcystic CCAMs can be followed closely up to 26–28 weeks' gestation, and then the interval between ultrasound examinations can be lengthened, while macrocystic CCAMs require close follow-up throughout the duration of the pregnancy.[29,33]

If the fetus is of a viable gestational age in the presence of hydrops, early delivery should be considered. In instances where one dominant macrocystic lesion is present in a previable fetus, thoracoamniotic shunt may reverse the hydrops fetalis. Needle drainage has not proven to be an effective option as rapid re-accumulation of fluid occurs. Fetal thoracotomy with resection is an option in the previable fetus with a microcystic CCAM or one without the presence of a dominant cyst. The fetal thoracic space is exposed through a fifth intercostal space thoractomy after maternal hysterotomy. The lobe containing the CCAM is identified and brought out through the wound. The pulmonary hilar structures are then mass ligated using an endoloop or a vascular endostapling device. The thoractomy is then closed in layers.[34–36]

The experience with CCAM at the UCSF and the Children's Hospital of Philadelphia (CHOP) was reviewed. One hundred and thirty-four women pregnant with fetuses with CCAM were diagnosed *in utero*. Of this group, 120 elected to continue their pregnancies. Seventy-nine fetuses had no evidence of hydrops. Of these, 76 were followed expectantly and all survived. Three fetuses without evidence of hydrops with large dominant cysts underwent thoracoamniotic shunt placement and all three of these fetuses survived. Twenty-five hydropic fetuses were followed with no intervention. All mothers delivered prematurely and all fetuses died perinatally. Sixteen fetuses with hydrops underwent intervention: 13 underwent open fetal surgery while three underwent thoracoamniotic shunt placement. Two of three survived in the group that underwent shunt placement while eight of 13 survived in the open fetal surgery group.

Recently, it has been shown that fetuses with large CCAMs and hydrops can be treated by the administration of maternal steroids. This finding was discovered serendipitously at UCSF after several hydropic fetuses were identified and, in preparation for fetal surgery, maternal steroids were administered to enhance fetal lung maturity.[37] Subsequent ultrasound surveys showed the resolution of hydrops. These findings were later identified in similar patients at CHOP.[38] A multicenter, prospective trial is now underway in order to investigate the role of steroids in the treatment and management of hydrops in large fetal CCAMs.

Sacrococcygeal teratoma

Sacrococcygeal teratoma is a rare tumor that is being diagnosed with increasing frequency *in utero*, allowing for observation of the prenatal natural history of the disease and appropriate perinatal management. As with CCAM, fetuses with SCT are susceptible to *in utero* demise. SCT tumors can grow to a tremendous size in relation to the fetus, resulting in a vascular shunt, and, in the extreme form, high output cardiac failure and non-immume hydrops. Rarely, tumors bleed either within the tumor or externally and may cause fetal anemia and hypovolemia. Other potential problems with a fetus with a large SCT are those of dystocia and preterm labor. Delivery can be particularly difficult when the diagnosis has not been made prenatally. Traumatic delivery may result in hemorrhage or tumor rupture. Most clinicians would favor Cesarean delivery for fetuses with large SCTs. Thus, prenatal diagnosis and careful obstetrical planning are critical in the appropriate management of the fetus with an SCT.

The UCSF experience with prenatally diagnosed SCT included the management of 17 fetuses and mothers. Of the 17 fetuses, 12 developed hydrops while five did not. All five of the non-hydropic fetuses delivered near term and survived. Of the 12 hydropic fetuses, seven underwent fetal intervention with three survivors. Five hydropic fetuses were followed without fetal intervention and none of this group survived.[39] Hydrops in fetuses with SCTs has been shown in other groups to correlate with an exceedingly high rate of fetal demise. The group at CHOP recently published their experience with 30 fetuses with SCT. In their patient cohort, there were 14 survivors. Four fetuses were terminated. Fifteen fetuses had solid tumors, and of those, four developed signs of hydrops and underwent fetal debulking operations. Three of four survived.[40]

The most common method of fetal intervention is hysterotomy with resection or debulking of the tumor. A predominantly cystic lesion may be amenable to percutaneous drainage or placement of a shunt. Effectively debulking the tumor with percutaneous coagulation, such as with radiofrequency ablation or laser coagulation to decrease the vascular shunt, are minimally invasive alternatives to open resection that warrant further investigation.[27,41]

ABNORMALITIES OF TWIN GESTATIONS

Twin–twin transfusion syndrome

Twin–twin transfusion syndrome (TTTS) is the most common complication of monochorionic twin pregnancies, complicating approximately 10%.[42] In monochorionic twin pregnancies, the two fetuses share one placenta, and there are normal vascular connections between them. TTTS occurs when there is net flow from one twin to the other. As a result of the transfusion of blood from the donor twin to the recipient twin, hemodynamic compromise can occur in both or either twin. The donor twin suffers from a low flow state and can sustain injuries to the brain and kidneys. Conversely, the recipient twin has fluid overload, and may develop congestive heart failure and hydrops. The hallmark of TTTS is oligohydramnios in the donor twin and polyhydramnios in the recipient. In addition, often there is size discordance between the twins with the donor being smaller than the recipient. Advanced disease is evidenced by progressive discordance in fluid volumes with the donor becoming 'stuck' in its amniotic sac due to a complete lack of fluid. In addition, worsening cardiac changes in the recipient portend a grave prognosis. If left untreated, TTTS carries 80–90% mortality for both twins. In addition, in monochorionic twins, if one twin dies, the other is at risk of neurologic injury due to a sump phenomenon in the placenta and demised fetus and from embolism.[43–45]

Clinicians have attempted a variety of treatments aimed at achieving improved outcome in one or both twins. The most commonly used treatment is high-volume amnioreduction of the fluid of the polydramniotic sac. Because polyhydramnios may incite labor, the initial aim of amnioreduction was to

reduce uterine volume to decrease the risk of preterm labor. High-volume amnioreduction resulted in the survival of 58% of twins from the International Amnioreduction Registry.[46]

Several groups have used fetoscopic guidance to laser ablate intertwin vascular connections. This can be done either nonselectively, by ablating all intertwin connections, or selectively, by ablating only AV connections with flow in the causative direction. Fetoscopic laser ablation can be performed either percutaneously using 1.0–2.0 mm endoscopes or by maternal laparotomy with 3.0–5.0 mm endoscopes. A maternal laparotomy is favored with use of the larger scopes in order to close the uterine defect created by placement of these devices. All scopes are placed through ports that have side channels for irrigation and placement of the laser. Recently, two large prospective trials have been published comparing amnioreduction to laser ablation of intertwin vessels. The European trial enrolled 70 women in the amnioreduction arm and 72 women in the laser ablation arm. The trial was stopped early after interim analysis showed a clear survival advantage to laser therapy: 76 versus 51% single survivor and 36 versus 26% for dual survivor.[47] The North American trial was also stopped early after randomizing 42 mothers: 20 in the amnioreduction arm and 22 in the laser ablation one. There was no survival benefit to either intervention, but their study was underpowered due to the early termination of the trial. This trial was complicated by the reluctance of referring physicians to send their patients to the various centers in order to be randomized.[48]

Twin reversed arterial perfusion

Twin reversed arterial perfusion (TRAP) sequence is a rare disease of monochorionic twins that occurs when one normal twin acts as a 'pump' for an acardiac, acephalic one. The normal twin is put at risk for high output heart failure and hydrops as it has to maintain blood flow throughout the entire placenta as well as to the acardiac twin. The blood flow in the acardiac twin is characteristically reversed, and thus the acronym TRAP was coined to describe this anomaly. The natural history of TRAP is greater than 50% mortality in the pump twin due to hydrops.[49,50] The risk of hydrops increases as the mass of the acardiac twin increases relative to the normal twin. Generally, we choose to intervene when there is evidence of hydrops in the pump twin, or when the estimated fetal weight of the acardiac twin is 50% or more relative to the pump one.

Multiple techniques have been used to separate the vascular supplies in TRAP pregnancies: open hysterotomy and delivery, fetoscopic ligation, bipolar cautery, harmonic scalpel division, thermal coagulation, and laser coagulation. At UCSF, we have been using RFA to coagulate the umbilical cord insertion site on the abdomen of the acardiac twin.[51–53] These devices were originally designed for ablation of solid tumors, but their small size and effective coagulation has been ideal for this application.[54] We recently published our results with RFA for TRAP, identifying 29 patients who underwent RFA between 18 and 24 weeks' gestation. Survival was 86% percent overall, with 92% survival in monochorionic, diamniotic pregnancies.[5]

Myelomeningocele

Myelomeningocele (MMC), or spina bifida, is characterized by an open neural tube and exposed spinal canal elements. MMC can occur anywhere along the spine, but most commonly occurs in the lumbar or cervical vertebral levels. Complications include neurologic deficits with motor and somatosensory abnormalities which correspond to the level of the spinal defect. In addition, autonomic function is also commonly deranged with an inability to control bladder or bowel function. Finally, nearly all patients with MMC develop the Arnold–Chiari II malformation of the hindbrain and most will require ventriculo-peritoneal (VP) shunting for hydrocephalus. Unlike previous patients considered for fetal intervention, fetuses with MMC are generally born alive and healthy, but the attendant morbidity from neurologic abnormalities is severe, and up to 30% of patients die before reaching adulthood due to respiratory, urinary, or central nervous system complications. Current therapy for MMC is postnatal repair of the spinal defect and extensive rehabilitation.[55]

The rationale for fetal intervention in MMC is the 'two-hit' hypothesis, where the first hit is the original neural tube defect that results in the open spinal canal. The second hit is postulated to be due to direct trauma to the exposed neural elements while the fetus is *in utero*.[56,57] It is this second hit that could potentially be ameliorated by fetal surgery.[58] Various animal models for fetal MMC were created in rats, lambs, rabbits, and non-human primates in order to test this hypothesis. The data from these experiments showed improved distal neurologic function as well as correction of the Arnold–Chiari II malformation.[57,59]

These animal data led to pilot studies in human fetuses. Initial attempts at human MMC repair were performed via open hysterotomy and fetoscopic techniques.[60,61] A review of initial results demonstrated no improvement in distal neurologic function, but did show improvement in the Arnold–Chiari II malformation with reduced hind-brain herniation, as well as a possible decrease in the need for VP shunting when compared with historic controls.[62–64] MMC is unique as it is the first nonlethal anomaly for which fetal surgery has been undertaken. However, it is associated with significant morbidity, and refinement of techniques have minimized the risk to the mother as much as possible during these open fetal operations. Based on these data, as well as animal studies, the NIH has sponsored a prospective, multicenter, randomized controlled trial to investigate the efficacy of fetal surgery for MMC.

THE FUTURE

The requirements for intervention to correct a fetal defect remain the same:

- experimental work to prove the pathophysiology of the defect;
- careful study of the natural history of the untreated disease; and
- ability to select the fetus that will benefit from prenatal treatment.

Stem cells and gene therapy

Gene therapy for prenatally identifiable diseases is currently experimental, and is being actively pursued for specific disorders. The rationale behind *in utero* therapy with stem cells and/or virally directed genes include avoiding the progression of disease in the fetus during gestation as well as taking advantage of the developing immune system of the fetus, thus potentially avoiding issues of tolerance, rejection, and graft versus host disease.[65]

Specific issues for *in utero* treatment of genetic diseases include timing of diagnosis, timing of therapy, delivery of stem cells or genes, sources for stem cells, and durability of treatment. With the advent of chorionic villus sampling, genetic diseases can be identified in the first trimester. Timing of potential treatments is crucial in order to take advantage of the possible 'pre-immune' status of the fetus, making fetuses potentially more receptive to exogenous genes or cells. Several investigators have utilized hematopoetic stem cells (HSC) as a vector to attempt to induce chimerism in order to treat the disease. Others have investigated the use of retroviral vectors in order to insert genetic material into fetal animals. This approach reduces the problem of obtaining the large numbers of stem cells needed to create even a modest amount of chimerism. Other approaches include the use of maternal stem cells or genetic material as studies have demonstrated early cross-trafficking of maternal cells in the fetus. Candidate diseases include hematologic, immunologic, metabolic, and neurologic abnormalities (Box 22.1). To date, there have been over 30 reports of *in utero* therapy with HSCs; however, the only durable treatment has been in patients with pre-existing immunologic defects.[66,67] Currently, *in utero* gene therapy and stem cell therapy are in their infancy but remain an active topic of research and investigation.

Box 22.1 Candidate diseases for fetal gene therapy and stem cell therapy

- Hematologic
  - Alpha-thalassemia
  - Fanconi anemia
  - Chronic granulomatous disease
  - Hemophilia A
- Immunologic
  - SCID
  - Wiscott–Aldrich syndrome
- Metabolic
  - Wolman disease
  - Type II Gaucher disease
  - Pompe disease
  - Osteogenesis imperfecta
  - Cystic fibrosis
- Neurologic
  - Lesch–Nyhan syndrome
  - Tay–Sachs
  - Sandhoff disease
  - Niemann–Pick disease
  - Leukodystrophies
  - Generalized gangliosidosis
  - Leigh disease

SUMMARY

Fetal surgery has progressed from an investigational therapy to an accepted mode of therapy for selected fetal diseases. Multidisciplinary teams are critical for the success of a fetal treatment program, and regular, weekly meetings are necessary to keep all members of the team abreast of developments and new patients. Diseases that historically have a high perinatal mortality rate have shown improved survival with fetal surgery. NIH-funded, prospective trials have been performed for CHD and TTTS. Current clinical trials include those for MMC, hydrops, and CCAM, and reversible tracheal occlusion for CDH. Initially, fetal interventions were reserved for fetuses with lethal anomalies in order to maximize the fetal benefit balanced with minimizing maternal risk. Myelomeningocele is the first nonlethal anomaly that has been treated with fetal surgery.

As minimal access techniques improve, and maternal risks are further reduced, indications for fetal surgery will continue to broaden. New areas of investigation include tissue engineering, stem cell therapy, and gene therapy. Maternal safety must remain paramount, and the risk to the mother should be minimized at all times. The study of these new techniques and areas of investigation should take place initially with animal models, and then in humans under the rubric of prospective, clinical trials and, as many of these disease are rare, they will likely require multicenter input.

Over the years, the progress seen in fetal intervention is directly related to the investigation process, i.e. the understanding of the pathophysiology in the laboratory, the documentation of the natural history in the human fetus, and the push for less and less invasive procedures. Many people have contributed to this development but it is also important to acknowledge the important contribution of the patients and their families to this enterprise. Families who chose to undergo fetal therapy have been able to understand the benefits and risks of unproven treatment, be tough enough to withstand the pressures and disappointments, and dedicated enough to appreciate their own contribution to helping other families in the future.

Liver transplantation

ALASTAIR JW MILLAR

INTRODUCTION

One of the prime stimuli for the development of liver transplantation was the inevitable mortality from infant liver disease and many of the advances in liver transplantation techniques were prompted by the need to tailor the procedure for the pediatric patient. The first ever human transplant was attempted in 1963 by Starzl on a three-year-old child with biliary atresia.[1] The infant did not survive the operation and it was not until four years later that he obtained 'success' in achieving survival for 400 days in an 18-month-old girl with a malignant liver tumor. She died from disseminated metastases. Over the next decade one-year mortality remained high at around 50% and it was not until cyclosporine was introduced in 1980 that survivals dramatically increased. Eleven of the first 12 recipients receiving cyclosporine and prednisone immune suppression therapy lived more than one year and seven survived at least 12 years.[2,3] In June 1983 at the National Institutes of Health Consensus Development Conference liver transplantation was declared a valid treatment for end stage liver disease. The introduction a decade later of tacrolimus, a similar but more powerful drug, pushed the boundaries of success even further.[4] Further technical advances included reduced size liver transplantation,[5] split liver transplants,[6] and living related transplants.[7,8]

Advances in patient selection, organ preservation, surgical technique, anesthetic management, pre- and postoperative care and refinements in immunosuppression and management of the immune suppressed patient over the last four decades has resulted in a much improved outcome with an ever-increasing list of indications being identified and indeed a changing pattern of indications (Box 23.1).[9]

In infancy, the most frequent reasons for liver transplantation are infantile liver failure due to hemochromatosis and biliary atresia.

Current expected five-year survival is now greater than 90% and one-year survival of 100% has been achieved.[10,11] Excellent quality of life is the rule rather than the exception but does to some extent depend on pretransplant morbidity, particularly from the nutritional deprivation which occurs with chronic liver function impairment and cholestatis leading to neurodevelopmental delay.[12] The longest survivor is well 40 years after transplantation. Current anxieties remain over organ donor scarcity militating against timely transplant, the long-term side effects of the immunosuppressive therapy, financial implications, and some ethical issues. The focus of attention has now shifted from an initial target of early post-transplant survival to quality of life in the long term. Shortage of donor organs has been tackled in an imaginative way with increasing use being made of size reduction of the donor liver even into a single segment, splitting the liver into two functioning units for two recipients, as well as the use of living related donors and non-heart beating donors.

INDICATIONS

Liver disease has been generally underestimated as a cause of death in infants and children.[11] This is probably because many liver conditions in children have led to rapid deterioration and death in the past. Almost all forms of liver disease in children can be complicated by hepatocellular failure.[13,14] These would include acute and subacute liver failure from metabolic, toxic, or viral insults and chronic parenchymal disease of varying causes of which biliary atresia, biliary hypoplasia, autoimmune hepatitis, viral hepatitis, and some metabolic diseases are the most common.[14–19] The widespread introduction of hepatitis B virus (HBV) and hepatitis A virus (HVA) vaccines have significantly reduced the incidence of acute hepatic failure in some countries. In some metabolic diseases, the manifestation is in hepatocellular disease and in others there may be more widespread effects such as with tyrosinemia, Wilson's disease, hyperglycoproteinemia, some glycogen storage diseases, and hyperoxaluria (Box 23.1). New treatments for acute liver failure from neonatal hemochromatosis using antenatal i.v. immunoglobulin (IVIG) for the mother and

Box 23.1 Indications for which liver transplantation has been performed in children

I Metabolic (inborn errors of metabolism)
- Alpha-1 antitrypsin
- Tyrosinaemia
- Glycogen storage disease type III and IV
- Wilson's disease
- Perinatal hemochromatosis
- Hypercholesterolemia
- Cystic fibrosis
- Hyperoxaluria (pre-emptive or + renal transplant)
- Hemophilia A + B
- Protein C deficiency
- Crigler-Najjar syndrome
- Urea cycle defect

II Acute and chronic hepatitis
- Fulminant hepatic failure (viral, toxin or drug induced)
- Chronic hepatitis (B, C, etc. toxin, autoimmune, idiopathic)

III Intrahepatic cholestasis
- Neonatal hepatitis
- Alagille syndrome
- Biliary hypoplasia
- Familial cholestasis
- Primary sclerosing cholangitis

IV Obstructive biliary tract disease
- Biliary atresia
- Choledochal cyst with cirrhosis

V Neoplasia
- Hepatoblastoma
- Hepatocellular carcinoma
- Sarcoma
- Hemangioendothelioma

VI Miscellaneous
- Cryptogenic cirrhosis
- Congenital hepatic fibrosis
- Caroli's disease
- Budd–Chiari syndrome
- Cirrhosis from prolonged parenteral nutrition

exchange transfusion and IVIG for the newly diagnosed neonate may reduce the need for liver transplantation in this group of patients.[20,21]

In infants with hyperoxaluria, an innovative strategy may be that of early liver transplantation followed by later renal transplantation.[22]

Hemangioendothelioma in infancy is an occasional indication if medical treatment with steroids, propranolol, and surgical treatment with resection hepatic artery ligation or embolization fails, but outcome is guarded.[23,24]

More recently, liver transplantation has been successfully used in infants with short bowel syndrome and parenteral nutrition-associated liver failure, where adaptation can be expected, and in patients with cystic fibrosis and liver disease.[25]

Re-transplantation is less frequently required in the early post-transplant period but will become a more frequent indication as greater numbers of transplant recipients live long term and achieve adult status.

ASSESSMENT

In general, liver transplantation should be considered as a therapeutic option in all cases of chronic liver disease before the condition of end stage liver disease is realized,[26,27] and in acute liver failure with defined parameters indicating a poor prognosis.

There are indeed few reasons for refusal for transplantation (Box 23.1).[26,27] These include uncontrolled systemic bacterial, viral or fungal infections, malignancy outside the liver, cyanotic pulmonary arterio-venous shunting with pulmonary hypertension, active chronic hepatitis B, HIV/AIDS not controlled with anti-viral treatment, as well as other major cardio-respiratory and/or neurological disease which would be incompatible with quality long-term survival.[28] To a certain extent these are all relative contraindications. Psychosocial factors may be a reason for refusal. Parental substance abuse, severe psychiatric problems and poor preoperative compliance with therapy are factors that need to be carefully examined. In developing countries, the socioeconomic factors such as poor sanitation and lack of access to adequate medical follow-up are often contraindications to transplantation.

Compliance is more difficult to predict in families of children with acute hepatic failure, as time from presentation to decision to transplant is much shorter. Good adherence is one of the factors thought to contribute to the slightly better outcome after living donor transplantation as the bond and responsibilities between donor and recipient is that much greater.

As the outcome of the operation is so much better in recent years, indications for early transplant in patients with chronic liver disease would be evidence of impaired synthetic function, including prolonged prothrombin time, reduced serum cholesterol levels and low serum albumin. Clinical indicators include presence of ascites, bleeding from esophageal varices not controlled by sclerotherapy/banding, and poor response to nutritional resuscitation. Those with acute hepatic failure who develop encephalopathy, hypoglycemia, a prothrombin time of greater than 50 seconds, and a factor V level of less than 20% should be considered for transplant, as almost all of these children die without transplantation.

All patients require initial confirmation of the diagnosis, intensive medical investigation, nutritional resuscitation, and active treatment of the complications of the liver disease, portal hypertension, and nutritional deprivation (Box 23.2). Immunization status must be reviewed and supplemented with hepatitis A and B immunization, *Hemophilus influenzae*, pneumococcal, varicella, and meningococcal vaccine in most cases. Blood group identical or compatible donors are much preferred as the long-term survival with blood group incompatible donors has been significantly less but there have been recent reports of excellent outcomes with blood group incompatibility, particularly in infants under one year

Box 23.2 Summary of common postoperative problems

1. Biliary tract
   a Stenosis or stricture
   b Anastomotic leak – often associated with hepatic artery thrombosis
   c Infection
2. Rejection
   a Acute
   b Chronic (vanishing bile duct syndrome)
3. Infection – bacterial, viral, (CMV, EBV, herpes zoster, hepatitis B), fungal (Candida, Aspergillus), parasitic (pneumocystis)
   a Abdominal (peri- or intrahepatic abscess)
   b Biliary tree
   c Pulmonary
   d Reactivated virus
   e Gastrointestinal tract
   f Catheter associated (i.v., urinary tract)
4. Vascular (thrombosis, stenosis)
   a Hepatic artery
   b Portal vein
   c Inferior vena cava (supra and infrahepatic)
   d Hepatic vein (left lateral segment grafts), Budd–Chiari recurrence
5. Renal dysfunction
   a Calcineurin inhibitor or other drug-induced injury
   b Tubular necrosis due to hypoperfusion
   c Pre-existing disease (hepato-renal syndrome)
   d Hypertension
6. Miscellaneous
   a Encephalopathy (cyclosporin, tacrolimus, hypertensive, metabolic)
   b Bowel perforation (steroid, diathermy, hypoxia)
   c Diaphragm paresis/paralysis
   d Gastrointestinal hemorrhage (peptic ulceration, variceal)
   e Obesity (steroids)
   f Other drug side effects

of age. Patients are generally listed according to urgency on a UNOS score from 1 to 4 with 1 being the most urgent or according to the pediatric end stage liver disease (PELD) score. Young age (less than six months), creatinine clearance (<90 mL/1.73 m^2), pretransplant hospitalization, pretransplant ventilation, retransplantation, and transplant for reasons other than cholestatic disease have been associated with a reduced survival.[29]

Blood group compatibility of the donor with the recipient should be respected but in infants better results have been achieved if circumstances militate for urgent transplant and only an incompatible ABO blood group donor organ is available. There are also specific strategies to reduce the potential adverse immune consequences of a blood group incompatible organ including the use of a CD20 monoclonal antibody, i.v. immunoglobulin, and plasma exchange.[30]

SURGICAL TECHNIQUE

Donor organ suitability and function is difficult to predict. Increasingly marginal donors are being used with a surprisingly low incidence of primary poor or nonfunction. Age limits are being extended.[31] However, stable donors aged under 45 years with a short intensive care unit stay (less than 3 days), little requirement for inotropic support, and normal or near normal liver function are preferred, with an expected $<5\%$ incidence of impaired function after transplant. Liver biopsy is useful if steatosis is suspected. Greater than 50% fatty infiltration would preclude the use of the liver in most centers. Viral screening of the donors is essential. This would include hepatitis B (HBsAg, HBV IgG core Ab) and C, cytomegalovirus (CMV), Epstein–Barr virus (EBV), and human immunodeficiency virus (HIV) screening. HBV IgG core antibody and HCV positive donors would only be considered in selected viral infected recipients and, if appropriate, post-transplant hepatitis B prophylaxis could be given.

Surgical techniques used for donor retrieval and recipient liver removal and engraftment have evolved over the last 40 years.[32,33] The majority of donor livers are removed as part of a multi-organ procurement procedure, which would include various combinations of kidneys, liver, heart or heart and lungs, small bowel and pancreas. University of Wisconsin solution and histidine-tryptophan-ketoglutarate (HTK) solution are both widely used as the preservation solutions of choice.[34]

The principal two techniques are a careful dissection and excision technique or the so-called rapid technique described by Starzl.[33,35]

DONATION AFTER CARDIAC DEATH

Donation after cardiac death has been established practice for many years for renal transplantation but recently, in an effort to expand the donor pool, this has been extended to other organs. The concept of cardiac death may be more acceptable to some and could increase the number of potential donors. Although there are considerable logistic problems to overcome, some success has been achieved with acceptable graft function even in segmental liver transplantation using a 'super-rapid' technique and keeping both cold and warm ischemic times to a minimum.

The graft should be of an appropriate size both to provide adequate function but not too large to compromise abdominal compartment domain. A minimum graft size should be $>0.8\%$ of body mass (normal $\sim 2\%$), i.e. 40% of estimated standard liver volume. Grafts of smaller size have a poorer outcome from graft failure due to 'small-for-size' syndrome due in part to excessive portal flow.

The recipient operation is commenced so that the estimated hepatic graft ischemic time is less than 12 hours. Much longer preservation times have been recorded, but this leads to an increased incidence of cholestasis and graft dysfunction.

Careful dissection is required when split liver transplantation is being used; that is when the liver is divided into two functional units for two recipients; and decisions must be

made as to which porta hepatis structures will go with which graft. It is advisable to perform a portable cholangiogram to confirm bile duct anatomy as there are many variations in biliary anatomy. Depending on local preference, many centers opt to export the right-sided graft with the full complement of structures of bile duct, portal vein, and hepatic artery, keeping the left lateral segment for the local graft in much the same way as a living donor transplant. Where a reduced size liver is used, the caudate lobe is always excised. The division of liver tissue may be performed using the standard forceps clamp or bipolar diathermy technique with titanium clip and/or suture and ligation of vascular and biliary structures. The ultrasonic dissector (CUSA), Ligasure R, or Harmonic Scalpel may also be used. The cut edge of the liver is then sprayed with two layers of tissue glue. If the recipient inferior vena cava is to be preserved, this is simplest done by carefully excising the diseased liver clear of the cava and when the liver has been removed, individually suturing closed all small areas of leakage from divided direct caudate lobe hepatic veins. The IVC is prepared for the donor liver by dividing the bridges between the separate hepatic veins. This creates a wide orifice for the hepatic vein to cava anastomosis. The inferior vena cava should be incised distally for approximately 1–2 cm to make a triangular orifice for the 'piggy-back' graft.[36]

Engraftment should begin with the upper caval anastomosis taking into account the need to rotate the liver anticlockwise 60° with reduced size liver grafts. Split grafts and living donor segmental grafts may need to lie in an orthotopic anatomical position and a number of techniques of stabilizing the graft have been used so as to avoid torsion at the hepatic vein to caval anastomosis and to facilitate vascular anastomoses without using interposition grafts. Prior to completion of the anastomosis, the liver is flushed of preservation solution via the portal vein with recipient blood, normal saline, or a colloid solution. It is important for the portal vein to be of adequate size and length and it should lie without tension. If the recipient vein is too narrow and sclerotic, interposition of a donor iliac vein is indicated.[33] Likewise with the arterial anastomosis, if the recipient vessel is too small or the donor artery too short, an interposition graft is placed onto the supraceliac or infrarenal aorta. The bile duct is trimmed back and spatulated in pediatric donors such that there is good bleeding from the cut edge and a wide anastomosis is obtained. With reduced and variant size grafts, a Roux-en-Y choledochojejunostomy is always performed using fine absorbable sutures.[37–41]

Occasionally in pediatric cases, a duct-to-duct anastomosis may be performed with a whole liver graft in a recipient with a normal extrahepatic biliary system or for infants with short bowel syndrome undergoing isolated liver transplant. Stents or T tubes are optional but less used as there is some evidence of an increased incidence of biliary complications associated with their use.

SPLIT LIVER TRANSPLANTATION AND LIVING RELATED DONATION

In split liver transplantation a whole cadaver donor organ is divided into two functional units. Segments 2 and 3 are used for an infant and the right liver for an adult recipient. The graft can be further reduced in size by removing segments 2 or alternatively segment 2 is used as the graft and segment 3 is resected and discarded. The disadvantage of using a segment 3 graft is the greater anterior posterior dimension, which may be difficult to accommodate in an infant abdomen (Fig. 23.1).[42] Living related donation of the left lateral segment, first successfully performed by Strong, has become widely accepted as a method of acquiring a liver graft in the face of severe donor shortages, particularly in countries with cultural or religious reticence to accept brain death in a ventilated heart-beating donor.[42,43] There are clear advantages in the planned nature of the procedure, preferably before end stage liver disease in the recipient, the excellent quality of the graft, and short ischemic time. In general, the use of a living donor also increases the availability of donor organs for other patients on the waiting list. The only advantage to the donor is a psychological one and there is a current morbidity of around 10% (wound sepsis, hernia, bile leak, and adhesive bowel obstruction). There is also a reported mortality of around 0.2%, although in one center in Japan more than a 1000 of these operations were carried out without donor mortality.[44] There are ethical concerns, which appear justified, as with more widespread transplant activity increasing mortality and morbidity has been recorded in adult-to-adult donation but adult-to-child donation has a very low morbidity and mortality. The donor should first undergo a thorough screening, both clinical and psychological, without coercion and be given an option to withdraw from the procedure at any time before the

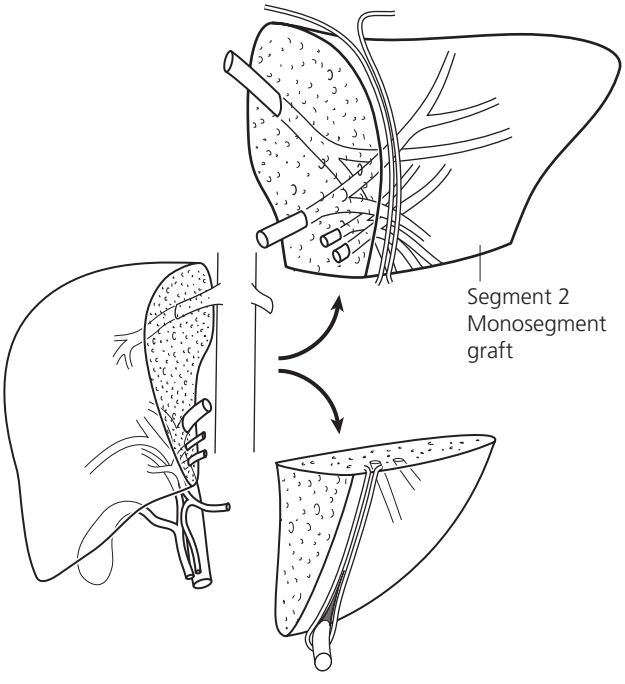

Figure 23.1 Left lateral segment transplant from a living donor or split liver, further reduced in size to a monosegment graft by resection of segment 3.[42]

transplant.[45,46] This process may have to be accelerated where donation is for fulminant hepatic failure. Cholangiography is essential as there is considerable variety in the intrahepatic biliary anatomy.[47] Angiography is desirable but not essential. MR imaging has made interventional radiographic techniques obsolete.

MEDICAL MANAGEMENT

Immunosuppression

Most protocols employ triple therapy with cyclosporine/tacrolimus, azathioprine, or mycophenolate mofetil (MMF) and methylprednisolone. Both tacrolimus and cyclosporine are effective in preventing acute rejection but tacrolimus is more likely to prevent steroid-resistant rejection (94 versus 70%).[48] Increasingly, particularly for small children, tacrolimus is used as primary immunosuppression. In addition, there are a number of other strategies in place to reduce the amount of nephrotoxicity, which is a toxic side effect of both calcineurin inhibitors. Thus, mycophenolate mofetil, an inosine monophosphate dehydrogenase inhibitor, may be used instead of azathioprine and a monoclonal interleukin-2 (IL-2) receptor antibody may also be used with some steroid-sparing.[49,50] Rapamycin, an mTOR inhibitor and mostly used as the synthetic compound sirolimus, is structurally similar to tacrolimus, and prevents proliferation of T cells, but acts at a different stage of T-cell activation than either cyclosporine or tacrolimus. Rapamycin does not interfere with transcription and production of IL-2, rather it antagonizes the action of IL-2 on its receptor. It has the advantage that it is not nephrotoxic but can be hepatotoxic and may be synergistic with cyclosporine. It may cause proteinuria and increases serum triglyceride levels. It may cause hepatic artery thrombosis and delay wound healing and is thus not recommended in the early postoperative period.

Regular monitoring of the renal function is essential as renal-sparing regimens are more effective if started before irreversible renal dysfunction occurs.[51]

IL-2 antibodies such as dacluzimab and basiliximab, which selectively block IL-2 receptors on activated T cells, are particularly useful in children with renal impairment as lower doses of calcineurin inhibitors can be used.[52]

Tacrolimus is increasingly used as primary immunosuppression in pediatric transplantation in place of cyclosporine because of less hirsutism, soft tissue overgrowth, and gingival hyperplasia. Balanced against this is the neurotoxicity in the form of leukoencephalophathy, not infrequently seen in children.

Use of anti-CD25 monoclonal antibodies given before and during the first week of the transplant in conjunction with calcineurin inhibitors has reduced the incidence of acute rejection in the first three months by around 30%, but long-term graft survival is essentially the same as when these agents have not been used. The other polyclonal anti-lymphocyte immunoglobulins are rarely used but have been used with low dose calcineurin inhibitors in tolerance inducing techniques.

Postoperative care

Patients are monitored intensively postoperatively and usually require ventilation for a period of 24–48 hours. Liver ultrasound with color flow Doppler is performed frequently to confirm vascular patency and the absence of biliary dilatation. Liver biopsies are performed if indicated by increasing serum liver enzyme activity or by bilirubin levels, using the Menghini technique (Hepafix needle (Braun), diameter 1.4 mm), unless biliary dilatation is observed on ultrasonography. Biopsies are routinely assayed for viral and bacterial activity.

Diagnosis of rejection can be made on the basis of clinical, biochemical, and histologic changes and usually presents in the first few weeks after transplant with fever, malaise, a tender graft, and loose stools. The grade of rejection is assessed according to established histological criteria according to the Banff schema.[53]

Acute cellular rejection can usually be managed by either switching from cyclosporine to tacrolimus or maintaining adequate trough tacrolimus levels (10–15 ng/mL). If necessary, mycophenolate mofetil can be used instead of azathioprine. If there is ongoing rejection, pulsing with i.v. methylprednisone can be used; four doses of methylpredisnolone at 10 mg/kg for the first three doses on successive days and the fourth on the fifth day after commencing treatment. Monoclonal antibodies and antilymphocyte globulin are very rarely used for steroid-resistant rejection. Once rejection is under control and liver function tests have returned to normal, the tacrolimus dosage can be reduced to a maintenance dose, obtaining trough levels of around 5 ng/mL.

Immunosuppression naturally leads to susceptibility to bacterial, fungal, protozoal, and viral infections. Antibiotics are given as prophylaxis and according to culture and sensitivity of blood, sputum, and body fluid. In infants there is a low threshold for antifungal therapy with either amphotericin or fluconazole. Antiviral prophylaxis for CMV is advisable in all CMV naive recipients and when the donor is CMV IgG positive. There is some debate about the efficacy of prolonged ganciclovir or valganciclovir for EBV control.[54] Trimethoprim/sulfamethoxazole is routinely given for pneumocystis prophylaxis.

Anti-tuberculosis prophylaxis is given only if the reason for transplant is a reaction to anti-tuberculosis drugs with fulminant hepatic failure, where evidence of tuberculosis is found before surgery and if a close family contact has tuberculosis.

Ofloxacin, rifampicin, ethambutol, or pyrazidamide may be used in addition to isoniazid but very careful monitoring of liver function tests is required because all of these drugs may be hepatotoxic and, particularly rifampicin, may result in a decrease in the levels of cyclosporine or tacrolimus levels due to enzyme P450 induction with increased drug metabolism.

Acute postoperative hypertension is almost universal in pediatric transplantation and persists in 25% of recipients.[55] It is usually initially managed with nifedipine sublingually in conjunction with diuretic agents. Subsequently, long-acting oral calcium channel blockers or ACE inhibitors may be

given in appropriate dosage. Aspirin, 3 mg/kg, given on alternate days is used as prophylaxis against arterial thrombosis and a proton pump inhibitor is given for gastric mucosal protection.

Nutritional and vitamin supplementation should be commenced within 72 hours of surgery and may be supplemented by nasogastric feeding or parenteral nutrition in the early phase if there is a delay in restoration of bowel function. Phosphate and magnesium deficiency is common and requires replacement therapy in nearly all patients.

Surgical complications

Surgical complications may be reduced to an absolute minimum with meticulous technique.[56–58] These may present early and late. Biliary complications continue to be a significant problem with an overall incidence of between 10 and 20%, particularly in living related left lateral segment grafts.[59] A proactive management approach is taken with close monitoring of vascular patency using Doppler ultrasound scanning and CT or MR angiogram if there is any doubt. Radiological intervention techniques have been used successfully for later complications of biliary strictures and portal vein stenosis.

Medical follow-up and late complications

Most patients can be discharged from the intensive care unit within the first week after transplantation. The majority of infections can be prevented. However, should the patient require excessive immunosuppression for persistent rejection, almost inevitably they will develop some opportunistic infections.[60–74]

In this situation, not only must specific therapy be directed at the pathogen but also immunosuppression must be reduced. CMV and EBV is best monitored with quantitative polymerase chain reaction (PCR) measurement of the virus.

Post-transplantation lymphoproliferative disorder (PTLD) presents from the first few weeks after transplant to several years later, with a mean time of onset around nine months. Risk of PTLD relates to the intensity of immunosuppression (5–7% in liver transplant recipients) and pretransplant EBV status. Regular EBV PCR monitoring and appropriate reduction in immunosuppression reduces the risk. A typical presentation is initially with acute membranous tonsillitis and associated cervical lymphadenopathy, which is resistant to antibiotic therapy. However, the disease may be widespread and gastrointestinal and central nervous system involvement is common.

Management strategies include reduction of immunosuppression, which may require complete withdrawal along with chemotherapy, anti-CD20 monoclonal antibodies, and adoptive immunotherapy, particularly with the monoclonal PTLD.[75] Mortality varies from 20 to 70% or more. Prophylactic i.v. ganciclovir, given for a prolonged period (100 days), may be effective in preventing EBV activation, which is the promoter of PTLD in most cases.[54]

Hepatitis B infection has been a problem, particularly if hepatitis B IgG core antibody positive donors are used in the absence of prophylaxis where HBV in the graft occurs in up to 80% of cases. There is frequently progression to chronic hepatitis and cirrhosis although antiviral therapy using lamivudine along with hepatitis B immunoglobulin may be effective in controlling the virus, which is monitored with regular HBV DNA levels. Newer antivirals such as tenofovir and entecavir are not licensed for pediatric use.

Children are frequently hypertensive and require antihypertensive therapy for a period of time post-transplant. A degree of renal impairment is almost inevitable in those patients suffering from chronic liver disease with cholestasis. With the additional burden of the use of nephrotoxic immunosuppressive drugs such as cyclosporine and tacrolimus, many have significant impairment of renal function in the long term. The importance of renal sparing strategies in immunosuppression is becoming increasingly evident as 4–5% long-term survivors present with drug-induced renal failure requiring renal replacement therapy.[51]

Chronic rejection is an irreversible phenomenon, which is chiefly intrahepatic and ductular rather than a vascular phenomenon in contrast to other organ transplants. This is usually manifested by disruption of bile duct radicals with development of the vanishing bile duct syndrome. The incidence seems less frequent with tacrolimus-based immunosuppressive regimens as opposed to cyclosporine, where an incidence of up to 10% has been recorded. Late chronic rejection may also be associated with a vasculopathy affecting larger arteries.

RE-TRANSPLANTATION

Ten to 20% of patients may suffer graft failure at some time and need re-transplantation. Early indications may be primary nonfunction, early hepatic arterial thrombosis, severe drug-resistant acute rejection, and established chronic rejection. Early re-transplantation is technically a much less traumatic procedure than the original transplant, although the patient may be in a poorer condition. Outcome largely depends on the indication for re-transplantation and is quite good for technical causes but less satisfactory for rejection and infection. An increasingly poorer outcome can be expected after third and fourth re-transplants and the efficacy and ethics of these interventions are in question.

LONG-TERM SURVIVAL AND QUALITY OF LIFE

One-year survival of >95% is being achieved in the best centers with predicted 10-year survivals of around 70–75%.[76–80] Patients grafted for acute liver failure have done less well with a higher early death rate, usually associated with cerebral complications and multi-organ failure. Excellent quality of life can be achieved and most children are fully rehabilitated.

However, it is increasingly evident that prolonged cholestatic jaundice and malnutrition in infancy may have late

effects and despite good physical rehabilitation evidence of significant cognitive deficits, which present during early schooling as learning difficulties and attention deficit disorder, are common.[81]

Catch-up growth post-liver transplant improves if steroids are reduced, used on alternate days, or withdrawn.[82,83] However, steroid withdrawal comes with the risk of development of chronic rejection or *de novo* hepatitis.[84–86] As with any immunosuppressed patient, the incidence of neoplasia in a lifetime is greatly increased (12% skin and other malignancies).[87] Renal function impairment aggravated by hypertension and calcineurin and antibiotic toxicity is frequent with up to 25% developing chronic renal failure at ten years post-transplant.[88]

Fibrosis on histology is an increasingly recognized phenomenon which seems to be more related to factors at the time of the transplant (cold ischemic time, young age, donor:recipient weight ratio, use of partial grafts) rather than immunological or infective factors.[89]

At a workshop on long-term outcomes, the following factors were identified as requiring further research: risk factors associated with long-term immunosuppression complications; development of tolerance-inducing regimens; definition of biomarkers that reflect the level of clinical immunosuppression; development of instruments for the measurement of health wellness; identification of risk factors that impede growth and intellectual development before and after liver transplantation, and identification of barriers and facilitators that impact non-adherence and transition of care for adolescents.[90]

In the unusual indication of isolated liver transplant for short bowel and intestinal failure-associated liver disease (IFALD), liver transplantation is a lifesaving option. Revised criteria are proposed: progressive IFALD; 50 cm functional bowel in absence of the ileocecal valve (ICV) or 30 cm with ICV; 50% daily energy intake tolerated enterally for 4 weeks with satisfactory growth; and children with dysmotile bowel should be assessed for combined liver/bowel transplant unless the dysmotility is resolved and associated with minimal line infections. Non-transplant surgery may be required to facilitate full adaptation but a >50% long-term survival can be expected.[25]

ADOLESCENCE

Non-adherence in adolescent transplant recipients (~20%) is a particular concern.[91,92] In addition to coping with the usual issues of autonomy, peer pressure with regard to alcohol, recreational drugs, and sex, the transplant teenager has to cope with the cosmetic side effects of immunosuppression, regular medical monitoring, and strict adherence to drug regimens. These issues often occur at the time of transfer to an adult unit. It is important to actively involve teenagers in the decision making, discuss issues of sexuality, risks of pregnancy, and appropriate contraception. A planned transfer to an adult program is essential as the risk of noncompliance and graft loss is great during this period. Use of mobile phone text messaging has been shown in one study to reduce non-adherence among teenagers.[93]

Transplantation in infancy appears to result in a reduced incidence of non-adherence in adolescence compared with later transplantation.

CONCLUSION

Careful planning, extensive preparation of personnel and a broad base of skills along with good teamwork between health professionals are required for the development of a successful pediatric transplant program. Surgical technique, anesthetic skills, and medical care of the highest order are essential. Size of the recipient is only important in so far as making the graft fit the recipient abdomen but long-term outcomes are excellent.

A patient with a liver transplant is a patient for life and requires complete commitment from the transplant medical and surgical team, which cannot be abrogated after discharge from hospital.

The need for pediatric liver transplants has been assessed at approximately 1–2 children per million per year. Thus transplant activity should be concentrated in specific centers with pediatric surgical and medical expertise. The shortage of donor organs will continue and future efforts must be focused on maximum use of cadaver donors and increasing living related donation. No child with end stage liver disease should be denied the opportunity of receiving appropriate treatment.

These challenges must be met to offer any infant or child requiring liver replacement a chance of a life. The ultimate aim is to restore the child to normal health such that he/she can grow up into a productive healthy adult who can make his/her contribution to society and develop all of his/her human potential.

Choanal atresia

STEPHEN M KIERAN AND JOHN D RUSSELL

INTRODUCTION

Choanal atresia is a congenital abnormality in which the nasal cavity does not open into the nasopharynx (Fig. 24.1). The malformation was first described in 1755 by Roederer.[1] The condition may be either unilateral or bilateral. Bilateral choanal atresia presents acutely in the neonatal period with respiratory distress, in view of the fact that the neonate lacks the ability to mouth breathe. A unilateral defect may go undetected for months or even years prior to diagnosis. Treatment involves surgical repair of the defect and has evolved from transmaxillary, transeptal, transpalatine, and sublabial intransal approaches to modern endoscopic techniques. Despite the acceptance of the endoscopic approach as the current gold standard, controversies still exist in how to best manage patients with this condition, particularly regarding the use of adjuvant topical medications following the surgical repair and the use and duration of postoperative stenting.[2]

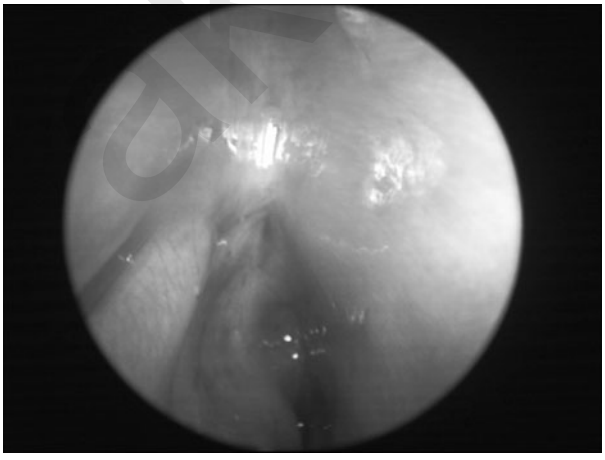

Figure 24.1 Endoscopic view of a right sided choanal atresia as viewed from the nose.

EPIDEMIOLOGY

Choanal atresia occurs in one of 5000–8000 live births and is twice as common in females as in males.[3] Unilateral choanal atresia is more common than bilateral malformations and accounts for 65–75% of cases. Approximately 50% of all patients have other associated congenital abnormalities, which rises to approximately 75% in patients with bilateral disease.[4] The atretic plate may be either mixed bony or membranous in nature. A 90% rate of bony stenosis and 10% membranous stenosis rate was classically reported, but modern imaging suggests a mixed bony/membranous obstruction in 70% and a pure bony obstruction in 30%.[5] Associated syndromes include CHARGE, Crouzon, Pfeiffer, Antley-Bixler, Marshall-Smith, Schinzel-Giedion, and Treacher Collins.

EMBRYOLOGY AND ANATOMIC CONSIDERATIONS

The nasal placodes derive from the ectoderm and appear during the third week of gestation. Around the fifth week, these placodes invaginate into pits that extend posteriorly to form the nasal cavity, which is separated from the oral cavity by a thin nasobuccal membrane. This eventually ruptures at approximately 6 weeks forming the posterior choanae.

In choanal atresia, the abnormality is complex, representing more than just an obstruction membrane across the posterior choanae. The lateral nasal wall and medial pterygoid plates form part of the obstruction and need to be addressed during the surgical repair.[6] The boundaries of the atretic plate are composed of the undersurface of the sphenoid body superiorly, the medial pterygoid laterally, the vomer medially, and the horizontal portion of the palatine bone inferiorly.

A number of embryological theories as to the development of choanal atresia have been proposed; persistence of the buccopharyngeal membrane; failure of perforation of the

nasoubuccal membrane of Hochstetter; or more recently misdirection of neural crest migration.[7] Choanal atresia has also been associated with abnormalities of vitamin A metabolism and maternal use of thionamides (methimizole or carbimazole) during pregnancy.[1]

The CHARGE association (Coloboma, Heard defect, Atresia Choanae, Retarded growth, Genital hyoplasia, Ear anomalies) is associated with choanal atresia in approximately 30% of cases.[8] All patients diagnosed with choanal atresia should have a systematic examination for other features of the CHARGE association.

CLINICAL FEATURES

Clinical presentation depends on whether the malformation is unilateral or bilateral and whether other congenital abnormalities are present. Unilateral atresia may be picked up in the newborn period during routine nasal catheter screening. However, if the catheter rolls up in the nasal cavity, choanal atresia may not be diagnosed until later when the child presents with unilateral nasal obstruction (no misting of mirror) and an associated thick unilateral foul smelling nasal discharge.

Bilateral choanal atresia presents in the neonatal period with respiratory distress, since neonates lack the capacity for mouth breathing.[9,10] The infant presents with airway obstruction and paradoxical cyanosis (the infant turns pink when crying as they breathe through an open mouth). Examination reveals no misting of a mirror placed in front of the nares and failure to pass a nasal catheter. The diagnosis is usually confirmed using a fiberoptic nasendoscope, which after suctioning of mucous, reveals the atretic plate at the posterior choanae. Acute airway stabilization can require an oral airway, a McGovern nipple (a nipple from a feeding bottle with the end opened to allow respiration), or even intubation.

RADIOLOGICAL INVESTIGATIONS

Traditional plain radiography in the supine position with the nasal cavity filled with radiopaque contrast has been replaced by computed tomography (CT). CT of the paranasal sinuses and skull base is recognized as the investigation of choice, but is not necessary until after the patient has had their airway stabilized. Thin section (1–2 mm) axial images provide the best view of the obstruction, but coronal reconstructions should also be provided to identify intraoperative landmarks. Ideally, the nasal cavity should be suctioned prior to the scan as thick mucus can be hard to differentiate from a membranous atretic plate.[5] Imaging provides details as to the nature (bony versus membranous) and thickness of the obstructing segment.[11,12] Imaging will also differentiate choanal atresia from other conditions that present with bilateral nasal obstruction such as pyriform aperture stenosis and bilateral nasolacrimal duct cysts. In unilateral cases, CT again confirms the diagnosis as well as differentiating the condition from others that make up the differential diagnosis of unilateral nasal obstruction; nasal foreign body, large nasal polyp, or nasal tumor.

MANAGEMENT

Infants with bilateral choanal atresia will require airway stabilization with at least an oropharyngeal airway as outlined above. Such devices need to be carefully kept in place and an orogastric tube passed to facilitate feeding until definitive surgical repair can be attempted. Surgical repair should be performed early (even in the first week of life) in patients with bilateral atresia. The only contraindication being medical ones associated with other congenital abnormalities (i.e. cardiac abnormalities in those patients with the CHARGE association). Those with unilateral atresia, however, can generally wait until one year of age, when the risk of general anesthetic has diminished. Occasionally, patients with unilateral atresia have significant airway difficulties and will require earlier intervention.

A number of surgical techniques have been described since the first reported repair of choanal atresia by Carl Emmert in 1854. Transnasal puncture of the atretic plate using urethral sounds was initially performed blindly.[13] However, this technique has now largely been superseded by endoscopic resection using powered instruments.[1]

Endoscopic resection

This approach is preferred by the authors as it allows excellent visualization of the operative field. A tonsil (Boyle–Davis) mouth gag is inserted and a suture is placed through the uvula and clipped to provide retraction of the soft palate. A 120° 4 mm endoscope is passed through the mouth into the nasopharynx and a view of the poster surface of the obstructed choanae obtained (Fig. 24.2). The nasal cavity is decongested with 1:10 000 adrenaline patties and the atretic plate injected with 1% lignocaine with 1:200 000 adrenaline. The atretic plate is perforated with a small urethral sound using the 120° telescope which is passed

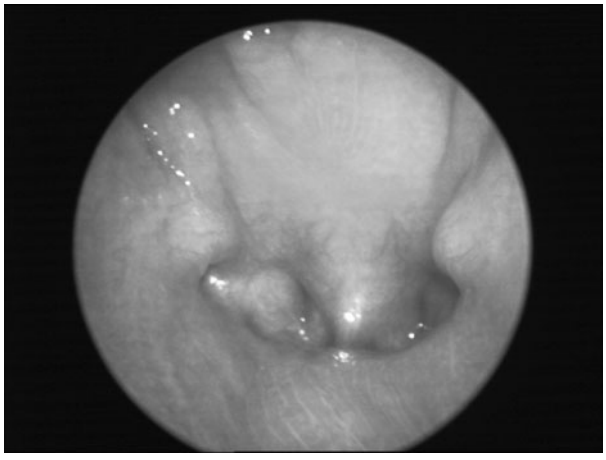

Figure 24.2 Endoscopic view of choanal atresia from the nasopharynx as viewed through a 120° telescope.

through the mouth to view the atretic plate at the time of perforation (Fig. 24.3). The sound is passed to the medial and inferior aspect of the atretic plate to avoid inadvertent injury to the skull base or sphenoid. Even with thick atretic plates, the sound can usually be passed without much force being required. Progressively larger sounds are introduced until the sound can no longer pass through the anterior choana. The drill is then inserted through the nose until it reaches the nasopharynx. We use a specialized drill (Medtronic) which has a protective sheath over the shaft preventing trauma to the nasal cavity. The drilling is performed medially over the vomer and laterally over the medal pterygoid plates. The posterior aspect of the vomer is then removed using a back biting forceps into the nasopharynx and removing the posterior half of the vomer. This creates a common cavity posteriorly which minimizes the chance of restenosis. We insert stents for 6 weeks. An oval shape is cut from the centre of an endotracheal tube. The tube is then inserted in the right and left nasal cavities, through the posterior choanae, and the cut oval section placed over the columella to allow nasal breathing. These are secured in place using a suture. Postoperatively, the stents are kept patent with saline drops. Beclamethasone drops, although unproven, are applied to the nasal cavities to minimize edema. The child is brought back to the operating theatre 6 weeks postoperatively and the stents are removed. Any granulations present are removed at this point with a microdebrider.

Multiple procedures for further microdebridement and dilitations are often required with one large series reporting an average of 4.9 procedures.[14] A number of variations of the endoscopic technique are reported,[1] the most common variation from our technique is a complete transnasal approach using the 0° 4 mm (or 2.7 mm in neonates) telescopes. We find the sole use of the transnasal approach is associated with difficulty using two instruments in the same nasal cavity, particularly with limited space available in the newborn. Similarly, mucosal sparing flaps are advocated by some surgeons in an attempt to improve re-epithelialization.[15,16] However, the authors experience is that these flaps are difficult to perform in the newborn's nose and are generally not viable at the end of the procedure. CT-based image guidance systems are now widely used in pediatric endoscopic nasal surgery.[17] While not mandatory, we advocate its use in this procedure if available.

Figure 24.3 Endoscopic view of urethral sound being passed through an atretic plate as viewed from the nasopharynx using a 120° telescope.

Transpalatal resection

The transpalatal approach was the first approach to the choanal abnormality that provided good exposure of the operative field. Alongside simple blind dilatation it remained the mainstay of surgical repair until the advent of endoscopic techniques. A U-shaped incision on the hard palate is made 5 mm from the dental arch. A posteriorly based superiosteal flap is raised to gain access to the nasopharynx. The inferior vomer is encountered and removed prior to drilling of the lateral atretic plate. This technique remains useful in patients with a small nasopharynx and low skull base, such as infants with Treacher Collins syndrome or where an endoscopic approach has failed. The transpalatal approach is associated with a higher complication rate than endoscopic techniques. Potential complications include postoperative pain, palatal fistula, and reduced midface face growth leading to a high arched palate and associated dental malocclusion which occurs in approximately 50% of patients.[18]

ADJUVANTS TO SURGERY

Mitomycin C

Mitomycin C is an aminoglycoside which is produced by the bacteria stremptomyces, and crosslinks DNA inducing apoptosis. When applied to healing tissue, it has an antiproliferative effect that inhibits fibroblast growth and proliferation. Mitomycin C is widely used in laryngeal and ophthalmic surgery to prevent scar formation and was thus proposed as an agent to reduce restenosis following choanal atresia resection. However, several small studies have not shown mitomycin C to be effective in improving long-term outcomes following choanal atresia repair and there are concerns about using a potentially oncongenic medication in children.[19] Therefore, this is not routinely used following initial choanal atresia repair.

Stents

The use of postoperative nasal stents is traditional yet controversial. Despite the absence of evidence of efficacy in reducing restenosis,[19] the majority of pediatric otolaryngologists employ stents in the postoperative period.[20] However, recent reports are emerging that suggest that stents are not always necessary after endoscopic surgery and there seems to be a current trend away from their use, particularly in older patients.[21–23] However, most surgeons still use stents in those

patients who have high restenosis rates such as neonates. Stents are not without potential side effects with necrosis of the external nose, septum, and palate reported. Furthermore, stents have a tendency to become blocked with secretions, requiring lavage and suctioning on a routine basis by both the parents and nursing staff. When stents are used, the optimum duration of use is unclear with the literature reporting a range of 24 hours to 12 weeks.[1]

OUTCOMES

The primary outcome measure is restenosis as evidenced by a need for reoperation. Reported revision rates for endoscopic resection vary from 0 to 36%.[1,7] Restenosis appears more likely to be required in patients who undergo surgery in the neonatal period for bilateral disease and suffer from gastro-oesophageal reflux. Favorable outcomes may be predicted by the absence of associated facial anomalies, higher weight at the time of surgery (>2.3 kg), and larger stent size.[19,24] One long-term study has demonstrated moderate hyposmia in adults who underwent bilateral choanal atresia repair as a child.[25]

A considerable array of surgical techniques (including adjuvant therapies) exist for the management of choanal atresia in the newborn. To date, no randomized control trials exist to determine optimum treatment protocols, even for the more controversial questions such as the postoperative use of stents. Unfortunately, due to overall rarity of the condition, this absence of evidence is likely to remain unchanged and management guidelines will continue to be based on personal reports and case series.

Pierre Robin Sequence

UDO ROLLE AND ROBERT SADER

INTRODUCTION

Pierre Robin Sequence (PRS) is still considered a 'surgical' cause of neonatal airway obstruction and some of the affected patients truly require surgical procedures to achieve appropriate airway and nutritional management. The various features of clinical presentation and the respective conservative or surgical treatment of Pierre Robin Syndrome will be displayed within the following chapter.

HISTORY

The condition is named after the French dental surgeon Pierre Robin (1867–1950). He described micrognathia, glossoptosis, and respiratory distress in his first paper (1923).[1] In a later publication, Pierre Robin added cleft palate to the list of symptoms.[2] There had been previous reports describing the triad of micrognathia, cleft palate, and glossoptosis resulting in dyspnoea and cyanosis.[3–5] Pierre Robin introduced the term 'glossoptosis' to describe the tendency for the tongue to fall back and cause pharyngeal obstruction.

The condition was traditionally called 'Pierre Robin Syndrome'. After 1975, a series of nosologic changes took place, including Robin anomalad,[6] Robin malformation complex,[7] and then Robin sequence.[8]

The term 'sequence' is used to reflect the hypothesis that the three cardinal symptoms develop sequentially, though it is still not proven what the correct sequence is. The traditional hypothesis states that a mandibular anomaly leads to an anomalous palate (cleft palate) and subsequent airway obstruction.[9] Even if this concept seems to be supported by animal experiments,[10] actual functional therapy results also support the opposite hypothesis that a malpositioned tongue leads to altered mandibular growing patterns.[11–13]

ETIOLOGY, PATHOPHYSIOLOGY, INCIDENCE

The etiological hypothesis is as follows: hypoplasia or abnormal development of the mandible around 7–11 weeks gestational age displaces the tongue high within the nasopharynx. The tongue, unable to descend because of either the lack of mandibular growth or severe retropositioning of the mandible, obstructs the palatal shelves from fusing. The cause of the growth insult to the mandible is uncertain and, presumably, is of heterogeneous etiology. Reported possible causes included: (1) positional or mechanical deformation, as in oligohydramnios, which can be caused by a number of factors; (2) intrinsic mandibular hypoplasia, as in numerous congenital malformation syndromes; (3) neurological or neuromuscular abnormalities, such as myotonic dystrophy or arthrogryposis; and (4) connective tissue disorders, such as Larsen syndrome.

In all these cases, sequential events would lead to the changes seen in Pierre Robin Sequence. A logical assumption is that a variety of factors may lead to persistent mandibular hypoplasia with the resulting postnatal manifestations.[11,14] Since mandibular abnormalities might have numerous causes, PRS cannot be regarded as a specific disease entity. A differentiation should be made between isolated PRS and patients in which PRS is part of a recognized syndrome, part of a complex of multiple anomalies, or part of an unrecognized syndrome.

The proportion of number of cases with isolated PRS varies in different studies from 40 to 74%.[6,15] There are more cases in females, with a male:female ratio of 3:2,[16] which is equal to the ratio comparing male and female children with cleft palate.[17]

The most common PRS syndromes are Stickler syndrome (20–25% of all cases) and velocardiofacial syndrome (15% of all cases). Nager syndrome, spondyloepiphyseal dysplasia congenital, and other recognized syndromes comprise the rest of the syndromic PRS cases (Fig. 25.1).

The severity and persistence of the clinical pathology is probably related to the nature of the insult, as illustrated by the difference in outcome between 'syndromic' and 'non-syndromic' micrognathia.[18–20]

The reported incidence of PRS varies from one in 2000 to one in 30 000 live births.[21,22] The reported differences in the prevalence of PRS at birth are due to the variations of the case definitions.

CLINICAL FEATURES

PRS consists of three essential components:

1. Micrognathia or retrognathia
2. Glossoptosis, possibly accompanied by airway obstruction
3. Cleft palate (usually U-shaped, but V-shape also possible).

It should be mentioned that cleft palate does not have a complete penetrance and can only be seen in about 80% of the Pierre Robin patients.[9,16]

The airway obstruction in PRS requires early and proper management, since it may lead to hypoxia, cor pulmonale, failure to thrive, and cerebral impairment. Generally, syndromic cases are more severe and have worse prognosis than non-syndromic PRS.

Generally, it is expected that patients with non-syndromic PRS will show catch-up growth of the mandible.

AIRWAY MANAGEMENT

Airway obstruction due to glossoptosis can occur at or immediately after birth, but may take much longer (up to 3 weeks) to become apparent.[23] Most neonates present with an isolated PRS and not one of the syndromes, which typically present more significant clinical problems, i.e. airway and feeding difficulties. The airway obstruction in PRS is due to the narrowing or complete obstruction of the pharyngeal space by the posteriorly displaced tongue. This airway obstruction could be intermittent. Most of the complications and unfavorable outcomes of PRS are directly related to delayed or inappropriate airway management.[24–26] Therefore, special vigilance is required, even in patients with only minor defects. Typical clinical signs of upper airway obstruction are increased respiratory effort, stridor, subcostal retractions, and cyanotic or apneic spells. In an otherwise asymptomatic child, choking attacks, cyanosis during feeding, or repeated aspiration events may be due to intermittent airway problems.

Every child with symptoms of airway obstruction should be nursed prone with the head to one side. The head should be maintained in a level position to prevent either glossoptosis or gastroesophageal reflux. Usually, affected children can be successfully fed by mouth in this position.

Persistence of airway difficulties requires further intervention.

Nasopharyngeal tube

The nasopharyngeal airway bypasses the oral pharynx and the obstruction due to the glossoptosis. A regular Portex endotracheal tube (Portex., Wilmington, MA, USA), cut to the appropriate length, is inserted by nasal route and securely strapped in place. The nasopharyngeal airway is a very effective, temporary form of airway management within the intensive care unit (ICU). Usually, patients with nasopharyngeal tubes in place would not be sent home, as dislodgement of the tube can result in an acute airway obstruction.

Endotracheal tube

Endotracheal intubation serves as a short-term support if the nasopharyngeal airway is not successful or during resuscitation or anaesthesia.

Tongue–lip adhesion/glossopexy

Essentially, in this technique, the tongue is sutured to the lower lip. After the child has demonstrated catch-up growth, the tongue–lip adhesion can be released. The efficacy of the tongue–lip adhesion technique remains a controversial issue.

Glossopexy consists of suturing the tongue base to the mandible. Due to the relatively soft consistency of the mandible, a permanent glossopexy is difficult to achieve, therefore this technique is also controversial.

Tracheostomy

Tracheostomy should be avoided if possible, and it should only be employed if all other techniques fail. Tracheostomy should be performed by an appropriately skilled surgeon who is familiar with infantile airways. Tracheostomy requires closed monitoring but enables oral feeding. Tracheostomy could be removed after the child's airway obstruction has resolved, which usually happens within the first year of life.

Distraction osteogenesis of the mandible

Distraction osteogenesis comprises a relatively new technique. The mandible needs to be cut near the angle of the mandible on both sides. A specialized mechanical device distracts these two portions every day by approximately 1.5–2 mm. Using this technique, the mandible gradually elongates over a period of 2–3 weeks. Timing of performing a mandibular distraction can be in newborns to prevent tracheostomy or at a later stage to remove a tracheostomy tube.

Distraction osteogenesis has been carried out only during the last 5–10 years. Therefore, long-term follow-up results of this promising technique are not available. Nevertheless, the distraction osteogenesis technique should be reserved for severe cases of non-syndromic Pierre Robin and syndromic PRS, since in most cases of non-syndromic PRS physiologic catch-up growth of the mandible occurs.

Tongue positioning and stimulation plate

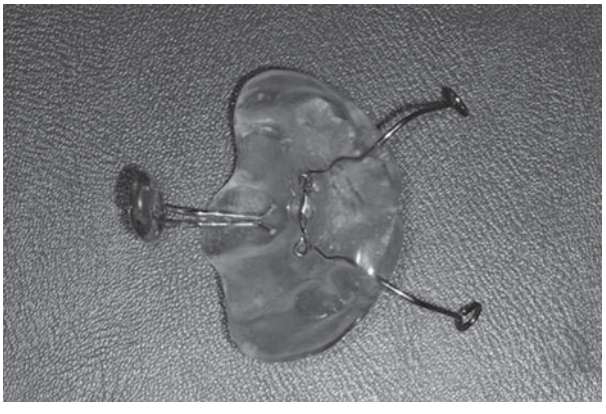
During the last decade, a new, nonsurgical technique was developed by orthodontists that guarantees, in most cases, a free airway space and treats the hypoplastic mandible causally. Immediately, a palatal plate is produced, similar to the feeding plate for cleft palate newborns, but with a dorsal spur that goes shortly to the epiglottis (Figs 25.2–25.4). Sometimes endoscopic control is necessary during positioning to avoid irritation of the epiglottis. To accomplish this, the tongue is positioned anteriorly and the airway is kept

Figure 25.1 Typical Pierre Robin Sequence facies with receding chin.

Figure 25.2 Pierre Robin Sequence patient with stimulation plate.

Figure 25.3 Result of stimulation plate after 15 months.

(a)



(b)

Figure 25.4 (a and b) Stimulation plate with dorsal spur.

patent. Moreover, via functional stimulation of the tongue, the mandible starts to grow during the following months and will be quite normal when the palatal closure is performed at the age of about six months. Feeding is also supported, but problems remain in some cases.[13,27]

NUTRITIONAL MANAGEMENT

Most of the children with PRS have feeding difficulties. Initial treatment consists of bottle-feeding in a prone position with the head slightly elevated. This method of feeding is appropriate in children with catch-up growth of the mandible.

If this is not satisfactory, gavage or feeding tubes can be used temporarily to improve nutrition. If the feeding is still not successful, the child might need a gastrostomy, which could be removed after gaining the ability to be feed orally.

It has been shown clearly that infants with PRS require adequate caloric intake. It is important to achieve the maximum growth rate of the mandible since the resolution of the airway problems is directly related to mandibular growth. Only recently has increased work of breathing been appreciated as an important component of calorie consumption. It may be necessary to provide these children with several times the normal caloric requirement of an infant to compensate for up to a ten-fold increase in respiratory work.[28] Indeed, failure to gain weight despite maximum nutritional intake should suggest the need for more aggressive airway management.[29] The availability of total parenteral nutrition should prevent any instances of failure to thrive, but it is rarely needed if other aspects of the condition are managed correctly.

CLEFT PALATE

Cleft palate is present in at least 80% of patients with PRS. Cleft palates are typically repaired while patients are infants. A palatal plate can be used in patients with a cleft of the hard palate to improve feeding. The plate also corrects the tongue position by moving it anteriorly. In patients with a cleft of the soft palate alone, a palatal plate has no positive effect on feeding, but it can improve the tongue position and stimulate mandibular growth. To enhance this effect, the plate can be modified by an anterior stimulus according to Castillo-Morales.[30]

Surgical protocols differ from center to center, and cleft closure is performed not only by different techniques (i.e. Langenbeck, Furlow, Wardill), but also at different ages, ranging from four to 36 months.

It is currently assumed that early surgery will provide a better chance of normal palatal function and speech development.

MICROGNATHIA/RETROGNATHIA

The first described functional therapy for micrognathia was the use of the orthodontic palatal plate to achieve growth stimulation of the mandible. It was not clear until today whether the growth potential of the mandible after this stimulation is sufficient to achieve the normal dimensions. However, it has been shown, based on physical examinations until age five, that the mandible can barely regain its growth in relation to a normal population.[31] A retrospective longitudinal study by cephalograms and lateral photographs of American patients with PRS and cleft of the soft palate showed that the mandible achieved only partial catch-up growth and, in adults, a smaller maxilla, mandible, and a narrow respiratory airway space persisted.[32] Studies in the Finnish population showed the same result.[33–35] An increased mandibular growth was seen during the first two years of life, but normal craniofacial dimensions were never achieved. At the young adult stage, even if the patient's profile appeared less retrognathic due to masking by the overlying soft tissues or the patient's teeth showed neutral occlusion, cephalograms revealed retrognathia and caudal-dorsal rotation of the mandible. Thus, it seems in accordance with today's knowledge that the microgenia in PRS can be balanced only partially by growth processes. Frequently, orthodontic therapy is necessary in childhood. In severe cases, surgical advancement of the mandible combined with a genioplasty can be beneficial, as well.

SKELETAL ANOMALIES

Around 11–21% of children with PRS have limb defects.[17,36] Common anomalies are talipes equinovarus, syndactyly, short, or absent digits and hypoplastic long bones. Occipito-atlanto-axial instability has also been described, emphasizing the need for very experienced clinicians to undertake the intubation of such patients. Orthopedic and radiological consultation should be sought in children with suspected skeletal problems. Rare neuromuscular defects can also occur, resulting in a tendency for glossoptosis to persist despite mandibular growth.[11]

EAR PROBLEMS

Malformations of the ear have a frequency of 10.5% and consist of defects in the auditory capacity and anomalies of the shape of the ear. One main concern is the frequently recurring infections of the middle ear, which also occur in patients with a cleft palate and are based on disturbed function of the Eustachian tube. Therefore, a hearing screening has to be performed at birth. At a later date, control of the middle ear tube function has to be achieved and grommets placed, if necessary.[37,38]

CARDIOVASCULAR ANOMALIES

Intrinsic cardiac defects are found in up to 20% of infants with PRS.[17,36,39] Septal defects are common, but more complex lesions can also occur. A thorough cardiovascular

examination should be performed in PRS babies, particularly since airway difficulties may aggravate the cardiac status.[40]

OCULAR ANOMALIES

Retinal detachment and micrognathia occur as part of Stickler syndrome,[41] but 10% of infants with non-syndromic PRS also have eye defects, such as strabismus, ptosis, and microphthalmia. More severe defects, such as cataract and congenital glaucoma, have also been reported, and ophthalmologic consultation is recommended in all cases.[17,36,42]

NASAL OBSTRUCTION

Choanal atresia is a rare accompaniment of PRS,[43] but it may complicate the respiratory difficulties in small infants who do not mouth-breathe. It is important to ensure nasal patency, especially if one nostril is to be utilized for a nasogastric feeding tube. Choanal obstruction by itself can lead to glossoptosis, with consequences identical to those of PRS.[44]

COMPLICATIONS AND OUTCOME

In isolated PRS, the long-term outcome is directly related to the quality of the management at the onset of symptoms. With adequate nutrition, mandibular growth will achieve normal or near-normal proportions, and the glossoptosis will resolve.[14,45,46] One study has suggested that there is no significant difference in proportional mandibular growth during the first year of life between PRS infants and controls[46] but, in the majority of affected infants, symptoms are relieved within a few months. Airway protection during this period is vital. The previously documented high incidence of mental retardation in PRS patients was almost certainly due to unrecognized episodes of hypoxia, and with good airway management this complication is uncommon.[17,36]

Undiagnosed hypoxia may also lead to pulmonary vasoconstriction, with resultant pulmonary hypertension and cor pulmonale.[40] Some instances of sudden death in PRS were likely due to this problem. The presence of cardiomegaly on a chest x-ray should alert the physician to the possibility that hypoxic episodes have been overlooked, and appropriate steps should be taken immediately.

Although airway patency improves with growth, there remains a potential for obstruction, particularly after invasive procedures such as intubation or cleft palate repair.[47] In some children, obstruction may occur during sleep, causing occasional apnea with potentially hazardous consequences.[44,48,49] A degree of mandibular hypoplasia may persist for several years, resulting in malocclusion and the need for dental treatment.[50,51]

The overall mortality rate in infants with PRS is approximately 25%. The majority of deaths (70%) occur in children with associated anomalies, particularly those with cardiac defects or an underlying syndrome.[17,36,51] These facts must be considered when counseling parents of affected children. With good medical and nursing care, the prognosis for children with isolated PRS should be excellent.[52]

Macroglossia

GEORGE G YOUNGSON

INTRODUCTION

Macroglossia (primary form) is defined as a resting tongue which protrudes beyond the teeth, or in the case of the neonate, the alveolar ridge.[1] Pseudo-macroglossia arises when the tongue itself is normal, but relative protrusion occurs because of a small mandible, as is seen in Down syndrome or in Pierre–Robin syndrome (see Chapter 25, Pierre Robin Sequence).[2]

ETIOLOGY

The causes of primary macroglossia include hypothyroidism, lymphangioma, hemangioma, idiopathic hyperplasia, and chromosomal abnormalities. Macroglossia is one of the most constant features of the Beckwith–Wiedemann syndrome, which is characterized by an omphalocele or umbilical hernia, with associated visceromegaly, somatic gigantism, or hemi-hypertrophy and hypoglycemia.[3] When displaced because of adjacent pathology such as cystic hygroma, cysts in the lingual thyroglossal duct, neurofibromatosis, or tumors such as rhabdomyosarcoma, then the term secondary macroglossia can be used. Heterotopic or ectopic tissue will rarely contribute to enlargement and intraoral and intralingual enteric duplication cysts have been detected *in utero*.[4–6] The differential diagnosis of such intralingual anomalies also includes dermoid cyst, hemangioma, and ranula.

PATHOLOGY

The histological features depend upon the underlying disorder. In addition to the conditions mentioned above, macroglossia can also be found in the triad of intrauterine growth retardation, transient diabetes mellitus, and macroglossia.[7] It is also seen in a number of syndromes including Behmel, Hurlers, Laband, and Tollner syndrome.

PRESENTATION

Lymphangioma is the most common cause of macroglossia to present in the neonatal period (Fig. 26.1a,b) and prenatal diagnosis by ultrasound is possible when associated with Beckwith–Wiedemann syndrome[8] and some of the intraoral cystic lesions discussed above. The clinical presentation includes noisy breathing and drooling, as well as the obvious physical features and, when difficulties in feeding occur, then failure to thrive and poor weight gain develop. Moreover, when lymphangioma is the cause, verrucous lesions may appear on the surface and these can ulcerate and exude a serous discharge.

If unrecognized or untreated in the neonatal period, the lesion may become more problematic in infancy or later in childhood when it may present with minor trauma, for example a lingual lymphangioma. This can then result in intralesional hemorrhage and/or sepsis (usually cellulitis from group B hemolytic *Streptococcus*). In this event, abrupt enlargement may compromise the airway and produce a life-threatening emergency necessitating tracheostomy and gastrostomy until definitive tongue reduction can be carried out (Fig. 26.2).

If treatment is inappropriately delayed, protracted dental defects develop including prognathism, anterior open bite, and an increased angle between the ramus and body of mandible.[9] Speech defects occur and articulation is subsequently defective, especially expression of consonants which are precluded by inadequate tongue movement as a consequence of the increased bulk in a limited cavity. Regression of macroglossia is not a regular feature when due to lymphangioma and a conservative approach to the lesion has no merit.

DIAGNOSIS

Investigation, following thorough physical examination for secondary causes of macroglossia, comprises thyroid function testing, echocardiography, and karyotype analysis. Magnetic resonance imaging to detail the extent of tongue involvement is indicated, particularly when the volume of lingual tissue affected is not clinically apparent.

MANAGEMENT

Preoperative

Multidisciplinary involvement is, as ever, helpful, with speech therapists, dieticians, and pediatric dentists valuable contributors to patient and parental management. If airway occlusion with associated respiratory distress exists, then airway management requires involvement of anesthetists/intensivists. Biopsy is rarely indicated with histology becoming available on the resected specimen. However, needle aspiration of intralingual cystic lesions may be a useful temporizing procedure,[5] but requires confident exclusion of vascular anomalies by pre- or postnatal imaging.

When the tongue is particularly large, nursing the infant in the lateral or prone position assists in airway management and skin care, especially if drooling is a prominent feature. In cases of Beckwith–Wiedemann syndrome, the tongue is seldom grossly enlarged and treatment must be seen in the context of the care requirements of the infant in relation to the other features of this condition. Similarly, surgical intervention is inappropriate if hypothyroidism is the primary diagnosis. However, massive enlargement may precipitate the need for early intervention and the challenge of anesthesia and endotracheal intubation point towards the need for tracheostomy and close collaboration with a pediatric otolaryngologist.

Alternatives to reduction glossectomy include intravascular photocoagulation[10] and embolism of vascular tongue anomalies,[11] but early surgery (preferably before seven months of age)[12] confers optimal opportunity for rehabilitation of tongue movement and avoiding complications, such as glossitis, hemorrhage, and secondary speech and maxillofacial abnormalities. Clearly, postponing surgery in the newborn period is preferable for avoidance of unnecessary morbidity but the timing thereafter is a matter of individual clinical judgment.

Steroid treatment may confer temporary benefit during management of the acute airway obstruction and penicillin-based antibiotic therapy is indicated for the treatment of septic complications. These problems, however, are usually seen later in infancy and childhood rather than the neonatal period and result from inappropriate delay of surgery.

Operative

Reduction glossectomy is the mainstay of treatment and options include central wedge resection, circumferential

wedge resection, or a combined transoral and transcervical approach for a massive infiltrative lymphangioma.[13]

The aims of reduction are to allow intraoral position of the tongue in the floor of the mouth to restore normal tongue movement and to permit speech and deglutition. Implicit in these objectives is the fact that surgery should be conservative and a repeat tapering procedure is preferable to removal of excess tissue.

V-shaped resection of the anterior tongue has been previously described.[14,15] The principles involve careful hemostasis by use of a tourniquet or, alternatively, by use of a YAG laser, CO_2 laser,[16] or harmonic scalpel.

Nasal intubation or tracheostomy secures airway protection. The head is placed in a silicone ring and the neck extended. A suture placed on the apex of the tongue and two hemostatic/traction sutures tied over silicone rubber dams at the base of the tongue provide the requisite traction (Fig. 26.3).

Traction on these three sutures delivers the necessary exposure and hemostasis sufficient for central wedge resection. The resection should not usually extend into the posterior one-third where the extrinsic muscles of the tongue are inserted. The lateral margins of the incision extend from the level of the anterior gum, with the tongue in a resting position, to the apex, and this incision is beveled such that more ventral than dorsal tissue is removed. This recreates the natural concavity of the central tongue (Fig. 26.4). A straight needle is a useful adjunct to creating this bevel.

The divided lingual arteries are ligated. Restoration of the tongue flaps and the midline is performed incorporating mucosa and a few mm of muscle (Fig. 26.5).

The opportunity to place a percutaneous gastrostomy should be taken if protracted delay in feeding is anticipated.

Postoperative

Antibiotics should be continued into the postoperative period to provide prophylaxis against sepsis in the floor of the mouth. Oral hygiene is maintained with chlorhexidine or saline oral toilet. The appropriate tracheostomy care, if required, is given and secondary orthodontic and speech therapy follow up arranged.

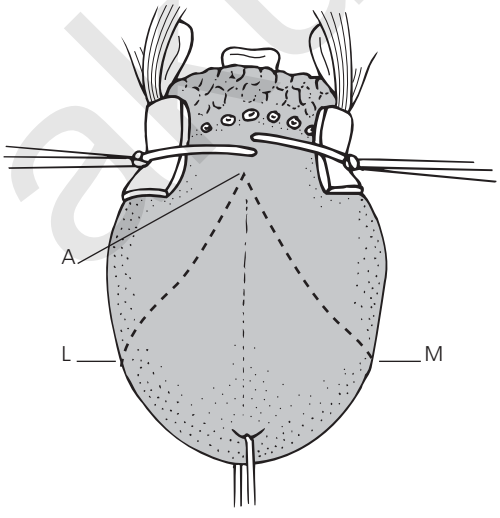

Figure 26.3 Traction sutures allow good exposure and good hemostasis during reduction glossectomy.

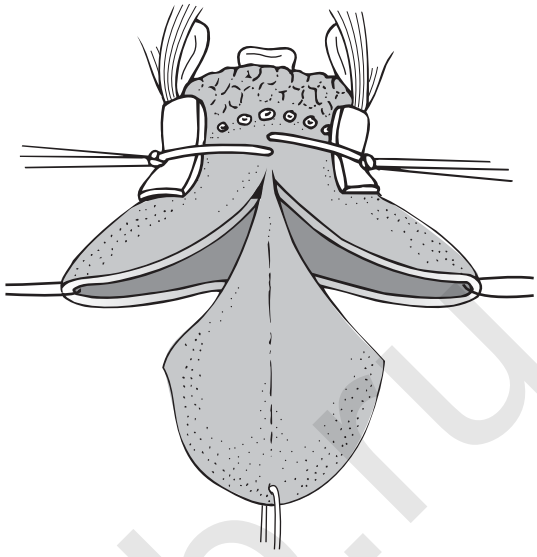

Figure 26.4 Wedge of tissue incorporating more of the ventral than the dorsal aspect of the tongue is removed.

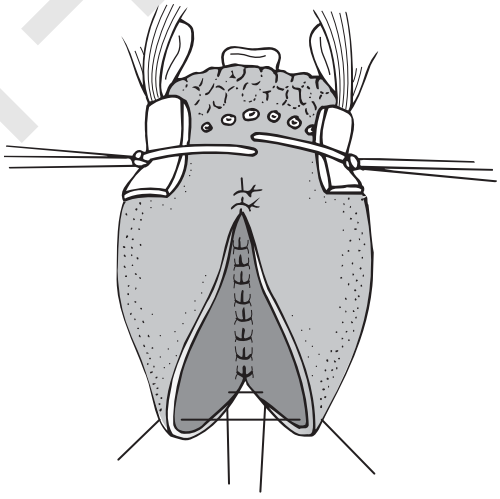

Figure 26.5 The remaining lateral segments of the tongue approximated in the midline.

Tracheostomy in infants

THOM E LOBE

INTRODUCTION

Neonatology and technology have made great strides over the last few decades. Pulmonary disease remains the primary indication for tracheostomy in preterm infants. However, in general, because of the routine use of surfactant and steroids, it is now less common to see infants dependent on a ventilator for lung disease alone, and it is neither unusual nor unsafe to leave an infant on a ventilator with an endotracheal tube in place for months on end. Term infants who need a tracheostomy do so because of an inadequate airway. These infants otherwise are ready to go home or to a facility for technologically dependent children, but still require ventilatory assistance.

This chapter will discuss the indications and techniques for insertion and maintenance of a tracheostomy in infants.

INDICATIONS FOR TRACHEOSTOMY

The indications for tracheostomy in infants fall into five main categories: (1) airway immaturity, (2) obstructing congenital anomalies, (3) acquired obstructions, (4) tumors, and (5) trauma.

The immature airway manifests itself as laryngomalacia, tracheomalacia, or a combination of the two conditions. These infants present with inspiratory stridor and some degree of nasal flaring and chest retractions. Other related conditions are congenital vocal cord paralysis, which is usually due to a central nervous system deficit, phrenic nerve injury, which may be associated with a difficult delivery, and recurrent laryngeal nerve injury, which may occur after ligation of a patent ductus arteriosus.

Some patients with choanal atresia and Pierre Robin syndrome may be candidates for tracheostomy. Other craniofacial deformities such as Freeman Sheldon syndrome, Cerebro-costo-mandibular syndrome, arthrogyposis multiplex congenital, and others also may require a tracheostomy for airway maintenance.

Patients with a congenitally stenotic airway or tracheal agenesis are special cases. In the case of agenesis, an emergency tracheostomy may be necessary where the trachea re-establishes distally. Usually, however, these patients can be ventilated best using a mask because the bronchi come off the esophagus and an esophageal tube can cause obstruction. Technology today allows bedside bronchoscopy in such infants with tenuous airway status so that proper decisions can be made before one risks transporting the infant to the operating room. There are several acquired conditions that require tracheostomy including infection, papillomatosis, neuromuscular failure, chronic aspiration, and subglottic stenosis.

Occasionally, the management of a tumor such as a cervical teratoma or sarcoma in infancy will mandate a tracheostomy. More likely a hemangioma or lymphangioma will compromise the airway to the extent that a more stable airway is needed. Infants with congenital high airway obstruction (CHAOS) are often diagnosed *in utero* today and an EXIT procedure (trachesotomy performed with maternal–fetal circulation intact), may be required.

Rarely, trauma will prompt the surgeon to perform a tracheostomy. This can be related to birth trauma, child abuse, or accidents.

PREOPERATIVE EVALUATION

Most infants who need a tracheostomy already have an endotracheal tube in place. Infants suspected of laryngotracheomalacia may require direct laryngoscopy and/or bronchoscopy to assess the situation.

The surgeon should make certain of the coagulation status, hemoglobin level, and electrolytes as indicated by the patient's condition. The nutritional status of the patient should also be taken into consideration. Poor nutrition will complicate nearly any condition in infancy and may weigh in favor of an earlier tracheostomy than would be indicated otherwise.

When an infant is not intubated but is under consideration for tracheostomy, the extent to which the child maintains oxygenation and demonstrates adequate ventilation, as judged by the PCO_2 measured by transcutaneous monitoring, will determine the need for a more direct assessment before a decision for tracheostomy is made.

Finally, patients with persistent aspiration, despite correction of any gastroesophageal reflux, may necessitate a tracheostomy to prevent severe pulmonary consequences.

TECHNIQUE

The infant is placed supine on the operating table, sufficiently toward the foot of the table so that the surgeon can access the infant's neck easily, but not so far down on the table that the anesthesiologist cannot reach the patient to manipulate the endotracheal tube when required.

These cases should be performed under a general anesthetic unless the infant is so ill as to be unable to tolerate the drugs. Even so, an anesthesiologist or anesthetist should maintain control of the airway while the surgeon is exposing and manipulating the trachea.

The patient's cardiorespiratory status should be monitored during the case. This should consist of a cardiac monitor for heart rate, a blood pressure monitor, and ideally a pulse oximeter to assess the infant's oxygenation.

If there is any question as to the status of the airway, bronchoscopy should be performed to assure that the tracheal lumen will accept a tracheostomy without difficulty. Special issues, such as a tracheostomy to stent an airway for severe tracheomalacia, can be assessed by bronchoscopy to determine the proper length of the proposed cannula, which may have to be specially ordered. In some cases, it may be necessary to use an ordinary endotracheal tube placed through the cervical incision and secured to the skin of the neck until this temporary tracheostomy cannula can be replaced with the specially ordered device.

When positioning the infant on the operating table, the neck should be extended sufficiently to allow complete access to the neck. Sometimes, on chubby infants, it is still difficult to see the entire neck, despite the best attempts. A roll should be placed under the infant's shoulders to facilitate proper positioning (Fig. 27.1).

The endotracheal tube should be secured so that the anesthesiologist can easily remove the tube at the appropriate time. This means that any tape should be loosened beforehand. If there is a feeding tube in place, it should be removed so that it does not interfere with endotracheal tube manipulation.

When the infant is properly positioned and monitored, the entire neck from the lower lip to below the nipples should be prepped with a suitable surgical prep and draped.

The superiormost surgical drape should allow easy access to the patient by the anesthesiologist.

Once prepped and draped, the surgeon should carefully palpate the infant's neck to locate the trachea that hopefully is in the midline. The surgeon must remember that the infant's trachea is quite mobile and compressible, and may be difficult to palpate. The anesthesiologist can jiggle the endotracheal tube from above to assist with its location.

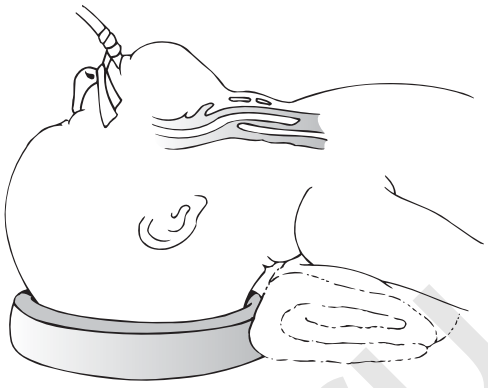

Figure 27.1 Position of infant for tracheostomy. The shoulders are elevated on a roll; the head is hyperextended on the neck and supported by a doughnut-form support.

A transverse skin incision is best. We make our incision in the lower neck crease, about the width of one finger above the jugular notch. If the incision is too low, the endotracheal tube will end up in the mediastinum and the cannula will be placed too low in the trachea. We first score the skin with a scalpel, then use a needle-point electrocautery device to deepen the incision, taking care not to burn the skin. This incision is extended through the subcutaneous fascia and platysma muscle, which is quite thin in the small infant. It is helpful to insert two right-angled retractors in the corners of this incision to better expose the operative site.

Next, we use two atraumatic forceps to grasp the anterior cervical fascia on either side of the midline and open it vertically in the midline. We extend this incision inferiorly to the jugular notch and superiorly to the thyroid gland.

The strap muscles, immediately beneath the anterior cervical fascia, are similarly separated in the midline. Usually, there are few to no blood vessels in the dissection thus far. Occasionally, the surgeon will encounter a few small vessels that cross the midline. These should be cauterized and divided as they are encountered.

Once these muscles are separated, we place the two retractors deep to the muscle edges and gently retract laterally to better expose the trachea below. Sometimes it is necessary to free the muscle edges sufficiently to allow room for the blade of the retractor to gain a secure purchase.

The trachea should be visualized easily. If not, then palpation in the wound with manipulation of the endotracheal tube by the anesthesiologist will help locate the trachea.

The proposed tracheostomy cannula should be selected, opened, and its outer diameter visually checked against the exposed trachea to judge the correctness of its size. If it seems that the initial selection was incorrect, then a tracheostomy cannula of a more appropriate size should be selected.

The pretracheal fascia should be lightly scored with the cautery to coagulate any tiny vessels on the surface of the trachea in the midline. Again, the blades of the retractors should be deep in the wound on either side of the trachea for optimal exposure.

A suture of 4-0 Prolene or its equivalent should be placed on either side of the midline scored anterior trachea (Fig. 27.2). Each suture incorporates one or two tracheal rings. These sutures are not tied onto the tracheal wall, but can be tied at their ends and should be left 6–8 cm in length. At the end of the case, these sutures should be taped securely to the anterior chest wall and used to locate the tracheal incision in the event of a postoperative emergency in which the newly placed tracheostomy cannula dislodges. These sutures can also be used to hold open the edges of the tracheal incision for ease of placement of the tracheostomy cannula at operation.

The surgeon should request that the endotracheal tube be loosened and prepared for removal. Using a No. 11 blade, a vertical incision is made through the tracheal wall along the score mark (Fig. 27.3). Two or three tracheal rings should be divided, usually rings 2, 3, and 4. Rarely, it is necessary to divide the isthmus of the thyroid gland for proper tracheostomy positioning. A transverse tracheal incision or removal of a tracheal ring is likely to result in a tracheal deformity and thus should be avoided. Similarly, unless one is dealing specifically with a localized stenosis or deformity, tracheal wall resection is to be avoided.

Suction should be available in case blood or secretions interfere with the surgeon's view of the tracheal lumen. The tip of the cannula to be inserted should be lubricated with a water-soluble surgical lubricant and positioned over the incision, poised for insertion when the endotracheal tube is withdrawn.

The surgeon should then ask the anesthesiologist to withdraw the endotracheal tube sufficiently to clear the lumen so that the tracheostomy cannula can be inserted and directed caudally toward the carina.

One way to avoid misplacement is to insert a suction catheter through the lumen, beyond the tip of the cannula (Fig. 27.4). The suction catheter then can be inserted into the tracheal lumen first and serve as a guide over which the cannula can be passed. This technique is also useful should the cannula become dislodged after the procedure.

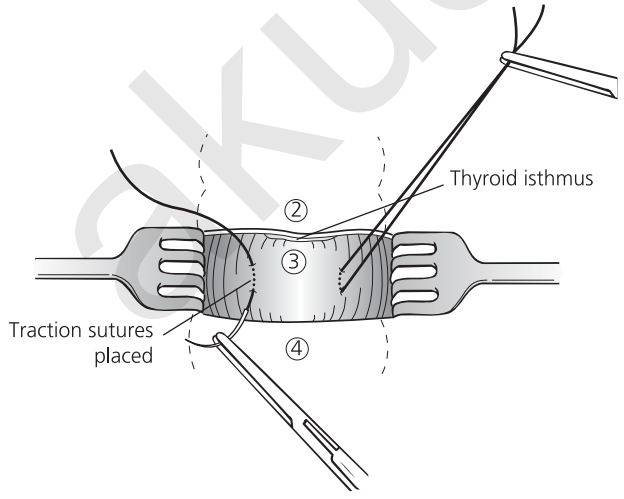

Figure 27.2 Traction sutures of fine silk are placed around the third tracheal ring to stabilize the trachea before incision. The sutures are tied in loose loops and later taped to the anterior chest wall. The sutures are left in place for 4 days as a precaution against accidental decannulation postoperatively.

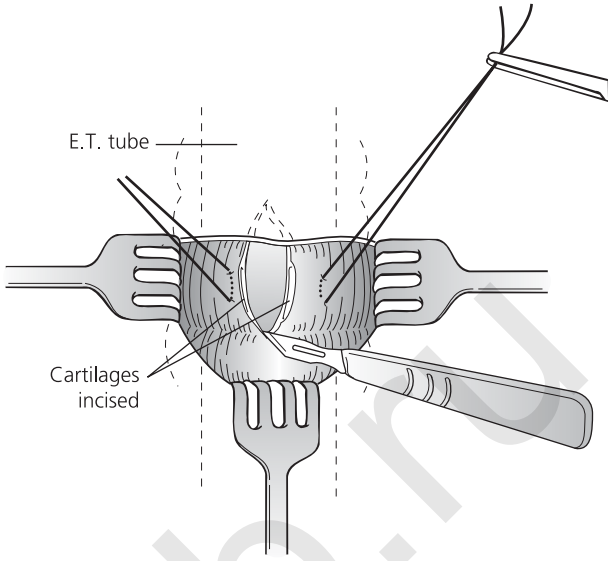

Figure 27.3 The trachea should be opened through a midline vertical incision across 2–3 tracheal rings. The incision must be long enough to avoid excess tube pressure against the cartilages. A tight tube can result in pressure deformity and reabsorption of cartilage.

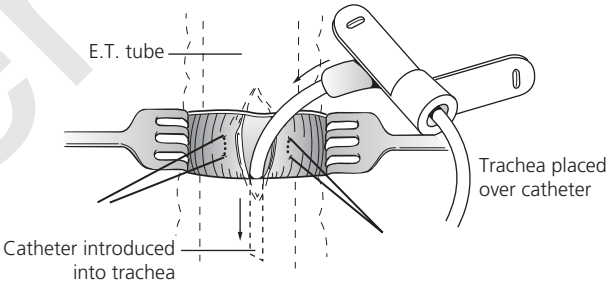

Figure 27.4 Tube insertion into the trachea is accomplished by shifting the endotracheal tube up to the cephalad margin of the new stoma, inserting a tracheal suction catheter into the trachea through the newly established opening, and then advancing the tracheostomy tube over the catheter in the trachea. This is safer than using the tube obturator, the short tip of which sometimes slips out of the stoma and allows the tracheostomy tube to pass anterior to the trachea and into the mediastinum.

If, for any reason, the tracheostomy cannula does not fit easily into the trachea, it should be removed and the endotracheal tube advanced beyond the tracheal incision so that ventilation will not be compromised. This might occur if the diameter of the tracheal lumen has been overestimated and the previously selected tracheostomy is too large to fit into the trachea. In the latter case, a smaller cannula should be selected.

As soon as the cannula is in place, the obturator or suction catheter should be removed and the anesthesiologist should disconnect the ventilator hose from the endotracheal tube

and connect it to the tracheostomy cannula. Once that is done, the anesthesiologist should administer several deep breaths to the patient to confirm that the cannula is in the proper place and that the infant can be ventilated satisfactorily. If it appears that although the cannula width is appropriate, the cannula is too long and its tip rests on the carina, then several pieces of gauze can be used to build up the gap between the neck and the tracheostomy collar, thus backing the tip of the cannula away from the carina. Once adequate ventilation is confirmed, then the endotracheal tube can be removed completely.

Once the cannula is connected to the ventilator, the cervical wings of the body of the cannula need to be secured to the patient. We do not rely on a tie placed around the neck, but accomplish this with the aid of sutures.

For each wing, a suture of 3-0 silk or its equivalent is passed through the skin of the neck, then through the upper edge of the wing of the cannula (midway between the midline and the end of the wing), through the lower edge of the wing, then again through the skin. When this suture is tied, the skin will be drawn over the wing and usually will cover it. After these sutures are placed, both wings will be securely fixed to the skin of the neck.

The two ties that were placed in the anterior tracheal wall should now be taped securely to the anterior chest wall in such a fashion that ensures that their ends are easily accessible in case they are needed in an emergency to reinsert the cannula (Fig. 27.5).

Finally, the umbilical tape or tie that usually comes with the cannula is passed through the holes in the end of the wings and tied around the neck to further secure the cannula. This should be tied at the back of the neck. A simple gauze dressing with antibiotic ointment applied is placed underneath the wings of the cannula over the cervical incision to complete the procedure.

We send our infants to the intensive care unit after a fresh tracheostomy in case of emergency.

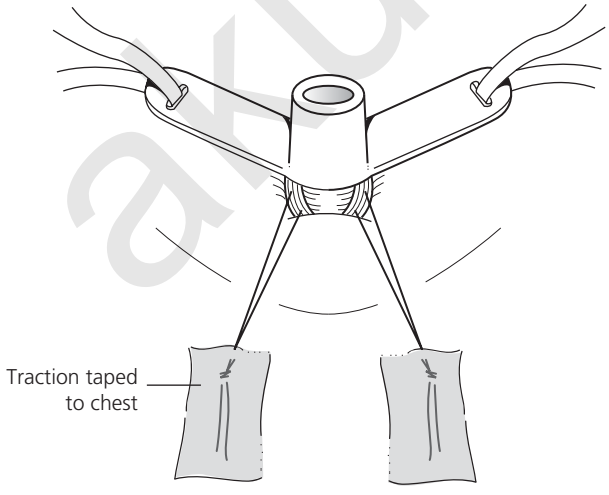

Figure 27.5 Prevention of accidental decannulation is the surgeon's responsibility. The tube should be taped to the anterior chest for 4 days in case an unexpected tube change should become necessary.

PERIOPERATIVE MANAGEMENT

If the skin of the patient's neck is infected with a bacterial or fungal infection, this should be cleared before any operation is undertaken unless emergency tracheostomy is required to save an infant's life.

In patients with short, fat necks, it may be necessary to place the infant in a position of neck extension to facilitate clearing any skin infection or breakdown that is due to chronic moisture. Simply exposing the infant's neck to air for drying is often sufficient to clear any problem.

Immediately after the tracheostomy is secured, the roll under the patient's neck should be removed and an x-ray of the chest should be reviewed before the patient is removed from the operating room. This is important to make certain that the tip of the cannula is sufficiently clear of the carina and will not become obstructed as the patient's neck is manipulated.

The fresh tracheostomy should be left in place for about 10 days before it is disturbed. At least once each day the site should be cleaned with a cotton applicator soaked in a solution of hydrogen peroxide, and an antibiotic ointment should be applied to the incision site.

The sutures securing the tracheostomy should be left untouched for the initial 10-day period, after which they can be cut. The sutures to the edges of the tracheal incision should be left until the tracheostomy is changed successfully for the first time.

If the patient is unusually agitated or the ventilator tubing is so heavy that dislodging the cannula is highly likely, then sedation or paralysis may be helpful until the wound has matured and reinsertion can be done more safely.

After the cannula is free and the umbilical tape is untied, the cannula can be removed and replaced. Ideally, the parents or ultimate caretakers should observe the exchange, particularly if the patient is close to discharge.

If a temporary endotracheal tube is being replaced with a specially ordered tracheostomy cannula, the new cannula should be inserted as described earlier.

Once it is obvious that the cannula can be changed with ease, is in its proper position, and that the patient can be ventilated, it is safe to remove the sutures to the edges of tracheal incision.

Suctioning of the newly placed tracheostomy should be carried out as often as necessary, particularly immediately after the procedure. Care must be taken, however, to restrict the passage of the suction catheter to no further than the tip of the cannula. Routine suctioning beyond the tip of the cannula promotes the development of granulation tissue that may obstruct the airway later on.

HOME INSTRUCTION AND CARE

Patients should be discharged home with an extra tracheostomy cannula in case a problem occurs. The caretakers should be instructed and checked out on tracheotomy change and cardiopulmonary resuscitation (CPR). They should know how to suction the cannula and be sent home with a suction

machine. They should know how to use an Ambu bag for ventilation in conjunction with suctioning.

An air filter should be attached to the tracheostomy cannula if a ventilating device or some other humidification device is not connected. Of course, the family or caretakers must know how to use and troubleshoot in case of problems with using any of the devices chosen, especially the cannula and its attachments.

It is often helpful to arrange for home nursing visits until the family becomes familiar and comfortable with the new devices; this is especially true when it comes to the first scheduled tracheostomy change if it is to be done at home.

The physician may choose to do the first tracheostomy change in the office and take the opportunity to further instruct and reassure the family or caretakers.

COMPLICATIONS

Hemorrhage is an unusual complication that can occur at the time of operation or as a delayed event. When hemorrhage occurs at operation, it can be controlled easily with electrocautery or vessel ligation. Rarely, especially in the smaller newborn, the thyroid gland is near the incision site on the anterior trachea and is inadvertently divided or lacerated. The resultant hemorrhage can usually be controlled with sutures or electrocautery.

Late hemorrhage is often more problematic and can be more serious. First, it must be ascertained whether the hemorrhage is from the tracheal lumen or from the incision. This can be accomplished by suctioning the cannula and inspecting the wound. Occasionally, a small skin vessel will bleed briskly but can be easily seen and controlled with a simple suture or even with an injection of 1% lidocaine containing 1:100 000 epinephrine.

More problematic is the possibility of hemorrhage from one of the great vessels, such as the innominate vein or artery. This can occur from erosion of the vessels when the cannula fits too snugly in the thoracic inlet and partially compresses the vessels against the manubrium or clavicle. This type of hemorrhage often presents with a so-called 'herald bleed', which starts briskly but stops, and usually requires a trip to the operating room to repair the damaged vessel.

Aside from hemorrhage, the cannula can become dislodged. We are compulsive about securing the cannula in place using the techniques described earlier in order to avoid this complication. Even so, despite our best efforts, a suture will pull loose or one of the plastic wings will tear, allowing the cannula to dislodge.

We prefer to keep our infants in the intensive care unit during the immediate postoperative period. We anticipate that if the cannula becomes dislodged, it will be noticed immediately. Replacing the cannula in the immediate postoperative period can be a treacherous ordeal that under ideal circumstances should be performed by someone familiar with cannula insertion. If a surgeon or intensivist is readily available, then one of them should replace the cannula and resecure the device. The sutures to the tracheal incision should be taped in such a manner as to be easy to access, untape, and retract to expose the tracheal lumen. Good lighting is essential to see well and either the obturator should be inserted into the cannula before reinsertion is attempted or a suction catheter should be used as a guide.

It is very undesirable to force the cannula outside the trachea. Proper positioning is assured by administering a deep breath or two with an Ambu bag once the cannula is in place. If the chest does not rise immediately, it is possible that the cannula is not in the proper place and should be replaced. A chest x-ray should be taken to assure proper cannula position.

It is not usually necessary to use instruments to insert the cannula because the sutures attached to the edges of the tracheal incision should lead directly to the opening in the trachea. If difficulty arises, two small right-angled retractors should be sufficient to complete the job. In the event that the cannula cannot be reinserted, then the ventilation using an Ambu bag and mask can be used to maintain oxygenation until the infant can be returned to the operating room.

Infection is an unusual complication and should be treated with the appropriate antimicrobials according to culture results.

Injury to the vagus nerves or, more likely, the recurrent laryngeal nerves can occur. In experienced hands with a surgeon well versed in the anatomy of the infant's neck, this injury should be rare.

While unlikely, it is possible to place the cannula into the esophagus. This can occur if the trachea is retracted laterally, out of the field, and the esophagus is entered in error. If this occurs, the esophagus should be repaired primarily and a drain should be left in place. The trachesotomy cannula can then be inserted properly.

Endotracheal granulation tissue can result from the chronic irritation of the tip of the tracheostomy cannula against the tracheal wall or from the repeated suctioning of the trachea. It is common for granulation tissue to develop at the stoma. This can be exophytic at the level of the skin, or can be intralumenal. The exophytic granulation tissue at the skin should be cauterized with silver nitrate during an outpatient visit. This may need to be carried out every month or so if bothersome hemorrhage or chronic irritation with infection is present.

If the granulation tissue develops immediately within the trachea at the stoma, it usually can be left alone until it is time for decannulation. Only if the granulation tissue is so bulky that it interferes with routine tracheostomy changes or causes significant hemorrhage should it be removed before decannulation is contemplated.

The development of granulation tissue at the tip of the cannula can present with obstruction, sometimes resulting in a 'ball-valve' effect, with trapped air and difficulty with ventilation. This can be diagnosed by slipping a flexible bronchoscope through the cannula to visualize the tracheal lumen beyond the tip of the cannula. If the results of this diagnostic maneuver are unclear, rigid bronchoscopy may be necessary.

We believe that this type of granulation tissue is best removed with laser. Our preference is for the KTP/532 laser or an equivalent wavelength that operates using a flexible fiber. The technique for laser vaporization of granulation tissue is beyond the scope of this discussion.

The mortality in infants with tracheostomy is near 40%; however, the tracheostomy-related mortality is between 0 and 6%.

SPECIAL SITUATIONS

Occasionally, there exist special circumstances which require careful thought and planning. Such is the case with tracheal stenosis. Simple acquired subglottic stenosis can be easily managed with a tracheostomy inserted as described, except for the size of the endotracheal tube. A small endotracheal tube may be difficult to palpate, however, thus locating the trachea may be difficult.

With a particularly stenotic airway, mask ventilation may be the only way to maintain ventilation. The most difficult part of the case is locating the trachea without an endotracheal tube.

For patients with distal tracheal stenosis, tracheostomy insertion may be inappropriate. While beyond the scope of this discussion, the infant should be carefully studied if this diagnosis is suspected. Usually, plain radiographs of the chest may lead one to suspect the diagnosis. Computed tomography or bronchoscopy may be required for confirmation. When the distal trachea is stenotic in an infant who is difficult to ventilate, a conventional tracheostomy cannula is inappropriate and may interfere with tracheal reconstruction.

Patients who are candidates for congenital heart surgery, and in whom the ultimate need for a tracheostomy is anticipated, may be best managed by completing the cardiac surgery before tracheostomy is performed. Otherwise, the sternal incision is so close to the tracheostomy site that the risk of cardiac infection is greatly increased.

DECANNULATION

Decannulation is usually anticipated well in advance. Its timing depends largely on the indication for the tracheostomy. Patients with severe subglottic stenoses may have their tracheostomy removed at the time of their laryngoplasty. The timing of this procedure, then, depends on the surgeon and may occur any time between four to six months and two years, or later.

In patients whose tracheostomy was placed because of tracheomalacia, it would be unusual to attempt decannulation before the infant is one year of age. The infant should undergo periodic bronchoscopic examination to assess the status of the malacia. Once it is certain that the airway is sufficiently mature as to be able to maintain its patency, decannulation can be attempted.

The first step is to make certain that the airway is mature and free of any potential obstructing lesions such as granulation tissue. This is best accomplished with rigid bronchoscopy. Any residual malacia or granulation tissue can be documented and dealt with as needed.

At the time of attempted decannulation, we bring the patient to the operating room, positioned as described earlier for insertion of the cannula with the neck extended, and perform the bronchoscopy. In order to assess whether malacia is present, the patient should not be paralyzed and the anesthesia should be light. This is to determine whether the airway remains patent, with the patient breathing spontaneously.

Once committed to decannulation, the bronchoscope and neck roll should be removed and the patient is observed for any difficulty, such as severe chest retraction or deoxygenation, that would suggest the continued need for the tracheostomy. If, on the other hand, the patient ventilates with ease, then the patient should be fully awakened and allowed to recover in a unit that permits careful observation.

We usually keep these patients in the hospital overnight, or longer if there is any concern, to assure that the tracheostomy is no longer required.

Once the cannula is removed, a snug dressing of plain or petroleum jelly-saturated gauze is secured over the tracheostomy stoma to occlude it. The caretakers or parents should be instructed on how to change this dressing until the stoma closes completely.

Occasionally, we encounter a stoma that does not close spontaneously. If the stoma remains open after several months, then operative closure of the stoma can be performed as an outpatient procedure. Usually, this is simply a matter of excising the stoma and placing a simple stitch or two in the anterior trachea. A larger persistent opening may require an anterior wedge excision for proper repair. This may necessitate admission to the hospital.

If after the patient leaves the operating room decannulated, the infant becomes fatigued or demonstrates other signs of respiratory distress, the dressing can be removed and another cannula should be reinserted. A smaller cannula size can be inserted if desired.

This technique is often used to serially wean a patient to progressively smaller-sized cannulae until decannulation is certain to be successful.

If, after decannulation, it is necessary to reinsert a tracheostomy, the procedure should be carried out in the operating room. While this is usually done with an endotracheal tube in place, there are some patients for whom it may be undesirable to insert an endotracheal tube. This avoids airway irritation and prevents restenosis. That being the case, the surgeon can inject a local anesthetic around the stoma, dilate the stoma with Hegar dilators (or possibly make a small incision with a No. 11 scalpel blade), and reinsert a cannula of an appropriate size. This maneuver should only be attempted if the anesthesiologist can maintain an adequate airway during the procedure.

Congenital cysts and sinuses of the neck

YOUSEF EL-GOHARY AND GEORGE K GITTES

INTRODUCTION

Cervical masses in infants and children are frequently encountered by pediatric surgeons with intriguing clinical presentations. Some can be easily diagnosed with a good history and physical examination, such as the thyroglossal cyst. Others require more extensive investigation and imaging to accurately diagnose and treat. The vast majority are benign in origin, however rarely they can be malignant.[1] They frequently form residual structures from embryologic development that have failed to resorb completely or mature. Knowledge of the embryological origins of these cysts and sinuses, along with the detailed neck anatomy, is essential for proper management and for ultimately a successful dissection and excision. In this chapter, we will discuss the embryology of the neck, followed by a brief review of the common neck cysts and sinuses, along with their management.

EMBRYOLOGY

During early embryonic stages, the primitive gut tube, which is derived from the endoderm germ layer during gastrulation, is divided into the foregut, midgut, and hindgut domains, each of which will give rise to specialized regions due to the regional specification of the gut tube.[2] The foregut, which includes the pharyngeal (branchial) apparatus, extends between the bucco-pharyngeal membrane and ends at the origin of the liver bud.

The pharyngeal apparatus, which consists of arches, pouches, and clefts, will eventually give rise to the various muscles, nerves, bones, and cartilages in the head and neck region as illustrated in Fig. 28.1 and Table 28.1. There are six pharyngeal (branchial) arches, each consisting of a core of mesoderm, with its own nerve and arterial supply, surrounded by an outer ectodermal and inner endodermal lining. The mesoderm of the second pharyngeal arch proliferates and causes the arch to grow caudally, overlapping the third and fourth arches, and in the process burying the second, third, and fourth pharyngeal clefts and creating a temporary cervical

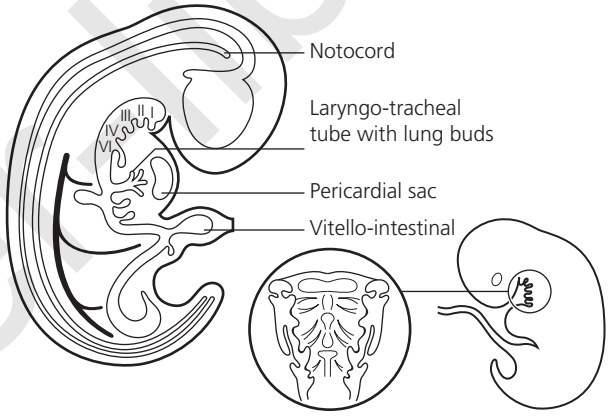

Figure 28.1 Schematic illustration of the embryo with the pharyngeal arches (I–VI).

sinus, which normally disappears (Fig. 28.2). The first pharyngeal cleft will give rise to the external auditory meatus and the fifth arch disappears. It is the incomplete closure or obliteration of these ectodermal portions of the second, third, and fourth pharyngeal clefts that leads to the various neck anomalies, including cartilaginous remnants, that pediatric surgeons encounter today. The remnants of these clefts form the cervical sinus which remains connected to the surface via a narrow canal called the 'external' branchial fistula, which may drain a branchial cyst. Rarely does the branchial fistula connect to the pharynx, near the tonsil area, via the 'internal' branchial fistula.

INCIDENCE

Branchial clefts and fistualae represent about 23% of cervical masses in children.[3] The 'rule of 80' is often applied in adults, which states that 80% of non-thyroid neck masses in adults are neoplastic and that 80% of these masses are malignant. A neck mass in a child, on the other hand, has a 90% probability of being benign.

Table 28.1 Summary of the derivatives of the pharyngeal arches.

Arch	Muscles	Nerve	Cartilage, bone, and ligament
I	Muscles of mastication	Mandibular division of trigeminal nerve	Malleus, incus, spheno-mandibular ligament
II	Muscles of face and scalp	Facial nerve	Stapes, styloid process, styloid ligament, lesser horn and upper part of body of hyoid bone
III	Stylopharyngeus	Glossopharyngeal nerve	Greater horn and lower part of body of hyoid bone
IV	Crico-thyroid	Superior laryngeal branch of vagus nerve	Thyroid cartilage
VI	Intrinsic muscles of larynx	Recurrent laryngeal branch of vagus nerve	All laryngeal cartilages except thyroid cartilage

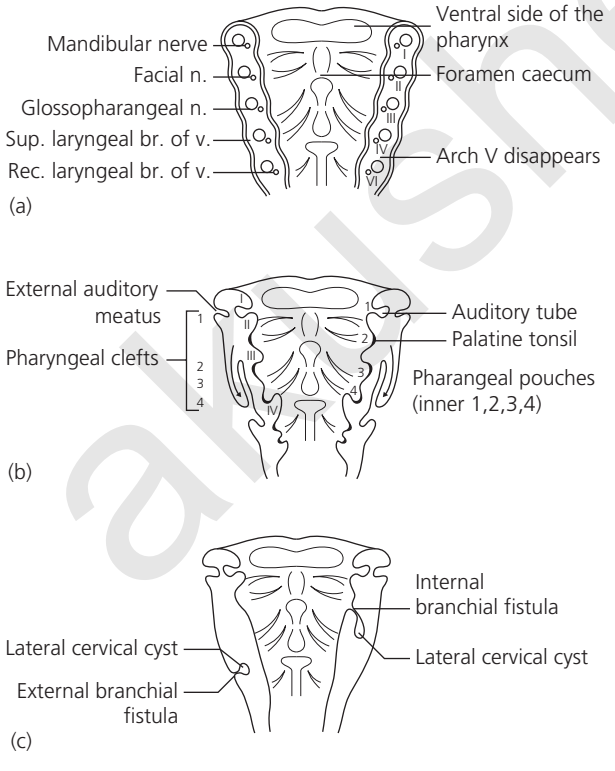

Figure 28.2 Illustration of the pharyngeal arches (I–IV) with their own nerve supply. The mesoderm of the second pharyngeal arch grows downwards, burying in the process the second, third and fourth pharyngeal clefts (a,b). Incomplete closure of these pharyngeal clefts leads to the formation of branchial anomalies such as a cyst or fistula (c).

BRANCHIAL ANOMALIES

First branchial cleft anomalies account for less than 10% of all branchial cleft defects.[4] They have a wide range of presentations, manifesting in a sinus, fistula, or cyst anywhere between the floor of the external auditory meatus and the submandibular region (Fig. 28.3). Clinically, they can present with either a persistent purulent discharge from the ear, pre-auricular swelling in the parotid area, or fistula in the neck above the hyoid bone. However, they are most commonly associated with an infection, often being initially treated with a course of antibiotics or unnecessary repeated incision and drainage of an abscess.[4,5] The relationship of the facial nerve to the anomaly is variable, with careful and meticulous surgical dissection needed to avoid nerve paralysis. In a series of 39 patients with first branchial cleft anomalies reported, six patients developed temporary facial nerve paralysis and only one (2.5%) patient developed permanent damage.[6] Diagnosing first cleft anomalies can be challenging, with the anomaly often closely related to the parotid gland. Examining the external auditory meatus may reveal a fistula; thus linking the parotid swelling or lateral neck mass to a first cleft anomaly. Preoperative imaging with magnetic resonance imaging (MRI) allows assessment of the extent of the anomaly, especially in the parotid area, and high-resolution computed tomography (CT) imaging shows its exact relationship with the external auditory canal and the middle ear.[6] Complete surgical excision is the treatment of choice, which often necessitates a superficial parotidectomy, with careful preservation of the facial nerve. Methylene blue injection into a draining tract prior to excision may facilitate removal. Recurrent infections or previous surgical interventions will increase the morbidity of the operation. That is why it is essential for an adequate preoperative work up prior to any surgical intervention.

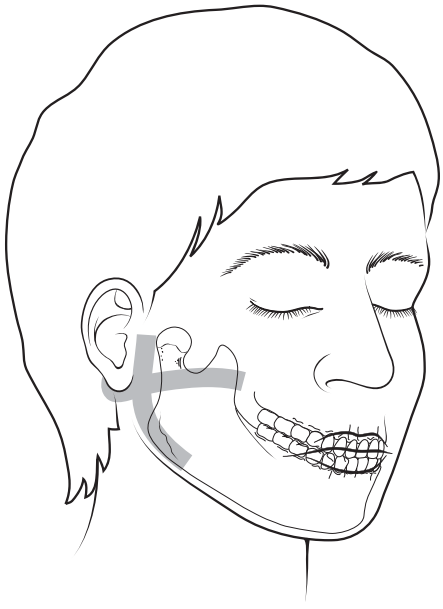

Figure 28.3 Shaded area on the face represents locations where first branchial cleft anomalies would be generally located.

Second branchial cleft anomalies are the most common (95%),[7] often presenting along the anterior border of the sternocleidomastoid muscle as a sinus, fistula, or cyst, typically at the junction of the upper two-thirds and lower third. The fistula goes deep to the platysma muscle along the carotid sheath between the external and internal carotid artery, above the hypoglossal and glossopharyngeal nerves and ends near the tonsillar fossa (Fig. 28.4). Deep fistulas or sinuses would generally necessitate two or three 'step-ladder' or McFee incisions in order to completely remove the entire tract. However, the majority of the anomalies manifest as cysts[8] and rarely present as a full fistula tract.[7]

Bailey[9] described four types of cysts. Type 1 is superficial and lies beneath the platysma and cervical fascia but anterior to sternocleidomastoid process. Type 2 cysts, which are the most common, characteristically lie on the great vessels and may be adherent to the internal jugular vein. Type 3 cysts course between internal and external carotid artery and extends to the lateral wall of the pharynx. Type 4 cysts lie against the pharyngeal wall. Complete surgical excision is the treatment of choice, with recurrence being the most common postoperative surgical complication. A large series of 208 cases showed recurrence in 21% of those with a history of prior surgical intervention, 14% with a history of infection, and 3% with a history of neither.[10]

Third and fourth branchial cleft anomalies are rare, accounting for 2–8% and 1–2% of all branchial anomalies, respectively.[4,11] Clinically and radiologically, it can be difficult to distinguish between the two, as both types begin at the pyriform sinus and end blindly in the paratracheal or thyroid regions. Ninety-seven percent of the lesions occur on the left side.[10] Although rare anomalies, they can have devastating respiratory consequences presenting as an acute stridor[12,13] or acute thyrioditis.[14,15] Diagnoses can be quite challenging, as these cysts are generally subjected to repeated incision and drainage, being mistaken for a simple abscess. A plain film showing air or fluid levels within the cyst can help differentiate a branchial anomaly from other causes of pediatric neck masses. The pharyngeal opening may be visualized by flexible fiberoptic nasopharyngoscopy or demonstrated using a barium meal.[16] In a series of 43 patients with acute suppurative thyroiditis, nearly 88% of the patients were documented to have a pyriform sinus fistula.[15] Therefore, it should be a consideration for any patient presenting with acute thyroiditis to have a potential third or fourth branchial anomaly as an underlying cause, and promote a search for it. The only definitive way of distinguishing an anomaly as being a third or fourth arch is through surgical dissection, which is the treatment of choice ensuring that the tract is completely excised to avoid risk of recurrence. This is done by demonstrating the relationship of the tract to the recurrent and superior laryngeal nerves. A tract that goes inferior to the superior laryngeal nerve (fourth arch) and superior to the recurrent nerve (sixth arch) is derived from the fourth pouch. However, if the tract passes superior to the superior laryngeal nerve (fourth arch) then a third pouch origin is likely. Vocal cord paralysis is a potential complication as a result of the dissection.

CT scan and MRI are the imaging modalities of choice to assess the extent and depth of any branchial cleft cysts.

THYROGLOSSAL DUCT CYSTS AND SINUSES

Thyroglossal duct anomalies are the most common congenital anomalies of the neck, constituting nearly 70% of all cervical neck masses in children.[17] They represent remnants from the embryological migration of thyroid tissue from the foramen caecum to the thyroid fossa. Clinically, they usually present as a palpable, non-tender midline neck mass that elevates with swallowing or protrusion of the tongue (see Fig. 28.5). It is

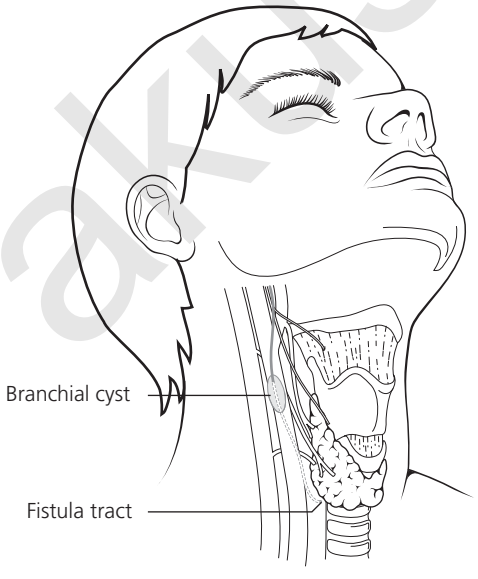

Figure 28.4 Second branchial cleft cyst and fistula tract coursing between the internal and external carotid arteries, above the IX and XII nerves, ending near the tonsillar fossa.

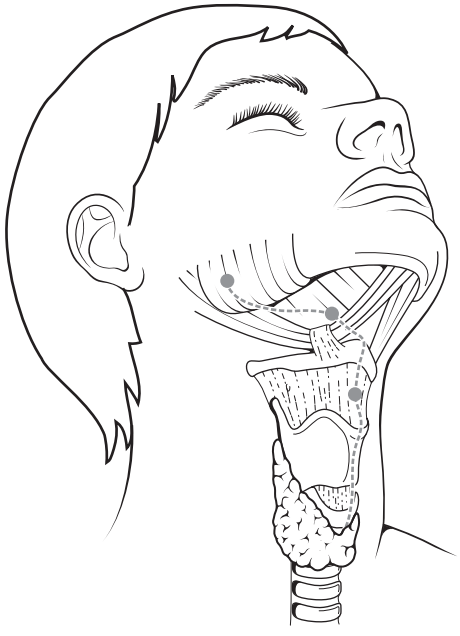

Figure 28.5 Illustration of the thyroglossal duct tract.

important to note that 10–24% of these cysts are located laterally, often to the left.[18]

Ultrasonography is the imaging technique of choice for these lesions, especially to rule out thyroid ectopia. The reported incidence of an ectopic thyroid being misdiagnosed as a thyroglossal cyst is 1–2%.[19]

Sistrunk's procedure, with dissection of the tract up to the hyoid bone, including its midportion, is accepted as the main operation of choice with the lowest recurrence rate.[20,21] Malignancy of the thyroglossal duct cysts is rare (1%)[19,22] with the majority (80%) of histological examination revealing a papillary adenocarcinoma.[23,24]

CONGENITAL MIDLINE CERVICAL CLEFTS

Congenital midline cervical clefts are rare developmental anomalies with differing severities from patient to patient with various length and width.[25] The embryological origin has not been fully elucidated, but it is thought to be a result of failed mesodermal fusion along the distal branchial arches in the midline.[26] The common characteristic features include midline fissure of atrophic skin, subcutaneous fibrous cord, and a thickened nipple-like projection at the superior aspect of the lesion.[27] It can occur anywhere along the midline of the neck from the symphysis of the mandible to the suprasternal notch. Midline cervical clefts are generally excised because, if left untreated, the cleft will cause cicatrical skin contracture. It is recommended to excise the cleft between 10 and 12 weeks of age before tethering of the anterior skin occurs.[28] Simple linear closure has been reported to result in hypertrophic scarring and recurrent neck contracture.[29] As a result, Z-plasty closure is the preferred surgical management of this congenital abnormality as it provides a superior cosmetic result compared to linear closure, and adds the lengthening effect on the anterior neck skin that aids in preventing recurrent contracture.[28]

DERMOID CYSTS

Cervical dermoid cysts are benign tumors that are frequently mistaken for a thyroglossal cyst due to similar presentation and distribution. They are of ectodermal and mesodermal origin, and a definitive diagnosis is usually made during histologic examination revealing hair follicles, smooth muscle, sebaceous glands, and connective tissue elements.[30] They are thought to arise due to trapping of epithelial rests during midline fusion of the first and second branchial arches.[31] Surgical excision is the treatment of choice.

PREAURICULAR SINUSES AND CYSTS

Preauricular sinuses are congenital malformations, usually noted during physical examination as small pits adjacent to the external ear, usually at the anterior margin of the ascending limb of the helix.[32] The incidence varies between different races, with the reported incidence ranging between 0.02 and 5%, with higher incidence among African-American and Asian populations.[33–36] They are mostly unilateral with usually an asymptomatic presentation, however they can present as a purulent discharge from the sinus opening resulting in facial cellulitis or abscess formation, which is the most common indication for a fistulectomy. Surgery should be performed once the infection has resolved, whenever possible, with the recurrence rate after surgery being reported between 3.7 and 36%, with the rate much higher if infection preceded surgery.[32,36,37] In the process of excising the sinus tract, various techniques can be used to identify its extension, but it is recommended to combine the use of dye injection with probing using a fine lacrimal duct probe at the time of surgery as it is associated with the least incidence of recurrence.[34,36]

RANULA

Ranulas are divided into simple and plunging ranulas. Simple ranulas are either mucus retention cysts that are restricted to the oral cavity floor, or mucus extravasation pseudocysts, whereas plunging ranulas are mucus extravasation pseudocysts that originate from the sublingual gland, herniate through the mylohyoid muscle to present as a cervical neck swelling, which may be confused with a submandibular mass when there is no intraoral component.[38] The ideal management for both of these lesions remains controversial, ranging from injecting sclerosing agents to different surgical techniques. Although most would agree to surgically excise them, the general consensus for the ideal technique and approach still remains unknown.

Injecting oral and plunging ranulas with OK-432 (a mixture of a low virulence strain of *Streptococcus pyogenes* incubated with benzylpenicillin) has a reported success rate of 74 and 100%, respectively, however this was achieved after multiple injections.[39,40] Most advocate marsupialization of the oral ranula, as illustrated in Fig. 28.6, which is associated with a recurrence rate of around 20%.[41] Others advocate surgical excision of the cyst alone, which has a recurrence rate of 12%.[41] Some authors prefer to remove the sublingual gland, seen as the definitive treatment with the least recurrence rate, along with the cyst. However, this is associated with a low morbidity of lingual nerve and submandibular duct damage due to the more invasive intervention. Others simply excise the sublingual gland transorally along with evacuation of the ranula, which is seen as the modality yielding the lowest recurrence (1–2%) and complication rates for both oral and plunging ranulas.[41,42] A transoral approach for plunging ranulas is associated with a lower morbidity and complication rate compared to the cervical approach, as the latter places the marginal mandibular and hypoglossal nerves at risk of damage.[43,44] Removing the origin of the disease, usually the sublingual gland, is the key to successful treatment of simple and plunging ranulas.

CYSTIC HYGROMA

Cystic hygroma or lymphangiomas are non-malignant cystic (uni- or multilocular) abnormalities of the lymphatic system, mostly occurring in the cervicofacial region with a predilection to the left side, and has a prevalence of one in every 6000 live births.[45] It can occur in the axilla, mediastinum, retroperitoneum, and rarely in the extremities with variable sizes, ranging from a few centimeters in diameter to large masses, potentially filling a large portion of the thorax.[46,47]

The term 'hygroma' is derived from Greek meaning moist or watery tumor and has equal sex distribution. They rarely self-resorb with aspiration of the cystic fluid, which is usually clear or amber-colored, and are occasionally hemorrhagic,[47] usually resulting in rapid reaccumulation. They can present as a congenital birth defect or be acquired at a later stage in life, with the majority (80–90%) presenting by two years of age.[48,49]

They are thought to arise due to the failure of lymph vessels to communicate with the venous system, with abnormal budding and/or sequestrations of primitive embryonic lymphatic tissue.[50] Lymphangiomas are often classified into three types based on histology: capillary lymphangioma or lymphangioma simplex, composed of small thin-walled lymphatics; cavernous lymphangioma, consisting of larger lymphatic channels with advential coats; and cystic lymphangioma (hygroma) made up of larger macroscopic lymphatic spaces.[51,52] Immunocytochemical staining for CD31 (platelet-endothelial cell adhesion molecule-1), a stain that is intended to reveal the endothelium of small vessels, confirms the diagnosis.

Diagnosis can be made with a good history and clinical examination due to the characteristic clinical appearance, usually soft, compressible, and transilluminating with light. In a series of 168 patients with lymphangiomas, 41% were diagnosed based on clinical examination alone. Ultrasonography is a useful aid in diagnosis revealing a cystic structure rather than solid, however CT or MRI can show the full extent of the lesion and its relationship with the surrounding structures.[48,53] The radiologic characteristics of cystic hygroma are consistent with a fluid-filled, multiseptate mass with enhancing septal walls.[46]

Malignant transformation has not yet been reported, however complete surgical excision is the surgical treatment of choice. It is generally recommended to remove the mass due to its potential large size, which can compromise the airway if in the cervicofacial area, as well as disfigurement and recurrent bouts of inflammation, which unfortunately does not induce regression.[54] Aspirating the lesion may be useful for emergency decompression. Complete surgical resection can be difficult in the infiltrative form. They can be complicated with recurrences after surgical excision, which is reported to be 12% in patients who have undergone complete excision for neck lesions,[48] as well as with lymphangitis and cellulitis, which can lead to sepsis, prompting the need for i.v. antibiotics. It is advised that the initial approach for patients with recurrences after complete excision is to observe and wait, as spontaneous regression has been reported in up to 12% of patients after surgery. Other alternative treatments include intralesional injection with bleomycin or OK-432 with a reported response rate of 55–60%,[55,56] and argon beam ablation and laser treatment. These modalities maybe useful in patients with complex diffuse lesions when surgical therapy may be difficult to achieve a complete cure, or when vital structures are engrossed with the lesion.[57–59]

TORTICOLLIS

Torticollis or sternocleidomastoid tumor results from shortening of the sternocleidomastoid muscle, which may lead to limitation of neck movement and craniofacial deformity. The term 'torticollis' is derived from two Latin roots, 'tortus' meaning twisted and 'collum' which means neck.[60] It is considered one of the most common congenital musculoskeletal anomalies after developmental dysplasia of the hip and clubfoot, with an incidence rate of 0.3–2%.[60–62] Although various theories have been proposed with regard

to its etiology, such as birth trauma, intrauterine malposition, infectious myositis, and compartment syndrome, an exact cause has not yet been identified.[60] Diagnosis is usually established on clinical examination of a firm, spindle-shaped mass within the sternocleidomastoid muscle. Ultrasonography is the imaging modality of choice to confirm the diagnosis, usually hypoechoic compared to muscle.[63] This unilateral contraction of the muscle results in the head tilting toward the affected side and the face rotating to the opposite side, as seen in Fig. 28.7. This therefore can induce plagiocephaly and facial asymmetry at presentation. Treatment includes physical therapy, which is the primary treatment modality, with over 95% of achieving passive cervical rotation after physiotherapy.[64] This involves stretching the affected muscle to an over-corrected position by gentle, even, and persistent motion with the infant lying in a supine position. The head is flexed forward and away from the affected side and the chin is rotated toward the affected side. Some use botulinum toxin injection as an adjunct to physical therapy in those who have not responded to three months of conservative management.[65] Failure to respond to conservative treatment after the age of one year may necessitate the need for surgical intervention. Surgical options include unipolar or bipolar release, release with Z-plasty, transaxillary endoscopic release, and muscle resection. The transaxillary subcutaneous endoscopic approach has recently been developed to avoid the potential for poor cosmesis from neck scars.[66] The overall outcome from all these treatment modalities is excellent.

Congenital thoracic deformities

KONSTANTINOS PAPADAKIS AND ROBERT C SHAMBERGER

INTRODUCTION

Congenital thoracic deformities present a wide spectrum of abnormalities. They include a myriad of complete and incomplete sternal defects: thoracic ectopia cordis, thoraco-abdominal ectopia cordis (Cantrell's pentalogy), and bifid sternum. The most frequent are the deformities of the ribs – including pectus excavatum, pectus carinatum, and Poland's syndrome. Asphyxiating thoracic dystrophy (Juene's syndrome) and spondylothoracic dysplasia (Jarcho–Levin syndrome) pose the greatest surgical challenges.

ECTOPIA CORDIS

The first description of an exposed heart through a split sternum was described in 1671–1672, by N Stensen.[1] Later reports, by Weese in 1818[2] and Todd in 1836,[3] proposed classifications of this disorder.

Infants with this anomaly are classified by the precise location of the heart: cervical (3%), cervicothoracic, thoracic (60%), thoraco-abdominal (7%), and abdominal types (30%).[3,4] In cervical ectopia cordis, the heart protrudes at the base of the neck and occurs in association with other severe deformities of the fetus. The cervical type is not compatible with life.

Thoracic ectopia cordis includes infants with an entirely bare heart which is outside the thorax with cephalic orientation of the cardiac apex. It protrudes through a central sternal cleft and lacks a parietal pericardium and overlying skin. This condition may be associated with separate epigastric omphalocele or upper abdominal wall defect. Thoracic ectopia cordis must be distinguished from cleft sternum, in which the heart is covered by normal skin in an orthotopic intrathoracic position and is anatomically normal.

In thoraco-abdominal ectopia cordis, also known as Pentalogy of Cantrell, the heart is covered by skin or an omphalocele-like membrane. It is associated with a constellation of anomalies. The classic pentalogy includes: (1) a midline, supraumbilical abdominal wall defect; (2) a defect of the lower sternum; (3) a deficiency of the anterior diaphragm (absence of septum transversum); (4) a defect in the diaphragmatic pericardium; and (5) congenital intracardiac defects. All five anomalies may not be present, and there can be an incomplete expression of the syndrome.[5] In contrast with thoracic ectopia cordis, the heart is covered and lacks severe anterior displacement and cephalic orientation. The world literature on ectopia cordis has been extensively reviewed previously.[6]

Ectopia cordis is diagnosed by prenatal ultrasound from early stages of gestation, which facilitates perinatal preparation.[7,8] Associated intrinsic cardiac anomalies and other anomalies can be defined by *in utero* studies in order to facilitate parental discussion regarding prognosis. The cause is unknown. There has been a weak association with trisomy 18,[9,10] triploidy, and familial X-linked inheritance.[10–13] The incidence is 5.5–7.9 per one million live births.[13]

Thoracic ectopia cordis

The presentation of the heart, naked and beating upon the chest wall, has stimulated many case reports (Fig. 29.1). Surgical repair has been described,[14,15] but long-term successes are limited by a combination of associated intrinsic cardiac malformations and abnormal rotation of the heart with the apex pointing cephalad.[16] The first successful repair of ectopia cordis was achieved by Koop in 1975, as reported by Saxena (Table 29.1).[17] An infant with a normal heart had skin flap coverage at 5 hours of age, with inferior mobilization of the anterior attachments of the diaphragm. At seven months of age, an acrylic resin of Dacron and Marlex mesh was inserted to widen the sternal cleft with primary skin closure. Necrosis of the skin flaps complicated the post-operative course; the infection of the prosthetic material required its subsequent removal. The child's long-term survival has been reported.[18] Lillehei (as reported by Hornberger) achieved successful repair of the only infant with an intrinsic cardiac anomaly, tetrology of Fallot with pulmonary atresia.[19] A combination of thoracic ectopia cordis and separate omphalocele with an intervening bridge

Figure 29.1 Infant with thoracic ectopia cordis. Heart lies anterior to the thoracic cavity and apex is directed cephalad.

Table 29.1 Successful repairs of ectopia cordis.

Author	Year	Cardiac lesion	Method of sternal closure
Koop	1975	None	Skin flap closure at 5 hours. Acrylic resin applied to sternal cleft at seven months (Saxena[17])
Dobell *et al.*[76]	1982	None	Perinatal skin closure in one stage. Second-stage repair with autologous rib grafts
Amato *et al.*[35]	1988	None	Skin flaps mobilized, diaphragm moved inferiorly. Gortex membrane used to close defect with skin flaps over it. Child survived but died of aspiration at 11 months of age
Lillehei	1996	Tetralogy of Fallot	Perinatal skin flap closure (Hornberger *et al.*[33]), Blalock–Taussig shunt at 4 days of life and complete repair at two years of age. No prosthetic tissue coverage

of normal skin can be particularly difficult to manage. In this group of patients, adequate skin and abdominal wall components to cover both areas is lacking and no survivors exist. The unifying theme of successfully managed cases is construction of a partially anterior chest cavity surrounding the heart and avoidance of attempts to return the heart to an orthotopic location.

For a successful outcome in infants with thoracic ectopia cordis, early definition of the associated cardiac malformation is necessary. Prenatal work up with echocardiography and magnetic resonance imaging (MRI) is often more successful than postnatal attempted ultrasonography, which is complicated by direct motion artifact of the heart and interference by air. Cardiac catheterization with angiography may be required in infants not diagnosed by antenatal studies. If the cardiac malformation is correctable, the infant should be taken from the catheterization laboratory directly to the operating room for cardiac repair. Some form of cardiac enclosure must then be provided. Use of prosthetic materials is associated with a high incidence of sepsis and death, especially when prosthetic materials have been used inside the cardiac repair.

Thoraco-abdominal ectopia cordis (Cantrell's pentalogy)

In 1958, Cantrell and coworkers[20] reported a series of a previously described congenital syndrome characterized by: (1) a midline, supraumbilical abdominal defect; (2) a defect of the lower sternum; (3) a deficiency of the anterior diaphragm; (4) a defect in the diaphragmatic pericardium; and (5) congenital intracardiac defects (Fig. 29.2). All five anomalies may not be present, and there can be an incomplete expression of the syndrome.[21] The pathogenesis of the defects present is unclear, but the occurrence of this syndrome is likely sporadic.[22] X-chromosome recessive inheritance has been postulated.[23] There have been associated cases with trisomy 13, 18, and 21.[24,25] Multiple etiologies, including viral infection,[26] maternal abuse of beta-amino-propionitrile,[27] and chlorine inhalation,[28] have also been implicated. The survival rate is less than one in 100 000 live births, and affects males 2:1, while affected females have more severe symptoms.[29] Due to the variable nature of expression, Toyama suggested further subclassification of this syndrome: class 1, definite diagnosis with all five defects present; class 2, probable diagnosis with four defects noted (including intracardiac and ventral abdominal wall abnormalities); and class 3, incomplete expression.[30]

The successful management of thoraco-abdominal ectopia cordis necessitates a multispecialty approach from the establishment of the antenatal diagnosis to the completed staged repairs. Immediate neonatal intervention is required in patients with a large upper omphalocele and lower sternal cleft (Fig. 29.3). In a staged repair, primary closure,

Figure 29.2 Newborn male with Cantrell's pentalogy. Flaring of the lower thoracic cavity is present with a large epigastric omphalocele. The septum transversum and the inferior portion of the pericardium were absent (From Welch[75] by permission of WB Saunders Co., Philadelphia).

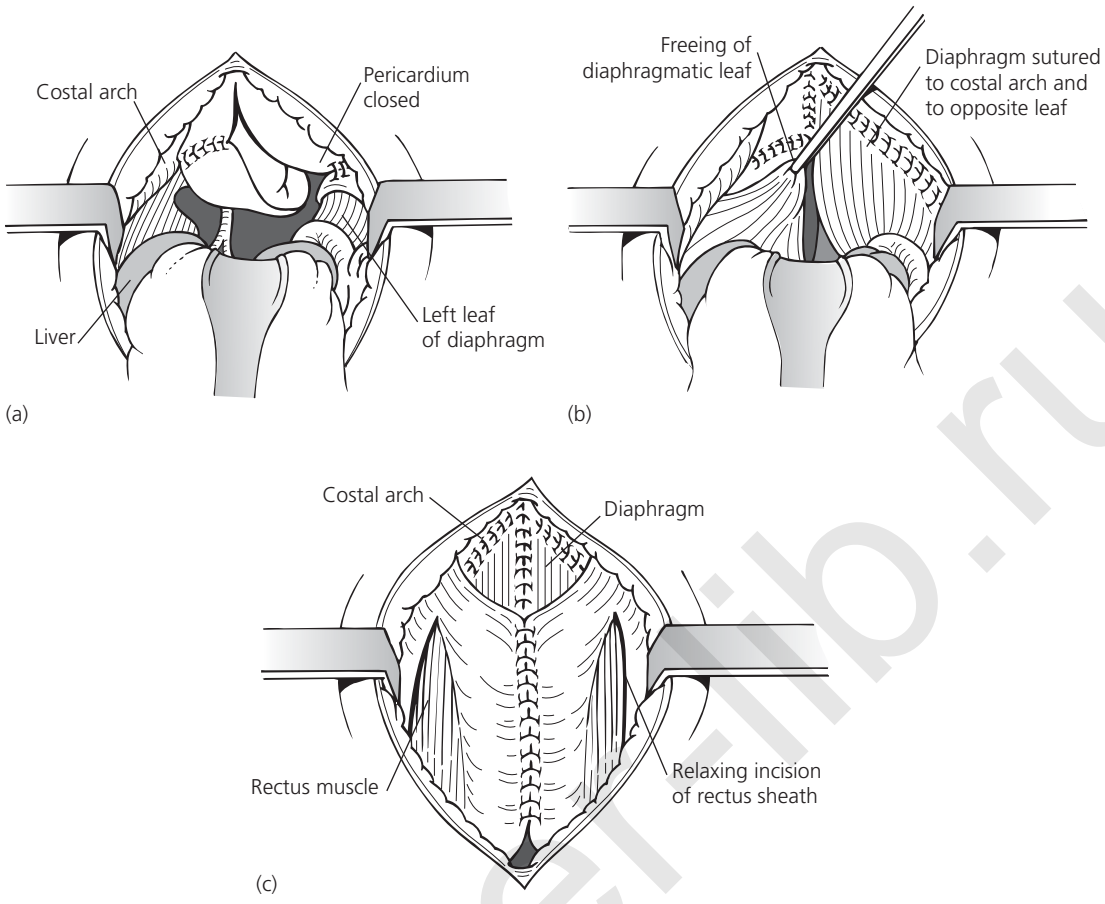

Figure 29.3 Repair of pentalogy of Cantrell is depicted. (a) The pericardium is closed after appropriate lateral and inferior dissection to the vena cava. The right and left dorsal leaves of the diaphragm which are widely separated are identified. The liver is retracted inferiorly after division of the falciform ligament. (b) Pedicles of the diaphragm are developed from each side and transposed medially. They are sutured together and to each costal arch. (c) After diaphragmatic closure, the falciform ligament is reconstructed. Closure continues by advancement of the anterior sheath of the rectus muscle to the midline. Lateral relaxing incisions are often required. Parietal repair can be accomplished at the time of cardiac correction. Prosthetic material may be required to obtain closure of the abdominal component of the repair (From Welch[75] by permission of WB Saunders Co., Philadelphia).

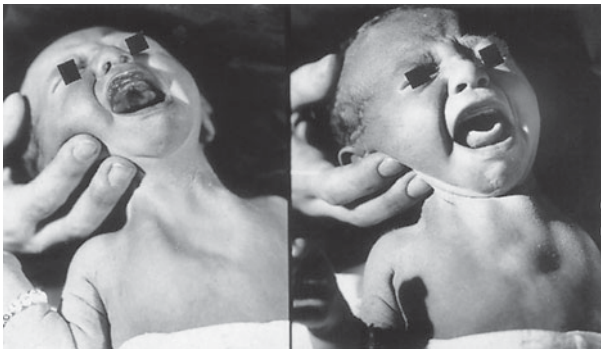
split-thickness skin graft, cadaveric skin graft or prosthetic material sutured to the skin edges[31–33] must be achieved to prevent fluid losses, cardiac dessication, or trauma to the heart. Subsequent stages may be needed to gradually reduce the heart to a more anatomic position.[32] Multiple procedures have been suggested to try to accommodate the heart; these include partial or total thymus excision, repair of the diaphragmatic defect, plication of a hemidiaphragm, or division of the costal cartilages. Some have even advocated a left lower lobectomy be performed in order to better accommodate the heart in the left pleural space.[34] In all procedures care must be taken to prevent kinking of the great vessels and to avoid phrenic nerve damage.[35] Other options include the use of alloplastic materials, such as creation of methyl methacrylate struts shaped as ribs and spaced to allow for future growth of ribs and thorax.[36]

BIFID STERNUM

Sternal clefts are malformations caused by the failure of fusion of the sternal elements. The etiology of sternal cleft deformity is unknown. There are studies on ventral body development in mice that indicate impairment in Hoxb gene expression as a possible factor.[37] Cleft sternum may be complete or incomplete and results from failure of the mesenchymal plate fusion process at the eighth week of gestation. No familial predisposition has been described. Alcohol intake and methylcobalamine deficiency have been implicated. There is a slight female predominance. Sternal clefts can be associated with cervicofacial hemangiomas (vascular dysplasia)[38] and PHACES syndrome.[39,40]

In all cases, there is a sternal separation and skin coverage of the midline defect, intact pleural envelopes, and a normal diaphragm. Omphalocele does not occur in association with this anomaly and the condition causes little difficulty other than a dramatic increase in the deformity with crying or valsalva maneuver (Fig. 29.4). The sternal defect involved an upper cleft in 46 patients, an upper cleft to the xiphoid in 33 patients, and a complete cleft in 23 patients. The cleft involved the lower sternum in only five reported cases. A total of 69 repairs has been reported, 25 with primary closure.[6] None of the infants and children had intrinsic congenital heart disease.



(a)

(b)

Figure 29.4 Newborn infant with a bifid sternum. (a) Vigorous crying produces retraction at the defect with inspiration (left) and protrusion with exhalation or Valsalva maneuver (right). (b) Following repair, normal configuration of the sternum is present.

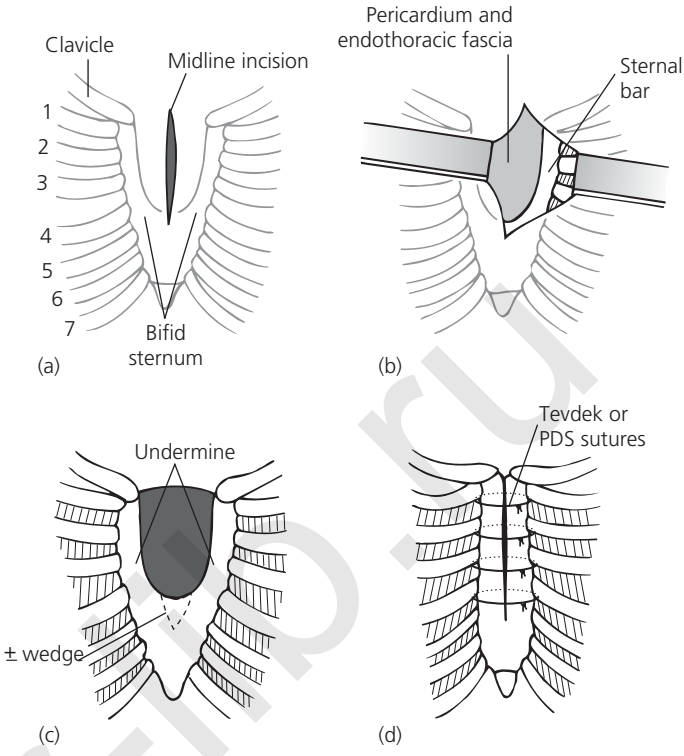


Figure 29.5 (a) Repair of bifid sternum is best performed through a longitudinal incision extending the length of the defect. (b) Directly beneath the subcutaneous tissues, the sternal bars are encountered with pectoral muscles present lateral to the bars. The endothoracic fascia and pericardium are just below these structures. (c) The endothoracic fascia is mobilized off the sternal bars posteriorly with blunt dissection to allow safe placement of the sutures. Approximation of the sternal bars may be facilitated by excising a wedge of cartilage inferiorly. Repair is best accomplished in the neonatal period because of the flexibility of the chest wall. (d) Closure of the defect is achieved with 2-0 Tevdek or PDS sutures (From Shamberger and Welch[6] by permission of Springer-Verlag, Heidelberg, Germany).

Most authors now recommend surgical treatment in the newborn period when all such malformations can be dealt with by simple direct closure without producing compression of the heart and avoiding the use of prosthetic materials (Fig. 29.5).[41,42] No reports of recurrence or delayed healing have been encountered. In older children, reconstruction of the anterior chest wall using multiple oblique sliding chondrotomies leaving the perichondrium intact was reported by Sabiston[43] and subsequently by others. This technique is useful in older infants and children with a less flexible chest wall and a wide defect. Closure employing composite cartilage grafts from the costal arch or prosthetic materials such as Marlex or Teflon mesh have also been reported, but these methods can be avoided with repair of the infants in a timely fashion.

Shamberger and Welch[6] reviewed their experience with sternal defects at the Children's Hospital Boston, MA, USA. A total of 16 patients with sternal defects were identified, five with ectopia cordis, eight with thoraco-abdominal ectopia cordis, and three with cleft sternum.[6] Thoracic ectopia cordis was uniformly fatal in their series; thoraco-abdominal ectopia cordis was fatal in five of eight cases and bifid sternum was successfully repaired in all three cases in infancy.

PECTUS EXCAVATUM

Pectus excavatum (funnel chest or trichterbrust) is a depression of the sternum and lower costal cartilages. It is generally identified within the first year of life (in 86% of patients) and in many infants it is noted at birth.[44] The extent of sternal and cartilaginous deformity is quite variable, but generally consists of posterior displacement of the sternum below the insertion of the second costal cartilage. The first and second costal cartilages are generally normal in contour, whereas the third to seventh are curved posteriorly to join the sternum. The ossified portion of the rib is normal in configuration in infancy. In infants, the extreme flexibility of the costal cartilages results in remarkable changes in the deformity with vigorous respiration or crying. Self-limited deformities are either gone or vastly improved by three years of age. Repairs should be avoided in all infants younger than two years of age or later if they have continued sternal flexibility. We generally delay open repair until children have achieved much of their chest wall growth to avoid the reported

occurrence of acquired thoracic dystrophy in younger children following repair.

Pectus excavatum may occur as frequently as one in 300–400 live births.[45] The etiology of pectus excavatum is unknown. A family history of some type of anterior thoracic deformity is present in 37% of patients.[44] Scoliosis is identified in up to 15% of patients with pectus excavatum, usually in children with an asymmetric thoracic deformity, but it is generally not seen in infancy. Patients with Marfan syndrome have a high incidence of associated chest wall deformities, often in the most severe form and usually accompanied by scoliosis.

PECTUS CARINATUM

Pectus carinatum, the anterior protrusion deformity of the chest, is much less frequent than pectus excavatum, comprising 16% of our combined series.[46] A spectrum of protrusion deformities exists and these are often divided into four types. The most frequent type consists of anterior displacement of the sternum with symmetric concavity of the costal cartilages laterally. Asymmetric deformities with anterior displacement of the costal cartilages on one side and a normally positioned or oblique sternum and normal cartilages on the contralateral side are less common. 'Mixed' lesions have a carinate deformity on one side and a depression or excavatum deformity on the contralateral side, often with sternal obliquity. Most unusual are the upper 'pouter pigeon' or chondromanubrial deformities, with protrusion of the manubrium and second and third costal cartilages and relative depression of the body of the sternum.

The etiology of pectus carinatum is unknown. There is overgrowth of the costal cartilages, with forward buckling and anterior displacement of the sternum. As with pectus excavatum, there is a clear-cut increased family incidence, suggesting a genetic basis. In a recent review, 26% of patients had a family history of chest wall deformity and 12% had a family history of scoliosis.[46] It is much more common in boys than girls, with a ratio of 4:1. Only the upper 'pouter pigeon' deformity is associated with congenital heart disease in 18% of cases.[47]

In contrast to pectus excavatum, patients with pectus carinatum have a much later appearance of the deformity. In a recent review, only one-sixth of the patients were noted to have a carinate deformity within the first year of life and, in almost half it was noted after the onset of the pubertal growth spurt at 11 years of age.[46] The deformity, which may be mild at birth, often worsens rapidly during puberty. Because of mild deformity at birth and flexible costal cartilages, this deformity is rarely repaired during the first two years of life and is probably best repaired in the early teenage years.

POLAND SYNDROME

In 1841, Poland described congenital absence of the pectoralis major and minor muscles, associated with syndactyly.[48] This is a diverse syndrome, often involving chest wall and breast deformity, as well as serious ipsilateral hand and arm anomalies. The extent of thoracic involvement may range from hypoplasia of the sternal head of the pectoralis major and minor muscles with normal underlying ribs, to complete absence of the anterior portions of the second to fourth ribs and cartilages, often called the second to fourth rib syndrome. Breast involvement is significant in females, ranging from mild degrees of breast hypoplasia to complete absence of the breast (amastia) and nipple (athelia). Hand deformities are frequent and occurred in the patient described by Poland. They may include hypoplasia (brachydactyly), fused fingers (syndactyly), and mitten or claw deformity (ectromelia).

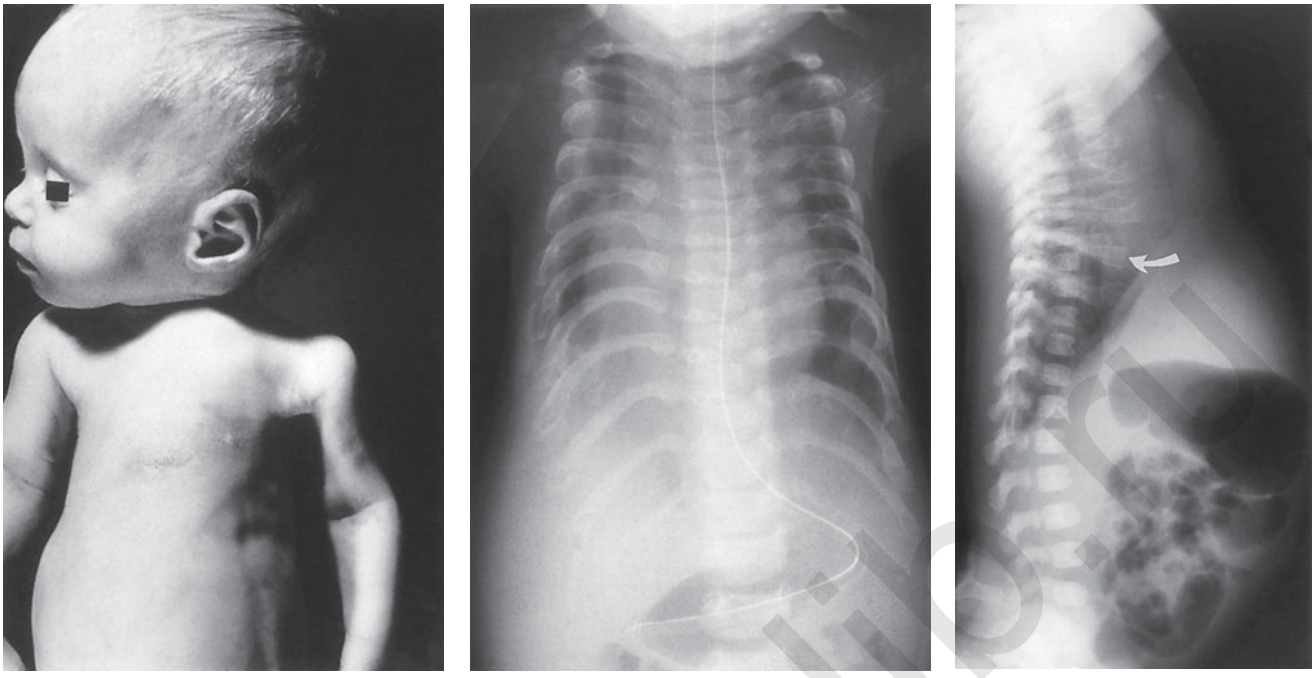
This condition is present at birth and has an estimated incidence of one in 30000–32000.[49] The etiology of this deformity is unknown, but it affects the developing somatic tissue for the entire limb bud and chest wall. Abnormalities in the breast can be recognized at birth by the absence of the underlying breast bud and hypoplastic, often superiorly displaced, nipple. Males predominate by at least 3:1 and show a right-sided predilection. Females show less sidedness. Familial cases, in either gender, occur equally on the left or the right.[50] In our series, chest wall reconstruction was required in 10 out of 41 cases, but never in infancy.[51]

THORACIC DEFORMITIES IN SKELETAL DISORDERS

Congenital asphyxiating thoracic dystrophy (Jeune's disease)

In 1954, Jeune *et al.*[52] first described a pair of siblings with a narrow rigid chest and multiple cartilage anomalies. The syndrome is also known as asphyxiating thoracic dysplasia (ATD) and thoracic-pelvic-phalangeal dystrophy.[53] This is a rare autosomal recessive disorder.[54] Other manifestations include dwarfism with short ribs and short limbs, with radiographic changes in the ribs and pelvis. There is some association with abnormalities of the kidneys, liver, pancreas, and retina.[55] Variable skeletal and radiographic severity occurs in this syndrome. Its most prominent feature is a narrow 'bell-shaped' thorax and protuberant abdomen. The thorax is narrow in both the transverse and sagittal axis and has little respiratory motion due to the horizontal direction of the ribs (Fig. 29.6). The ribs are short and wide and the splayed costochondral junctions barely reach the anterior axillary line. The costal cartilage is abundant and irregular like a rachitic rosary. Microscopic examination of the costochondral junction reveals disordered and poorly progressing endochondral ossification, resulting in decreased rib length.

The syndrome has variable expression and extent of pulmonary involvement. Lung hypoplasia is due to a restricted thoracic cage and may be the cause of death in infancy. The most common presentation is hypoventilation, caused by impaired chest expansion. Frequency of the condition is approximately one per 100000–130000 live births.[56] Reports have described the ability to diagnose fetuses suspected to have Jeune's syndrome with prenatal



(a) (b) (c)

Figure 29.6 Infant with asphyxiating thoracic dystrophy (Jeune syndrome). (a) Clinical photograph demonstrates small size of thorax relative to infant. (b) X-ray shows the short horizontal ribs and narrow thorax with limited lung volumes. (c) Lateral x-ray demonstrates the endings of the bony ribs at the mid-axillary line and the abnormal costochondral junctions (arrow).

ultrasonography.[57,58] The pathological findings in autopsy cases are variable and show a range of pulmonary development; in most cases the bronchial development is normal and there is a variable decrease in alveolar divisions.[59]

There have been many surgical attempts to treat this disorder. The main goal of surgery is to expand thoracic volume and allow improved lung expansion. Early surgical interventions were reported by Barnes and colleagues, Karjoo and coworkers and Mustard.[60–62] Early repairs reported attempts at thoracic enlargement by splitting the sternum, which was then held apart by a variety of graft materials. Authors used either autologous tissue, such as rib grafts or iliac crest bone, or synthetic materials including methyl methacrylate, and stainless steel wires. There are multiple reports of initial improvement in lung ventilation, but subsequent growth failure of the chest resulted in recurrent respiratory distress.[63,64] In 1995, Davis and coworkers described a new lateral thoracic expansion technique for ATD.[65] New bone formation is documented 3 weeks after the procedure. Long-term follow up for this procedure has not been reported.

Campbell and coworkers have described a vertical expandable titanium rib (VEPTR) procedure for use in a variety of pediatric conditions of 'thoracic insufficiency syndrome'.[66] Vertically oriented titanium struts are attached to ribs and or transverse processes of the spine and progressively lengthened, with a series of surgical procedures to allow progressive expansion of the chest cavity. Computed tomography (CT) imaging studies have documented postoperative increase in chest volume, however, improvements in pulmonary function tests (PFTs) have not been demonstrated. Few patients with Jeune syndrome[67] have had VEPTR procedures. In one series, 9% of those treated with VEPTR had Jeune syndrome and all died within two years of the procedure, two from respiratory complications, one from renal failure, and one from liver failure.[68] The ultimate results of all surgical attempts will depend on the degree of underlying pulmonary parenchymal impairment of the infants.

Spondylothoracic dysplasia (Jarcho–Levin syndrome)

Spondylothoracic dysplasia is an autosomal recessive deformity characterized by short trunk dwarfism associated with multiple vertebral and rib malformations.[69] The ribs have a crab-like appearance (Fig. 29.7). Death occurs early in infancy from respiratory failure and pneumonia.[70] Patients have multiple alternating hemi-vertebrae which affect most of the thoracic and lumbar spine. The ossification centers rarely cross the midline. Multiple posterior fusions of the ribs, as well as remarkable shortening of the thoracic spine, result in a 'crab-like' radiographic appearance of the chest. One-third of the patients with this syndrome have associated malformations including congenital heart disease and renal anomalies. Its occurrence has been reported primarily in Puerto Rican families (15 out of 18 cases).[71] Bone formation is normal in these patients. Successful prenatal diagnosis can be established by sonographic examination.[72] Thoracic deformity is secondary to the spinal anomaly which results in close posterior approximation of the origin of the ribs. Although most infants with this syndrome succumb before

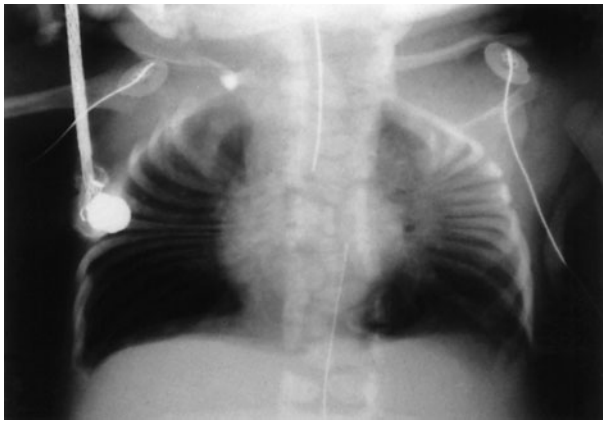


Figure 29.7 X-ray of infant with spondylothoracic dysplasia (Jarcho–Levin syndrome). Severe abnormality of the spine is apparent with multiple hemivertebrae and the 'crab-like' ribs with close approximation posteriorly and splaying out anteriorly.

15 months of age, no surgical efforts have been proposed or attempted.[73] Spondylothoracic dysplasia has a mortality rate approaching 50% from respiratory complications due to thoracic insufficiency syndrome. In spite of severe restrictive respiratory disease, adult survivors of spondylothoracic dysplasia appear to do well clinically for unknown reasons.[74]

Mediastinal masses in the newborn

STEPHEN J SHOCHAT

INTRODUCTION

Mediastinal masses in the newborn represent a wide variety of congenital and neoplastic lesions which can present interesting diagnostic and therapeutic challenges. However, despite the heterogeneous make up of this group of lesions, an accurate preoperative diagnosis can usually be established on the basis of the location of the mass. While the subject of this chapter deals with the treatment of masses in the newborn, it is helpful to discuss differences between various age groups when dealing with mediastinal masses in the childhood population.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of mediastinal masses in infants and children is simplified if the mediastinum is arbitrarily separated into three compartments (Fig. 30.1). For the purpose of this discussion, the mediastinum will be partitioned as follow: the anterior mediastinum lies anterior to the heart and lung roots and contains the thymus, anterior mediastinal lymph nodes, and rarely a substernal extension of the thyroid and parathyroiod; the middle mediastinum contains the trachea, bronchi, mediastinal lymph nodes, heart, and great vessels; the posterior mediastinum lies behind the heart and lung roots and contains the esophagus and intercostals sympathetic nerves. Anterior mediastinal masses include teratomas; thymic cysts, hyperplasia, or tumors; cystic hygromas and lymphomas. Masses within the middle mediastinum include the lymphomas, bronchogenic cysts, and granulomatous infections within the mediastinal lymph nodes. Posterior mediastinal lesions include the tumors of neurogenic origin, enterogenous cysts, and the undifferentiated sarcomas.

The age of the patient at the time of diagnosis is extremely important, since certain masses have a predilection for younger infants and others are predominantly seen in older children and adolescents. In newborns and children under two years of age, the most common mediastinal is the neuroblastoma within the posterior mediastinum. In addition, thymic hyperplasia and bronchogenic cysts are seen predominantly in children less than two years of age. The various lymphomas are the most common mediastinal masses seen in children greater than two years. The mean age of children with mediastinal Hodgkin's disease is approximately 13 years of age and the mean age of children who present with non-Hodgkin's lymphoma is 11 years of age.

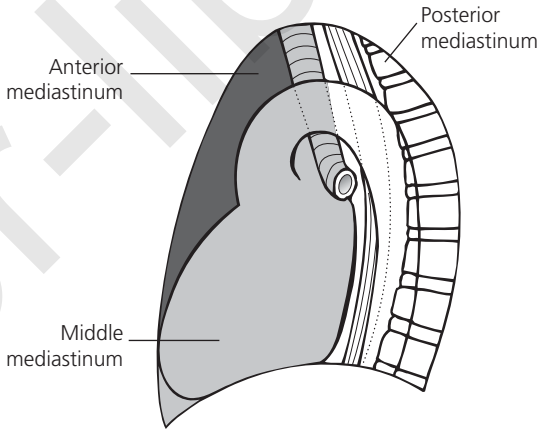

Figure 30.1 Compartments of the mediastinum.

The presenting signs and symptoms in infants and children with mediastinal masses vary depending upon age:

- acute respiratory distress;
- fever;
- cough;
- shortness of breath;
- cervical adenopathy;
- superior vena caval syndrome;
- Horner's syndrome;
- asymptomatic.

Infants under two years of age frequently present with signs of tracheal compression and acute respiratory distress. This is

due to the smaller, softer, more pliable tracheobronchial tree in infants, as well as the fact that they do not have a fixed mediastinum so that large mediastinal masses can cause a significant shift of the mediastinum with compromise of the contralateral hemithorax. Older children will present with symptoms of fever, cough, and shortness of breath. Approximately half the children with mediastinal lymphomas will present with cervical adenopathy. Superior vena caval obstruction is rare in children, but is occasionally seen. Horner's syndrome may be the presenting finding in infants with neuroblastomas or neurogenic tumors of the posterior mediastinum. Asymptomatic mediastinal masses are seen in children of all ages and are frequently noted on a chest x-ray performed for a mild upper respiratory infection or are discovered incidentally following imaging studies for symptoms unrelated to the mediastinal mass.

DIAGNOSIS

A systematic approach to the diagnosis of a mediastinal mass in the newborn is imperative:

- posteroanterior–lateral chest x-ray;
- barium swallow;
- ultrasonography;
- computed tomography (CT) scan;
- magnetic resonance imaging (MRI);
- bone marrow – lymph node biopsy;
- skin test – complement fixation;
- serum markers – AFP, HCG;
- urinary catecholamines.

The most helpful diagnostic technique in this age group is still the chest x-ray in the posteroanterior and lateral projections, in order to localize the position of the mass. Vertebral anomalies associated with a medistinal mass in an infant should raise the suspicion of the so-called neuroenteric variety of enterogenous cyst, which communicates with the meninges. Calcification within a posterior mediastinal mass suggests the presence of a neuroblastoma and anterior mediastinal teratomas frequently contain calcification. In cases of suspected enterogenous and brochogenic cysts, the esophagogram may be of value. Ultrasonography of the chest can be quite helpful in defining complicated mediastinal lesions and has been especially helpful in infants with suspected thymic hyperplasia. Echocardiography should be performed to delineate the heart and great vessels if lesions of these structures are suspected. A CT scan should be reserved for difficult diagnostic dilemmas and for delineating anatomical boundaries in preparation for tumor resection. MRI may be of help in differentiating masses of vascular origin from other mediastinal structures and may be helpful in infants with suspected thymic hyperplasia. In addition, MRI should be considered in cases of posterior mediastinal masses in order to detect intraspinous extension of tumor (dumbbell tumors).

Cervical lymph node biopsy should be considered in children with middle mediastinal lesions and suspected lymphoma. A bone marrow aspiration and biopsy should also be performed prior to other invasive studies in children suspected of having non-Hodgkin's lymphoma. Skin testing and complement fixation titers should be considered in infants with middle mediastinal masses to rule out granulomatous infections. Alpha fetoprotein determination and HCG titers should be performed in children with anterior mediastinal masses if malignant teratomas are suspected. Urinary catecholamine metabolites should be evaluated in infants with posterior mediastinal masses, both for diagnosis and for postoperative follow up in children with suspected neuroblastomas.

ANTERIOR MEDIASTINUM

Thymic hyperplasia is the most common anterior mediastinal mass seen in infants (Fig. 30.2). This diagnosis is usually not difficult as there is frequently a characteristic 'sail' sign on routine chest x-ray. Recently, ultrasonography has been very helpful in differentiating thymic hyperplasia from other mediastinal masses and should be considered in difficult cases. The use of steroids to help with the diagnosis of thymic hyperplasia in infants as listed below is rarely necessary and has not been required in our institution for some time. Benign teratoma is the most frequent anterior mediastinal neoplasm seen in children under two years of age (Fig. 30.3). These masses are usually well encapsulated and can be treated by total excision through a posterolateral thoracotomy. Cystic hygromas are also observed in infants, but usually have a cervical or axillary component which makes this diagnosis obvious. Thymic cysts are extremely rare in children and only 20 thymomas have been reported in childhood. Germ cell tumors of the anterior mediastinum are usually seen in older children and adolescents and many have an endodermal sinus or yolk sac component with an elevated serum alpha fetoprotein. AFP and HCG levels should be performed in all older children with anterior mediastinal masses as these markers are helpful not only in diagnosis, but in following response to therapy.

These tumors are highly malignant lesions and total resection rarely is possible. Evaluation of these patients requires a multidisciplinary approach with consultation between surgeon, pediatric oncologist, and radiation therapist.

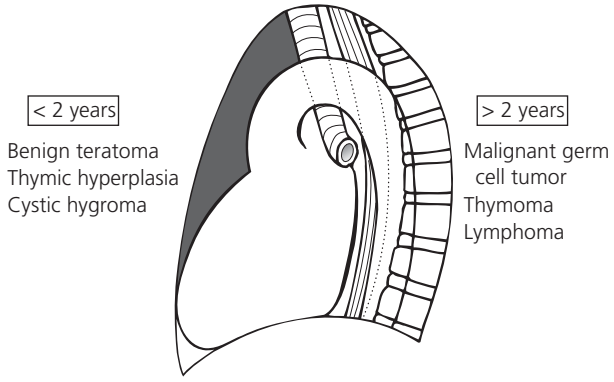

Figure 30.2 Anterior mediastinum.

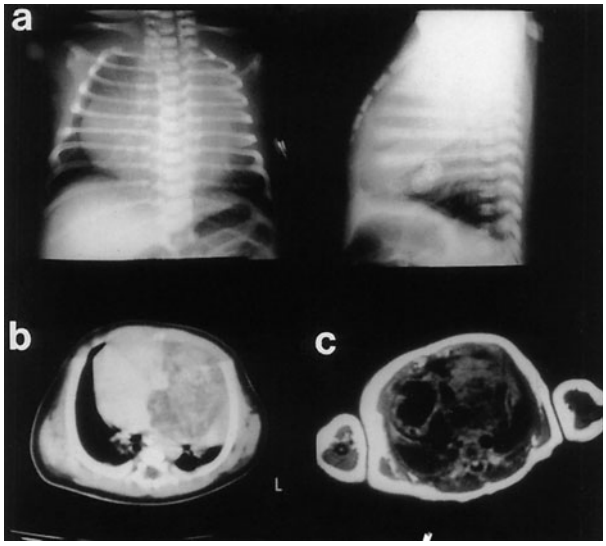

Figure 30.3 Cardiac teratoma with anterior mediastinal mass: (a) posteroanterior–lateral chest x-ray; (b) CT scan; (c) MRI.

In the rare case where total excision is possible, this should be carried out and followed by multi-agent chemotherapy. However, radical resection is not indicated. When the tumor is non-resectable, a biopsy rather than partial resection is followed by chemotherapy and delayed primary excision. While isolated lymphomas of the thymus do occur, the majority of lymphomas of the anterior mediastinum will also have a major middle mediastinal component which makes diagnosis straightforward.

MIDDLE MEDIASTINUM

Bronchogenic cysts may be seen in all age groups, but are the most frequent mass seen within the middle medistinum in infants and children under two years of age (Fig. 30.4). Bronchogenic cysts are located in the subcarinal region and are frequently associated with a characteristic expiratory stridor due to accentuation of the obstruction of the lower trachea during expiration. Bronchogenic cysts are frequently difficult to diagnose on routine chest x-ray, but there is usually a characteristic displacement of the esophagus on barium swallow (Fig. 30.5). Bronchogenic cysts occasionally are intimately attached to the membranous trachea and if this is the case a small portion of the cysts should be left attached to the trachea.

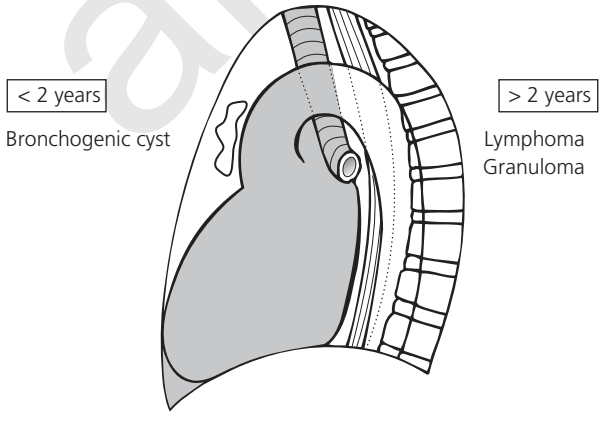

Figure 30.4 Middle mediastinum.

The most common mediastinal mass in individuals over two years of age is Hodgkin's or non-Hodgkin's lymphoma. Lymphomas are also the most frequent tumors involving the middle mediastinum.

The initial diagnostic work up in children with suspected lymphoma should include cervical or supraclavicular lymph node biopsy, as well as bone marrow biopsy. Mediastinoscopy, anterior mediastinotomy, or CT-guided needle biopsy are the procedures of choice to establish a tissue diagnosis in the absence of cervical adenopathy. A formal thoracotomy is rarely indicated for diagnosis or treatment in children with lymphoma. Children who present with a large middle mediastinal mass and respiratory distress and a suspected diagnosis of non-Hodgkin's lymphoma may be treated initially with steroids prior to biopsy because of the dangers of acute respiratory decompensation on induction of anesthesia. However, every attempt should be made to safely establish a diagnosis prior to the use of steroids since even a brief course of therapy can make subsequent diagnosis difficult. A multidisciplinary approach (surgeon, oncologist, radiotherapist) to the child with suspected mediastinal lymphoma is imperative and tissue obtained at the time of biopsy should be placed in saline so that immunologic surface marker studies can be performed. These studies are extremely important in the classification, and hence therapy, of the various non-Hodgkin's lymphomas.

Granulomatous infections of the paratracheal, subcarinal, or hilar lymph nodes are occasionally seen and can usually be diagnosed by appropriate skin tests and complement fixation titers. In the Midwest of the USA and other endemic areas, histoplasmosis seems to have a predilection for the azygous node which is characteristically enlarged in children with this infection. Diagnosis is confirmed by mediastinoscopy, mediastinotomy, or rarely thoracotomy.

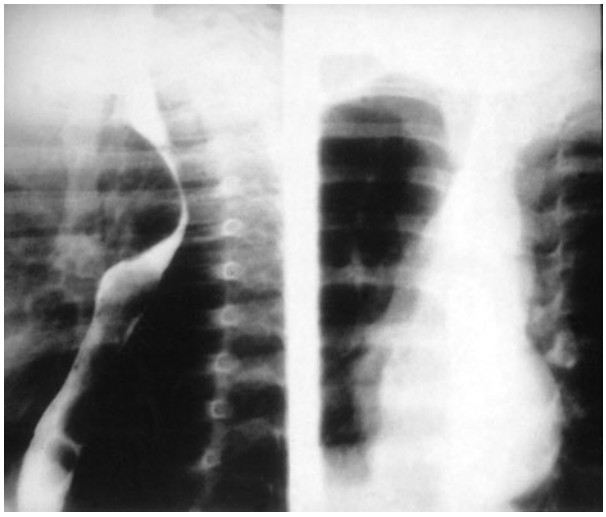

Figure 30.5 Bronchogenic cyst showing displacement of esophagus. Normal appearing chest x-ray.

POSTERIOR MEDIASTINUM

The most common mass of the posterior mediastinum, and in fact the most common mass in newborns, is a posterior mediastinal neuroblastoma (Fig. 30.6). Mediastinal neuroblastomas are interesting in that they seem to have a different biological behavior than intra-abdominal tumors. The majority of mediastinal neuroblastomas are localized or low-stage disease and have a favorable outcome following resection. These tumors are more often occult and are diagnosed on x-ray examination for other complaints. Respiratory distress due to compression or deviation of trachea is a feature in some cases. Thoracic neuroblastomas with dumb-bell extension may present with neurological symptoms due to spinal cord compression. While the treatment of mediastinal neuroblastomas in children is total excision if at all possible, this does not mean radical chest wall resection. In the rare case of a massive mediastinal neuroblastoma, that cannot be resected without a radical operation, a biopsy to establish the diagnosis is followed by chemotherapy and delayed primary excision. While this clinical situation is unusual, we have found that a tissue diagnosis can usually be obtained by a percutaneous core needle biopsy avoiding formal thoracotomy. In children with disseminated neuroblastoma, thoractotomy and resection should be carried out only after all metastatic sites are controlled with multi-agent chemotherapy. Despite impressive shrinking of tumor following chemotherapy and complete delayed primary excision, the prognosis continues to be discouraging.

Children with posterior mediastinal neuroblastoma can also present with unusual symptoms. The case in Figure. 30.7 presented with a three-month history of diarrhea. The mass turned out to be a large neuroblastoma that extended up into the cervical region. The tumor contained high concentrations of prostaglandin E which was the etiology of the diarrhea. Vasoactive intestinal polypeptide secreting neuroblastomas have also been described in children with profuse watery diarrhea. Ratner and Pelton reported an infant who presented with progressively worsening labored respirations and was found to have a neuroblastoma extending from the mediastinum, through the thoracic inlet, and into the neck.

Enterogenous cysts, while rare, represent an interesting spectrum of lesions. They may be intimately associated with

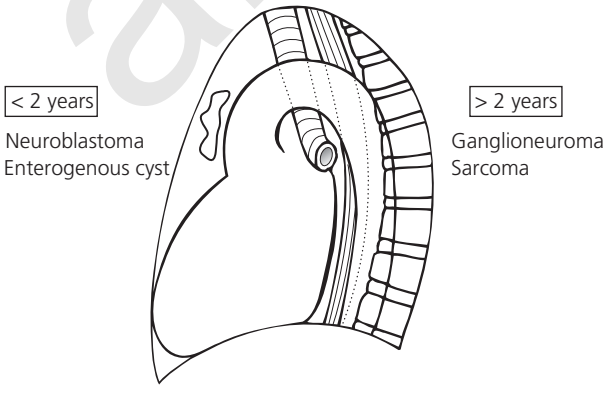

Figure 30.6 Posterior mediastinum.

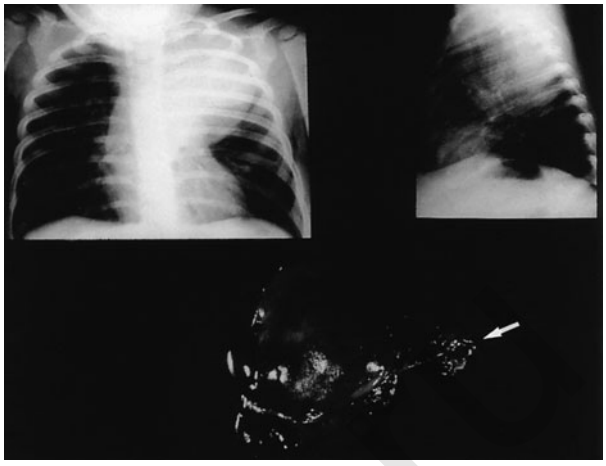

Figure 30.7 Posterior mediastinal neuroblastoma treated by total excision. Note cervical extension (arrow).

the esophagus and cause dysphagia or they can contain gastric mucosa which has been associated with peptic ulceration, perforation, and bleeding. Large cysts can have abdominal extensions and communicate with an intestinal duplication.

An interesting but rare variant is the so-called neurenteric cyst that communicates with the meninges through an intraspinous component. These infants present with a large mediastinal mass, respiratory distress, and rarely neurological symptoms. Characteristic deformities of the lower cervical and upper thoracic spine are always present on routine chest x-ray. During resection of these masses through a posterolateral thoracotomy, the communication between the thoracic and infraspinous component must be identified and ligated to prevent a spinal fluid leak and meningitis. These patients should be evaluated by MRI as the infraspinous cystic component may require laminectomy and excision.

ANESTHETIC MANAGEMENT OF INFANTS WITH A MEDIASTINAL MASS

Respiratory compromise on induction of general anesthesia in children with large mediastinal masses is a well-recognized complication that must be considered in the preoperative evaluation of any child with a mediastinal mass. Infants and small children have a small compressible airway, which is associated with significant increased airway resistance with even a modest degree of narrowing. In addition, infants do not have a fixed mediastinum and large masses can easily displace the mediastinal structures with compression of the tracheobrochial tree, superior vena cava, or right ventricular outflow tract. Cardiac output may also be diminished due to pressure on the great vessels. Induction of anesthesia is associated with a decrease in the functional residual capacity, decreased lung capacity, and an increase in lung retractile force. The above alterations are extenuated with the addition of paralysis. Narrowing of the trachea will also become smaller when the patient changes from spontaneous to positive pressure ventilation. All of the above factors lead

to the sometime critical condition that is associated with general anesthesia in these patients.

The most important factor in preventing anesthetic complications in children with mediastinal mass is recognition of the above problems and the anticipation of a possible airway problem. A very thorough radiologic evaluation should be performed and CT examination to determine the tracheal cross-sectional area may also be of help. Once the preoperative evaluation is completed, the anesthetic of choice can be determined depending upon the procedure that will be performed. Preoperative radiation therapy or chemotherapy may be required prior to primary excision or biopsy. Incisional biopsies can be performed under local anesthesia in older children and needle biopsy with local anesthesia can be performed in younger children and infants. In children with benign lesions, one lung anesthesia with placement of the endotracheal tube beyond the obstruction has been found to be helpful and occasionally ventilation through a rigid bronchoscope is necessary. While cardiopulmonary bypass of extracorporeal membrane oxygenation (ECMO) may be required, these techniques are usually not necessary in the majority of patients. A high index of suspicion, meticulous preoperative evaluation, and a multidisciplinary action plan decided upon by surgeons, anesthesiology, radiation therapist, hematology/oncologist, and pathologist can usually avert the potential catastrophe associated with general anesthesia in children with critical mediastinal masses.

OPERATIVE TECHNIQUE FOR REMOVAL OF MEDIASTINAL NEUROBLASTOMA

The tumor is usually approached through a standard posterolateral thoracotomy at the approximate level of the tumor. The lung is retracted medially to reveal tumor covered with pleura arising from the sympathetic trunk and an assessment made of it and obvious lymph node involvement in the vicinity. The pleura is incised around the tumor approximately 1 cm from it and the fascia and pleura mobilized towards the tumor. A plane of dissection can usually be developed superficial to endothoracic fascia. The tumor is now mobilized from the ribs by sharp dissection and intercostals vessels entering the tumor will need division. If the tumor extends far enough anteriorly, the azygos vein on the right side will need division between ties. Care is taken to avoid damage to the first thoracic nerve passing laterally across the first rib to join the brachial plexus. The superior intercostals artery normally descends between the first nerve and the sympathetic trunk. Other intercostal nerves may be sacrificed if they are intimate with the tumor.

Depending on how far the tumor has extended anteriorly, it will need to be dissected off the main structures in the superior mediastinum. This is most likely to be the esophagus and the closely applied vagus nerve, but in a large tumor the trachea may be involved. It may prove useful to have a large size tube in the esophagus to aid dissection. On the left side, the thoracic duct, arch of aorta with subclavian, and carotid branches along with the vagus will need protection.

It should now prove possible to dissect the tumor off the bodies of the vertebra and any extension into the intravertebral foramen should be carefully dissected out. Titanium clips may prove useful to control hemorrhage in small vessels, and these will not interfere with subsequent CT scanning. They may also be used as markers if all the tumor is not excised and radiation therapy is being considered. Any suspiciously involved lymph nodes locally should be taken for biopsy (staging). The chest is closed after leaving a chest drain.

Congenital airway malformations

RICHARD G AZIZKHAN

INTRODUCTION

Congenital airway malformations include a wide spectrum of pathology that occurs at various anatomic levels. Presentation varies widely, and is influenced both by the level at which obstruction occurs and the severity of obstruction. In view of the distinct anatomy of the pediatric airway and the possibility of airway symptoms quickly progressing to life-threatening airway compromise, early detection, diagnosis, and treatment are imperative. The aim of this chapter is to briefly discuss anomalies extending from larynx to the distal airway, highlighting symptomatology, patient assessment, and primary management strategies.

PATIENT ASSESSMENT

Medical history

Evaluating an infant with respiratory compromise should begin with a meticulous review of the infant's history of airway symptoms. Clinicians should explore circumstances that may elicit the onset of symptoms and should question parents regarding the duration of symptoms and symptom progression. They should also explore possible swallowing or feeding problems, the nature of the child's cry, and the possibility of foreign-body aspiration. Additionally, any history of endotracheal intubation, trauma, or previous cardiac surgery should be carefully reviewed. All of this information may provide important clues as to the underlying etiology, and may determine or affect management strategy.

Signs and symptoms

Patients with mild airway compromise may present with subtle symptoms such as irritability, restlessness, and feeding difficulties. Those with more severe obstruction frequently present with severe suprasternal and intercostal retractions, tachypnea, lethargy, and cyanosis. Stridor, defined as a harsh sound caused by turbulent airflow through a partially obstructed airway, can manifest during the expiratory or inspiratory phases of the respiratory cycle or can be biphasic. Inspiratory stridor usually indicates an airway obstruction in the extrathoracic airway, whereas expiratory stridor usually indicates a problem in the intrathoracic airway. Biphasic stridor typically signifies a fixed glottic or subglottic lesion. The pitch of stridor, as well as its relationship to the respiratory cycle, is generally helpful in establishing a differential diagnosis and in establishing priorities for patient assessment. Clinicians should be mindful of the fact that the degree of stridor does not necessarily reflect the severity of airway obstruction. More specifically, even minimal stridor can reflect the lack of airway movement across a critical airway.

Diagnostic studies

The most critical component of the airway assessment after physical examination is endoscopic evaluation. Depending on the type of suspected airway lesion, either flexible or rigid bronchoscopy or both are performed. To adequately assess the dynamic aspects of some suspected airway lesions (e.g. tracheomalacia), endoscopy should be performed with the patient spontaneously breathing. Seventeen percent of patients have a synchronous airway lesion; evaluation of the entire airway is thus required. Given that up to 45% of children with congenital airway obstruction also have significant non-airway anomalies, all patients require a thorough overall evaluation.

Imaging studies are helpful in diagnosis as well as patient management. Computed tomography (CT) and magnetic resonance imaging (MRI) studies provide a rapid and precise way of assessing and measuring the extent and length of airway narrowing or displacement. These investigations are also helpful in detecting associated mediastinal and pulmonary anomalies. Specifically, MR angiography is valuable in assessing the relationship of mediastinal great vessel anomalies

(e.g. vascular rings, pulmonary artery slings) to the airway. Newer computer software allows for three-dimensional image reconstruction and is helpful in planning surgical procedures. Echocardiography is valuable in identifying intracardiac defects and most associated great vessel anomalies. Contrast swallow studies are valuable in assessing esophageal motility, aspiration, and some mediastinal lesions that affect the airway. Fiberoptic endoscopic evaluation of swallowing (FEES) is performed to evaluate structural and functional disorders of swallowing and to identify functional problems of the larynx, pharynx, epiglottis, and proximal esophagus.

CONGENITAL LARYNGEAL ANOMALIES

Laryngomalacia

Laryngomalacia is the most common congenital laryngeal anomaly, accounting for up to 75% of laryngeal disorders in neonates. This condition is characterized by laxity of both the glottic and supraglottic tissues, which causes the epiglottis, arytenoids, and aryepiglottic folds to collapse and partially obstruct during inspiration. The reported incidence of secondary airway lesions in infants with laryngomalacia varies, with some authors documenting rates as high as 50[1] and 64%.[2]

Laryngomalacia is also the most common cause of stridor in neonates. This symptom is usually evident soon after birth or within the first few days of life. It is generally mild, but can be exacerbated by feeding, crying, or lying in a supine position. Fifty percent of children with laryngomalacia experience a worsening of stridor during the first six months of life, though in virtually all affected children, symptoms resolve by one year of age. When the disorder is severe, however, children may exhibit apnea, cyanosis, severe retractions, and failure to thrive, and thus require surgical intervention. In extremely severe cases, cor pulmonale can develop.

Flexible transnasal fiberoptic laryngoscopy is used to confirm the diagnosis. Pathognomonic findings include short aryepiglottic folds, with prolapse of the cuneiform cartilages. Collapse of the supraglottic structures is seen on inspiration, and inflammation indicative of reflux laryngitis is also frequently seen (Fig. 31.1). In some patients, a tightly curled (omega-shaped) epiglottis is observed.

The decision as to whether to intervene surgically is based more so on symptom severity than on the endoscopic appearance of the larynx. For patients with severe symptoms, supraglottoplasty (also termed epiglottoplasty) is the preferred operative procedure, with a reported surgical success as high as 94%.[3–5] Both aryepiglottic folds are divided and one or both cuneiform cartilages may be removed. If the aryepiglottic folds alone are divided, postoperative intubation is usually not required. Patients should be observed overnight in the intensive care unit. Antireflux management is advisable for helping to minimize laryngeal edema. This is especially important in patients with a synchronous airway lesion, as these patients are known to have a higher incidence of gastroesophageal reflux disease (GERD) than those without a synchronous lesion.[1,3] Synchronous airway lesions

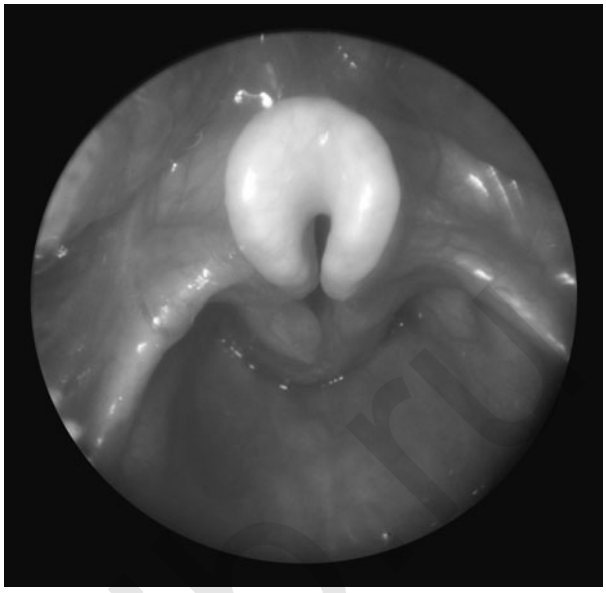

Figure 31.1 Endoscopic view of laryngomalacia in an infant showing partial collapse of the supraglottic structures during inspiration.

as well as neurologic conditions and pre-existing laryngeal edema can adversely affect operative outcomes.[6] Occasionally, an infant's obstructive symptoms continue despite an adequate postoperative appearance of the larynx. These infants may have an underlying neurologic problem that may become more evident over time. As such, they are much more likely to require tracheotomy placement.

Subglottic stenosis

Subglottic stenosis (SGS) is an anomaly that involves a narrowing of the subglottic lumen. It can be either congenital or acquired; however, the latter is seen far more frequently and is generally a sequela of prolonged intubation of the neonate. In the premature infant, SGS is considered present when this lumen measures 3.0 mm or less in diameter at the level of the cricoid, whereas in the full-term neonate, SGS is defined as a lumen of 4.0 mm or less in diameter at this level. Congenital SGS is thought to be caused by failure of the laryngeal lumen to recanalize during embryogenesis. It may occur as an isolated anomaly or may be associated with other congenital head and neck lesions and chromosomal anomalies such as a small larynx in patients with Down syndrome.[7]

Levels of SGS severity range from mild to severe, and are graded based on the Myer–Cotton grading system (Table 31.1). Patients with mild SGS (no obstruction–50% obstruction) may present with recurrent upper respiratory infections, often misdiagnosed as croup. In a young child, the greatest obstruction is usually 2–3 mm below the true vocal cords.[8] Patients with more severe narrowing (71–99% obstruction) may present with acute airway compromise and require endotracheal intubation or tracheotomy placement at delivery (Fig. 31.2). However, many of these infants, even those with grade III SGS (71–99%), may not be symptomatic for weeks or months. When stridor is present,

Table 31.1 Myer–Cotton grading system for subglottic stenosis.

Classification	Level of airway obstruction	
	From	To
Grade I	No obstruction	50% obstruction
Grade II	551% obstruction	70% obstruction
Grade III	771% obstruction	99% obstruction
Grade IV	No detectable lumen	

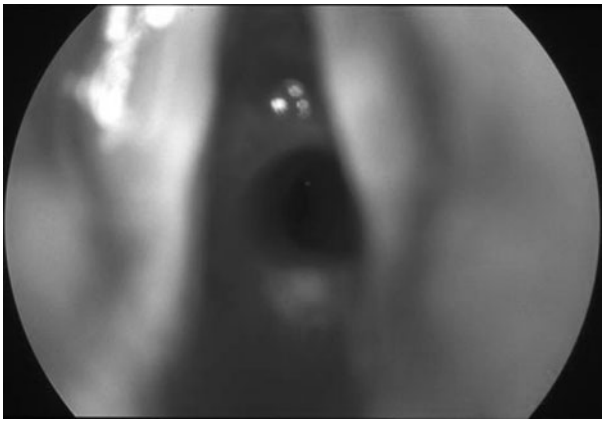

Figure 31.2 High-grade subglottic stenosis in a symptomatic neonate.

it initially occurs during the inspiratory phase of respiration. As SGS severity increases, stridor becomes biphasic.

Radiologic evaluation of the non-intubated airway can provide information regarding the site of the stenosis and its extent. Chest x-ray, inspiratory and expiratory lateral soft-tissue neck films, and fluoroscopy are helpful in revealing the dynamics of the trachea and larynx. High-kilovoltage airway films identify the classic steeple-like configuration seen in patients with SGS, as well as possible tracheal stenosis, and are therefore of utmost importance. Flexible and rigid endoscopy are used in a complementary fashion for airway evaluation and are both essential. Flexible endoscopy provides critical information regarding the structural dynamics of airflow in the hypopharyngeal and laryngeal airways. Rigid endoscopy provides an assessment of the entire laryngotracheobronchial airway.

In children with mild to moderate disease (grades I or II), congenital SGS improves with age. Children with a minor degree of SGS who experience mild symptoms, may, nevertheless, benefit from endoscopic intervention. Endoscopic options include radial laser incisions through the stenosis and laryngeal dilatation.[9] Outcomes are improved when mitomycin C is used concomitantly with this approach.[10] Less than 50% of these patients require tracheotomy placement to maintain their airway. Children with more severe disease are best managed with open subglottic airway reconstruction. Costal cartilage grafts can be placed through either the anterior or posterior lamina of the cricoid cartilage or both. This may be carried out as a single-stage laryngotracheoplasty[11,12] or as a two-stage procedure, requiring stenting and placement of a temporary tracheostomy.[13] For severe SGS, good results have been achieved by performing partial or complete cricotracheal resection and reconstruction; however, this is a demanding procedure with considerable risks. Successful outcome depends on the management of comorbidities such as GERD, eosinophilic esophagitis, and low-grade tracheal infection.

Vocal cord paralysis

Vocal cord paralysis can be congenital or acquired and can occur either unilaterally or bilaterally. Unilateral paralysis is usually an acquired condition caused by damage to the recurrent laryngeal nerve (RLN). Because of the length and course of the left RLN, this is far more likely to be damaged than the right RLN. Acquired paralysis thus generally affects the left vocal cord. Unlike unilateral vocal cord paralysis, bilateral paralysis is usually evident at birth. It is generally idiopathic, but often is seen with central nervous system conditions, such as hydrocephalus and Chiari malformation of the brainstem. Although most children with bilateral paralysis present with significant airway compromise, they have an intelligible voice and do not aspirate. In contrast, most children with unilateral vocal cord paralysis have an acceptable airway, but are at a slightly higher risk of aspiration and have a breathy voice.

The diagnosis is made by flexible laryngoscopy with the patient awake. Investigation aimed at finding the underlying cause is then carried out. Stabilization can be achieved with intubation, continuous positive airway pressure (CPAP), or high-flow nasal canula as an alternative temporizing measure. Almost all infants with bilateral paralysis require tracheotomy placement to ensure a safe and adequate airway. However, up to 50% of children with congenital idiopathic bilateral paralysis experience spontaneous resolution of their paralysis by the age of one.[14] In view of possible resolution, decannulation is almost always delayed to allow time for this to occur. Children with acquired bilateral paralysis may also experience spontaneous recovery, provided that the RLN was stretched or crushed but otherwise intact.

Because no single surgical approach offers a universally acceptable outcome, a number of surgical approaches have been used for children with bilateral paralysis. These approaches include laser cordotomy, partial or complete arytenoidectomy, and vocal cord medialization or lateralization (open or endoscopically guided).[15,16] The aim of each of these procedures is to achieve an adequate decannulated airway while maintaining voice and preventing aspiration.

Posterior laryngeal cleft

Posterior laryngeal cleft is a rare congenital anomaly that results from failure of the laryngotracheal groove to fuse during embryogenesis. This anomaly comprises five anatomic subtypes that differ with respect to involvement of the larynx and/or trachea (Fig. 31.3). Patients frequently have coexisting anomalies, many of which affect the airway. Associated airway anomalies include tracheomalacia (almost always present in varying levels of severity), tracheoesophageal

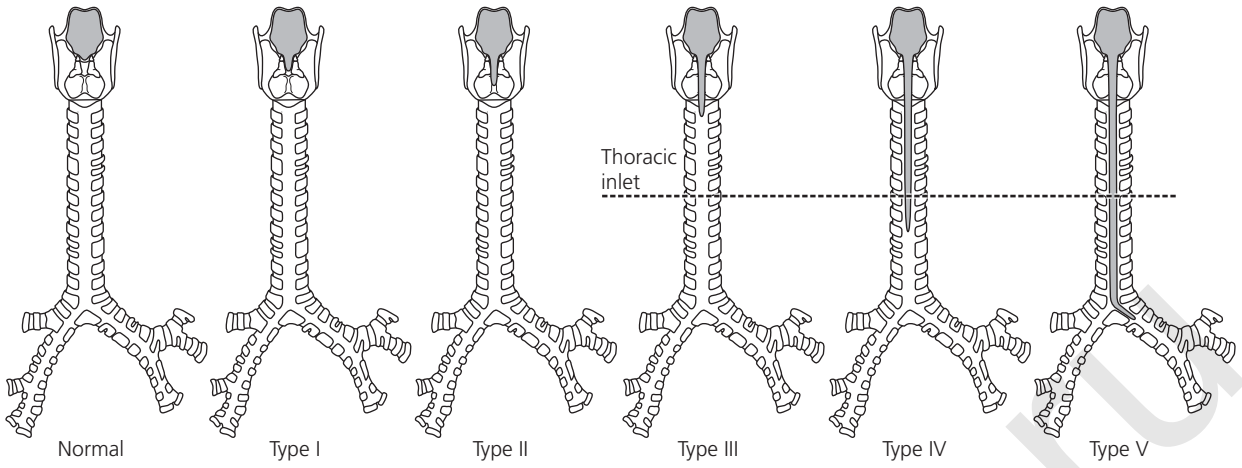

Figure 31.3 Posterior laryngeal cleft classification.

fistula formation (20%), laryngomalacia, vocal cord paralysis, SGS, and innominate artery compression. Associated non-airway conditions include anogenital anomalies, cleft lip and palate, congenital heart defects, and GERD, which affects most children. The most common associated syndrome is Opitz–Frias syndrome, which is characterized by hypertelorism, anogenital anomalies, and posterior laryngeal clefting.

Diagnosis can be extremely difficult, as presenting symptoms vary greatly. In type I and type II clefts, symptoms are often subtle, and may mimic those of other disorders such as GERD. Nonetheless, aspiration is a hallmark clinical feature of this spectrum of disease. With more severe clefts, gross aspiration may occur with associated apnea, cyanosis, and even pneumonia. For milder clefts, the symptoms are those of microaspiration, with choking episodes, transient cyanosis, and recurrent chest infections.[8,17] Airway obstruction manifested by stridor may also be present and is caused either by redundant mucosa on the edge of the cleft or a small cricoid ring. In patients with severe tracheomalacia, especially those with an associated tracheoesophageal fistula, the airway may be significantly compromised. Contrast swallow studies may demonstrate aspiration; however, rigid laryngoscopy and bronchoscopy are essential for definitive diagnosis. The interarytenoid area is specifically probed to determine if a posterior laryngeal cleft is present.

In children who are symptomatic and do not have other more severe anomalies, repair of the posterior laryngeal cleft should be performed as soon as possible to prevent chronic microaspiration with long-term pulmonary sequelae. Depending on the extent of the airway anomaly, tracheotomy and gastrostomy tube placement may be required before definitive surgical repair of the airway. Because of the high incidence of GERD, fundoplication is often required, and is preferably performed prior to surgical repair. Most type I and some type II clefts are amenable to endoscopic surgical repair, whereas clefts that extend into the cervical or thoracic trachea require open repair. A transtracheal approach is advised, as it provides optimal exposure of the cleft while protecting the recurrent laryngeal nerves. A two-layer closure is recommended, with the option of performing an interposition graft if warranted. Type V clefts, which extend to the carina or beyond and are often associated with multiple congenital anomalies, are exceedingly difficult to repair and are prone to anastomotic breakdown.[17] Success rates for cleft repair vary significantly (50–90%) depending on both the severity of the cleft and the presence of comorbidities.

Laryngeal atresia

CONGENITAL HIGH AIRWAY OBSTRUCTION SYNDROME

Congenital high airway obstruction syndrome (CHAOS) is a rare, life-threatening, prenatally diagnosed condition caused by complete or near-complete obstruction of the larynx and trachea. Fetal lung fluid becomes trapped, causing the lungs to become abnormally distended. This creates massive lung expansion that characteristically everts the hemi-diaphragms.

This type of fetal airway obstruction may be caused by multiple etiologies, including laryngeal atresia, laryngeal web, tracheal atresia, and laryngeal cyst.[18] Airway atresia is sometimes an isolated anomaly, but often is seen in association with genitourinary, vertebral, and cardiac anomalies as well as with hydrocephalus malformation of the Aqueduct of Sylvius, bronchotracheal fistula, esophageal atresia, tracheoesophageal fistula, and syndactyly. Regardless of the etiology, the clinical features and presentation of CHAOS are the same. Prenatal findings on ultrasound (US) include diffuse and enhanced echogenicity of the lungs, dilated airways, and flattened or everted diaphragms with associated fetal ascites and non-immune hydrops (Fig. 31.4). A fetus identified with these sonographic features is at significant risk of intrauterine death and faces a high likelihood of mortality should the pregnancy progress to delivery. Although US provides a good initial assessment of CHAOS, MRI is clearly superior in identifying severity and the level of airway obstruction, and optimizes planning for airway management at delivery.[19] These patients all require delivery by the *ex utero* intrapartum technique (EXIT) procedure. This procedure maintains placental circulation to the fetus while securing the airway at the time of delivery.[18] Securing the airway may include a full endoscopic diagnostic assessment and tracheostomy.

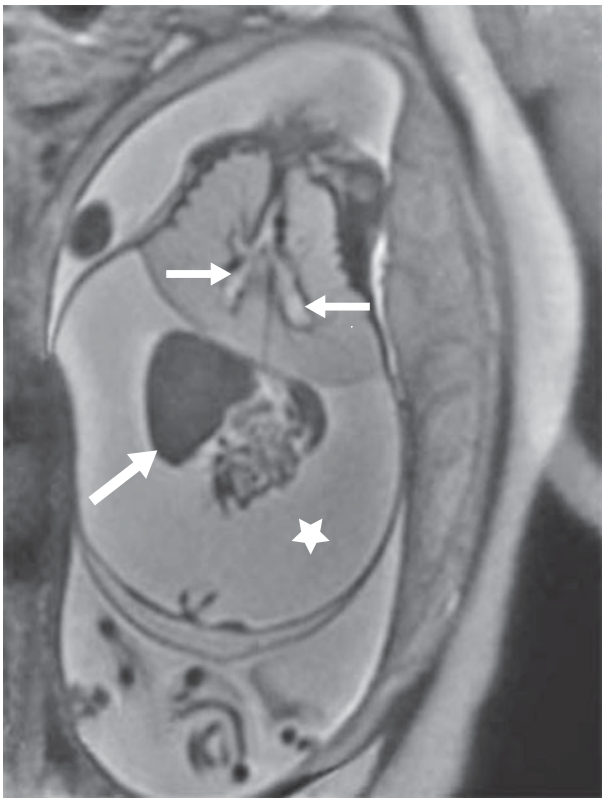

Figure 31.4 Fetal ultrasonography at 27 weeks' gestation demonstrating findings consistent with the diagnosis of congenital high airway obstruction: enlarged echogenic lungs, dilated airway (white arrow), flattened or everted diaphragms, and fetal ascites (white star) and hydrops. Fetal liver and intestines marked with a black arrow.

For the newborn diagnosed with CHAOS, securing and maintaining the airway is the highest priority. These patients are almost always extremely ill and require a prolonged period of critical care and ventilatory support. Once the infant's cardiorespiratory status is stable and other critical or potentially life-threatening anomalies are ruled out, careful endoscopic evaluation of the airway precedes elective laryngotracheal reconstruction; however, consensus has not been reached as to optimal timing of airway reconstruction. Although a functional airway can be constructed, patients do not always attain intelligible speech capabilities.

Diagnosis in the middle of the second trimester generally correlates with a poor perinatal outcome. A fetus presenting in the third trimester with CHAOS in the absence of associated anomalies or hydrops is likely to have incomplete obstruction, and is therefore more likely to survive.

ANOMALIES OF THE TRACHEA AND BRONCHI

Tracheal agenesis and atresia

Tracheal agenesis is a rare developmental anomaly that almost always results in death. Patients who are prenatally diagnosed and in whom the atresia involves only the proximal trachea occasionally survive by using an EXIT procedure and eventual tracheal reconstruction. In another form of tracheal agenesis, the entire trachea is absent and the bronchi come directly off the esophagus. Neonates present at birth with severe respiratory distress, attempting ventilation through bronchoesophageal communications. Temporary ventilation may be possible with esophageal intubation of the esophagus, but this is typically unsustainable. If there is no communication between the airway and the esophagus, CHAOS will result.[18]

Tracheal stenosis and webs

Tracheal stenosis encompasses a broad spectrum of rare tracheal anomalies. Affected segments of the trachea differ in the degree and extent of stenosis, which can range from extremely thin webs to more severe long segments of stenosis affecting the entire airway.

TRACHEAL WEBS

Tracheal webs involve an intraluminal soft-tissue stenosis of the trachea. These webs may be membranous or consist of thick, relatively rigid tissue. Patients typically present with biphasic stridor or expiratory wheezing, and the severity of these symptoms depends on the degree of the stenosis. Thin webs can be easily managed by hydrostatic balloon dilatation.[20] For thicker webs that are not associated with underlying cartilage deformity, laser ablation is often used.[21] The carbon dioxide (CO_2) or potassium-titanyl-phosphate (KTP) laser is beneficial for treating lesions in the proximal trachea. Lesions in the distal airway are best managed with the KTP laser, which can be used through small fiberoptic cables. For children with a web greater than 1 cm in length or those in whom the airway cartilage is thought to be structurally deficient or anomalous, operative treatment with segmental tracheal resection or slide tracheoplasty is usually carried out.

CARTILAGINOUS RING APLASIA

Cartilaginous ring aplasia is an extremely rare anomaly in which only a small region of the trachea lacks cartilage, creating a distinct anatomic area that is both malacic and stenotic. The remainder of the trachea is unaffected, and most children do not have coexisting congenital anomalies. Management entails segmental resection of the trachea, which successfully restores the airway.

TRACHEAL CARTILAGINOUS SLEEVE

Tracheal cartilaginous sleeve is also extremely rare. In children with this anomaly discrete cartilaginous rings are replaced by a fused cartilaginous cylinder, with or without a membranous portion. It is typically seen in children with craniosynostosis syndromes such as Pfeiffer, Apert, Crouzon, and Goldenhar.[22–24] Neonates usually exhibit respiratory illness. Patients presenting in early infancy often experience acute respiratory symptoms, which may include biphasic stridor with respiratory distress, cough, and frequent

respiratory infections. Because of tracheal rigidity, the mechanism for clearing secretions is impaired.

On endoscopy, the anterior tracheal wall appears smooth, though the membranous posterior tracheal wall may be normal, stenotic, or absent. CT and MRI are sometimes useful in determining the extent of the lesion. Tracheotomy placement may be used as a temporizing measure; however, resection and repair are imperative to achieve normal function.

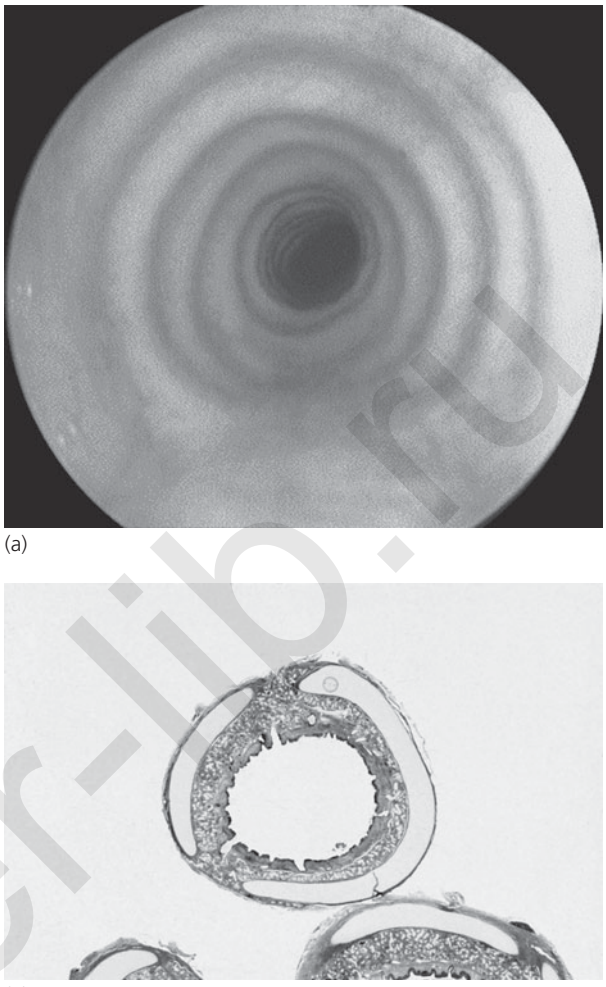
COMPLETE TRACHEAL RINGS

Although rare, complete tracheal rings are the most common congenital tracheal stenosis. With this spectrum of potentially life-threatening anomalies, either the trachea alone or both the trachea and bronchi are significantly narrowed. The tracheal cartilage in these patients is abnormally shaped and forms complete rings (Fig. 31.5). More than 50% of infants have a segmental stenosis. The clinical manifestations of complete tracheal rings vary from life-threatening respiratory distress during the perinatal period to subtle symptoms of airway compromise in older children. Most symptomatic infants exhibit deterioration of respiratory function over the first few months of life. Symptoms include stridor, retractions, cough, and alterations of cry. Atypical and persistent wheezing and rhonchi and sudden death can also occur. More than 80% of children with complete tracheal rings have other, and often multiple, congenital anomalies;[8] 50% specifically have congenital heart disease with or without great vessel anomalies.

In some patients, placement of an endotracheal tube may further exacerbate respiratory distress by causing acute swelling and inflammation of the mucosa. Partially obstructing tracheal lesions also may become life threatening following the onset of a respiratory infection. In an infant or child with an abnormal trachea, the cross-sectional area of airway can be significantly decreased with as little as 1 mm of edema. This accounts for the rapid worsening of symptoms in some children with acute inflammatory conditions and coexisting tracheal narrowing.

Prompt diagnostic evaluation to define tracheobronchial anatomy is essential. An initial high-kilovolt airway film may indicate stenosis; however, bronchoscopy is required to reveal the precise location and extent of the stenosis. Bronchoscopy should be performed with extreme caution, using the smallest possible telescopes, as any airway edema in the region of the stenosis may turn a narrow airway into a critical airway.[8] CT scans provide a rapid and precise method of measuring the extent and length of airway narrowing or displacement. Three-dimensional reconstruction of the airway and its relationship to the great vessels aids in operative planning. Furthermore, with new software enhancements, virtual bronchoscopic images can be obtained. These images are particularly useful in assessing the airway distal to the obstruction (Fig. 31.6). MRI is also valuable in evaluating the relationship of the mediastinal great vessels to the airway. Echocardiography is used mainly to determine whether intracardiac defects are present, and can identify most coexisting pulmonary artery slings.

About 10% of patients with complete tracheal rings are minimally symptomatic and can be managed non-operatively,



(a)

(b)

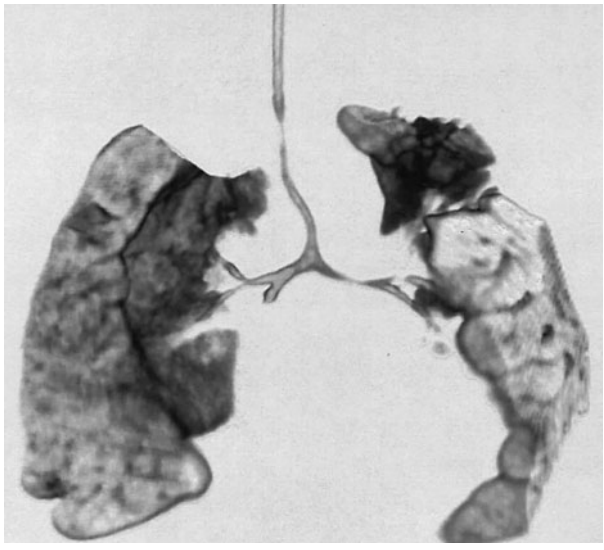

Figure 31.6 CT scan with three-dimensional reconstruction to demonstrate anatomy of the trachea in a patient with congenital tracheal stenosis involving the majority of the tracheal length.

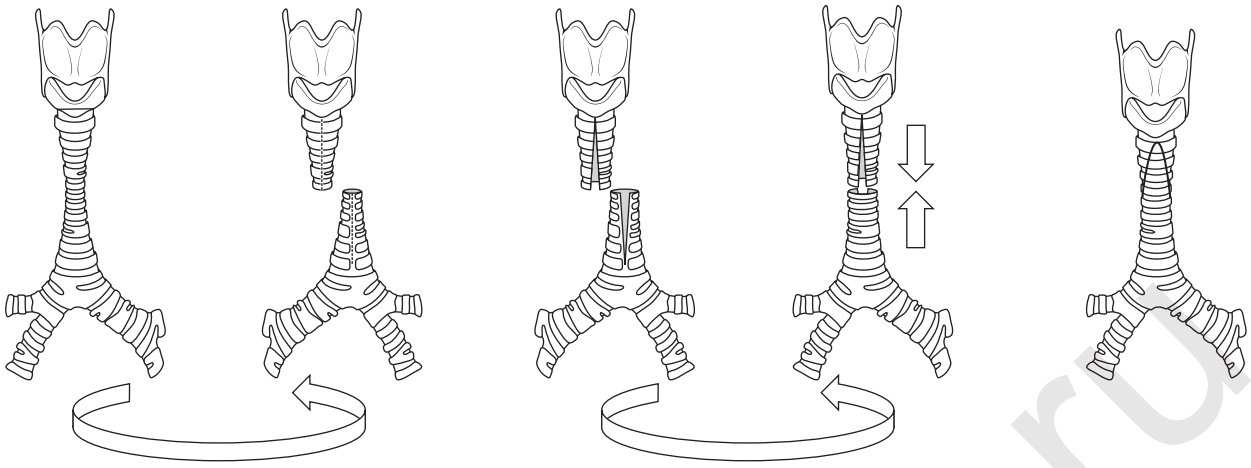

Figure 31.7 Slide tracheoplasty. The trachea is transversely divided at the midpoint of the tracheal stenosis. After proximal and distal tracheal mobilization, the posterior portion of the cephalic trachea segment and the anterior portion of the caudal tracheal segment are incised. The two tracheal segments are then overlapped and obliquely sutured together.

though they require ongoing observation.[25] Most children must undergo tracheal reconstruction.[25] Repair of coexisting anomalies, such as pulmonary artery sling or vascular ring, should be carried out concurrent with the tracheal repair. Although patch tracheoplasty was historically the preferred procedure for long segments of narrowing, slide tracheoplasty is now the procedure of choice for both short-and long-segment stenosis (Fig. 31.7).[26] This approach results in significantly less morbidity than other tracheal reconstruction techniques and is adaptable to all anatomic configurations of complete tracheal rings. Slide tracheoplasty uses only autologous tracheal tissue and is performed by transecting the trachea into two equal segments. The anterior wall of the lower half of the trachea and the posterior wall of the upper trachea are incised. These segments are then slid over each other and anastomosed with 5-0 monofilament and absorbable sutures. Postoperatively, the cross-sectional area of the airway has a four-fold increase and the length of the involved airway decreases by half. Airflow is increased 16-fold.

Postoperatively, endotracheal intubation is generally required for 1–2 days, though some patients with parenchymal pulmonary disease require longer ventilatory support. During the perioperative period, unnecessary movements of the endotracheal tube or unplanned extubation must be avoided so as to minimize the risk of damage to the newly reconstructed airway. Nasotracheal intubation is preferred, as the endotracheal tube can be more securely stabilized. Patients require continuous monitoring, careful pulmonary toilet, and endoscopic removal of any obstructing granulation tissue. Immediately prior to extubation, the integrity and patency of the reconstructed airway are assessed by flexible fiberoptic endoscopy through the endotracheal tube, thus ensuring a safe extubation.

Although airway configuration following slide tracheoplasty may resemble a figure eight, this does not indicate airway obstruction. The trachea generally remodels to a normal oval shape within one year of reconstruction. Long-term survival is currently 90% in our institution. Mortality is usually associated with severe comorbidities, such as cardiac disease rather than airway complications.

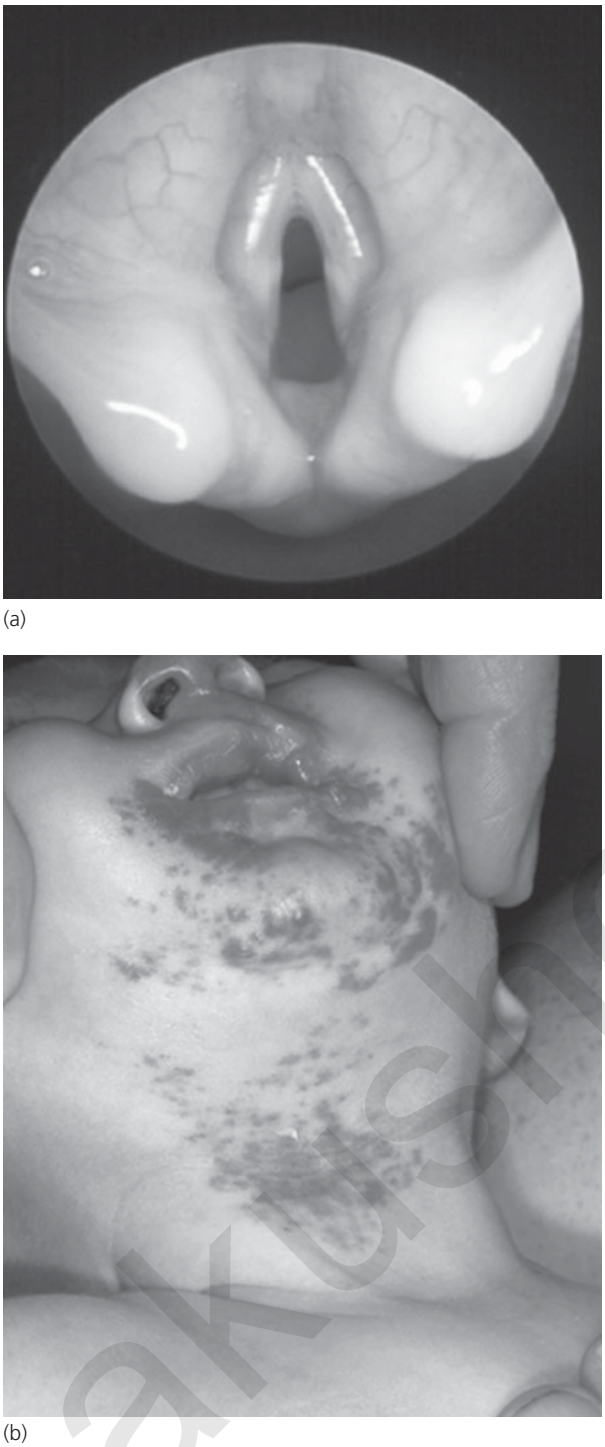
Tracheal diverticulum and tracheal bronchus

Tracheal diverticulum and tracheal bronchus are relatively common embryologic abnormalities of early tracheal budding. Tracheal diverticulum resembles a bronchus, though it originates from the trachea and ends blindly or communicates with a rudimentary lung. Tracheal bronchus most often affects the right upper lobe bronchus and may connect to an isolated intrathoracic lung segment or the apical segment of an upper lobe. Both anomalies frequently occur along with other tracheal, esophageal, and pulmonary anomalies. Diagnosis is established by airway endoscopy. Most children are asymptomatic and do not require treatment. Pneumonia and respiratory distress may be the presenting symptoms during the neonatal period. These symptoms are almost always associated with stenosis of a bronchus or other lung anomalies. Resection of involved lobe and bronchus in these patients is generally curative.

The most common cause of tracheal diverticulum is iatrogenic, following division of a tracheoesophageal fistula where a small remnant of the esophagus is left on the tracheal side. These defects can be readily managed with endoscopic resection.[27–29]

Airway malacia

Airway malacia is a condition in which the structural integrity of either the trachea or bronchi or both are weakened, and the cartilaginous rings of the airway lack the rigidity required to avoid airway collapse during expiration. Malacia may be localized or occur diffusely throughout the airway. Tracheomalacia is the most common congenital tracheal anomaly. This condition may occur in isolation or



(a)

(b)

Figure 31.8 (a) Endoscopic view of a subglottic hemangioma in a patient with infantile hemangioma in (b) bearded distribution.

in conjunction with other congenital anomalies. Tracheoesophageal fistula, esophageal atresia, and posterior laryngeal clefts are particularly common associations.[30] Premature neonates and children with chronic lung disease are at high risk for developing combined severe tracheobronchomalacia.

Presenting symptoms vary depending upon the severity, duration, and region of airway involvement. Most children are either asymptomatic or minimally symptomatic and most cases involve posterior malacia of the trachealis, with associated broadening of the tracheal rings. Presenting symptoms may include a honking cough, stridor, wheezing, respiratory distress when agitated, and cyanosis. Some children are misdiagnosed with allergic asthma and unsuccessfully treated with bronchodilators. Diagnosis is best established by bronchoscopy, with the patient breathing spontaneously; this demonstrates dynamic distortion and compression of the trachea. In children who are minimally symptomatic, symptoms often resolve by the age of three. These children are managed with observation alone. Children who experience symptom progression require medical or surgical intervention.[30] For some patients, respiratory monitoring with nasal CPAP may be sufficient to effect improvement.

Segmental tracheal involvement is managed with endoscopic or open aortopexy, with thymectomy and anterior suspension of the ascending arch of the aorta to the posterior periosteum of the sternum.[31] More diffuse malacia may require tracheotomy placement with positive pressure ventilation over a long duration. For patients with severely problematic tracheobronchomalacia that is unresponsive to nonoperative therapy or unsuitable for surgical treatment, intratracheal stents are placed. This approach is, however, associated with serious complications, such as stent collapse, stent dislodgement, or rarely, stent erosion into the great vessels. Additionally, stent removal can cause tracheal tearing or major hemorrhage.

Esophageal bronchus

Isolated bronchial connection between the esophagus and the airway is extremely rare and occurs more frequently in females (2:1). Associated cardiac, genitourinary, vertebral, and diaphragmatic anomalies are common. Esophageal bronchus is thought to develop from a supernumerary lung bud arising from the esophagus. Most commonly, a lower lobe is aerated by this ectopic bronchus; however, an entire main bronchus and lung may be affected. As in pulmonary sequestration anomalies, the pulmonary vasculature may be abnormal, with the arterial supply coming off the aorta and venous drainage going into either the systemic or pulmonary veins.

Inadequate bronchial drainage usually results in recurrent pulmonary infection and parenchymal damage.[32] Nonetheless, some patients remain undiagnosed until adolescence or adulthood despite recurring pneumonias and persistent x-ray abnormalities. Although x-ray findings vary with the segment of the lung affected by the anomaly, collapse, consolidation, cavitation, and cyst formation within the pulmonary parenchyma are commonly seen. The diagnosis is confirmed by a contrast study of the esophagus, though false-negative results sometimes occur. Excision of the abnormal lung and closure of the bronchoesophageal fistula is the treatment of choice in patients beyond the neonatal period. Prognosis depends on early diagnosis and treatment and the severity of associated anomalies. Bronchotracheal reconstruction has been successfully accomplished in neonates diagnosed with esophageal bronchus.[33]

Tracheobronchial–biliary fistula

A congenital tracheobronchial-biliary fistula is an anomalous tract that connects the respiratory tree with the biliary tree. This is an extremely rare developmental anomaly that is thought to arise from the distal trachea or either mainstem bronchus. To date, only 25 cases have been reported in the English language literature.[34] An association with other foregut anomalies also has been reported.[35] Children usually present with recurrent pneumonias, respiratory distress, and failure to thrive, often starting early in the neonatal period; however, the cardinal symptom is bile-stained sputum. Symptom severity varies and primarily depends on whether the bile from the left lobe of the liver has normal drainage channels to the duodenum or only drains through the bronchobiliary fistula.[35–37] The diagnosis is established either by bronchoscopy or endoscopic retrograde cholangiopancreatography (ERCP); however, a recent case report offers optimism for using contrast-enhanced CT of the chest and abdomen as a method of diagnosis.[34] Surgical interruption of the fistulous tract is the only effective therapy for this malformation.

Subglottic hemangioma

Hemangiomas of infancy (also referred to as infantile hemangiomas) are the most common vascular tumors, affecting one in ten white infants in North America[38] and occurring with a three-fold female preponderance. These benign lesions usually follow a predetermined phase of growth (proliferation) and later tumor regression (involution). The involutive phase occurs at 12–18 months and is generally complete by the first decade of life.

Hemangiomas generally present cutaneously but can occur in any organ or anatomic site. Lesions within the tracheobronchial tree most commonly occur in the subglottis. Their natural history generally mirrors that of cutaneous lesions. More than 50% of patients with a subglottic hemangioma also have cutaneous lesions. The latter may therefore provide an indication of the possible presence of a subglottic lesion. The highest risk (65%) patients are those with a hemangioma occurring in a beard distribution[39] or those with PHACE association, which is characterized by posterior fossa abnormalities, hemangiomas of the cervicofacial region that are usually plaque-like and segmental, arterial defects, cardiac and aortic arch defects, and eye abnormalities.[40,41]

As a subglottic hemangioma undergoes proliferation, progressive worsening of the airway usually occurs. Presenting symptoms include biphasic stridor with retractions. The degree of obstruction varies and can be exacerbated by certain positions or crying, both of which increase venous pressure and lead to vascular engorgement. When airway narrowing is severe, apnea, cyanosis, and 'dying spells' may result.

The diagnosis is based on medical history and findings on airway endoscopy. Lesions are typically asymmetric and may be covered by a normal smooth mucosa (Fig. 31.8a). Because of the risk of hemorrhage, biopsy is not advised. Most patients require treatment and combining various treatment modalities is often essential. Depending on both the severity of the obstruction and the expertise of involved clinicians, early symptoms are managed with systemic steroids and, recently, with propranolol. Important to note, dramatic results have been achieved with propranolol, and these results have already changed the paradigm of both pharmacologic and surgical treatment.[42–45] For critical airways, some surgeons advocate laser fulguration or translaryngeal resection, whereas others place a tracheotomy below the lesion, with the expectation of removal following involution of the hemangioma.[40,46]

Bronchogenic cyst

Bronchogenic cysts stem from aberrant embryogenesis of the bronchial tree in which a segment of the lung bud develops independently. The walls of the cyst often contain fibrous tissue and cartilaginous remnants, while the internal surface consists of ciliated columnar epithelium.[47] Lesions usually expand, causing extramural compression of the airway. The most commonly seen symptom in infants is respiratory distress. Coughing, wheezing, or chest pain also may be present. A plain chest x-ray may suggest the presence of a bronchogenic cyst. A CT scan or MRI is valuable in establishing a definitive diagnosis (Fig. 31.9a). Patients are successfully managed by open or thoracoscopic resection (Fig. 31.9b).[48,49]

Bronchial atresia and bronchial lobar agenesis

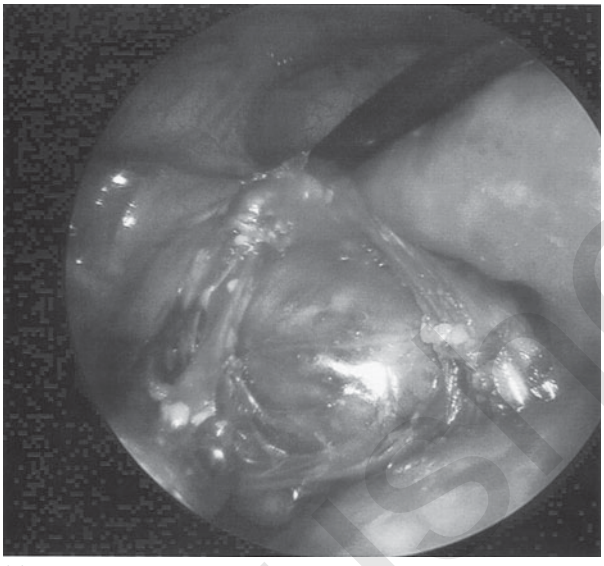
BRONCHIAL ATRESIA

Localized bronchial atresia is a rare abnormality in which the atretic bronchus impedes the flow of secretions and air from the distal lung to the main tracheobronchial tree. This condition may mimic lobar emphysema or a mediastinal mass.[50] At birth, the affected lung retains fluid. Eventually, however, the anomalous lobe or segment becomes hyperaerated as air enters through the pores of Kohn. Secretions accumulate proximal to the atresia, resulting in the formation of a mucocele.[51] Emphysema of the segment may cause atelectasis of the normal lung tissue, which may be manifested by wheezing and stridor. Plain chest films may reveal a hilar mass with radiating solid channels surrounded by hyperinflated lung. A CT chest scan may show a cystic central mucocele and is valuable in distinguishing bronchial atresia from a bronchogenic cyst or lobar emphysema. Although children may initially be asymptomatic, secretions trapped in the lung may result in serious pulmonary infection. Surgical resection of the affected lobe restores normal lung function.

BRONCHIAL LOBAR AGENESIS

Bronchial agenesis is more commonly seen than tracheal agenesis and, unlike tracheal agenesis, it is compatible with life.

(a)



(b)

Figure 31.9 (a) MRI demonstrating a right-sided bronchogenic cyst just below the right main bronchus. (b) Thoracoscopic view of a bronchogenic cyst. The parietal pleura has been opened in the process of removal.

Several anatomic forms have been described; these include lobar, bronchial, and parenchymal agenesis. In the most severe form, complete agenesis of the lung and its bronchus and blood supply may occur.[50] Also, there may be a rudimentary bronchus and aplasia of the lung. As with most airway malformations, children may have coexistent congenital anomalies; most commonly these anomalies involve the skeletal, cardiovascular, gastrointestinal, and genitourinary systems. Diagnosis is established by chest x-rays and airway endoscopy. Most patients can be managed non-operatively. These abnormalities are important to identify in that they may mimic other airway anomalies requiring treatment (e.g. bronchial stenosis or extraluminal airway obstruction by tumors or masses).

Bronchial stenosis

Isolated congenital bronchial stenosis is extremely rare, with causality including compressive vascular, cardiac, and congenital cystic lesions or soft tissue cartilaginous stenoses. Symptoms and treatment vary, depending on both the severity and anatomic location of the lesion. Surgical management includes resection and reconstruction of the bronchus and slide bronchoplasty.[52,53]

Acquired bronchial stenosis is more common than its congenital manifestation, and is a significant cause of morbidity and mortality in infants who have undergone prolonged intubation and respiratory support. Most such cases can be managed with endoscopic balloon dilatation or laser resection.[21]

Vascular rings

BENJAMIN O BIERBACH AND J MARK REDMOND

INTRODUCTION

Vascular rings are unusual congenital anomalies that occur early in the development of the aortic arch and great vessels. The primary symptoms associated with vascular rings relate to the structures that are encircled by the ring, namely, the trachea and esophagus.

DEFINITION AND HISTORY

A vascular ring is a rare congenital condition in which an anomalous configuration of the aortic arch or associated vessels surrounds the trachea and esophagus, to form a complete compressing ring around them. Several other related vascular anomalies involving aortic arch vessels do not form complete rings but have been grouped descriptively with vascular rings because they can produce similar symptoms related to compression of the trachea and or esophagus. In common usage, however, the definition of a complete vascular ring is extended to include pulmonary artery slings which do not completely surround the trachea and esophagus but may compress them. Both complete and incomplete rings and slings are discussed in this chapter.

The first vascular ring described was that of a double aortic arch by Hommel in 1737.[1] Subsequently, Bayford reported a retroesophageal right subclavian artery in 1794 after performing an autopsy on a woman who had experienced dysphagia for years and died of starvation. Maude Abbott described five cases of double aortic arch in 1932 and made the suggestion that surgical intervention should be undertaken in such cases.

The term 'vascular ring' was first used by Dr Robert Gross in his report describing the first successful division of a double aortic arch in 1945.[2]

In 1954, Potts and Holinger coined the term 'pulmonary artery sling' when they reported the first successful repair of this anomaly in a five-month-old infant with wheezing and intermittent episodes of dyspnea and cyanosis.[3] This anomaly was, however, first reported by Glaevecke and Döhle in 1897 in a post-mortem study in a seven-month old infant with severe respiratory distress.[4]

Although innominate artery compression syndrome and pulmonary artery sling are not complete anatomic rings, they have been traditionally classified with classic vascular rings because of the similarities in patient presentation, diagnosis, and surgical therapy.

FREQUENCY

Vascular rings are uncommon anomalies and make up less than 1% of all congenital cardiac defects. They occur with about equal frequency in both sexes. No geographical or racial predominance exists. Some vascular rings are associated with other congenital heart defects, while others may be isolated malformations.

The two most common types of complete vascular rings are double aortic arch and right aortic arch with left ligamentum arteriosum. These make up 85–95% of cases. Two other complete vascular rings that are extremely rare (<1%) include right aortic arch with mirror-image branching and left ligamentum arteriosum, and left aortic arch with retroesophageal right subclavian artery, right-sided descending aorta, and right ligamentum arteriosum.

Other anomalies that produce symptoms but do not form a complete anatomic vascular ring make up the remainder and include the anomalous innominate artery and the anomalous right subclavian artery with left-sided aortic arch and left ligamentum arteriosum.

The anomalous left pulmonary artery or pulmonary artery sling makes up about 10% of cases, and, although it is not associated with anomalies of the aortic arch or its branches, it arises from an abnormality of the sixth branchial arch and produces a complete ring. This anomaly is associated with intracardiac defects in 10–15% of cases.

EMBRYOLOGY

In 1922, Congdon reported his extensive experience with the study of the embryogenic development of the human aortic arch system (Fig. 32.1).[5] Edwards developed a schematic model with a double aortic arch system and bilateral ductus arteriosus.[6]

Vascular rings are a group of congenital anomalies caused by different regressions and involutons from the embryonic aortic arch system. Several recent papers report the close association of band 22q11 deletion with anomalies of the aortic arch, as well as other congenital cardiac abnormalities. In the embryonic aortic arch system, the ventral and dorsal aorta are connected by six primitive aortic arches. The embryo then utilizes the mechanism of programmed cell death, so called apoptosis, to eliminate redundant and unnecessary components. The multiple branchial arches in the human embryo are an excellent example. They represent the blood supply of gill breathing organisms which lie in our phylogenetic past. They are transiently present during human development but, either partially or completely, disappear as the pulmonary circulation develops and connects with the heart. Only a few segments usually remain. In case unnecessary segments persist, anomalies such as vascular rings result.

The paired right and left dorsal aortae, one of which will eventually become the descending thoracic aorta, are present in the embryo by approximately the 21st day of intrauterine life. Subsequently, the first to sixth branchial arteries form bilaterally, each with its own aortic arch communicating from the aortic sac to the dorsal aortas.

At this point in development, therefore, multiple vascular rings are present. The first and second arches largely resorb and contribute only to minor facial arteries, while the third arches form the carotid arteries. The left fourth arch forms distal aortic arch and aortic isthmus from the origin of the left common carotid artery to the origin the descending thoracic aorta, which itself represents a persistence of the left dorsal aorta. So, if the right fourth arch involutes, a normal left arch is formed, which means that the aorta passes from the anterior to posterior mediastinum to the left of the trachea and esophagus. If the left fourth arch involutes, a right aortic arch is formed. In this case, the aorta courses to the right of the trachea and esophagus from the anterior to the posterior mediastinum.

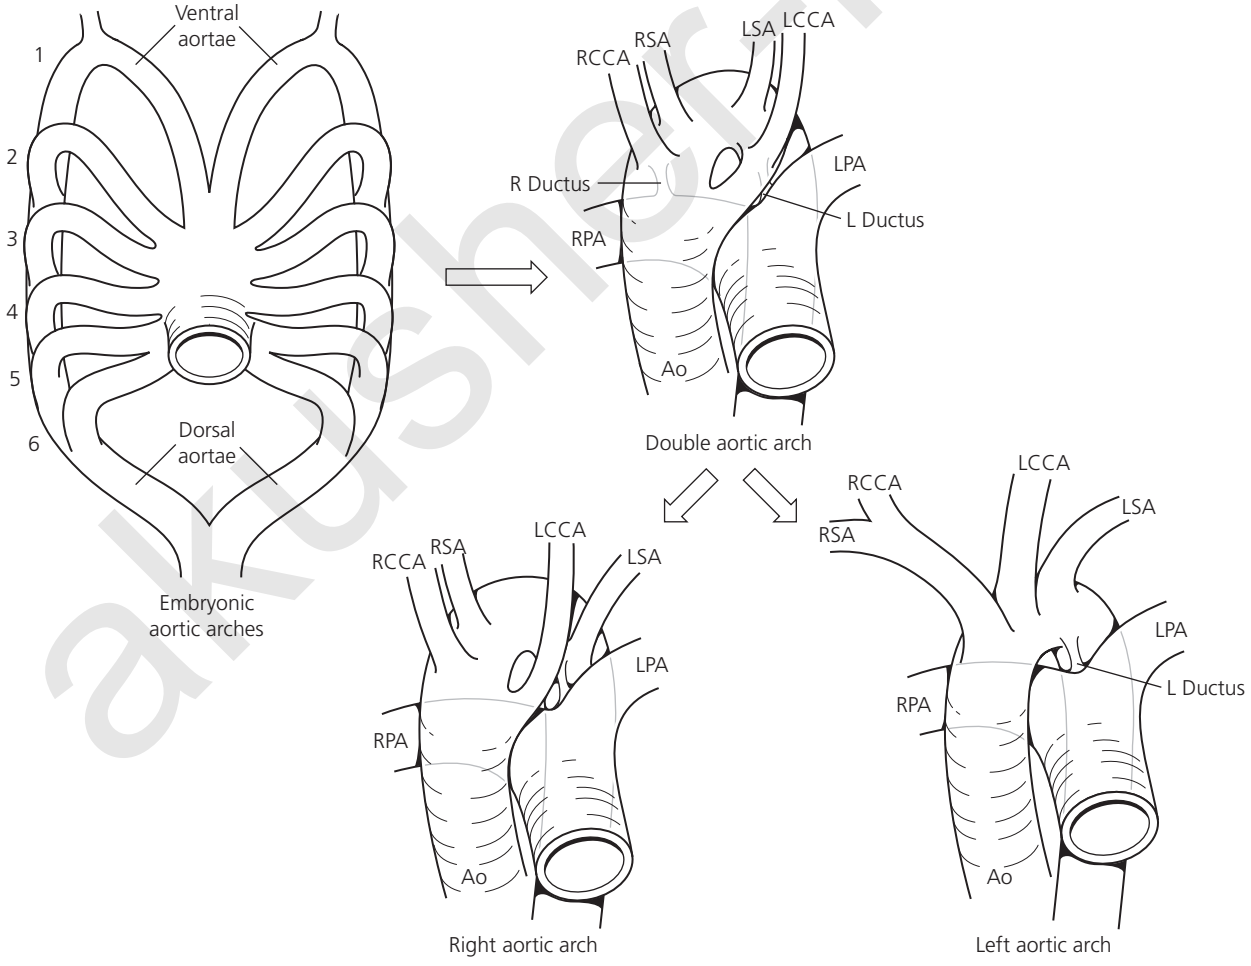

Figure 32.1 Diagram of the embryonic aortic arches. Six pairs of aortic arches originally develop between the dorsal and ventral aorta. The first, second, and fifth arches regress completely. Preservation or deletion of different segments of the rudimentary arches results in a double aortic arch, a right aortic arch, or the normal left aortic arch. Ao, aorta; LCCA, RCCA, left or right common carotid artery; LPA, RPA, left or right pulmonary artery; LSA, RSA, left or right subclavian artery.

Proximally, septation of the conotruncus produces the ascending aorta, which joins with the fourth left arch. The right dorsal aorta ultimately contributes to the right subclavian artery. The first, second, and fifth arches involute to form Edward's classic double aortic arch.

Stewart *et al.* summarized these pathologic, embryologic, and roentgenographic correlations of the lesions contributing to anomalies of the aortic arch.[7]

FORMS

Different variations of vascular anomalies exist (listed by incidence):

1. Double aortic arch
2. Right aortic arch
3. Pulmonary artery sling
4. Vascular rings associated with left aortic arch
5. Cervical aorta

Double aortic arch

Double aortic arch is an anomaly in which both right and left arches are present and may be one of several variations (Fig. 32.2):

- both arches widely patent;
- hypoplasia of one arch (usually the left);
- atresia of one arch (usually the left).

Double aortic arch represents a persistence of both right and left embryonic fourth branchial arches joining the aortic

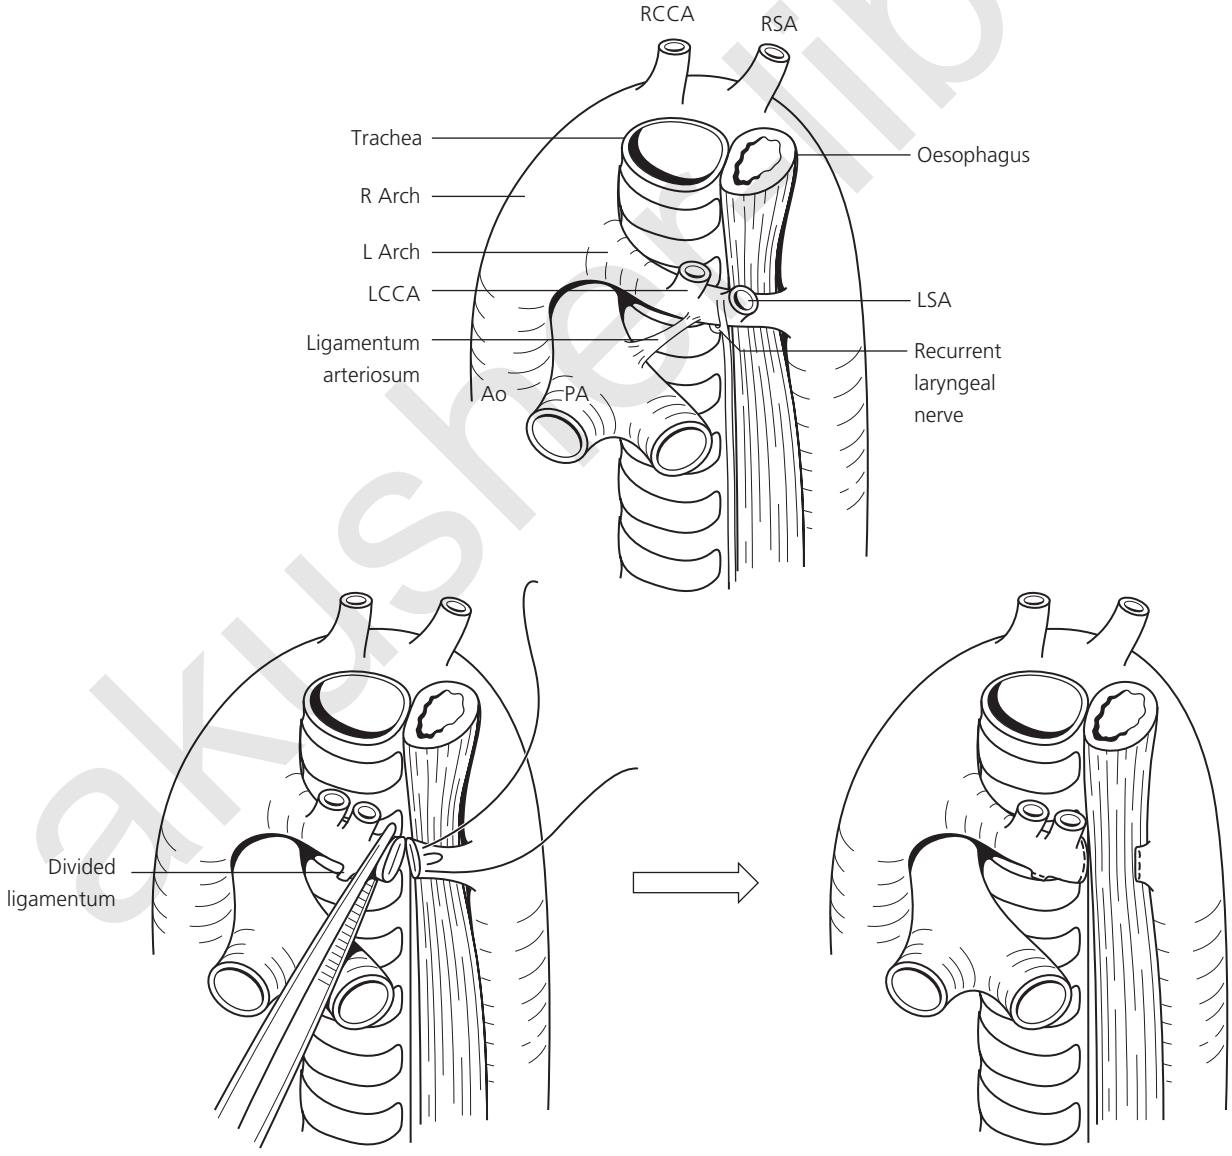

Figure 32.2 Division of a double aortic arch (from left to right). Double aortic arch with a dominant right aortic arch. The lesser left aortic arch is divided between two applied vascular clamps. The stumps are oversewn and this opens up the desired space for trachea and esophagus. Ao, aorta; LCCA, RCCA, left or right common carotid artery; PA, pulmonary artery; LSA, RSA, left or right subclavian artery.

portion of the truncoaortic sac to their respective dorsal aorta. The ascending aorta bifurcates anterior to the trachea and each arch course either to the left or to the right of the trachea or esophagus. The larger of the two arches usually crosses posterior to the esophagus and joins with the other arch in the posterior mediastinum to form the unified descending aorta. Thus a complete vascular ring is formed. Note that the right recurrent laryngeal nerve has to pass around the right aortic arch, rather than being in its usual position around the right subclavian artery. Double aortic arch is rarely associated with congenital heart disease but, when present, tetralogy of Fallot and transposition of the great vessels are most common.

Right aortic arch

In cases of individuals in whom the left fourth branchial arch involutes and the right remains, a right aortic arch is present (Fig. 32.3). Right aortic arch occurs less frequently than one in 100 000 times in the general population and may exist in the absence of any other anomalies. Its presence is suggestive of the existence of an associated anomaly. About 30% of patients with Tetralogy of Fallot have an associated right aortic arch. Persistence of the right arch with involution of the left creates a situation in which the origins of the left subclavian artery and ductus arteriosus can vary. Several of these configurations can produce a vascular ring.

RIGHT AORTIC ARCH WITH ABERRANT LEFT SUBCLAVIAN ARTERY AND LEFT LIGAMENTUM ARTERIOSUM

In this anomaly, the right arch first gives off the left carotid artery, which travels anterior to the trachea. It then gives off the right carotid, followed by the right subclavian artery, and, lastly, the left subclavian artery, which courses in a retro-esophageal position and gives rise to the ligamentum arteriosum from its base. The ligamentum arteriosum connects the left subclavian or descending aorta to the left pulmonary artery. The trachea and esophagus are surrounded by the ascending aorta anteriorly, the aortic arch on the right, the descending aorta posteriorly, and the ligamentum arteriosum and left pulmonary artery on the left. Almost 10% of these defects are associated with an intracardiac defect.

RIGHT AORTIC ARCH WITH MIRROR-IMAGE BRANCHING AND RETROESOPHAGEAL LIGAMENTUM ARTERIOSUM

In these cases, only partial resorption of the distal left fourth arch occurs. The first brachiocephalic vessel originating from the right arch is the left innominate artery, which, in turn,

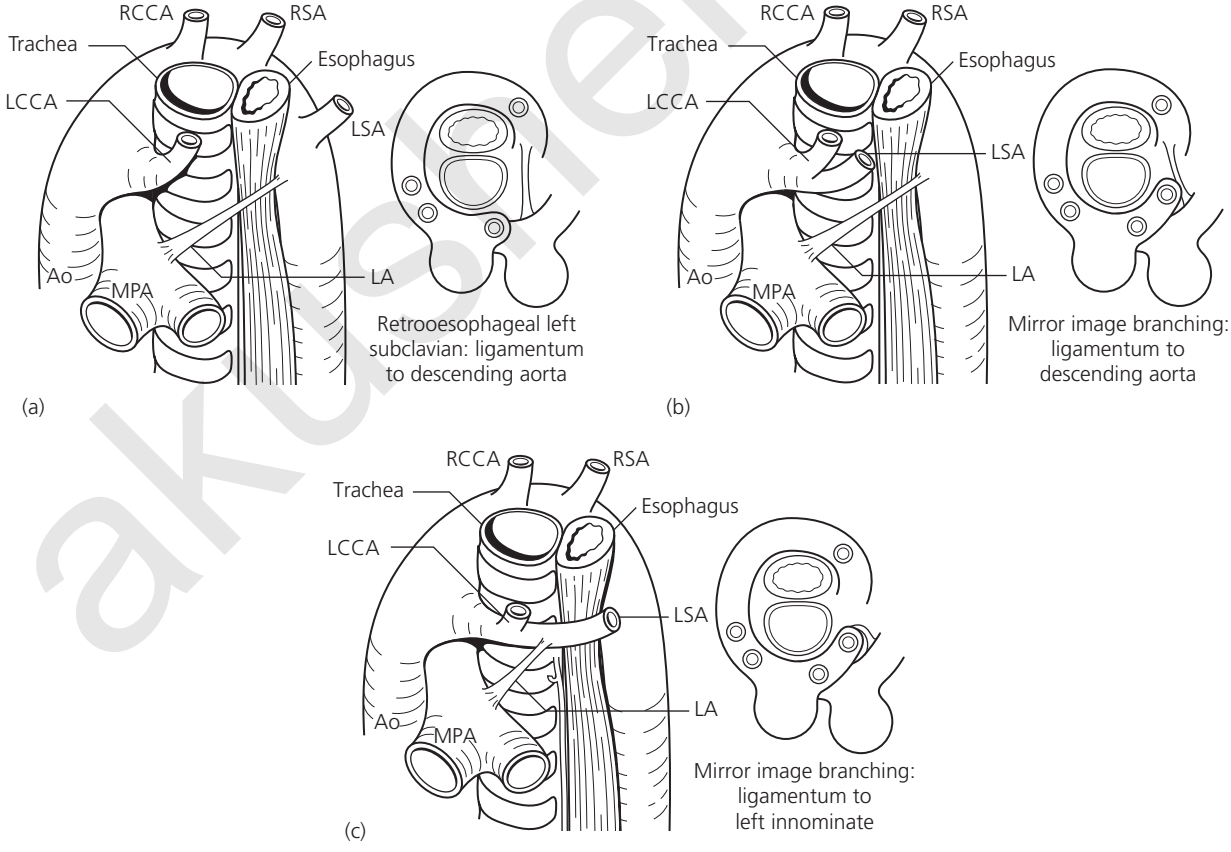

Figure 32.3 Right aortic arch types. (a) Retroesophageal left subclavian artery, ligamentum arteriosum to descending aorta. (b) Mirror image branching, ligamentum arteriosum to descending aorta. (c) Mirror image branching, ligamentum arteriosum to the left innominate artery. Ao, aorta; LCCA, RCCA, left or right common carotid artery; MPA, main pulmonary artery; LSA, RSA, left or right subclavian artery.

branches into a left carotid and left subclavian artery. These vessels course anterior to the trachea. Following these, a right carotid artery and then a right subclavian artery arise. The ligamentum arteriosum is the final structure arising from the arch in this sequence. It originates from an area called Kommerell diverticulum, which represents the nonresorbed remnant of the left fourth arch and is situated at the point of merger between the right arch and the proximal descending thoracic aorta. The ligamentum passes leftward and behind the esophagus and then travels anteriorly to join with the left pulmonary artery and complete the ring.

More commonly, in cases of right aortic arch with mirror-image branching, the ligamentum arteriosum travels from the mirror-image innominate or left subclavian artery to the left pulmonary artery. A complete ring is not present in these cases. Most importantly this type of vascular ring has a more than 90% association with intracardiac defects.

Pulmonary artery sling

Typically, the left pulmonary artery arises directly from the right pulmonary artery and passes leftward between the trachea and the esophagus (Fig. 32.4).[8] The ligamentum arteriosum passes posteriorly from the origin of the right pulmonary artery where it arises from the main pulmonary artery to the undersurface of the aortic arch and thus creating a vascular ring surrounding the trachea but not the esophagus. The left pulmonary artery is often relatively hypoplastic. In opposition, the right pulmonary artery appears larger than normal and almost like a direct extension of the main pulmonary artery. The small caliber of the left pulmonary artery may explain the high incidence of anastomotic problems that have been observed in the past with attempts to reimplant the vessel at the main pulmonary artery.

This lesion is often associated with hypoplasia and other abnormalities of the tracheal and bronchial cartilages. Most patients are symptomatic by one month after birth. Respiratory symptoms predominate, as the most severe compression is on the trachea. More than 50% of infants also have severe tracheobronchial anomalies, such as absence of the posterior membranous component, tracheomalacia, stenosis, webs, or complete tracheal rings. Although the presence of complete rings does not imply that high graded stenosis will be observed, the trachea is often narrower than normal. The complete rings may be localized at the region where the sling passes around the trachea, although in some cases the entire trachea consists of complete ringed cartilages. Severe stenosis can involve the carina and extend for a considerable distance into one or both mainstem bronchi.

Intracardiac defects are also seen in 20% of these infants.

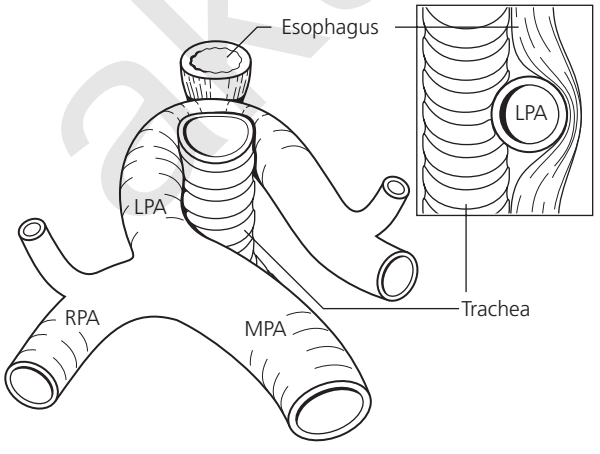

Figure 32.4 Pulmonary artery sling. MPA, LPA, RPA: main pulmonary artery, left pulmonary artery, right pulmonary artery; Inset: Lateral view of anterior compression of the esophagus.

Vascular rings associated with left aortic arch

Two extremely rare complete rings occur in the presence of a left aortic arch, and both are associated with a right-sided descending thoracic aorta.

LEFT AORTIC ARCH WITH RIGHT DESCENDING AORTA AND RIGHT LIGAMENTUM ARTERIOSUM

The first arch vessel to exit the left aortic arch is the right common carotid, which passes anterior to the trachea. The left carotid is next, followed by the left subclavian artery. The right subclavian artery arises more distally as a branch of the proximal right-sided descending aorta. The ligamentum arteriosum arises from the base of the right subclavian artery or a nearby diverticulum and travels to the right pulmonary artery.

LEFT AORTIC ARCH, RIGHT DESCENDING AORTA, AND ATRETIC RIGHT AORTIC ARCH

The brachiocephalic vessels arise from the left-sided arch in a normal arrangement. The left arch passes behind the esophagus to join a right-sided descending aorta. An atretic right arch is present and completes the ring.

LEFT AORTIC ARCH AND LEFT LIGAMENTUM ARTERIOSUM WITH RETROESOPHAGEAL RIGHT SUBCLAVIAN ARTERY

This is the most common of the arch vessel anomalies, occurring in about 0.5% of the population (Fig. 32.5). In these cases, the right subclavian artery does not arise from an innominate trunk with the right carotid artery but originates as the last brachiocephalic branch from the descending aorta and takes a retroesophageal route to its destination, as depicted in the image below. A normally positioned ligamentum arteriosum is present on the left. If a right ligamentum arteriosum were present instead of one on the left, its course would proceed from the base of this anomalous right subclavian artery to the right pulmonary artery and a complete ring would exist. Instead, no true vascular ring is present in these cases. Most patients are symptomatic, but the occasional patient may present with dysphagia.

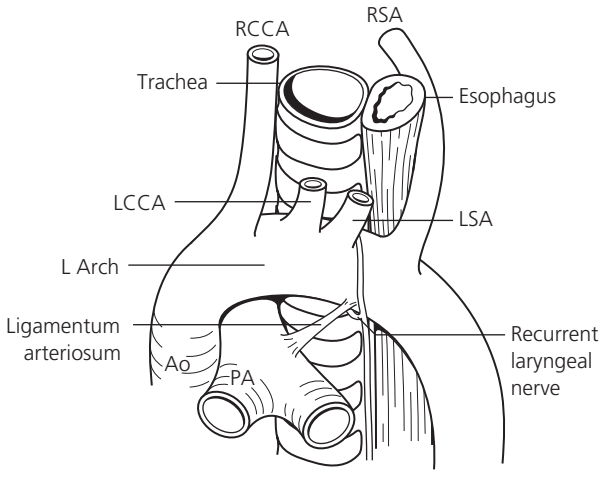

Figure 32.5 Left aortic arch with aberant right subclavian artery compressing the esophagus. Ao, aorta; LCCA, RCCA, left or right common carotid artery; PA, pulmonary artery; LSA, RSA, left or right subclavian artery.

LEFT AORTIC ARCH WITH ANOMALOUS ORIGIN OF THE INNOMINATE ARTERY

The actual prevalence of this abnormality is widely debated. This is because, in as many as 90% of cases in which symptomatic tracheal compression is produced by the innominate artery, the vessel is noted angiographically to have a normal origin from the aorta (Fig. 32.6). When an anatomic abnormality is noted in these cases, the innominate artery appears to originate from a more distal and leftward position on the arch than normal. As it takes its course from left to right, it crosses the trachea anteriorly and in doing so may produce compression of the trachea.

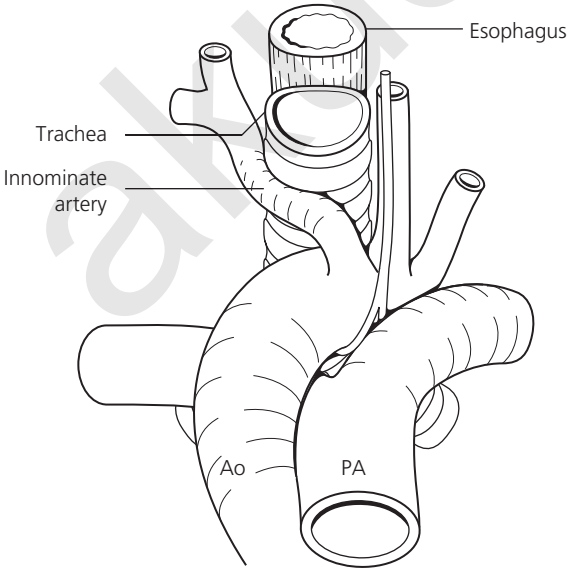

Figure 32.6 Innominate artery compression of the anterior trachea. Ao: Aorta; PA: pulmonary artery.

CERVICAL AORTA

This a rare anomaly in which the aorta ascends into the neck on the right or left side, forming a pulsatile mass in the supraclavicular region. Several morphological types have been described according to side of the aortic arch (contralateral or ipsilateral) and the origin of the head and neck vessels.[9]

CLINICAL FINDINGS

Clinical manifestations are related to the nature of malformation and tightness of the ring. Most children with vascular rings present with symptoms in the first few months of life and require surgery within the first year of life.[10] The classic symptom of a child with a vascular ring is the 'seal-bark' cough. In addition, noisy breathing may be heard both during inspiration and expiration (biphasic stridor), while in asthma, the noise is mainly at the end of expiration. A common finding in all forms of vascular rings is the fact that recurrent respiratory infections occur.

In children with double aortic arch if both arches are widely patent, the rings are tight and patients present with biphasic stridor in the first weeks of life. In case one arch is hypoplastic or atretic, the rings are usually looser, with presentation at 3–6 months of age. Rarely does double aortic arch present in adulthood. Children with double aortic arch are often small, poorly developed, and hold their head in hyperextension. Repeated severe respiratory infections may occur.

Children with a pulmonary artery sling and or complete tracheal rings often have severe respiratory distress requiring emergent intubation and ventilation.

Children with the innominate artery compression syndrome often present with apnea as initial symptom.

Feeding difficulties occur when solid food is introduced to the infant. This results in dysphagia and only tends to occur in older children. Gastroesophageal reflux with concomitant pain or fear of food intake is observed. Cyanotic spells in these young patients may have caused episodes that are termed apparent life-threatening events (ALTE) or death spells, in which acute apneic or severe obstructive events are accompanied by cyanosis.

Physical examination may be within normal limits, but one may see coughing, dyspnea, drooling, or dysphagia. Infants will feed poorly due to respiratory distress and may have life-threatening episodes of apnea and cyanosis.

Cardiac examination will most often be normal. Lung examination may or may not show evidence of pneumonia.

ASSOCIATED SYNDROMES AND NON-CARDIAC CONDITIONS

Double aortic arch is associated with a chromosome band 22q11 deletion in approximately 20% of patients. Band 22q11 deletion is responsible for DiGeorge, velocardiofacial, and conotruncal anomaly face syndromes, which are often

referred to using the unified terms CATCH-22 syndrome or chromosome band 22q11 deletion syndrome. In patients with double aortic arch, the frequency of phenotypes satisfying the clinical criteria for these various syndromes is not known. Rather, the important point is that double aortic arch may be associated with band 22q11 deletion, which has various other possible manifestations. These include, but are not limited to, palatal abnormalities, laryngotracheal anomalies, speech and learning delay, characteristic facial features, hypocalcemia, abnormalities of T-cell-mediated immune function, and neurologic defects.

Occasionally, patients with double aortic arch may have anomalies consistent with either vertebral, anal, cardiac, tracheal, esophageal, renal, and limb (VACTERL) or posterior coloboma, heart defect, choanal atresia, retardation, genital, and ear (CHARGE) associations. Double aortic arch has also been reported in association with other chromosomal anomalies, such as trisomy 21 and other syndromes.

One of the more important non-cardiac features that sometimes is found in association with double aortic arch is esophageal atresia, insofar as an undiagnosed arch anomaly may complicate repair of the esophageal atresia, which is usually recognized earlier than the double aortic arch.

Another non-cardiac anomaly that may be associated with vascular rings is a congenital laryngeal web, which may present with the same symptoms and signs as a vascular ring. Accordingly, patients with persistent stridor or upper airway obstruction after repair of a vascular ring, particularly those with a chromosome 22q11 deletion, should be evaluated for the presence of a congenital laryngeal web.

LABORATORY STUDIES

No laboratory screening or diagnostic study exists for this abnormality.

IMAGING STUDIES

Chest x-ray

Children usually present with symptoms of respiratory difficulty, therefore chest x-ray is always the first and most commonly performed test. Look for the position of the aortic arch, which is usually identifiable on the plain chest x-ray. The identification of a right aortic arch on chest x-ray in a child with airway difficulties, respiratory distress, or dysphagia should alert the clinician to a higher likelihood of a vascular ring. An ill-defined arch location is often observed in patients with double aortic arch. Such a finding should raise the suspicion of an arch anomaly in a symptomatic child. Other x-ray findings that may be noted with vascular rings include compression of the trachea and hyperinflation and/or atelectasis of some of the lobes of either lung. A specific finding associated with anomalous left pulmonary artery is hyperinflation of the right lung. In general, chest x-ray is not very sensitive in the diagnosis of vascular rings.

Barium esophagram

Most authorities consider barium esophagram to be the most important study in patients with a suspected vascular ring, and it is diagnostic in the vast majority of cases. Double aortic arch (Fig. 32.7) produces bilateral and posterior compressions of the esophagus, which remain constant regardless of peristalsis. The right indentation is usually slightly higher than the left, and the posterior compression is usually rather wide and courses in a downward direction as it goes from right to left. Patients having anomalies in which the right subclavian artery takes a retroesophageal course have a posterior defect slanting upward from left to right. The posterior defect in these cases is usually not as broad as that found in double aortic arch. In opposition, in patients with left aortic arch and aberrant subclavian artery the oblique filling defect is mirror imaged. An experienced radiologist can usually distinguish a double aortic arch from the retroesophageal subclavian artery based on the esophageal impression.[11]

An anterior indentation of the esophagus is, however, typical of an anomalous left pulmonary artery or so-called pulmonary artery sling. No posterior compression is present with this anomaly. Cases of abnormally located innominate artery causing tracheal compression have normal findings on esophagram.

Figure 32.7 Barium esophagram in antero-posterior projection in a patient with double aortic arch.

Echocardiography and color-flow Doppler

Echocardiographic studies have been increasingly used for the diagnosis of a vascular ring. This study has replaced

pulmonary angiography at many centers to determine the presence of an anomalous left pulmonary artery. It is essential in the diagnostic work up of associated congenital cardiac defects. Some limitations in diagnosis using this study exist. Structures without a lumen, such as a ligamentum arteriosum or an atretic arch, have no blood flow and are difficult to identify with color-flow echocardiography. Also, identification of compressed midline structures and their relationship to encircling vascular anomalies may be difficult to detect, especially for the less experienced echocardiographer.

Computed tomography scan, magnetic resonance imaging, and digital subtraction angiography

Computed tomography (CT) scan, magnetic resonance imaging (MRI) (Fig. 32.8), and digital subtraction angiography (DSA) can be useful diagnostic tools because they reveal the positions of vascular, tracheobronchial, and esophageal structures and their relationships to one another. Although these modalities provide excellent delineation of all of the associated structures, they should be reserved for cases in which the results of barium esophagram do not provide a clear diagnosis. MRI has been proposed as an excellent substitute for angiography. All of these studies have drawbacks. CT scan and DSA expose the patient to radiation and require i.v. contrast. MRI requires patients to remain very still, so very young patients who are unable to understand verbal instructions require sedation. This may be particularly risky in young children with existing airway compromise. The expense encountered with these investigations must also be considered.

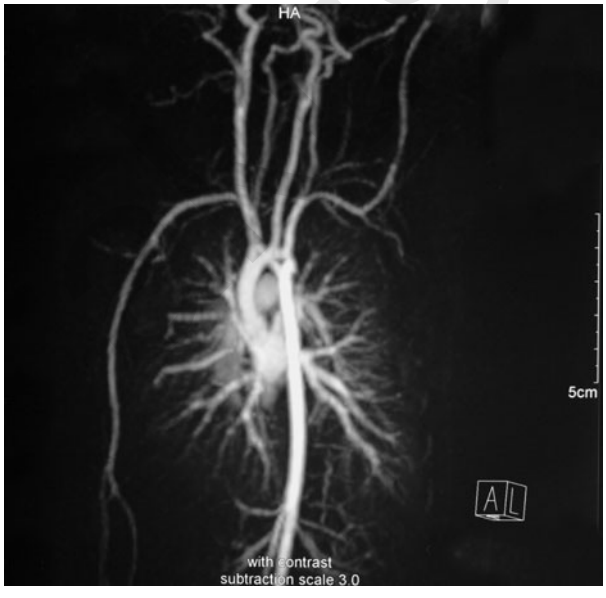

Figure 32.8 Magnetic resonance imaging in left anterior oblique projection in a patient with double aortic arch. Both aortic arch segments are of equal calibre and widely patent.

Aortic angiography and cardiac catheterization

In the past, diagnostic aortography was performed in selected cases to delineate the anomalous arch vasculature. It is generally agreed at present that, in the vast majority of cases, this study adds very little to the information obtained from a barium esophagram. If additional studies are required, echocardiography, CT scan, or MRI can usually provide the required information. However, reported cases exist of rare arch anomalies in which aortography was the only study from which the correct anatomic configuration was identified.[12] This study may be required in cases in which the diagnosis and arch configuration remains in question after other less invasive studies fail to provide a definitive answer.

Cardiac catheterization is useful in cases in which associated cardiac abnormalities are known or suspected.

Bronchoscopy

This diagnostic study has been used in the evaluation of children with symptoms of airway obstruction or compression. It is an essential part of the work up for congenital tracheal stenosis. It is rarely required in the diagnosis of the various types of complete vascular ring. In case a simple vascular ring was diagnosed by other tests, a bronchoscopy should not be performed due to the added risks and costs.

In the presence of a vascular ring, pulsatile external tracheal compression is easily observed. Note that compression of the airway by a vascular structure in the pediatric patient does not represent an unyielding obstruction and should not pose a problem for passage of the bronchoscope. In cases of an abnormally placed innominate artery, obvious pulsation is observed in the anterior wall of the trachea corresponding to the area of compression.

INDICATION FOR INTERVENTION

Surgical division of the vascular ring is indicated in any patient who is symptomatic with airway or esophageal compression.

MEDICAL THERAPY

No medical therapy exists for the definitive treatment of vascular rings. Preoperatively, the patient should be given adequate nutritional support, as well as general respiratory care and appropriate treatment of any respiratory tract infection. Surgery should not be delayed in the presence of a respiratory tract infection, because the division of the ring allows more adequate and complete clearing of respiratory secretions.

SURGICAL THERAPY

Surgical division of symptomatic vascular rings is the only appropriate form of therapy (see Box 32.1). Surgery should be performed promptly after the diagnosis is made, especially in patients with stridor, apnea, or other symptoms of respiratory

Box 32.1 Surgical management

Double aortic arch
- Left thoracotomy inmuscle sparing technique – fourth interspace
- Division of lesser of the two arches at insertion with descending aorta
- Preserve blood flow to head and neck arteries
- Ligate and divide ligamentum arteriosum
- Leave pleura open

Right aortic arch with left ligamentum arteriosum
- Left thoracotomy in muscle sparing technique – fourth interspace
- Ligate and divide ligamentum arteriosum
- If present, resect Kommerell's diverticulum and transfer left subclavian to left carotid artery
- Lyse adhesive bands
- Leave pleura open

Pulmonary artery sling
- Median sternotomy
- Commence extracorporeal circulation
- Resect left pulmonary artery (LPA) at its origin at the right pulmonary artery (RPA)
- Oversew resulting defect in RPA
- Reimplant LPA into main pulmonary artery anterior to trachea
- Tracheal sliding plasty to for affected segment of tracheal stenosis

Innominate artery compression syndrome
- Right anterolateral thoracotomy (left sided thoracotomy also possible) – third or fourth interspace
- Resect right lobe of thymus
- Suspend innominate artery to posterior sternum
- Postoperative bronchoscopy

distress. Delay in operative intervention can result in complications of a serious nature. Left thoracotomy is the surgical approach of choice for the division of a vascular ring in the majority of cases. In the past, anomalous left pulmonary artery has been corrected using the left thoracotomy approach. More recently, the use of median sternotomy and cardiopulmonary bypass has been shown to produce better long-term results. The extremely rare configurations associated with left aortic arch and right descending thoracic aorta are the lesions that should be approached via a right thoracotomy for division of the ring. General anesthesia with a single lumen nasotracheal or orotracheal tube is used for infants and small children. Bilateral radial arterial lines and a femoral arterial line together with oxygen saturation probes on all extremities is ideal.

Division of a double aortic arch

TRADITIONAL THORACOTOMY APPROACH

The surgical approach to a double aortic arch is through a left thoracotomy in the fourth intercostal space with a muscle-sparing technique, and the components of the vascular ring are visualized. The pleura overlying the vascular ring should then be opened and careful dissection performed to clearly identify all the pertinent vascular structures (Fig. 32.9). The right, or posterior, arch does not require mobilization unless it is the lesser of the two arches and is to be divided. In such cases, the proximal descending aorta should be reflected anteriorly to visualize the area where the right arch enters.

The goal of surgical therapy is to divide the smaller of the two arches at a site that does not compromise the blood flow to the head vessels. A likely site for division of the minor, or atretic, arch is at its point of juncture with the descending aorta. Identify and avoid the recurrent laryngeal and vagus nerves. Before dividing the arch, it should be temporarily occluded and the anesthesiologist asked to check right and left radial and carotid pulses. Arch division should always be done between vascular clamps with oversewing of the divided stumps with non-absorbable sutures. Simple ligation and division has been associated with ligature slippage and subsequent catastrophic hemorrhage. The divided stumps typically separate by 1.5 to 2 cm, and disappear into the posterior mediastinum making precise hemostasis quite important. The operative repair is completed by freeing up all adhesive bands surrounding the esophagus in the area of the divided ring (Fig. 32.10).

Closure of the mediastinal pleura is not performed to avoid the development of adhesive scarring in the already affected area of the trachea and esophagus. The thoracotomy incision is closed without a chest tube by evacuating air from the plural space with a small suction catheter. It may take up to one year for the child's noisy breathing to disappear as the tracheo-bronchomalacia caused by the ring resolves.

VIDEO-ASSISTED TECHNIQUE

A couple of groups advocate this technique as the method of choice for treatment of vascular rings, unless preoperative studies suggest that a patent segment of a double aortic arch is present.[13–15]

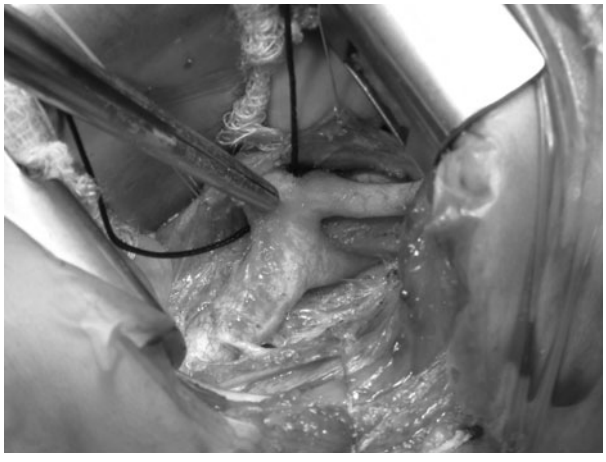

Figure 32.9 Operative photograph taken during dissection after postero-lateral thoracotomy in a patient with double aortic arch. The parietal pleura is opened and the vascular structures are dissected. The left-sided ductus arteriosus is looped by a silk tie.

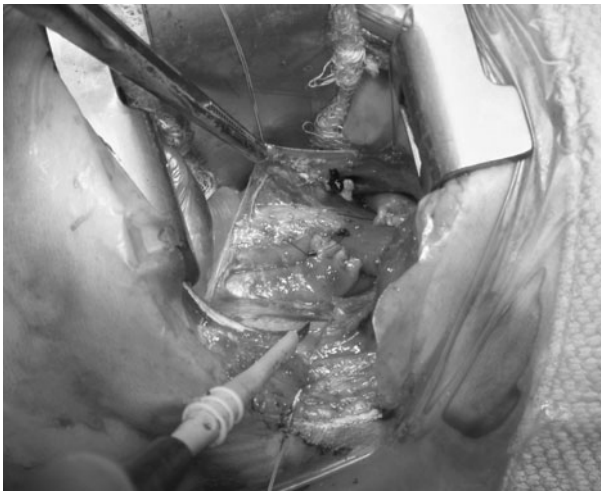

Figure 32.10 Operative photograph taken after division of a double aortic arch via postero-lateral thoracotomy. The parietal pleura is opened and the anterior arch is divided and oversewn. The left-sided ductus arteriosus is tied and only the aortic component is still visible. Note the resulting gap between the two stumps of the anterior aortic arch.

The patient is placed in the right lateral decubitus position following single lumen endotracheal intubation. Four small stab incisions are made in the posterolateral chest wall to admit, from medial to lateral, a grasping forceps, a lung retractor, a video scope, and an L-shaped cautery probe. Exposure is achieved by retracting the inflated left upper lobe inferiorly and medially. The mediastinal pleura is incised over the left subclavian artery which leads to the other components of the vascular ring. The ring is dissected free from the esophagus and surrounding structures. The atretic segment of the vascular ring and ligamentum are identified. Clips are placed and the ring and the ligamentum are divided between clips. Fibrous bands over the esophagus are also freed. A small chest tube is placed under direct vision and the wounds are closed with steri strips.[13,16]

Right aortic arch

Surgical treatment of this condition also consists of dividing the ductus arteriosus or the ligamentum arteriosum. Division of the left subclavian artery is not generally necessary for relieving tracheal compression. Patients with an anomalous left subclavian artery and Kommerell's diverticulum[17] are at risk of developing severe tracheal compression. Backer *et al.* have recommended resection of the diverticulum and reimplantation the left subclavian artery to the left carotid artery as a primary operation.[18,19] Surgery is performed through a muscle sparing left lateral thoracotomy in the fourth intercostal space. After dissection of the vascular structures and division of the ligamentum arteriosum, the patient is anticoagulated. Any adhesive bands are lysed, and the recurrent laryngeal and phrenic nerves are carefully identified and protected. The base of the Kommerell's diverticulum is taken in a side-biting clamp and the distal subclavian artery is occluded with a vascular clamp prior to its division. The diverticulum is resected and its base oversewn. The left subclavian artery is then anastomosed to the origin of the left carotid artery.

Pulmonary artery sling

Although the traditional approach has been through a left-sided thoracotomy with reimplantation at the original site of the left pulmonary artery, as performed in 1953 by Potts,[3] and then reimplantation of the left pulmonary artery on the left side of the main pulmonary artery, as described by Hiller and MacIean in 1957,[20] currently the preferred method is to undertake repair via median sternotomy. With this approach and utilizing cardiopulmonary bypass, reimplantation of the left pulmonary artery onto the left side of the main pulmonary artery without application of a side biting clamp is carried out without aortic cross-clamping. Then tracheal repair can be performed. This technique was introduced in 1986 by Kirklin and Barrat-Boyes.[21] Different techniques are utilized for tracheal repair depending on the length and site of the tracheal stenosis. Over recent years, many different types of repair have been undertaken, ranging from simple end-to-end repair,[22,23] various forms of patch tracheoplasty,[24,25] tracheal homograft implantation,[26,27] and slide tracheoplasty.[28–33]

A review of these methods is beyond the scope of this chapter, but more comprehensive reviews are available.[33,34]

Left aortic arch with anomalous origin of the innominate artery

The surgical treatment of this anomaly is based on the suspension of the innominate artery to the posterior aspect of the sternum. This operation can be performed from either side.[35,36] The thymus lobe of the corresponding side is resected and the pericardium opened respecting the phrenic nerve. The ascending aorta or the innominate artery is approximated to the posterior aspect of the sternum by two or three interrupted pledget-supported heavy sutures. Bronchoscopy is then performed to confirm the tracheal relief. In order to relieve the compression of the trachea, it is essential not to dissect a plane between the great vessels and the trachea, so the tension applied by the suture on the vessels is transferred to the trachea's anterior wall.

Other authors have described using a median sternotomy with division of the innominate artery and reimplantation into the ascending aorta at a site more rightward and anterior to the native site.[37] This technique sacrifices the active suspending mechanism on the tracheal wall provided by the classical suspension maneuver. In addition, there seems to be some risk of cerebrovascular accident, although Grimmer *et al.* report no cerebrovascular injury in a long term follow-up study.[38]

Results

TRADITIONAL THORACOTOMY APPROACH

One of the largest reports of vascular anomalies causing tracheoesophageal compression is a report by Backer *et al.* from the Children's Memorial Hospital in Chicago, USA published in 1989[10] and updated in 2005.[19] The authors described 204 infants and children with a mean age of 13 months who had undergone surgical procedures for tracheoesophageal obstruction. Of these, 113 patients had a vascular ring, 61 with a double aortic arch, and 52 with a right aortic arch and left ligamentum. The operative mortality rate was 4.9% with a late mortality rate of 3.4%. However, there were no operative deaths within the last 28 years. At a mean follow up of 8.5 years, 92% of the patients were essentially free of symptoms.

In 1994, Cordovilla Zurdo *et al.* reported on a series of 43 patients with one hospital and one late death.[39] Over a mean follow up of 11 years, 90% of the patients were asymptomatic. Similarly, Anand *et al.* reported on 44 patients operated on for vascular ring or pulmonary artery sling from 1977 to 1990.[40] In this series, three deaths due to cardiac failure after repair of complex anomalies were reported.

Further studies report on good long-term results with low operative mortality. Mortality seems to be limited, and only occurring in patients with complex cardiac anomalies.[41–44]

VIDEO ASSISTED TECHNIQUE

Only a limited number of publications are currently available reporting on results after throcoscopic division of vascular rings.[13–16] In these series, no mortality was observed. However, stay on ICU and in hospital was no different from the conventional technique. It should be taken into account that this technique offers only a limited amount of control and in addition the surgical times are much longer than the conventional procedures. In addition, the video-assisted technique is only applicable if the vascular structures to be divided are obliterated.

Pulmonary artery sling with tracheal repair

Kocyildirim *et al.*[45] reports in his study on 34 patients with long-segment tracheal stenosis (21 patients with pulmonary artery sling). Cardiopulmonary bypass was used in all operations. Before the establishment of the multidisciplinary tracheal team, pericardial patch tracheoplasty was performed in 15 of 19 patients. Twelve patients had a suspended pericardial patch tracheoplasty, two (17%) of whom died late after the operation. Of the three patients who had had a simple unsuspended patch, two (67%) died early after the operation. Four patients were operated on with the tracheal autograft technique, two (50%) dying early in the post-operative period. After multidisciplinary tracheal team formation, in the era between 2001 and 2004, 15 patients were operated on with slide tracheoplasty, and there were two (13%) early postoperative deaths. A significant reduction in cost and duration of stay has been shown both in the intensive care unit and the hospital.

Backer *et al.*[46,47] reports on 28 infants after pericardial tracheoplasty for long-segment tracheal stenosis. Seven of these infants required reoperation or stenting for residual or recurrent tracheal or bronchial stenosis. Revisions were performed 2–6 months after the original procedure with cardiopulmonary bypass and bronchoscopic guidance. Two patients underwent repeat pericardial patch tracheoplasty, and four patients underwent insertion of a rib cartilage graft. Two of these patients required Palmaz wire expandable stents and one other patient also underwent stent placement. There was one late death one year after cartilage graft insertion. The authors identified three risk factors for reoperation after tracheoplasty; younger age at initial surgery and associated pulmonary artery sling or tracheal right upper lobe bronchus. Good intermediate results are possible in this difficult group of children using a selective and inclusive strategy for tracheal enlargement that includes repeat pericardial tracheoplasty, autologous cartilage grafts, and expandable wire stents.

Pulmonary air leaks

PREM PURI AND JENS DINGEMANN

INTRODUCTION

Pulmonary air leaks include urgent life-threatening neonatal emergencies like pulmonary interstitial emphysema, pneumomediastinum, pneumothorax, or pneumopericardium.[1–4] The incidence of pulmonary air leaks in the neonates has increased in recent years, possibly because an increasing number of sick infants with respiratory distress on assisted ventilation are now surviving to develop this complication.[5] The sequence of events in the occurrence of pulmonary air leaks is similar regardless of whether it is caused by uneven alveolar ventilation, air trapping, and high transpulmonary pressure swings. The rupture of terminal air sacs causes air to escape into the pulmonary interstitium, resulting in pulmonary interstitial emphysema. The air tracks along the sheaths of pulmonary blood vessels to the lung hilum and air may then rupture into mediastinum, pleura, or pericardium.[6] It has also been suggested that air directly enters the pleural cavity following a rupture of a subpleural bleb.[7] Rarely, systemic air embolism may be a terminal event of pulmonary air leaks.[8,9]

PULMONARY INTERSTITIAL EMPHYSEMA

Pulmonary interstitial emphysema (PIE) is predominantly seen in preterm infants with respiratory distress syndrome (RDS) who are on assisted ventilation.[10] Occasionally, it follows vigorous resuscitative efforts. The lesion represents air that has dissected along perivascular sheath within pulmonary interstitium. The compression caused by interstitial 'air conduits' interferes with ventilation and reduces pulmonary perfusion leading to CO_2 retention and hypoxemia.

The incidence of PIE increases with low birth weight and prematurity. In one series, 20 out of 303 ventilated low birth weight (LBW) babies developed PIE,[11] but significantly high incidences of 32 and 42% have been reported in other series.[12,13]

Presentation and diagnosis

Pulmonary interstitial emphysema may be diffuse or localized. It is a radiological diagnosis found on the chest x-ray of an ill neonate. The radiological features consist of hyperinflation and multiple cyst-like lucencies that appear to radiate outward from the hilum of the lung (Fig. 33.1). Suspect

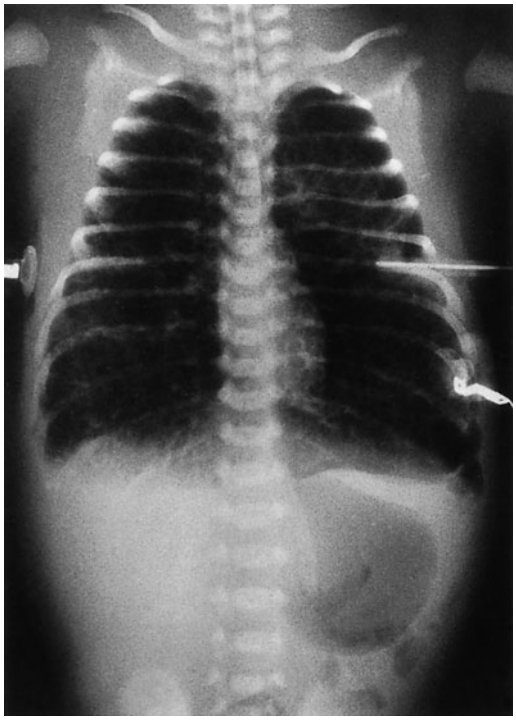

Figure 33.1 Diffuse pulmonary interstitial emphysema in a baby weighing 1200 g and requiring prolonged positive pressure ventilation for hyaline membrane disease. The lungs are grossly hyperinflated with a diffuse cystic pattern in this film at 7 days of life. Note narrow heart shadow due to tamponade effect of the distended lungs. A shallow pneumothorax is present in the left upper zone and a left chest drain has been inserted.

neonates should be monitored by daily chest x-ray for an earlier diagnosis of PIE.

Treatment

PIE, diffuse or localized, makes ventilatory management difficult. It is mandatory to use appropriate ventilation strategies to prevent PIE or its deterioration, respectively. Ventilatory pressures should be kept at a safe minimum while aiming for acceptable blood gas values of PaO_2 >6–7 kPa, pH >7.25, and $PaCO_2$ <8 kPa.[14]

No specific surgical treatment is indicated for diffuse PIE. Benefit has been demonstrated for both high frequency positive pressure ventilation (HFPPV) and triggered ventilation with regard to a reduction in air leak and a shorter duration of ventilation.[14] Also, the prophylactic application of surfactant has been shown to be beneficial for the outcome of preterm infants with PIE.[15] An aggressive approach of decompressing the lungs and creation of artificial pneumothorax has been described for patients in whom conservative management fails. This approach has been shown to successfully remove interstitial gas and, after re-evacuation of the pneumothorax, ventilation could be discontinued shortly.[16]

If the disease is unilateral or localized, selective partial or complete atelectasis of the desired segment can be achieved by selective bronchial intubation[17,18] or by placing the infant with his hyperinflated lung dependent in the lateral decubitus position at all times.[19] Localized pulmonary interstitial emphysema cases have also been successfully treated by resection of the diseased lobes.[20,21]

Prognosis

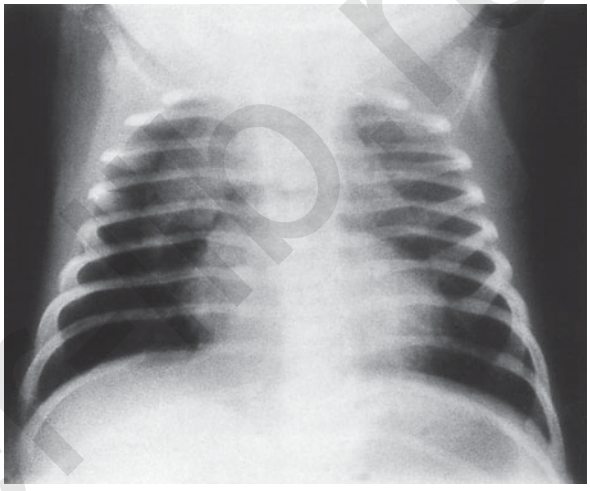
The mortality rate from diffuse PIE has been reported to be from 24% to as high as 60%.[11,22] There have been no significant differences in neonatal parameters between infants who died or survived. However, the survivors had a significantly lower maximal peak inspiratory pressure and FiO_2 on the first day of ventilation.[22]

PIE is invariably fatal in the group of neonates with RDS who weigh <1600 g at birth and who develop bilateral PIE within the first 48 hours of life, needing FiO_2 above 0.6 on the first day. High positive inspiratory pressure on day 1 was found to be the most significant parameter associated with fatal pulmonary interstitial emphysema. A cut-off level of 26 cm H_2O was found to be discriminant.[23] These criteria may be useful in selecting neonates who might benefit best from the new modes of ventilation. In preterm infants, additional application of surfactant significantly reduces mortality of PIE.[15]

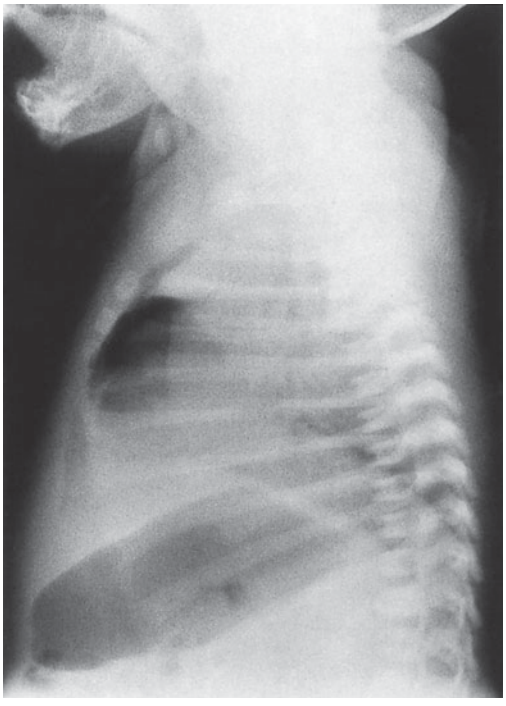
PNEUMOMEDIASTINUM

Pneumomediastinum develops when interstitial air in PIE migrates to the mediastinum. Also, spontaneous pneumomediastinum without any history of mechanical ventilation or concomitant lung disease has been reported.[4,24] If the collection of air is small, it remains asymptomatic. However, large collections of mediastinal air may produce respiratory distress.[24] Heart sounds are muffled and the sternum may appear bowed.

The diagnosis is made on chest x-ray. The antero-posterior views may show the characteristic 'angel-wing' sign produced by air elevating the thymus gland (Fig. 33.2a). It has also been described as having a crescentic configuration resembling a 'spinnaker sail'.[4] Lateral x-ray of the chest shows marked hyperlucency in the anterior mediastinum (Fig. 33.2b). Ultrasound can be used to diagnose pneumomediastinum. It has been reported to be superior to x-ray under certain



(a)



(b)

Figure 33.2 Pneumomediastinum. (a) Anteroposterior view demonstrates the characteristic 'angel wing' sign produced by air elevating the thymus from the heart. (b) Lateral view confirms air in the anterior mediastinum.

conditions and should be considered if a pneumomediastinum is clinically suspected and x-ray shows no typical findings.[25]

Retrocardiac pneumomediastinum has a strong association with other manifestations of extra-alveolar air leaks such as PIE, pneumothorax, dissection of air into the soft tissues of the neck, and pneumoperitoneum.[26] Tension pneumomediastinum has also been described to cause isolated left ventricular inflow obstruction.[27]

Symptomatic pneumomediastinum is managed by ultrasound-guided needle aspiration of the anterior mediastinal compartment.[28] In asymptomatic cases, air is absorbed spontaneously and no treatment is indicated.

PNEUMOTHORAX

Pneumothorax is far more frequent in the newborn period than in any other period of life – symptomatic pneumothorax occurs in 0.08% of all live births[29] and in 5–7% of infants with birth weight of $\leq$1500 g.[30,31] It is bilateral in about 20% of cases.[32] Pneumothorax in the newborn predominantly occurs in patients with hyaline membrane disease, meconium aspiration syndrome, pulmonary hypoplasia, and infants requiring vigorous resuscitation at birth.[32–34]

In ventilated preterm infants, it has been shown to be attributed to high peak inspiratory pressure low FiO_2, pulmonary hemorrhage and high arterial CO_2 while a decreased risk was associated with high positive end-expiratory pressure.[35]

The overall incidence of pneumothorax in the newborn with respiratory difficulties has been reported to be as high as 34% of those who are ventilated.[36] Pneumothorax can also be caused as a complication of deep endotracheal tube suction[37] and by other iatrogenic perforation of the bronchus.[38] A rare association of spontaneous pneumothorax with congenital cystic adenomatoid malformation[39] and early spontaneous pneumothorax with common pulmonary vein atresia[40] have been reported. The 'surgical' cases of pneumothorax and/or pneumomediastinum at the Liverpool Neonatal Surgical Centre included infants with gross renal anomalies, large exomphalos, a rare type of vascular sling, and spontaneous perforation of esophagus. In half of the cases, the etiology was less obvious.[41]

Presentation and diagnosis

Pneumothorax should be suspected in infants with respiratory distress who suddenly deteriorate. Tachypnea is a uniform finding and is often accompanied by grunting, chest retractions, and cyanosis. Physical findings in unilateral pneumothorax include a shift of the cardiac impulse to the unaffected side, diminished or absent breath sounds, and a hyperresonant percussion note on the affected side. In tension pneumothorax, arterial hypotension, apnea, and bradycardia are usually the initial signs.

A large pneumothorax can be diagnosed by transillumination using a high-intensity light with fiberoptic probe.[42] The advantage of this method is the rapidity with which large life-threatening pneumothoraces can be diagnosed and treated. The gold standard for diagnosis is x-ray of the chest. A large pneumothorax is easily recognizable in infants by identification of the visceral pleural line, which is most readily seen over the apex and along the costal surface of the lung (Fig. 33.3). Other important observations in pneumothoraces are a mediastinal shift and absence of lung markings. Small volume pneumothoraces are more difficult to identify and, in these cases, lateral decubitus cross-table views are very helpful in showing the rise in pleural air to the lateral or medial side of the hemithorax (Fig. 33.4).

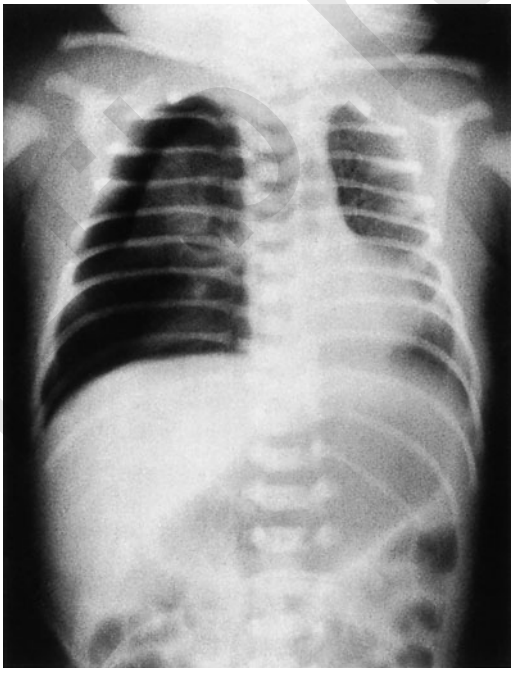


Figure 33.3 Right pneumothorax complicating interstitial emphysema in an infant with hyaline membrane disease. Note air lucency around right lung with absence of lung markings. The mediastinum is shifted to the left, indicating tension.

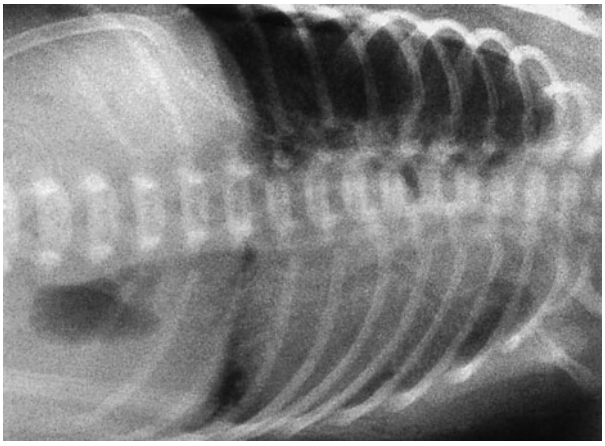

Figure 33.4 Small-volume pneumothorax demonstrated in the lateral decubitus view with the right side raised.

Treatment

Most small pneumothoraces with no symptoms need only close observation and monitoring in a neonatal intensive care unit.[43] The ventilatory management should aim to keep pressures at lower acceptable values including the use of patient triggered ventilation and high frequency positive pressure ventilation,[14] such as adjuvant neuromuscular paralysis of the infant.[44] A pneumothorax should be drained in the following situations:

- radiological signs of tension pneumothorax;
- cardiorespiratory symptoms;
- infants on intermittent positive pressure ventilation (IPPV), even if asymptomatic.

The infant should be temporarily disconnected from the ventilator during the introduction of a chest drain or aspiration of a pneumothorax to avoid the risk of lung damage.[45]

In a desperately ill neonate, a life-saving emergency needle aspiration of a tension pneumothorax can be done before formal insertion of a chest drain. A butterfly (18-gauge) or i.v. cannula with a three-way tap and a 20 mL syringe can be used for decompression. Aspiration is performed through the second intercostal space in the mid-clavicular line. The insertion of the needle is oblique through the muscle plane to avoid entry of air once the needle is removed. Occasionally, a single aspiration may be enough but all these babies must be closely observed and monitored clinically and radiologically as nearly all of them require a tube thoracostomy on follow-up.

Tube thoracostomy is required in the majority of cases. A chest drain (10–14 French gauge) is inserted through the second intercostal space in the mid-clavicular line or the sixth space in the mid-axillary line under local anesthesia. Some surgeons prefer to leave a purse-string stitch around the site of the catheter insertion, even though this is not absolutely necessary in neonates. The tip of the chest tube should be placed anteriorly retrosternally for better drainage.[46] After fixing the catheter firmly, it is connected to an underwater seal drain with or without a low-grade suction of 5–10 cm H_2O. Once the lung is expanded and stable, the tube can then be removed. A chest x-ray after removal of the tube to ensure that a pneumothorax has not recurred should only be carried out if this is clinically suspected.

Use of conventional chest drains is not free from complication as they can cause lung perforation[45] or phrenic nerve injury related to abnormal location of the medial end of the chest tube.[47]

There are pigtail pleural drainage catheters available which have been designed to prevent iatrogenic damage of intrathoracic organs.[48] However, even these catheters made from softer material can be the cause of pulmonary injury in premature infants.[49] In the majority of cases, a properly sized ordinary chest drain with an underwater seal or with a vacuum-control unit should be adequate. The Heimlich flutter valve, though useful clinically, adds to the resistance of the system, especially if fluid accumulates in the valve.[50]

Prognosis

Cases with pneumothoraces without underlying lung disease have a good prognosis. The mortality, though not the incidence, varies with birth weight and is in general double that of babies who have RDS but no airleak.[51] In one series of infants presenting with pneumothoraces within the first 24 hours of life, the overall mortality rate was 52%.[52] The mortality rate is inversely proportional to the infant's birth weight: 53% in infants with birth weights <1 kg.[53] The incidence of grades 3 or 4 intraventricular hemorrhage in infants with pneumothoraces associated with arterial hypotension is 89% as compared with neonates with pneumothoraces associated with normal blood pressure, which is only 10%.[54] This can have a detrimental effect on the neurological outcome. Ventilatory parameters may be helpful in making a prognostic assessment. The survivor group respond well to a fraction of inspired oxygen of less than 70% and a PEEP of 6 cm or less. A CO_2-retention associated with pneumopericardium and PIE is an unfavorable sign.[52]

PNEUMOPERICARDIUM

Pneumopericardium is the least frequent pulmonary air leak. However, recently it has been occurring with increasing frequency as a complication of ventilatory therapy. Pneumopericardium can develop while the patients are on high-frequency ventilation respiratory support.[55] Neonatal pneumopericardium has also been reported during nasal CPAP ventilation[56] and in a full-term neonate following a forceps delivery and mild asphyxia.[57] The exact etiology of pneumopericardium is not known; it is probably interstitial pulmonary air, secondary to alveolar rupture, which dissects into the mediastinum and then enters the pericardial space at the reflection of the pericardium onto the great vessels.

The pneumopericardium may be asymptomatic or symptomatic. Asymptomatic infants do well without any treatment. The clinical signs in symptomatic patients are those of cardiac tamponade, i.e. a sudden onset of bradycardia, muffled heart sounds, cyanosis, and hypotension. Changes in ECG axis and/or voltage may be observed. The classical radiological finding is a continuous radiolucent band of air that conforms to the cardiac outline and does not extend beyond the level of the great vessels (Fig. 33.5). Extra ventilatory air (PIE and pneumomediastinum) is present in over 90% of patients.

Simple needle pericardiocentesis is the appropriate therapy for most cases with cardiac tamponade. However, a few babies with pneumopericardium uncontrolled by needle aspiration require placement of a pericardial catheter for continuous drainage of air. The mortality rate in infants with pneumopericardium is high, especially in preterm infants.[2,51]

Chylothorax and other pleural effusions in neonates

RICHARD G AZIZKHAN

INTRODUCTION

Chylothorax results from the leakage of chyle from the thoracic duct into the pleural cavity. Although it is rare, it is a well-established clinical entity and is the most common cause of pleural effusion in the fetus and neonates.[1–3] Whether chylothorax is congenital or acquired, it frequently resolves with nonoperative measures aimed at optimizing ventilation and maintenance of nutrition. Relatively new on the horizon, somatostatin and its synthetic analog octreotide lend optimism to the possibility of adding new therapies to the current nonoperative treatment armamentarium.[4] When these measures fail to effect spontaneous healing, operative management becomes imperative. For patients in whom resolution does not occur, persistent chylothorax can become a life-threatening disorder, with profound respiratory, nutritional, and immunologic consequences.[1,5–7] While early diagnosis, aggressive initiation of nonoperative management options, and a number of alternative surgical procedures have significantly decreased the mortality rate from 50% before the 1950s[8,9] to current estimates ranging from 6 to 21%,[10–15] significant morbidity continues. This chapter presents an overview of key clinical aspects of fetal and neonatal chylothorax. A basic description of the anatomy and embryology of the lymphatic system and the pathophysiology of chyle provide the foundation for understanding this disorder. Other pleural effusions, including empyema and hemothorax, will also be briefly discussed. Since malignant effusions rarely occur in neonates, they have been omitted from the discussion.

ANATOMY AND EMBRYOLOGY OF THE LYMPHATIC SYSTEM

Lymph is collected in the cisterna chyli and reaches the venous system via the thoracic duct, which ascends in the posterior mediastinum between the azygos vein and the descending aorta. This duct crosses to the left at the level of the fifth thoracic vertebra, continues its ascent into the neck on the left of the esophagus, and opens into the venous system at the confluence of the internal jugular and subclavian veins. In the thorax, it receives lymph from the parietal pleura of both sides via several collecting trunks. Lymphatic branches from structures in the posterior mediastinum and from the left lung and its pleura join to form the left bronchomediastinal trunk; this trunk opens into the thoracic duct or directly into the great veins. There are also several potential lymphovenous communications that may function when the main duct is traumatized or blocked (Fig. 34.1).

The lymphatic system, a diffuse network of endothelial channels, appears during the sixth week of development. The growth of this system is a phenomenon of consecutive centrifugal budding from original lymph sacs. In the early 1900s, Sabin[16] demonstrated that these sacs originated from the endothelium of the adjacent veins, establishing venous endothelium as the primordial structure of the lining of the lymphatic system. She further recognized that all lymphatic channels are developed as outgrowths of the venous endothelium in six original lymph spaces: two jugular lymph sacs, two iliac sacs, a single retroperitoneal sac, and the cisterna chyli. These sacs invade the tissues by continuous growth and branching. The lymphatic system arises by confluence of perivenous mesenchymal spaces to form larger spaces. These in turn join to form continuous vessels that eventually drain into the venous system.

While the thoracic duct is usually a singular structure, its embryology underscores the potential for anatomic variations and congenital anomalies. It may develop in different anatomical patterns with several lymphaticovenous anastomoses. Variation in lymphatic pathways and the presence of accessory lymphatic channels can account for chylous effusions resulting from surgical procedures that do not expose the main thoracic duct.[4] Trauma to the duct in the posterior mediastinum can produce a unilateral or bilateral chylothorax. Increased intraductal tension leads to drainage of chyle into the thorax. A lesion to the thoracic duct below the level of the fifth lumbar vertebra will result in a right-sided chylothorax; a left-sided chylothorax occurs with lesions above this level.

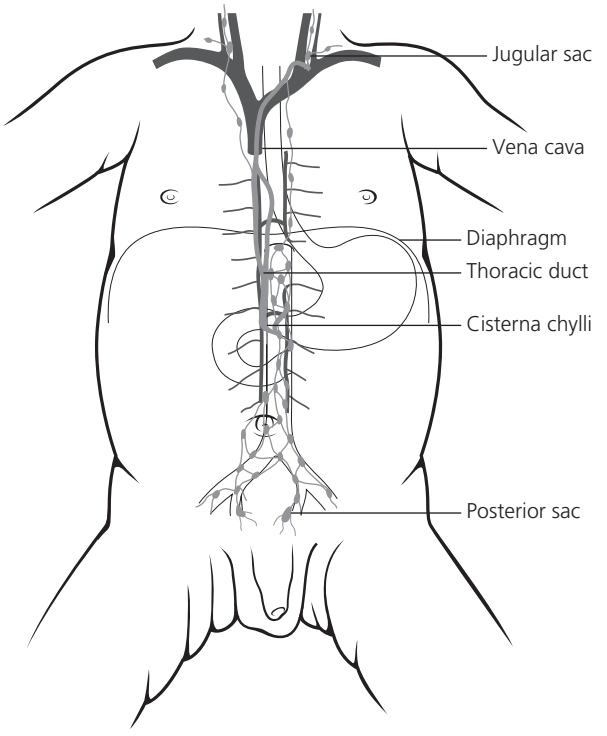

Figure 34.1 Anatomy of the lymphatic system.

PATHOPHYSIOLOGY OF CHYLE

At birth, chyle is clear and straw colored; soon after milk feeding begins, chylomicrons (emulsified fat globules) render it milky white. Depending on the amount of milk ingested, the fat content of the fluid varies from 0.4 to 4.0 g/100 mL, with a triglyceride content of >500 mg/100 mL.[17] Although the protein and electrolyte contents of chyle are similar to those in plasma, chyle is rich in T-cell lymphocytes, with a lymphocyte count of 80–100%. The volume of chyle loss per day can exceed 1.7 times the patient's blood volume, resulting in a serious state of depletion characterized by hyponatremia, hypoproteinemia, metabolic acidosis, and lymphocytopenia.[3] Untreated chylothorax is associated with severe respiratory compromise due to pulmonary parenchymal compression.

The thoracic duct drains most of the body lymph, including the entire intestinal lymph (chyle), into the venous system in the neck. Basal flow of the lymph from the duct averages 1.4 mL/kg per hour and varies with meals. Fatty meals may increase lymph flow up to ten times the basal rate, while lesser increases in the rate of flow are affected by the ingestion of proteins, carbohydrates, and even by oral intake of water.

ETIOLOGY OF CHYLOTHORAX

Congenital chylothorax

Congenital chylothorax is a common cause of neonatal pleural effusion and is classically a disorder of infants at or near term. Males are affected twice as frequently as females and 60% of cases involve the right side of the chest.[18] The occurrence of chylothorax in the absence of other demonstrable disease suggests the existence of congenital malformations of the lymphatic system. Congenital atresia of the thoracic duct or congenital fistulas due to failure of peripheral lymphatic channels to communicate with the major lymphatic network have moreover been assumed on the basis of diffuse chyle leakages seen during surgery.[2]

Congenital defects of the lymphatic system that may become evident with chylothorax are well documented in the literature, presenting clinically as lymphangiomatosis[19–24] or congenital pulmonary lymphangiectasis.[25–27] Congenital chylothorax is also associated with hydrops fetalis[28–32] and various syndromes, such as trisomy 21,[33–35] Turner syndrome, and Noonan syndrome.[36,37] The occurrence of chylothorax in combination with other uncommon disorders, such as autosomal recessive lymphatic anomalies, mediastinal neuroblastoma in neonates, and neonatal thyrotoxicosis, also has been documented.[38–40]

Acquired chylothorax

Acquired chylothorax results primarily from surgical or traumatic insult to the thoracic duct, and virtually every intrathoracic surgical procedure has been associated with it. Recent studies suggest an increase in the prevalence of postoperative chylothorax from the previously reported 1% or less[11,12,14,41] to 2.5–4.7%.[12,42,43] This has been attributed to the increased complexity of the surgery being performed and possibly to the earlier reintroduction of feeding after surgery.[42,43] Iatrogenic injury can occur during surgery in the region of the aortic arch for conditions such as patent ductus arteriosus, coarctation of aorta, vascular ring, and other congenital cardiovascular anomalies[42,44,45] as well as during esophageal repair or repair of congenital diaphragmatic hernia.[46–48] Acquired chylothorax also manifests as a complication of both subclavian and internal jugular venous cannulation and/or obstruction, superior vena caval obstruction secondary to central venous catheters, or elevated central venous pressures,[28,49–54] chest tube insertion,[55] and traumatic delivery.[56] Additionally, there have been anecdotal reports of chylothorax resulting from a blunt blow to the abdomen due to child abuse. (Rodgers, verbal communication, 2000) Chylothorax/chylopericardium is a rare complication, occurring primarily following surgery for congenital heart diseases.[15]

CLINICAL FEATURES OF CHYLOTHORAX

Presenting symptoms

Tachypnea, dyspnea, retraction of chest, and cyanosis mark the onset of chylothorax, with dullness and diminution of breath sounds on the affected side and displacement of the heart and mediastinum to the opposite side. In cases of congenital chylothorax, symptoms of respiratory distress may be noted shortly after birth or at any time up to 2 weeks of life. In contrast, the interval between surgery and the

occurrence of acquired chylothorax can vary from 1 to 25 days. The time is shortest when there is a direct injury to the duct (5–7 days) and longest when there is high pressure or thrombosis of the vena cava (10–14 days). Chyle may accumulate in the mediastinum for several days before extravasating into the pleural space.

Consequence of continuous chylous flow

The loss of large quantities of chyle over a period of time produces nutritional failure, sepsis, metabolic acidosis, and renal failure. Considerable loss of protein and large numbers of lymphocytes may result in immunodeficiencies, including hypogammaglobulinemia and abnormal cell-mediated immune responses.

DIFFERENTIAL DIAGNOSIS

X-rays of the chest typically show opacification of one or both hemithoraces, with compression of lung and displacement of mediastinal structures in unilateral chylothorax (Fig. 34.2). X-ray diagnosis in premature infants may, however, be difficult. Most of these infants already have significant pulmonary disease, and chest x-rays may appear to have areas of increasing consolidation rather than the more typical layering of pleural fluid seen in older children. Sonography is a reliable method of detecting chylothorax in these cases, and its use in obstetric practice as the primary method of imaging the fetal chest has led to the increasing frequency with which fetal chylothorax is being diagnosed[57–61] (see below under Fetal chylothorax (hydrothorax)).

Diagnosis is confirmed after analysis of the pleural fluid drained by thoracentesis or chest tube placement. Initially, this fluid is serous; it turns chylous only after milk feedings have begun. Chyle is characterized by elevated total protein and albumin levels, a specific gravity of >1.012, the presence of white blood cells with a predominance of lymphocytes (80–100%) and elevated triglycerides, cholesterol, and total fat levels if the infant is milk fed.[62] In the unfed neonate, the fat content of the chylothorax may be quite low and the fluid does not have the characteristic milky appearance. The protein content is somewhat less than that of serum and the electrolytes approximate those of serum.

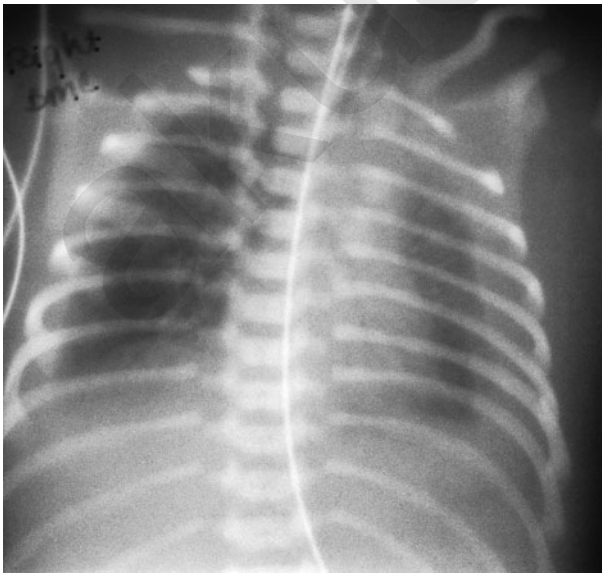

Figure 34.2 Chest x-ray in a term neonate demonstrating bilateral chylothorax.

MANAGEMENT OF CHYLOTHORAX

Historical overview and current consensus

Because chylothorax is associated with a wide array of disorders and accompanying clinical circumstances, the management of patients with this condition varies considerably. Historically, there has been a lack of consensus regarding nonoperative and operative treatment approaches, and to date there is no commonly accepted treatment protocol. The timing and type of operative intervention have been particularly controversial. A critical and unresolved issue is the early identification of babies for whom the morbidity of medical therapy will exceed that of early surgical therapy.[12,63] Differences regarding this issue are reflected in reported preoperative periods of medical therapy ranging from days to weeks.[64] Despite the differences, it is generally agreed that initial thoracentesis is diagnostic and may provide immediate relief of respiratory failure. If failure persists, mechanical ventilation may be required. A course of therapy that avoids the serious nutritional, metabolic, and immunologic sequelae known to the disease should then be chosen.[65]

If the infant is able to tolerate enteral feeding, initial nonoperative management generally consists of enteral feeding with medium-chain triglycerides (MCT). In recalcitrant or severe cases, patients may require total parenteral nutrition (TPN) or a combination of both modalities. This protocol is often successful in mitigating the most serious complication of chylothorax – protein-calorie malnutrition. More than 60% of ingested fats travel to the bloodstream via the thoracic duct. MCTs, which have a 6- to 10-carbon backbone, are the only fats to be absorbed directly via the portal system, bypassing the lymphatics.

There is general consensus that if lymphatic drainage does not resolve within a 2-week period with nonoperative management or if a patient's nutritional or metabolic status declines measurably during that time, surgical intervention should be undertaken.

General management principles

The general principles of management for chylothorax include the following:

- Thoracentesis is performed to provide immediate relief of respiratory failure and to confirm the diagnosis through chemical analysis of pleural fluid specimen.
- Supportive ventilation is instituted as required.

- Thoracostomy tube drainage is carried out if pleural fluid reaccumulates after one or two thoracenteses. (Repeating this procedure carries a risk of producing pneumothorax and introducing infection; chest tube drainage keeps the lungs fully expanded, which is necessary for sealing chyle leakage.)
- Nutritional losses are replaced through a high protein diet, rich in MCTs that are absorbed directly into the portal venous system.
- Parenteral feeding is instituted. (When superior vena caval thrombosis is present with chylothorax, TPN may need to be delivered via a peripheral vein.)
- The albumin, gammaglobulin, and fibrinogen that are contained in chyle, as well as fat-soluble vitamins, are adequately replaced.
- Full expansion of the lungs is maintained by continuous chest tube drainage of chyle. (These tubes may become obstructed and require replacement as necessary.)
- Prophylactic antibiotics are given when chest tubes are in place, since many of these infants have an acquired immune deficiency caused by lymphocytopenia. Some infants may also need salt restriction, diuretics, and digoxin.
- Somatostatin or octreotide may be used for cases recalcitrant to other medical therapies.
- Surgical intervention is warranted when medical therapies fail to significantly diminish chylous drainage for more than 14 days or if there is obvious deterioration in the patient prior to that period of time (Fig. 34.3).

Nonoperative management

As cited earlier, an initial trial of nonoperative management relying on adequate drainage of chyle, coupled with nutritional

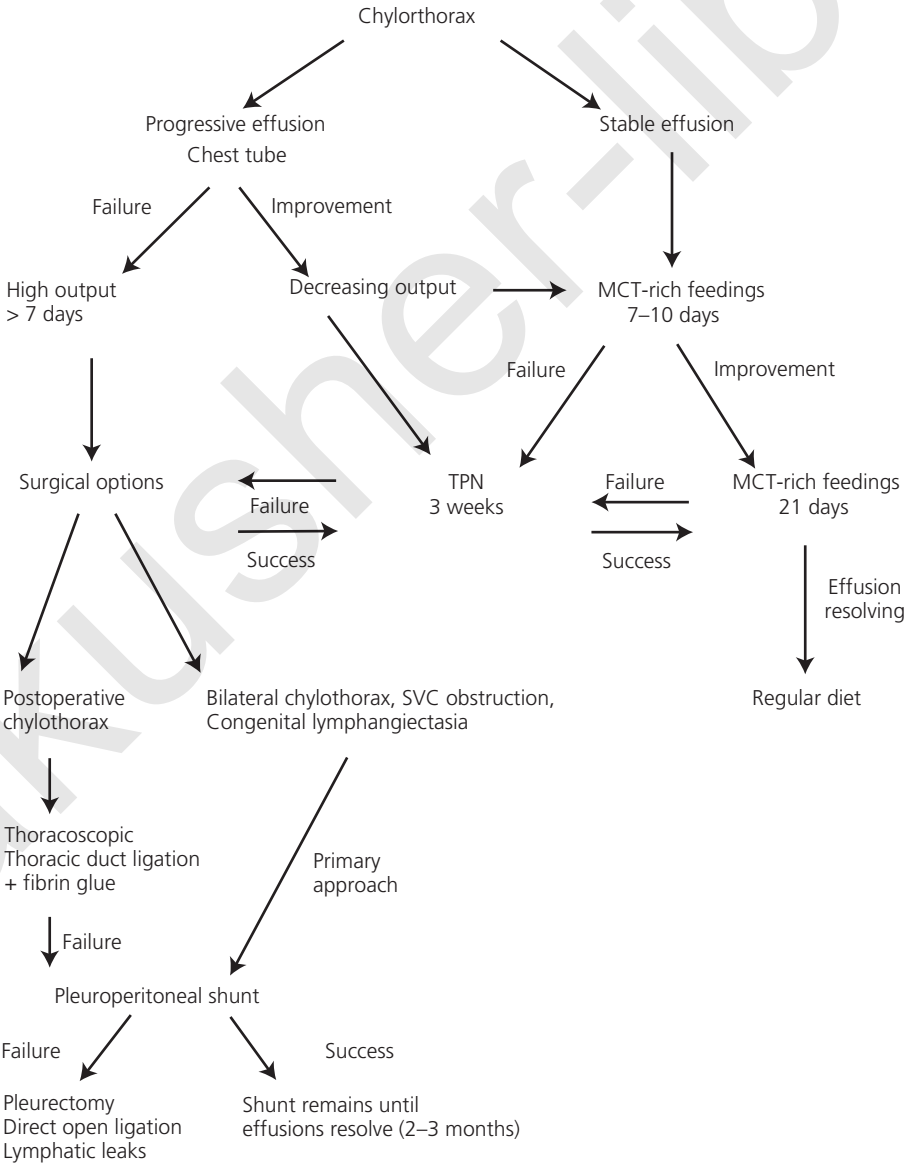

Figure 34.3 Algorithm of management principles. MCT, medium chain triglycerides; SVC, superior vena cava; TPN, total parenteral nutrition.

supplementation via MCT-enriched diets and/or TPN should be given in order to optimize the chance of recovery without surgery. Using this regimen, the majority of cases of congenital chylothorax and up to 77% of cases with traumatic chylothorax (postoperative) resolve spontaneously.[10,66,67]

Some investigators have observed no difference in MCT or TPN in regard to duration or amount of drainage.[15,66] Others have found that for patients with superior vena caval obstruction and congenital lymphatic malformation, MCT alone is not as effective; they thus recommend the rapid administration of TPN.[68]

Growing evidence from numerous uncontrolled case studies suggests that somatostatin (SST) and octreotide (OCT) exert a positive effect on persistent congenital and postoperative chylothorax.[69] At some institutions, these agents are gradually being integrated into treatment algorithms. SST is a polypeptide with mainly inhibitory actions on the release of various hormones (e.g. growth hormone and insulin) and lymph fluid excretion.[70,71] OCT is a synthetic SST analog with anti-secretory properties similar to those of SST. It is thought that octreotide may act directly on somatostatin receptors in the splanchnic circulation to reduce lymph fluid production.[72,73] Thoracic duct lymphatic flow depends on splanchnic vascular tone as well as gastric motility.[74] Octreotide decreases the volume of gastric, pancreatic, and biliary secretions, thus reducing the volume and protein content of fluid within the thoracic duct.

Current research suggests that OCT is well tolerated, even at the highest dosing ranges used (i.e. 80–100 μg/kg per day) for as long as 3 weeks, and that the earlier use of higher doses may be preferable to gradual upward tapering of the dose.[75] Potential adverse effects include cholelithiasis, liver impairment, renal impairment, transient glucose intolerance,[76,77] hypothyroidism,[78] and necrotizing enterocolitis.[79] It is thus prudent for patients to undergo routine monitoring of liver function, blood glucose, and thyroid parameters during the course of treatment.

Positive attributes of SST and OCT include a shorter duration of intensive care treatment, a reduction of recurrent thoracocentesis, and fewer fluid and plasma infusions, thereby reducing the risk of infection.[69] To date, however, no consensus has been reached as to the optimal route of administration, dose, duration of therapy, or strategy for discontinuation of therapy. Unfortunately, specific pharmacokinetic data are not yet available regarding these agents in infants and children.

Another novel though controversial medical treatment alternative is the use of OK-432 (Picibanil®) therapy. OK-432 is a lyophilized incubation mixture of the group A *Streptococcus pyogenes* of human origin. It is presently used to treat adults with chylothorax, though several authors have recently reported its successful use in treating fetal chylothorax and congenital cases resistant to OCT.[80] To date, information is sparse and reports emanate primarily from centers in Japan, where OK-432 is manufactured and readily available.

Operative management

The percentage of neonates requiring surgery and the timing of surgical intervention vary widely among reported series and are dependent upon the patient population being studied, etiology, and the clinical status of individual patients. Operative management has, however, been the mainstay of treatment for a number of clinical conditions that have a high failure rate with standard nonoperative management; these include postsurgical cases in which there is injury to the thoracic duct and massive lymph leakage, caval obstruction, or elevated central venous pressures.[13,15,68,81,82] Congenital chylothorax associated with superior vena caval thrombosis in the premature neonate is also particularly refractory to standard nonoperative therapy.[49] Since failure is associated with a high mortality rate, some investigators maintain that surgical intervention should be considered early in the management strategy of such cases.[69,83–85]

Several surgical options exist and they are often used in combination. They include pleuroperitoneal shunting, thoracic duct ligation (open thoracotomy or thoracoscopy), pleurodesis with different agents, pleurectomy, and intrapleural fibrin glue.

PLEUROPERITONEAL SHUNTS

Pleuroperitoneal shunts, first used by Azizkhan *et al.* in 1983[86] to treat five ventilator-dependent infants with persistent chylothorax, are currently used as a surgical treatment option at a number of major pediatric centers across North America. The procedure avoids the risks associated with a more complicated, open surgical procedure in high-risk infants and is considered safe, highly effective, and easy to perform. Nonetheless, it is associated with several drawbacks. These include having to manually press a pumping chamber several times a day and having the valve and pumping chamber become dysfunctional after several weeks due to an accumulation of fibrin and protein in the valve mechanism. It thus is ideal for patients who require a relatively short or stabilizing procedure.

A postoperative chest x-ray is obtained to make certain that the pleural catheter is properly placed. During the immediate postoperative period, the pumping chamber is compressed 50–100 times per hour in order to completely clear the hemithorax of chyle. As the infant's clinical status improves, a gradual decrease in the frequency of shunt compression is begun. Noninvasive transcutaneous oxygen saturation monitoring, arterial blood gas determination, and serial chest x-rays are used to assess shunt efficacy (Fig. 34.4). Manual compression of the shunt valve is discontinued when it is clear that chylothorax is resolved. This often occurs within 2–3 weeks. However, some infants require a more prolonged period of manual compression, lasting 6–8 weeks.

A high-flow, externally located valve reservoir designed to avoid some of the discomfort and positioning problems associated with a subcutaneous valve reservoir is available. Once the chylous effusion clears, parents are taught the technique of pumping the chamber and the patient is discharged from the hospital. Over the ensuing 2–3 months, the frequency of pumping is further reduced. When the chylous effusion completely resolves, the catheter is removed. This approach offers less interruption of the sleep cycle and

Figure 34.4 Chest x-ray showing resolution of a chylothorax after pleuroperitoneal shunt placement.

may facilitate a shorter hospital stay. Although this approach carries an increased risk of infection, this risk has not been documented in clinical studies.

While there has been some concern that elevated right atrial pressures transmitted to the venous and lymphatic bed of the peritoneal space may impair absorption of shunted pleural fluid, the successful use of pleuroperitoneal shunting with this patient population, even in the face of moderate elevations in right atrial pressure, has been reported.[84] Failure to resolve chylous effusions is associated with occlusion of the shunt catheter or significant intra-abdominal chylous ascites. When the latter occurs, a pleuroperitoneal shunt and a peritoneovenous shunt combination have been successfully used in some cases.

The same principle has been applied in the management of patients with chylopericardium. Case reports indicate that pericardial–peritoneal shunting provides an easy and effective alternative to prolonged pericardial draining, thoracotomy, or thoracic duct ligation in patients with chylopericardium of various etiologies.[87]

OTHER SURGICAL ALTERNATIVES

Although thoracic duct ligation has historically been the most common surgical therapy and has indeed been successful in resolving chylous leak, it requires an already compromised, frail, and often premature neonate to undergo a major surgical procedure. Despite this drawback, it remains an option when pleuroperitoneal shunting fails to resolve the chylous leak or when chylothorax is due to penetrating trauma. Giving cream through the nasogastric tube several hours before operations helps to identify the sites of leakage of the milky white fluid. Major leaks from the thoracic ducts can be closed by direct suturing or by ligating the duct above and below the leak. Pleurodesis and parietal pleurectomy have been used when there is generalized weeping of chyle from parietal pleura. However, these are extensive surgical procedures that may increase the possibility of pulmonary lymphedema, fibrosis, and further pulmonary compromise. Fibrin glue applied to the leakage site after patent ductus arteriosus ligation has been reported to successfully manage chylothorax in both a 3.5-month-old infant,[88] and a premature infant weighing 600 g.[89] The choice of either an open or thoracoscopic approach to thoracic duct ligation depends on the experience of the surgeon.

Video-assisted thoracoscopic procedures are being used with increasing frequency. These procedures offer the advantage of access to the entire hemithorax, with excellent visualization of the mediastinal structures. This approach allows application of clips to the thoracic duct at the hiatus or to the thoracic duct injuries or pleural defects. It also facilitates mechanical or chemical pleurodesis and application of fibrin glue. Despite its advantages, its use is limited by an infant's size and pulmonary status. Also, it may be difficult to correctly visualize leaks in the presence of a massive chylous effusion.

FETAL CHYLOTHORAX (HYDROTHORAX)

Primary fetal chylothorax (also known as hydrothorax), is the most common fetal effusion. It is a complication that occurs in one in 15 000 pregnancies,[60] and with the growth in sonography over the past several decades, it is being diagnosed with increasing frequency – from as early as 17 weeks' gestation to an average of 30 weeks gestation.[32] In contrast to chylothorax diagnosed at birth, primary fetal chylothorax is associated with a mortality rate as high as 50%.[60] Its clinical course varies considerably, ranging from complete resolution with a positive outcome to hydrops fetalis and perinatal death. Survival depends on multiple factors, including the presence of associated anomalies and the gestational age at which diagnosis is first made. The prognosis of small volume, unilateral, isolated fetal pleural effusion is usually good, with spontaneous resolution sometimes observed.[60,90–92] Prognosis is poor when effusion is associated with chromosomal aberrations, multiple malformations, and fetal hydrops.

The management of fetal chylothorax has been controversial and the optimal treatment approach remains unclear. Dissension is primarily focused on the following issues: (1) whether treatment should be attempted *in utero* or the infant should be delivered and treated after birth; (2) under what clinical circumstances antenatal intervention should be carried out; and (3) whether pleurocentesis or pleuroamniotic shunting should be used for thoracic decompression.

Most authors agree that fetal chylothorax with rapid progression warrants intervention. While reports of successful management with pleurocentesis or pleuroamniotic shunting have appeared in the literature,[60,61,93–95] pleurocentesis has been associated with rapid reaccumulation of the effusion and is therefore unlikely to be advantageous.[96–100] Thoracoamniotic shunting has been effective in selected

patients with progressive pleural effusions, especially when there is evidence of intrathoracic hypertension.[101] Most commonly, a Harrison double-pigtail catheter is used. Both techniques are associated with serious pregnancy risks, including preterm labor, prerupture of the membranes, intrauterine infection, bleeding, and maternal or fetal organ trauma. Additionally, technical failures such as shunt displacement and blockage are common.[96]

From a broad perspective, antenatal diagnosis is significant not only in that it can often identify the need for potentially helpful intrauterine intervention and facilitate preparation of appropriate postnatal outcome, but also in that it is a reliable predictor of fatal outcome. As such, it facilitates the communication of a more accurate prognosis to parents. Since most large pleural effusions discovered *in utero* lead to hydrops and pulmonary hypoplasia, such effusions have a high mortality rate. Retrospective studies show that the absence of hydrops predicts 100% survival; fetuses that initially present without hydrops and subsequently develop it have only a 38% survival.[32]

OTHER PLEURAL EFFUSIONS

Hemothorax

Although massive hemothorax is uncommon, accidental injury to the intercostal artery during thoracentesis or closed intercostal drainage can result in intrapleural bleeding.[102] Hemothorax has been reported as a complication of a variety of congenital malformations (e.g. sequestration, patent ductus, and pulmonary arteriovenous malformation) and of subclavian vein catheters.[103] It is also an occasional manifestation of intrathoracic neoplasms and blood dyscrasias, and bleeding diatheses. Additionally, it can occur spontaneously in neonates, sometimes in association with a pneumothorax. Symptoms reveal respiratory embarrassment similar to that seen in tension pneumothorax. However, the percussion note is dull and chest x-rays show opacification. More importantly, the infant may show signs of hypovolemic shock. Blood transfusion and urgent tube thoracostomy generally provide adequate control of bleeding. To avoid sudden circulatory collapse, transfusion should precede intercostal drainage. If massive blood loss continues, urgent thoracotomy and identification and securing of the bleeding site is required.[103]

Empyema

Owing primarily to improved antibiotic treatment of chest infections, empyema (purulent effusion) has become a rare condition in infants. The most common cause of empyema is a pneumonia caused by organisms such as *Staphylococcus areus*, *Pneumococcus,* and *Haemophilus influenzae*. It may, however, be incurred through the introduction of skin bacteria during thoracentesis or thoracotomy. Empyema may also be accompanied by anaerobic infection. Symptoms include indications of respiratory distress in addition to abdominal distension, lethargy, and at times, a septicemic state. Diagnosis is suspected by chest x-rays in which the effusion and pneumonic process is identified. Ultrasonography during diagnostic thoracentesis is helpful in localizing the fluid, if loculated. Prior to beginning a course of antibiotic therapy, a fluid specimen taken during thoracentesis is sent for a Gram stain and aerobic and anaerobic culture. Although most cases resolve with effective intercostal tube drainage and a prolonged period of systemic administration of antibiotics, anaerobic infection tends to be multi-locular and may thus require debridement, and in rare instances, decortication.

Congenital malformations of the lung

LI ERN CHEN AND KEITH T OLDHAM

INTRODUCTION

Congenital lung abnormalities are uncommon and diverse in their presentations. However, all those who care for infants and children must have an appreciation for the diagnosis and treatment of these anomalies because the potential consequences can be life threatening. In order to understand the pathophysiology of these malformations, one must have a basic understanding of the embryology of lung development, as well as lung anatomy and respiratory physiology, which are presented below. Classical lesions including lobar emphysema, congenital pulmonary airway malformation (CPAM), pulmonary sequestration, and congenital lung cysts will be discussed below, along with a number of the less common anomalies.

EMBRYOLOGY

During the third week of gestation, the human embryo develops a diverticulum of the ventral foregut which forms the primordium of the respiratory system. This is mainly of endodermal origin; however, cartilaginous and muscular elements will be derived from the splanchnic mesoderm that surrounds the primitive foregut. As the respiratory diverticulum grows caudad, it becomes separated from the foregut by the lateral esophagotracheal ridges which fuse to form a septum at the end of the fourth gestational week. Thus, the dorsal esophagus and the more ventral trachea and lung buds are defined. The larynx, which is formed from the fourth and sixth branchial arches, maintains communication between the pharynx and the trachea.

The lung buds penetrate the coelomic cavity by caudal growth, resulting in the formation of pleuroperitoneal canals on either side of the foregut. The expanding lung buds eventually come to nearly fill these canals, with the small residual spaces becoming the primitive pleural cavities. The right lung bud divides into three lobes, whereas the left forms two by the mid-portion of the embryo's sixth week. The bronchi continue successive dichotomous division, and by the end of the sixth month of gestation, 17 generations of subdivisions have formed. This period is also the time at which terminal bronchioles and alveoli are forming. An additional six divisions of the terminal airways will occur during early postnatal life, however, lung development probably does not cease until about eight years of age.[1] Thus, development of conductive airways is essentially complete by the end of the second trimester while terminal airways and alveoli, which are the site of gas exchange, continue to develop in late fetal life and indeed during infancy and early childhood. As one considers the various clinical lesions and their therapeutic options, this perspective is critical.[2,3]

The pulmonary vasculature begins to develop in the mesoderm around the primitive lung buds at 7–8 weeks of gestation. By the seventh gestational month, pulmonary blood flow has matured to the point where gas exchange is possible.

ANATOMY

A brief discussion of clinically relevant anatomy is appropriate; several excellent references are available for a more detailed review.[4,5] As seen in early gestational development of the lungs, the mature right lung is composed of three lobes in contrast to the two lobes of the left. The carina is positioned at the level of the fourth thoracic vertebral body in the term infant. The mainstem bronchus of the right lung follows a straighter, more caudad course and is usually shorter and larger in diameter than that of the left. This accounts for the preference of aspirated material to enter the right lower lobe or the posterior segment of the right upper lobe, as well as for right mainstem bronchus intubation during endotracheal tube placement.

The vascular supply of the trachea, bronchi, and lung parenchyma is systemic in origin and separate from the pulmonary arterial circulation which is dedicated to gas exchange. The trachea is supplied by branches of the paired inferior thyroid arteries, which anastomose with the bronchial

blood supply derived from the aorta on the left, and the third intercostal artery on the right. Venous drainage is via the azygous and hemiazygous systems. This systemic arterial supply and its accompanying venous drainage generally follow the segmental architecture of the lung and bronchi.[4–6]

CONGENITAL LOBAR OVERINFLATION OR CONGENITAL LOBAR EMPHYSEMA

Congenital lobar overinflation, also known as congenital lobar emphysema, is among the most common of the congenital lung anomalies. It is characterized by air trapping and overdistention of one or more lobes which are otherwise anatomically normal. This distention causes compression of adjacent normal lung parenchyma and can result in mediastinal shift and cardiorespiratory compromise (Fig. 35.1).

Although a specific etiology of this disorder cannot be demonstrated in up to half of reported cases,[7] it is believed to result most commonly from structural deficiency or absence of supportive cartilage in the affected lobar bronchus, thereby causing expiratory collapse of the conducting airway with impedance to expiratory flow.[8] Other reported etiologies include extrinsic compression from anomalous or enlarged blood vessels, congenital heart disease, mediastinal lymphadenopathy, bronchogenic and enteric cysts, and tumors.[9] Partial obstruction from a reversible endobronchial source, such as mucous plugging, inflammation, or aspirated materials, is a possible cause and should be ruled out by rapid and judicious bronchoscopic evaluation in order to avoid unnecessary lung resection.

Polyalveolar morphology mimics lobar emphysema in its clinical presentation. This is a descriptive histologic term that refers to unusual and abnormal anatomic findings characterized by an increase in the number of alveoli in a particular lobe, resulting in expiratory air trapping and lobar overdistension with respiratory compromise. This is in contrast to lobar emphysema where alveolar histopathology is normal except for overdistention. The diagnosis and treatment of polyalveolar morphology are not different than for congenital lobar emphysema.

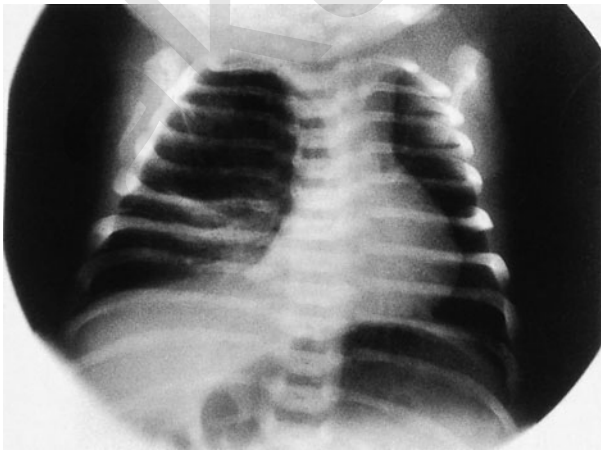

Figure 35.1 Congenital lobar emphysema. Chest x-ray in a 3-day-old infant who presented with respiratory distress, showing marked hyperinflation of right upper lobe.

Congenital lobar emphysema is most often seen in the Caucasian population with a two or three to one male predominance. It is most common in the left upper lobe (40–50%), with other sites affected less frequently; right middle lobe (30–40%), right upper lobe (20%), and lower lobes (1%).[10,11] In 15% of infants, lobar emphysema is associated with congenital heart disease or abnormalities of the great vessels;[12,13] therefore, routine echocardiography is recommended in the screening evaluation of these patients.

Presentation and diagnosis

While the structural characteristics of congenital lobar emphysema do not lend the lesion to easy detection by routine prenatal sonography, there have been several reports of prenatal diagnosis of this lesion.[14–16]

Contrary to its moniker, congenital lobar emphysema patients do not demonstrate respiratory problems immediately at birth, rather they develop symptoms as lobar distention progresses over time with expiratory air trapping in the course of postnatal breathing. Severity is usually related to age of presentation; the most threatening presentations typically occur in newborns. Approximately half of patients develop respiratory distress within the newborn period while the remainder with this symptom present around 4–6 months of age[7] or later. Presenting signs are those of respiratory embarrassment, including dyspnea, tachypnea, agitation, and wheezing. Depending upon the severity of adjacent lung compression, cyanosis and respiratory failure can result. Therefore, the surgeon must be available for emergent decompressive thoracotomy, particularly when positive-pressure ventilation is employed at procedures such as anesthesia induction or bronchoscopy. Older children may present with milder symptoms such as recurrent respiratory infections or cough, or may be asymptomatic altogether.

On examination, the patient with congenital lobar emphysema will demonstrate signs consistent with a hyperinflated lobe, including thoracic and respiratory asymmetry, decreased breath sounds and percussive hyperresonance of the ipsilateral chest. Findings of mediastinal shift such as tracheal deviation and displacement of the cardiac apical impulse are relatively late clinical signs.

Chest roentgenography is the initial and often the sole diagnostic maneuver of choice (Fig. 35.1). There is increased radiolucency over the affected side, with accompanying atelectasis of adjacent compressed parenchyma and a flattened ipsilateral hemidiaphragm. Mediastinal displacement to the contralateral side may also be apparent. The chest x-ray should be inspected closely to differentiate between congenital lobar emphysema and tension pneumothorax which may have similar presentation and appearance, but vastly different management. Contrary to congenital lobar emphysema, tension pneumothorax has no peripheral lung markings. In the first hours after birth, the affected lobe may still be filled with fetal lung fluid and therefore have the appearance of a mass with fluid density. Some authors

advocate ventilation-perfusion radioisotope scanning as a useful adjunct to the chest x-ray.[17] Others advise the use of computed tomography (CT) or magnetic resonance imaging (MRI). However, these studies are generally reserved for situations in which the diagnosis is in doubt.

Treatment

If a source of endobronchial obstruction cannot be found and corrected, then the often-progressive nature of this lesion as well as the risk of respiratory failure dictate lobectomy of the affected lobe in infants. This is done via either muscle sparing thoracotomy or thoracoscopy. For the older child without symptoms, this approach can be reasonably tempered. Reconstructive procedures such as bronchoplasty or segmental bronchial resection are generally not appropriate as the bronchial defects may not be focal or readily localized. In addition, lobectomy in the infant population is very well tolerated[18,19] and bronchial reconstruction in the newborn is fraught with technical limitations.

CONGENITAL PULMONARY AIRWAY MALFORMATIONS

CPAM are a rare group of cystic lobar hamartomatous lesions, also referred to as cystic adrenomatoid malformations. These represent up to 50–70% of the bronchopulmonary foregut malformations in some reports.[20] The lesions are generally large, firm, multicystic masses that are composed of terminal respiratory structures, usually bronchiolar in origin. CPAM are thought to result from developmental arrest in terminal bronchiole maturation, resulting in marked overgrowth of these structures in relation to alveoli. This lesion is characterized by a mass of interconnected and disorganized cysts on gross inspection. Because of the histopathology and associated disorders of organogenesis, it has been proposed that the pathogenic event occurs at 3–7 weeks' gestation, although the precise pathogenesis is unknown. Involvement is usually unilobar, with a slight predilection for the lower lobes; right and left sides are affected equally.

Histology demonstrates ciliated cuboidal or columnar cells lining the cysts, with a lack of organized architecture; usually no cartilage is present (Fig. 35.2). These malformations typically communicate with the normal bronchial tree and have a normal vascular supply, although aberrant systemic vasculature, sometimes derived from the aorta, has been described.[21] The classification of CPAMs has undergone constant modification in the past four decades. Adzick and colleagues described macrocystic and microcystic or solid lesions based on prenatal ultrasound imaging. The contemporary classification scheme proposed Stocker and colleagues grouped CPAM into five distinct pathologic types (Table 35.1).[22,23] This classification system, which is based on the presumed site of development of the malformation, carries both descriptive and prognostic significance.

With regard to outcomes, type 0 is composed of multiple small cysts less than 0.5 cm and the patients have a relatively poor prognosis. Type 1 CPAM accounts for about 65% of cases, and affected patients usually present with respiratory distress in the neonatal period. Patients usually have a good prognosis with lobectomy. Type 2 lesions have multiple smaller cysts (<2.5 cm), and are associated with other congenital anomalies (cardiovascular, genitourinary, and

Figure 35.2 Type 1 CPAM. Histology specimen of lung showing mucinogenic cells, papillary epithelium, and disorganized, irregular alveoli.

Table 35.1 Pathologic features of CPAM (from Shimohira *et al.*[23] with permission).

Stocker's type	0	1	2	3	4
Approximate frequency (%)	1–3	>65	20–25	8	2–4
Cyst size (max, cm)	0.5	10.0	2.5	1.5	7.0
Epithelial lining (cysts)	Ciliated; pseudostratified; tall columnar with goblet cells	Ciliated; pseudostratified; tall columnar	Ciliated; cuboidal or columnar	Ciliated; cuboidal	Flattened; alveolar lining cells
Muscular wall thickness of cysts (in μm)	100–500	100–300	50–100	0–50	25–100
Mucous cells	Present in all cases	Present in 33%	Absent	Absent	Absent
Cartilage	Present in all cases	Present in 5–10%	Absent	Absent	Absent
Skeletal muscle	Absent	Absent	Present in 5%	Absent	Absent

musculoskeletal) in up to 40% of patients. Type 3 lesions are more solid than cystic in nature. Both type 2 and type 3 lesions have a poor clinical outcome, presumably because they tend to be relatively large and noncompressible, thus limiting normal maturation and development of unaffected but adjacent lung. Malignant degeneration can occur in all congenital cystic lung lesions, including CPAM. Although this is rare, it is clearly a long-term risk to be considered as management decisions are made.[24]

Presentation and diagnosis

Since the advent of routine ultrasound in obstetric practice, the majority of cystic lung lesions are now discovered prenatally in many institutions. The location of the stomach aids in differentiation between CPAM and congenital diaphragmatic hernia (CDH), although prenatal MRI may be needed for definitive diagnosis in difficult cases.[25] Serial ultrasonographic exams may demonstrate shrinkage or even spontaneous resolution in up to 40% of fetal CPAMs.[19,26] Physiologic consequences of CPAM can be seen antepartum and occur secondary to mediastinal shift and compression of normal lung tissue. Large masses, especially those involving type 2 or type 3 lesions can result in nonimmune hydrops fetalis and fetal demise. The polyhydramnios is thought to result from esophageal compression, preventing fetal swallowing of amniotic fluid; the hydrops results from mediastinal shift from the mass effect, diminishing cardiac output by vena caval obstruction.[19] Either finding during pregnancy is associated with poor outcome.

In the neonatal period, some infants will demonstrate tachypnea, dyspnea, cyanosis, or impending respiratory failure. Although this can be dramatic, only a third of patients present in this manner. Of the remaining patients, most will present within the first few years of life with recurrent or persistent respiratory infections, pulmonary abscesses, or reactive airway disease due to the inability to effectively clear secretions from the abnormal lobe. Chronic pulmonary problems may also lead to failure to thrive.

As with all bronchopulmonary foregut malformations, the plain chest x-ray is the best initial diagnostic test in the neonate (Fig. 35.3). Nasogastric tube position is often helpful to distinguish CPAM from CDH as an intrathoracic stomach is quite common with left CDH. The x-ray findings are variable; x-rays taken early in the neonatal period may demonstrate fluid within the lesion, whereas later films may show air-filled cysts. Mediastinal shift, an ipsilateral flattened diaphragm, and compressed adjacent normal lung may also be present, depending on the severity of disease. It is advisable to obtain an axial imaging study, either a CT scan with i.v. contrast or MRI, in all patients with cystic lesions of the chest in order to establish a diagnosis, as well as delineate anatomic relationships prior to elective resection (Fig. 35.4). Even those who have had spontaneous intrauterine resolution of an apparent CPAM demonstrated by serial prenatal ultrasound should be evaluated with axial imaging following birth, as residual parenchymal abnormalities may be present.[26,27]

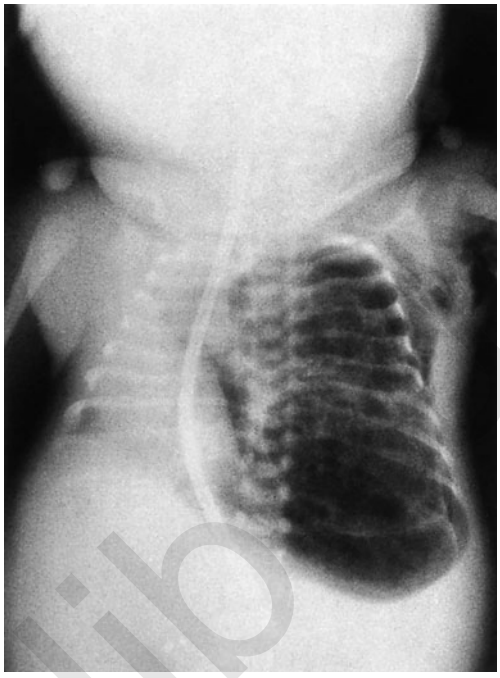

Figure 35.3 Congenital pulmonary airway malformation of the left lung with gross expansion of the lung, marked mediastinal shift to the right and downward displacement of diaphragm. Note surgical emphysema of left axilla and chest wall, indicating rupture of a cyst.

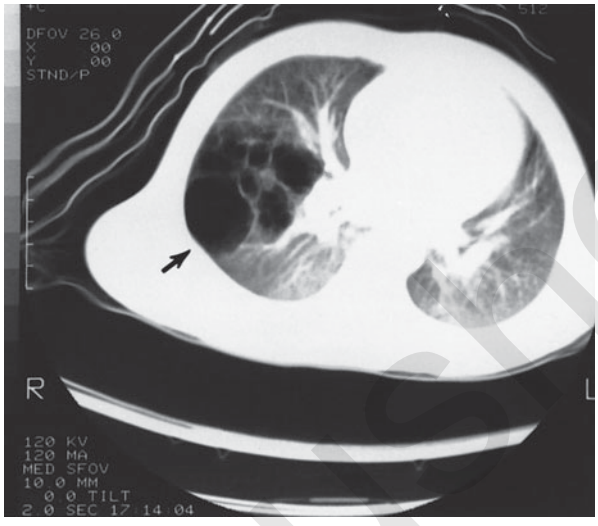
Treatment

The cornerstone of treatment in patients with CPAM is complete resection of abnormal tissue, which usually requires lobectomy. Again this is done via either open, muscle-sparing thoracotomy, or thoracoscopy. Patients with multilobular disease may benefit from segmental resection if possible, and total pneumonectomy is occasionally required.[28] Prenatal diagnosis of CPAM should prompt referral to a tertiary care center where critical care support and emergent pediatric surgical care are available. Like infants with congenital lobar emphysema, the postnatal phenomenon of breathing or positive pressure ventilation may rapidly precipitate a crisis in CPAM patients if there is progressive distention of the affected lobe. Older children who present with pulmonary infection may be managed acutely with antibiotics, then undergo subsequent elective lobectomy. Long-term expectant medical management is not appropriate due to the frequency and severity of recurrent infectious complications and the risk of malignant degeneration.[24]

As noted above, there are a number of reports of spontaneous regression and/or resolution of fetal CPAMs, and serial ultrasounds in the fetus are recommended to document findings. Even if asymptomatic at birth, these patients should undergo axial imaging at one month of age. Should persistent parenchymal abnormality be demonstrated, the infant should undergo elective resection, although this point is somewhat controversial.

A recent meta-analysis demonstrated significantly fewer operative complications when resection is performed prior to onset of symptoms.[29] Additionally, operation in a presymptomatic patient is associated with potentially parenchyma

(a)



(b)

Figure 35.4 (a) Plain chest x-ray of a nine-year-old child who presented with fever, pleuritic chest pain, and cough. The lesion is an infected type 1 CPAM of the right lower lobe. (b) The lesion in (a) is shown on chest CT scan after treatment with antibiotics and before surgical resection of the right lower lobe (with permission from Coran AG, Oldham KT, The pediatric thorax. In: Greenfield LJ, Mulholland MW, Oldham KT *et al.* (eds). *Surgery: scientific principles and practice*. Philadelphia: JB Lippincott, 1993: 944).

sparing resection such as segmentectomy with better long-term lung function.[30]

In the last decade and a half, various fetal interventions for CPAM have been described. The approaches have included thoracoamniotic shunting in lesions with a single predominant cyst, and resection in those with more complicated type 2 and type 3 CPAM.[31] It appears that difficulty with proper patient selection and technical hazards make the risk of maternal–fetal complications relatively high. The issue of appropriate prenatal patient selection is critical since many of these fetuses do well without intervention and a number of the lesions resolve entirely. However, CPAM associated with fetal hydrops or polyhydramnios carries a high mortality and fetal intervention at specialized centers may be an option in some of these cases. The subject remains controversial.[32]

An additional strategy to manage the fetus in whom significant respiratory distress is anticipated at birth is *ex utero* intrapartum therapy (EXIT). This involves resection of the CPAM via thoracotomy while maternal–placental–fetal circulation is maintained, followed by delivery of the infant.[33]

More recently, maternal administration of betamethasone has been a subject of investigation in the fetal treatment of CPAM. While the exact mechanism is unknown, steroids are thought to impair CPAM growth. Though the response of CPAM to steroids is variable, this treatment appears to have a role in improving survival in select fetuses.[34–36] This is currently the subject of further study.

PULMONARY SEQUESTRATION

Pulmonary sequestrations make up 10–30% of the cystic bronchopulmonary foregut malformations in most reports.[28,37] They are classified by whether the sequestration resides within the visceral pleura of the normal lung (intralobar sequestration) or is invested by its own visceral pleura (extralobar sequestration). In both types of pulmonary sequestration, however, there is no bronchial communication between the sequestrum and the normal tracheobronchial tree. In addition, the malformation receives its blood supply from aberrant systemic arterial vessels (Table 35.2).[38]

Intralobar sequestrations make up the majority (up to 75%) of pulmonary sequestrations and most commonly involve the posterior and basal segments of the left lower lobe.[39] As mentioned, these intralobar lesions are surrounded by normal lung parenchyma and pleura. The arterial supply is usually derived from aberrant branches of the descending thoracic aorta, although occasionally intercostal, brachiocephalic, or abdominal aortic aberrant vessels are encountered. Venous drainage is usually via the associated pulmonary vein. Although sequestrations are by definition nonfunctional and sequestered from the respiratory tree, intralobar sequestrations may communicate with neighboring alveoli in normal lung via abnormal air spaces, allowing some ventilation and air-trapping within the intralobar lesions.

Extralobar sequestrations are completely separated from the normal lung invested by an individual pleura. They are completely separate from the functional airways. They are found in the left lower chest most commonly, but may occur anywhere; rarely, subdiaphragmatic locations are reported.[39,40] A 3:1 male predominance is reported in most series for extralobar sequestrations. These sequestrations also derive arterial blood supply from the descending aorta, with up to 20% having an aberrant vessel traversing the diaphragm. Venous drainage into systemic veins, such as the azygous, hemiazygous, or the portal system, is typical for extralobar sequestrations. There is an association of extralobar pulmonary sequestrations with CPAM and congenital

Table 35.2 Characteristics of pulmonary sequestrations (from Shamji *et al.*[38] with permission).

Characteristic	Intralobar	Extralobar
Incidence	Uncommon	Rare
Incidence ratio	3	1
Sex	Equal	Male 80%
Side	60% left	90% left
Location	Usually in the posterior basal segment	Above the diaphragm, rarely below
Age at presentation and symptoms	Adolescent to young adults, 50% >20 years, recurrent pulmonary infections	Neonate 60%, <1 year, respiratory distress
Associated anomalies	Uncommon	Frequent (>50%), e.g. congenital diaphragmatic hernia (30%)
Diagnosis at neonatal autopsy	None	Frequent
Arterial supply	Systemic – from aorta, large vessels, often a single vessel	Systemic – from pulmonary or aorta, usually small vessels
Venous drainage	Pulmonary – inferior pulmonary vein	Systemic – azygos or hemiazygos vein; rarely portal vein
Anatomical relations	Not separate, within and part of normal lobe	Separate, has its own investment – visceral pleura
Connection with foregut	Very rare	More common
Bronchial communication	Present, small	None

diaphragmatic hernia, as well as a variety of other congenital defects.[6,28,41] Aberrant air space connections are not present, rather extralobar sequestrations are prone to hemorrhage or arterial-venous shunting and the patients may present with high output congestive heart failure.

The embryologic origin of pulmonary sequestrations is unclear, but they are thought to result from either abnormal budding of the tracheobronchial tree or accessory budding of the foregut, or a combination of the two. The stimulus is not known. Extralobar sequestrations are clearly congenital in origin. This conclusion is drawn by the frequent association with other congenital anomalies, their presence in neonatal autopsies, and the now routine discovery of these lesions on prenatal ultrasound.

Presentation and diagnosis

Although diagnosis of intralobar sequestration is improving, patients with intralobar sequestration often present with pulmonary infections due to abnormal air-space connections with inadequate drainage, or from compressive atelectasis of adjacent parenchyma. This pathophysiology explains why diagnosis is uncommon in infancy, and presentation occurs later in childhood or adulthood with complaints of recurrent or refractory pneumonias, lung abscesses, or hemoptysis.

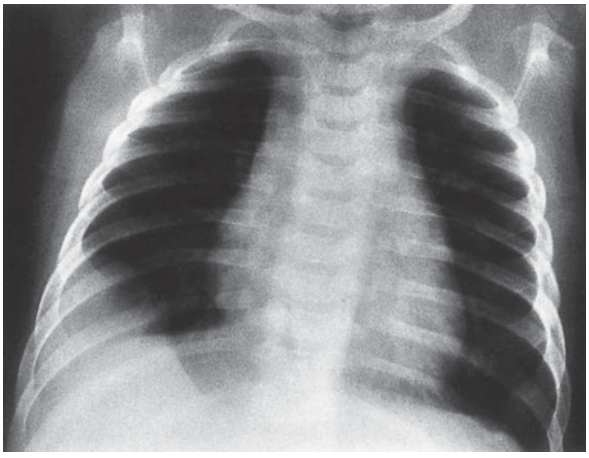
Extralobar sequestrations, on the other hand, are frequently seen on prenatal ultrasound. The infants are often asymptomatic at birth, however, these lesions can be associated with arterial-venous shunting and even congestive heart failure. The pathognomonic aberrant arterial blood supply may be identified prenatally if the ultrasound has Doppler capability. If the mass is large, shift of mediastinal structures, fetal hydrops, and fetal demise can occur. Due to the frequency of associated anomalies, extralobar sequestrations are often diagnosed early in infancy during evaluation for these other problems.

Plain x-rays of the chest will usually demonstrate an intralobar sequestration as a non-aerated, atelectatic mass, or as a cyst with an air-fluid level (Fig. 35.5a). Extralobar sequestrations most often appear as a left posterior mediastinal mass or triangular retrocardiac density on chest x-rays, although they may occur on the right as well.

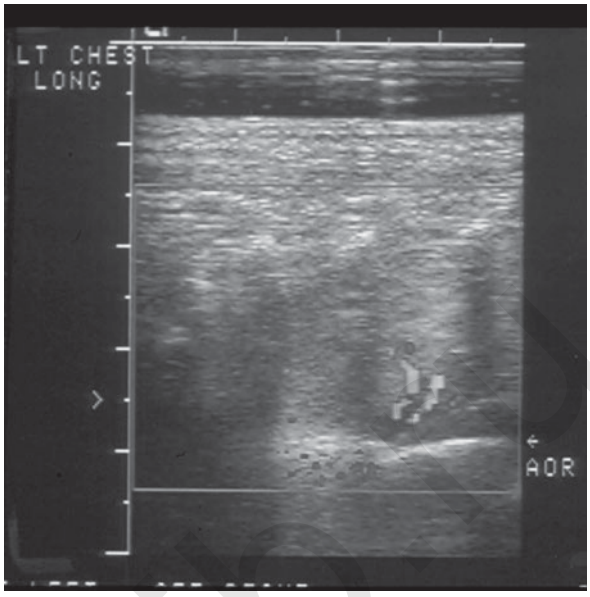
In most infants and children with pulmonary sequestration, additional imaging beyond the initial radiographs is recommended. Ultrasound with Doppler (Fig. 35.5b), CT angiogram (Fig. 35.5c), or MRI provide good anatomic detail and demonstrate relationships to neighboring structures. Importantly, all delineate the aberrant arterial vessels for purposes of both diagnosis and preoperative planning. Preoperative upper gastrointestinal contrast study may assist in identifying the 10% of patients who have anomalous foregut communication with their sequestration, but some experienced pediatric surgeons do not routinely do this, relying instead on intraoperative discovery.

Treatment

Treatment for pulmonary sequestrations consists of excision of the abnormal tissue. Although extralobar sequestrations may be asymptomatic, the cumulative risks of hemorrhage, infection, arteriovenous shunting, and late malignancy have generally been considered an indication for resection when diagnosed. In patients with extralobar sequestration, this is a relatively straightforward procedure performed via thoracotomy or by thoracoscopy. Intralobar sequestration is treated with lobectomy via thoracotomy or thoracoscopy, although in selected cases, segmentectomy may be appropriate.[42] Segmentectomy may be more feasible in situations where prenatal discovery offers an opportunity for resection prior to the onset of infectious complications.



(a)



(b)

(c)

Figure 35.5 Pulmonary sequestration. (a) Chest x-ray demonstrates a well-defined mass at base of right lung. (b) Prenatal Doppler ultrasound demonstrating two aberrant arterial vessels to extralobar sequestration (arrow). (c) CT angiogram demonstrates an enlarged bronchial artery arising from the distal descending thoracic aorta, supplying an intrapulmonary sequestration.

A critical element in resection of a pulmonary sequestration is the identification and control of the anomalous systemic arterial blood supply. Reports of unrecognized or uncontrolled hemorrhage from accidental division of the aberrant arteries emphasize this point.[43] This is especially true of vessels with a subdiaphragmatic origin that course through the inferior pulmonary ligament and are prone to retraction into the abdomen when severed or avulsed. Current imaging techniques allow preoperative assessment of the arterial and venous anatomy associated with these lesions and assist the surgeon in operative planning.

Other important technical points include particular care in identification of the phrenic nerve, which may travel adjacent and lateral to an extralobar sequestration. Abnormal foregut communications, whether diagnosed preoperatively or not, must be carefully sought and controlled appropriately intraoperatively. Although controversial, fetal interventions such as thoracoamniotic shunting and drainage may be helpful in certain cases of tension hydrothorax and hydrops fetalis.[19]

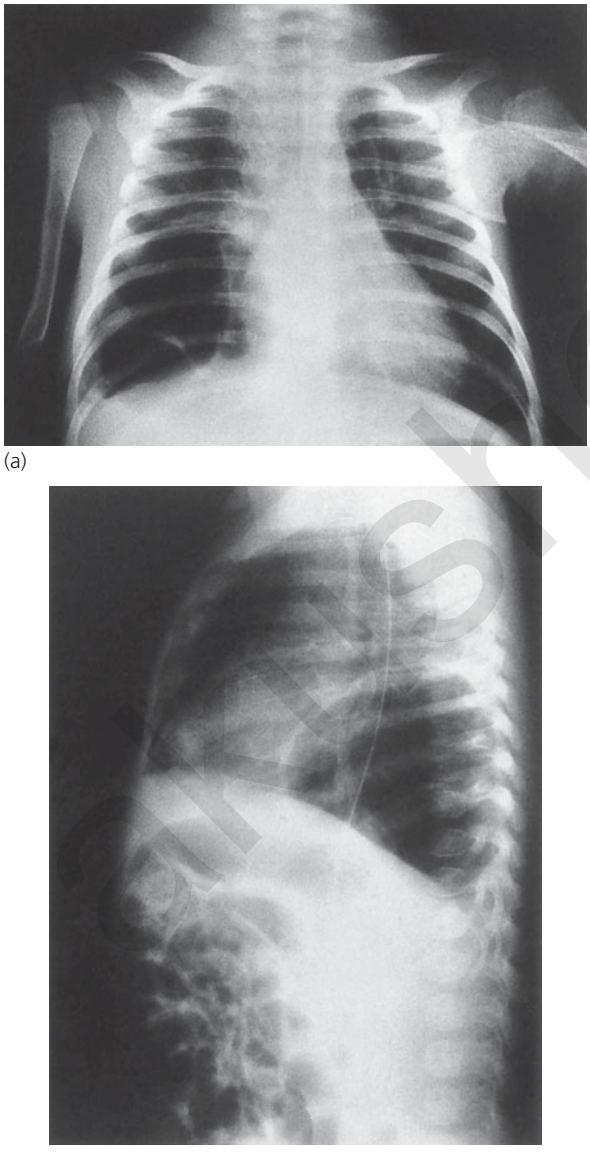
Due to the risk of infection and malignant degeneration, surgical resection is recommended for patients with pulmonary sequestration. In contemporary pediatric surgical practice, the outcome for affected infants and children should be excellent.[44,45] Similar to the CPAM population, resection is recommended before symptoms develop, and before the age of one year, when possible.

CONGENITAL BRONCHOGENIC LUNG CYSTS

Congenital lung cysts comprise up to one-third of bronchopulmonary foregut malformations in some reports.[46,47] The

most common of these lesions are bronchogenic cysts. Bronchogenic cysts are typically thick walled, unilocular lesions which are comprised of smooth muscle, cartilage, and mucous glands lined by pseudostratified ciliated columnar epithelium. It is believed that they become separated from the tracheobronchial tree during development but remain adjacent, which is where they are found clinically. Congenital lung cysts may develop at any time between the third and sixteenth weeks of gestation as the lung buds begin their initial segmental divisions and subsegmental dichotomous divisions progress.

Bronchogenic cysts arise from the trachea, bronchus, or other conducting airways but have usually lost their connection with the parent structure (Fig. 35.6). They are usually simple and contain mucus. However, air-fluid levels and infection may be seen if there is continuity with the tracheobronchial tree. Because these lesions result from abnormal development of bronchi, they may contain any of the cellular elements of the respiratory tract. In contrast to sequestrations, bronchogenic cysts have a normal bronchial blood supply. Although bronchogenic cysts may reside anywhere in the respiratory tract, including paravertebral, paraesophageal, subcarinal, and cervical areas, the majority are found in the lung parenchyma or mediastinum.[8,28,48,49]



(a)

(b)

Figure 35.6 (a) Chest x-ray showing a large cyst occupying the lower half of the right thorax. (b) Lateral view localized the cyst to the lower lobe.

More rare than the bronchogenic cysts are parenchymal lung cysts, which are thought to arise from abnormal budding of distal airways and other respiratory structures. Some consider these among the spectrum of bronchogenic cysts, however most consider them separate because of a more peripheral location and their origin from pulmonary parenchymal structures rather than a conducting airway. Regardless, the histology is variable but resembles that of the structure of origin. The general features of presentation and principles of management for peripheral lung cysts are similar to those of bronchogenic cysts, unless the anomalous structure is lymphatic in origin. In these cases, pulmonary lymphangiectasis may be present; this is manifested by diffuse bilateral cystic lung involvement and a poor clinical prognosis.[6]

Presentation and diagnosis

Some patients with bronchogenic cysts are asymptomatic. Of those with symptoms, the most common presentations are wheezing, tachypnea, or dyspnea, all related to compression of the adjacent conducting airway with partial obstruction or associated tracheomalacia. If there is a patent connection between the tracheobronchial tree and a bronchogenic cyst, patients may develop infection and present with productive cough, fever, chills, and hemoptysis. Rarely, the cyst may enlarge to the point where the mass effect leads to mediastinal displacement, airway compression, compression of normal lung, and cardiorespiratory failure.

Plain chest x-rays typically demonstrate a smooth, spherical, paratracheal, or hilar solid mass without calcifications. If airway communication or infection is present, an air-fluid level may be seen. Displacement of adjacent airway structures is commonly observed. While these cysts are generally unilocular, a honeycomb appearance can be seen in some forms of this lesion.

As with other congenital cystic lesions, axial imaging with CT or MRI will demonstrate anatomic relationships. Contrast esophagram and bronchoscopy are additional modalities by which to identify foregut communication or extrinsic compression.

Treatment

Acute respiratory decompensation from a large tense bronchogenic or lung cyst may necessitate needle or chest tube thoracostomy as a temporizing measure. Pre-existing pneumonias should be treated with preoperative antibiotics. Thereafter, or in patients with stable cysts, simple cystectomy should be performed with oversewing or stapling of any anomalous bronchial communications (Fig. 35.7). If a

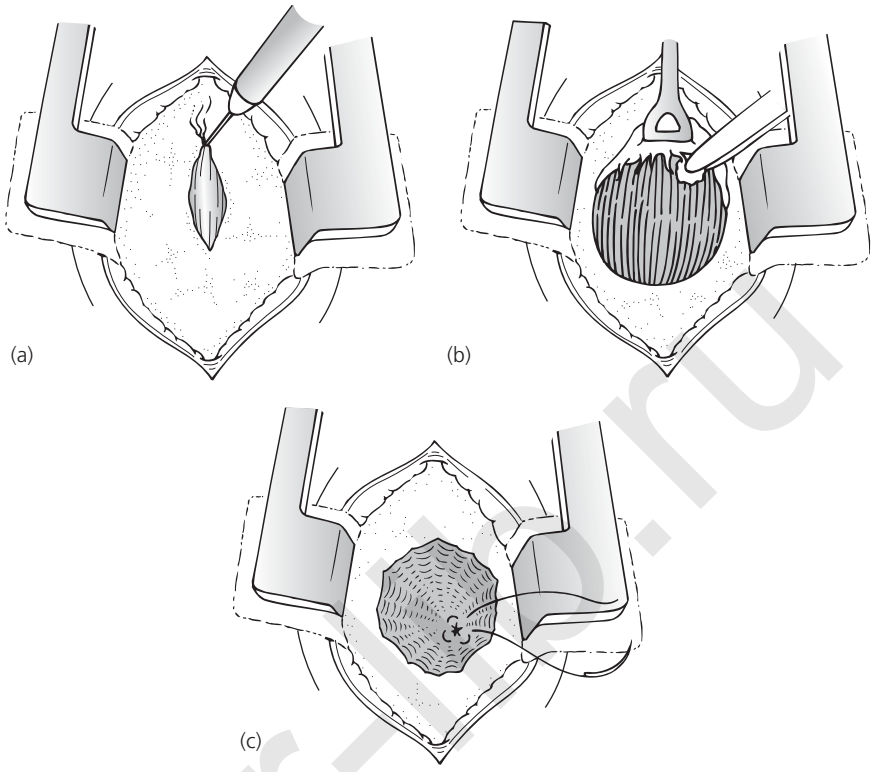


Figure 35.7 Operative technique of lung cystectomy. (a) Cyst wall exposed after incising lung tissue just above the cyst. (b) Dissection in the plane between the cyst and lung tissue. (c) Showing a small bronchus opening into the cyst – the opening is closed by oversewing it.

bronchogenic cyst cannot be removed in its entirety, remaining portions of cyst wall may be destroyed with electrocautery in this situation. For a parenchymal cyst, lobectomy, segmentectomy, or wedge resection may be necessary if simple cystectomy is judged inadequate. The principle in this circumstance is to preserve as much normal lung parenchyma as possible. Generally, lateral thoracotomy or thoracoscopy is employed for management of these lesions, although median sternotomy may be appropriate for certain central lesions. The thoracoscopic approach has been used successfully in recent years, and may be associated with shorter duration of thoracostomy drainage and hospital stay.[50]

PULMONARY HYPOPLASIA, APLASIA, AND AGENESIS

Pulmonary hypoplasia refers to the abnormal development of an entire lung or both lungs, resulting in a diminutive and potentially dysfunctional gas exchange organ. This occurs most commonly as a consequence of extrinsic compression during gestational development, although primary hypoplasia does occur. While a number of intrathoracic mass lesions may cause extrinsic compression of the lung, the most common are CDH and CPAM. Pulmonary aplasia results from developmental arrest during organogenesis some time after the sixth gestational week, resulting in a reduction in the number of alveoli. This may be marked. The physiologic consequences of both derangements can be severe and include pulmonary hypertension, persistent fetal circulation, and respiratory failure. Extraordinary measures of clinical support are frequently required,[37,51] including high-frequency oscillation, the use of inhaled nitric oxide, and extracorporeal membrane oxygenation.

Pulmonary agenesis is the complete absence of one or both lungs. The specific cause of this accident of embryogenesis is unknown, however, there is apparent failure of organogenesis at about the time the trachea divides into the two lung buds, early in the fourth week of gestation. Bilateral pulmonary agenesis is exceedingly rare and is inevitably incompatible with life. Unilateral pulmonary agenesis may be asymptomatic, however symptomatic patients may pose difficult neonatal management issues, not only from the standpoint of respiratory insufficiency, but also because of a high incidence of associated anomalies.[52–54] Older children may be asymptomatic or demonstrate non-specific respiratory symptoms including a history of failure to thrive, exercise intolerance, recurrent respiratory infections, and chest asymmetry or scoliosis. A shift in the location of heart tones and absent ipsilateral breath sounds are demonstrable on physical examination. Chest roentgenograms will demonstrate hyperinflation of the contralateral lung and possibly a fluid-filled ipsilateral hemithorax in the setting of marked displacement of the mediastinum. Absence of the ipsilateral mainstem bronchus or the pulmonary artery is a definitive finding and this can be established by endoscopy, echocardiography, axial imaging, or angiography.

LUNG SURGERY IN NEWBORNS

Although a full discussion of thoracic surgery in children is beyond the scope of this chapter, a brief description of surgical technique in neonates is relevant. A number of comprehensive texts are available.[55,56] Lung surgery in

neonates is generally similar to that in adults except that the diminutive size, the associated lesions, and the unique pathologic entities require certain special considerations. Of course, the smaller the child, the more care must be taken in order to avoid technical injury. As with all lung surgery, technical problems may result in serious and irreversible consequences. Collaboration with pediatric anesthesiologists familiar with the unique circumstances of pediatric chest surgery is essential.

Lobectomy

The patient is positioned in the lateral decubitus position, with the upper arm extended and placed over the head (Fig. 35.8a). Rolled towels and other positioning devices may be placed in order to optimize stabilization and exposure of the operative field. As always in pediatric surgery, heat loss is a concern, and insulating coverings should be placed over exposed areas without interference to the surgical site. Convective and radiant warmers should also be employed.

Optimal exposure is gained by transverse or oblique incision over the fourth or fifth intercostal space, below and lateral to the nipple to avoid cosmetic and functional damage to the breast tissue. There should be some space between the tip of the scapula and the posterior extent of the incision. This becomes important during closure of the muscle layers, especially if the incision must be extended posterolaterally. Underlying muscle and subcutaneous tissue is divided along the line of incision (Fig. 35.8b) by electrocautery. To limit postoperative morbidity from scoliosis, it is desirable and usually possible to employ a muscle sparing approach, which involves retraction of the serratus anterior and latissimus dorsi muscles, but leaves them intact. The scapula is elevated off the chest wall by retractor to gain exposure, and palpation is used to count the ribs to the correct interspace. In most situations in infants, the highest palpable rib is the second. Generally, the fourth interspace is used for a lobectomy although the fifth can be used effectively as well. The incision is then continued with electrocautery just superior to the lower rib of the selected intercostal space to avoid damage to the neurovascular bundle that runs along the inferior border of each rib (Fig. 35.8c). Care must be taken when entering the pleura to avoid injury to the lung parenchyma. A rib spreader is then placed to facilitate retraction (Fig. 35.8d). The incision may then be extended anteriorly or posteriorly if further exposure is needed. It is clear that thoracoscopic techniques in practiced hands yield similar good results, as do open techniques.

The following technique and illustrations are described for left upper lobectomy, however, the principles are the same for any lobe resection. Gentle lateral and inferior traction on the lobe exposes the hilum. The visceral pleura is carefully incised circumferentially, exposing the hilar structures (Fig. 35.9). Meticulous dissection reveals the left main pulmonary artery as it courses under the aortic arch (Fig. 35.10) and crosses the left upper lobe bronchus. Important structures to note are the left phrenic nerve anteriomedially along the mediastinum, and the recurrent laryngeal nerve branching from the vagus under the aortic arch. A review of segmental anatomy of the lung describes four main arterial branches supplying the left upper lobe, however this can be variable. These are individually encircled, ligated, and divided. This is typically done with heavy silk and using double proximal ligatures. Clips or stapling devices are suitable if appropriately sized.

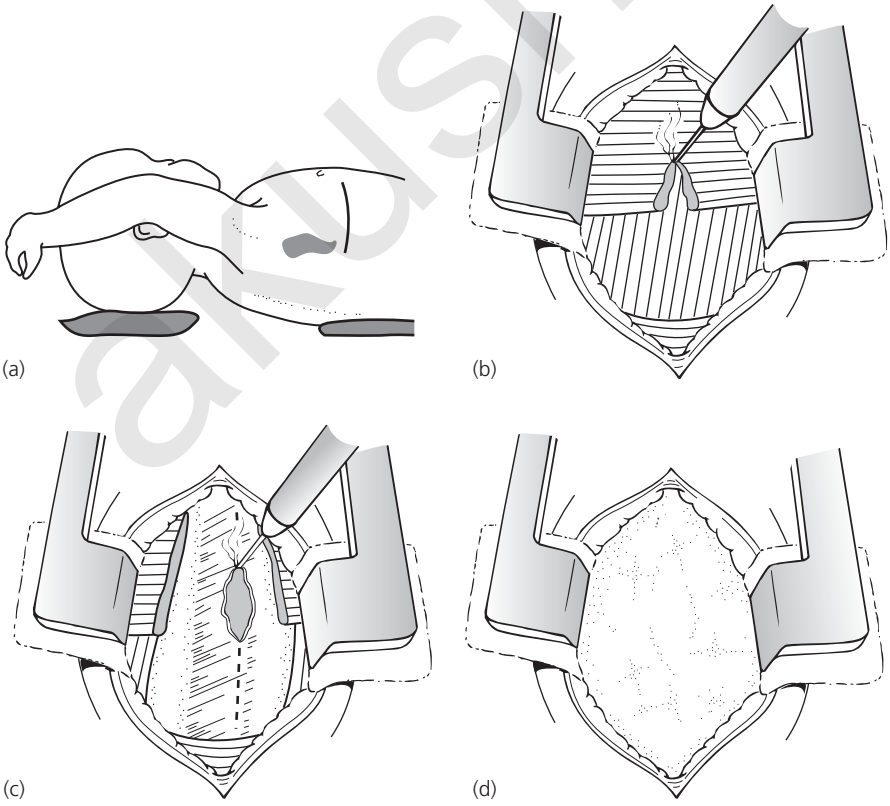

Figure 35.8 Operative technique of thoracotomy: (a) Transverse lateral incision; (b) division of external intercostal muscles; (c) division of intercostal muscles along the upper border of the lower rib; (d) retraction of ribs to expose the lung.

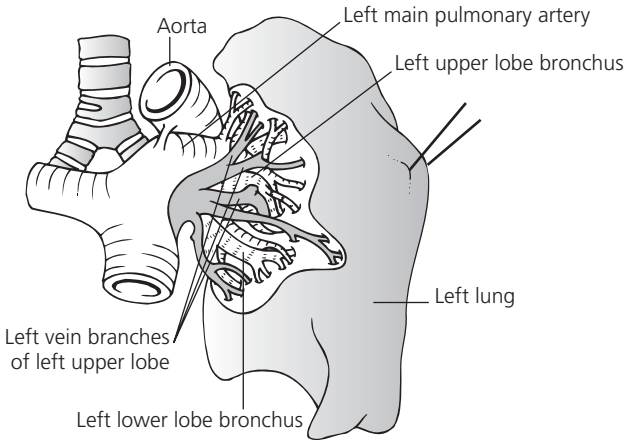

Figure 35.9 Normal anatomy of the left lung hilum containing the pulmonary artery, veins and bronchus.

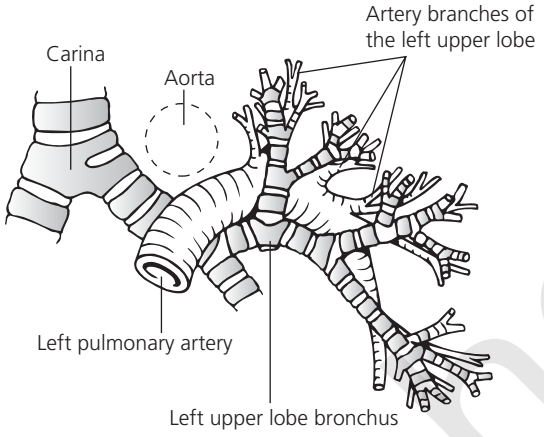

Figure 35.10 The main segmental pulmonary artery branches to the left upper lobe.

The bronchial blood supply traveling with the left upper lobe bronchus is likewise identified, controlled, and divided. Attention is then directed to the left upper lobe venous drainage. Again, individual branches are circumferentially dissected and ligated using the same approach as for the arterial circulation (Fig. 35.11). The bronchus is then dissected, clamped, and divided. Closure of the bronchial stump with commercial surgical stapling devices is appropriate in older children; however, size and other technical limitations may make this undesirable or impractical in infants. If so, a simple sewn closure is best (Fig. 35.12). Air leaks may be identified for suture repair by filling the chest with warm saline coincident with inflation of the residual lobe by the anesthesiologist. The inferior pulmonary ligament should be divided at this time to facilitate expansion of the left lower lobe, or it may be done early in the dissection to facilitate exposure. A tunneled chest tube is placed within the pleural space for drainage, and the wound or port site is closed in anatomical layers using absorbable suture. Postoperatively, the chest tube can be removed when there is no demonstrable air leak and output is minimal. Thoracoscopic

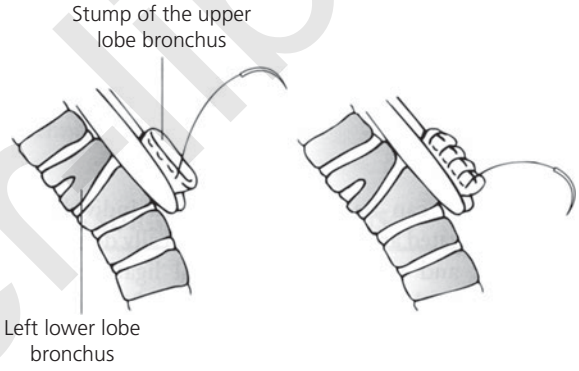

Figure 35.12 Vascular clamp placed across the left upper bronchus and the bronchus oversewn.

lobectomy employs the same surgical principles and anatomic approach, with access through three or four appropriately positioned ports.

Wedge resections and lobectomies are remarkably well tolerated in the pediatric population, although age at resection is a factor. Older children demonstrate less compensatory growth than infants. Even so, most children will have little or no functional deficit after these procedures.[18,19,57]

The need for pneumonectomy is much more limited in infants and children, but functional outcomes are still generally good. Postpneumonectomy syndrome, which is characterized by severe mediastinal shift, bronchial stretching and respiratory failure can complicate pneumonectomy. Placement of an expandable intrathoracic prosthesis has been described as a strategy to manage this potential problem.[58]

Congenital diaphragmatic hernia

PREM PURI AND TAKASHI DOI

INTRODUCTION

Congenital diaphragmatic hernia (CDH) is a common malformation characterized by a defect in the posterolateral diaphragm, the foramen of Bochdalek, through which the abdominal viscera migrate into the chest during fetal life. Recent population-based studies have reported the prevalence of CDH to be between 1 in 2600 and 1 in 3700 live births.[1,2] Approximately 80% are left sided, less than 5% are bilateral, and 15% are right sided.[1,2] The size of the defect varies from small (2 or 3 cm) to very large, involving most of the hemidiaphragm. Despite advances in neonatal resuscitation and intensive care, newborn infants with CDH continue to have high mortality. Current survival rates in population-based studies are around 55–70%.[1,2] Highly specialized centers report 80% and more, but discount the hidden mortality, mainly in the antenatal period. The high mortality and morbidity in CDH are mainly attributed to pulmonary hypoplasia and persistent pulmonary hypertension.[3,4]

EMBRYOGENESIS

The etiology of CDH is still not clearly understood. Although it is generally considered to be sporadic, there are reports of familial cases including known chromosomal aberrations, as well as autosomal recessive inheritance of unknown chromosomal origin.[5,6] The embryogenesis of CDH has been described as a failure of the pleuroperitoneal canals in the posterolateral aspect of the diaphragm to fuse during gestational week 8.[7] Consequently, the abdominal viscera including liver and bowel migrate into the thorax, which is thought to cause pulmonary hypoplasia by compression of the growing lungs. The pulmonary hypoplasia associated with CDH extends to all aspects of the lung, resulting in fewer alveoli, thickened alveolar walls, increased interstitial tissue, and markedly diminished alveolar air space and gas-exchange area.[8] Parallel to airway changes, pulmonary vasculature is abnormal with a reduced number of vessels, adventitial thickening, medial hyperplasia, and peripheral extension of the muscle layer into the smaller intra-acinary arterioles.[9] The morphology of the CDH lung furthermore has an immature appearance.[8,9] The ipsilateral lung is the most severely affected, but the changes usually extend to the contralateral lung, as well.

Recently, experimental studies have suggested that the classical view of embryogenesis of CDH may have to be revised. A toxicological nitrofen model of CDH has shown that abnormalities in the contralateral lung as well as the ipsilateral side are present even before the diaphragm starts to develop.[10] Keijzer *et al.*[11] proposed the dual-hit hypothesis to explain the observations on pulmonary hypoplasia in this model. This hypothesis proposes that the early retardation in lung development that occurs before the development of the diaphragmatic defect is caused by nitrofen, whereas the late-gestational increase in lung hypoplasia is caused by mechanical compression from herniated viscera. Kluth *et al.*[12] have shown that pleuroperitoneal canals are not wide enough to allow herniation of gut loops in rats. Several groups have shown an aberrant gene/protein expression of different growth factors and transcription factors in experimental models, as well as in infants with CDH.[13–15] Retinoid signaling pathway has been shown to be disrupted in the nitrofen model of CDH.[16,17] Vitamin A-deficient rats display pulmonary hypoplasia with CDH.[18] Furthermore, the lungs in experimental models of CDH exhibit a response to retinoic acid differing from normal lungs.[19–21] Recently, it has been reported that prenatal treatment with retinoic acid (RA), the active metabolite of vitamin A, in late gestation promotes pulmonary alveologenesis in the nitrofen model of CDH in rodents.[22] Furthermore, prenatal RA treatment has been shown to upregulate pulmonary expression levels of genes involved in lung morphogenesis in the nitrofen-induced hypoplastic lung.[23,24] Although prenatal use of RA has been controversial, these experimental data suggest that prenatal RA treatment may have a therapeutic potential to revert pulmonary hypoplasia associated with CDH.

PATHOPHYSIOLOGY

The onset and severity of symptoms depends on the amount of abdominal viscera in the chest and the degree of pulmonary hypoplasia. Postnatally, the most severely affected babies present with respiratory distress (cyanosis, tachypnea, and sternal recession) at birth. Although the major cause of this is pulmonary hypoplasia, the resulting hypoxia and hypercarbia will result in pulmonary vasoconstriction and pulmonary hypertension. This, in turn, will cause reversal to right-to-left shunting through the ductus arteriosus and the foramen ovale, and the infant enters a vicious, self-perpetuating cycle.

Several additional factors have been known to contribute to the severe pulmonary hypertension in CDH. The pulmonary vascular bed is abnormal, with increased muscularization of arterioles in a manner similar to infants with idiopathic persistent pulmonary hypertension of the newborn (PPHN).[9] Increased thickness of the media as well as the adventitia of arteries of all sizes has also been demonstrated.[25] Furthermore, vasoactive substances, such as endothelin-1 seem to be increased in infants with CDH. Kobayashi and Puri found increased blood levels of endothelin, as well as increased expression of endothelin-1 in endothelial cells in the pulmonary vasculature.[26] Endothelin-1 causes pulmonary vasoconstriction by binding to the endothelin A (ETA) receptor. The ETA receptor is ubiquitously present in the smooth muscle cells of the pulmonary vasculature,[27] and the increased endothelin-1 levels may thus adversely affect pulmonary vasoconstriction.

Hypoxia and hypercarbia may be further aggravated by a reported immaturity of the surfactant system in experimental animals and infants with CDH.[28] Others could, however, not confirm this deficiency,[29] and it has been postulated that the apparent surfactant deficiency may in fact be secondary to respiratory failure, rather than to a primary deficiency.[30]

DIAGNOSIS

CDH can be reliably diagnosed prenatally by ultrasonography at about 20 weeks of gestation. The diaphragm can be visualized and its absence is indirectly suggested by the intrathoracic presence of abdominal viscera and compression of thoracic organs.[31] An important feature to look for is the presence of the liver in thorax, if necessary using Doppler interrogation of the umbilical vein and hepatic vessels.[31] Differential diagnosis with other intrathoracic pathologies, including congenital cystic adenomatoid malformation (CCAM), bronchopulmonary sequestration, diaphragmatic eventration, and bronchogenic cyst, needs to be made. It is also of vital importance to exclude the presence of other anomalies, including neural tube defects, cardiac malformations, and chromosomal aberrations, e.g. trisomy 18 and 21. Furthermore, the degree of pulmonary hypoplasia should be assessed. The presence of liver in the chest in left-sided CDH indicates severe pulmonary hypoplasia.[32] The lung-to-head ratio (LHR – the area of the right lung at the level of the four-chamber view divided by the head circumference) has been shown to be a predictable estimation of the degree of pulmonary hypoplasia.[33] Currently, intrauterine lung measurement by magnetic resonance imaging (MRI) is being investigated as a means of estimating lung size.[34]

Postnatally, CDH should be suspected in infants with severe respiratory distress at birth or within the first few hours of life. Physical examination reveals a scaphoid abdomen, an increased anteroposterior diameter of the thorax, and mediastinal shift. Breath sounds are absent on the affected side. Associated congenital anomalies may also be seen or revealed on further examination. The definitive diagnosis is made by plain x-ray of the chest and abdomen by demonstration of air-filled loops of the bowel in the chest and a paucity of gas in the abdomen (Fig. 36.1). There is a

Figure 36.1 (a) Left congenital diaphragmatic hernia (CDH) with viscera visible in the left chest, pulmonary hypoplasia, and significant mediastinal shift to the right. (b) Right CDH with viscera visible in the right chest and mediastinal shift to the left side.

mediastinal shift to the opposite side, and only a small portion of lung may be seen on the ipsilateral side.

TREATMENT

An infant with respiratory distress requires endotracheal ventilatory support. Mask ventilation should be avoided as it will distend the stomach and further compromise respiratory status. A baby with CDH should be paralyzed and have a nasogastric tube placed to prevent distension of the stomach and bowel. CDH was previously considered a surgical emergency, where prompt surgery with reduction of the abdominal viscera allowed the lungs to expand. The increased knowledge of the pathophysiology of CDH has led to a different approach, where prolonged preoperative stabilization has proven useful. Most centers now prefer delayed surgery, with a delay of sometimes several days, waiting for the stabilization of the pulmonary circulation before surgery.[35] Surgery in CDH should be based on the optimization of clinical parameters, such as initial blood gases, to improve outcome.[36]

Preoperative treatment

An infant with respiratory distress requires endotracheal ventilatory support. Although previously aggressive hyperventilation and hypocarbia were widely used, a different approach, using gentle ventilation and permissive hypercarbia, has proven more useful in decreasing the mortality rate.[37,38] Without this approach, a high mortality rate from barotrauma can be expected.[39,40] Currently, more than 90% of international CDH registry centers cite the use of permissive hypercapnia, accepting higher $PaCO_2$ during the early course, rather than targeting low $PaCO_2$ to estimate viability and lower pulmonary vascular resistance, as a primary therapeutic guideline.[38] Several centers have shown improved survival as compared to historical controls, using a combination of gentle ventilation and delayed surgery.[38,39]

High-frequency oscillatory ventilation (HFOV) is a valuable tool in the treatment of infants with respiratory distress, since it provides effective ventilation while decreasing barotrauma. However, in CDH, HFOV has not been shown to improve the mortality or morbidity rates.[41,42] The impact of changes in HFOV settings must be monitored carefully, as high airway pressures may cause lung hyperinflation, with adverse effects on venous return, pulmonary vascular resistance, and ultimately in cardiac output.[38] In many CDH cases, the constant distending airway pressure associated with use of HFOV may be more detrimental than helpful.

Inhaled nitric oxide (iNO), which provides selective pulmonary vasodilatation without systemic hypotension, seemed to be a promising therapy,[43] but more recent conclusions seem to be that although selected infants may respond well to iNO, this response seems to be variable or temporary.[44,45] In consequence, iNO is usually used as an adjunct to conventional mechanical ventilation and HFOV while preparing for extracorporeal membrane oxygenation (ECMO) cannulation.

ECMO is a life support system used in the treatment of CDH when conventional mechanical ventilation fails. ECMO employs partial heart–lung bypass providing rest to the lungs for long periods of time during which it is hoped that the lung and pulmonary vasculature will mature. The evidence supporting the use of ECMO is conflicting,[46] although some evidence seems to support the use of ECMO in selected cases.[47,48] Several centers advocate the use of ECMO only in patients with evidence of a 'honeymoon period', i.e. patients with adequate gas exchange for a period preceding the deterioration in respiratory status. Others use preductal blood gases, where only patients with a period of normal preductal pO_2 and pCO_2 will be considered for ECMO.[38] It has recently been suggested that the late implementation of ECMO may lead to reperfusion injury, which causes reduced survival, and that ECMO intervention prior to reaching the cut-points may improve survival in CDH patients.[46]

Since some studies suggest surfactant deficiency in CDH infants, surfactant replacement has been tried as an adjunct to conventional mechanical ventilation or ECMO. The only randomized clinical trial using surfactant in CDH tested 17 infants >34 weeks' gestation who were already on ECMO.[49] The results suggest that postnatal surfactant deficiency may be more persistent in CDH infants than non-CDH infants on ECMO; however, the study showed no improvement with surfactant treatment. Thus, surfactant administration may not be without risk and the benefits still remain unclear.[38]

Several novel therapies of ventilation are in evolution, some of which have been tried in CDH infants. Partial liquid ventilation has been shown to be beneficial in some cases, and some preliminary promising results have been obtained by the use of intratracheal pulmonary ventilation (ITPV).[50] Both of these methods provide efficient ventilation, while apparently protecting the lung against barotrauma. However, none of these methods can improve the fundamental problem with the CDH lung, i.e. hypoplasia, and therefore share the shortcomings of ECMO treatment.

Appropriate fluid management, as well as the use of inotropic agents, is crucial in the treatment of CDH. Adequate sedation and pain management should be used, but the use of paralysis is controversial. Surgery should be performed when the infant is stable with minimal ventilator settings, is diuresing well, and the chest x-ray is improving.

Operative repair

The most straightforward part of the management of CDH is operative repair of the diaphragmatic defect (Fig. 36.2). The most commonly preferred approach is abdominal, offering good exposure, easy reduction of the abdominal viscera, and recognition and correction of associated gastrointestinal anomalies.[50] The contents of hernia are gently reduced in the abdomen. On the right side, the small intestine and the colon are first reduced and the liver is withdrawn last. After the hernia is reduced, an attempt is made to visualize the

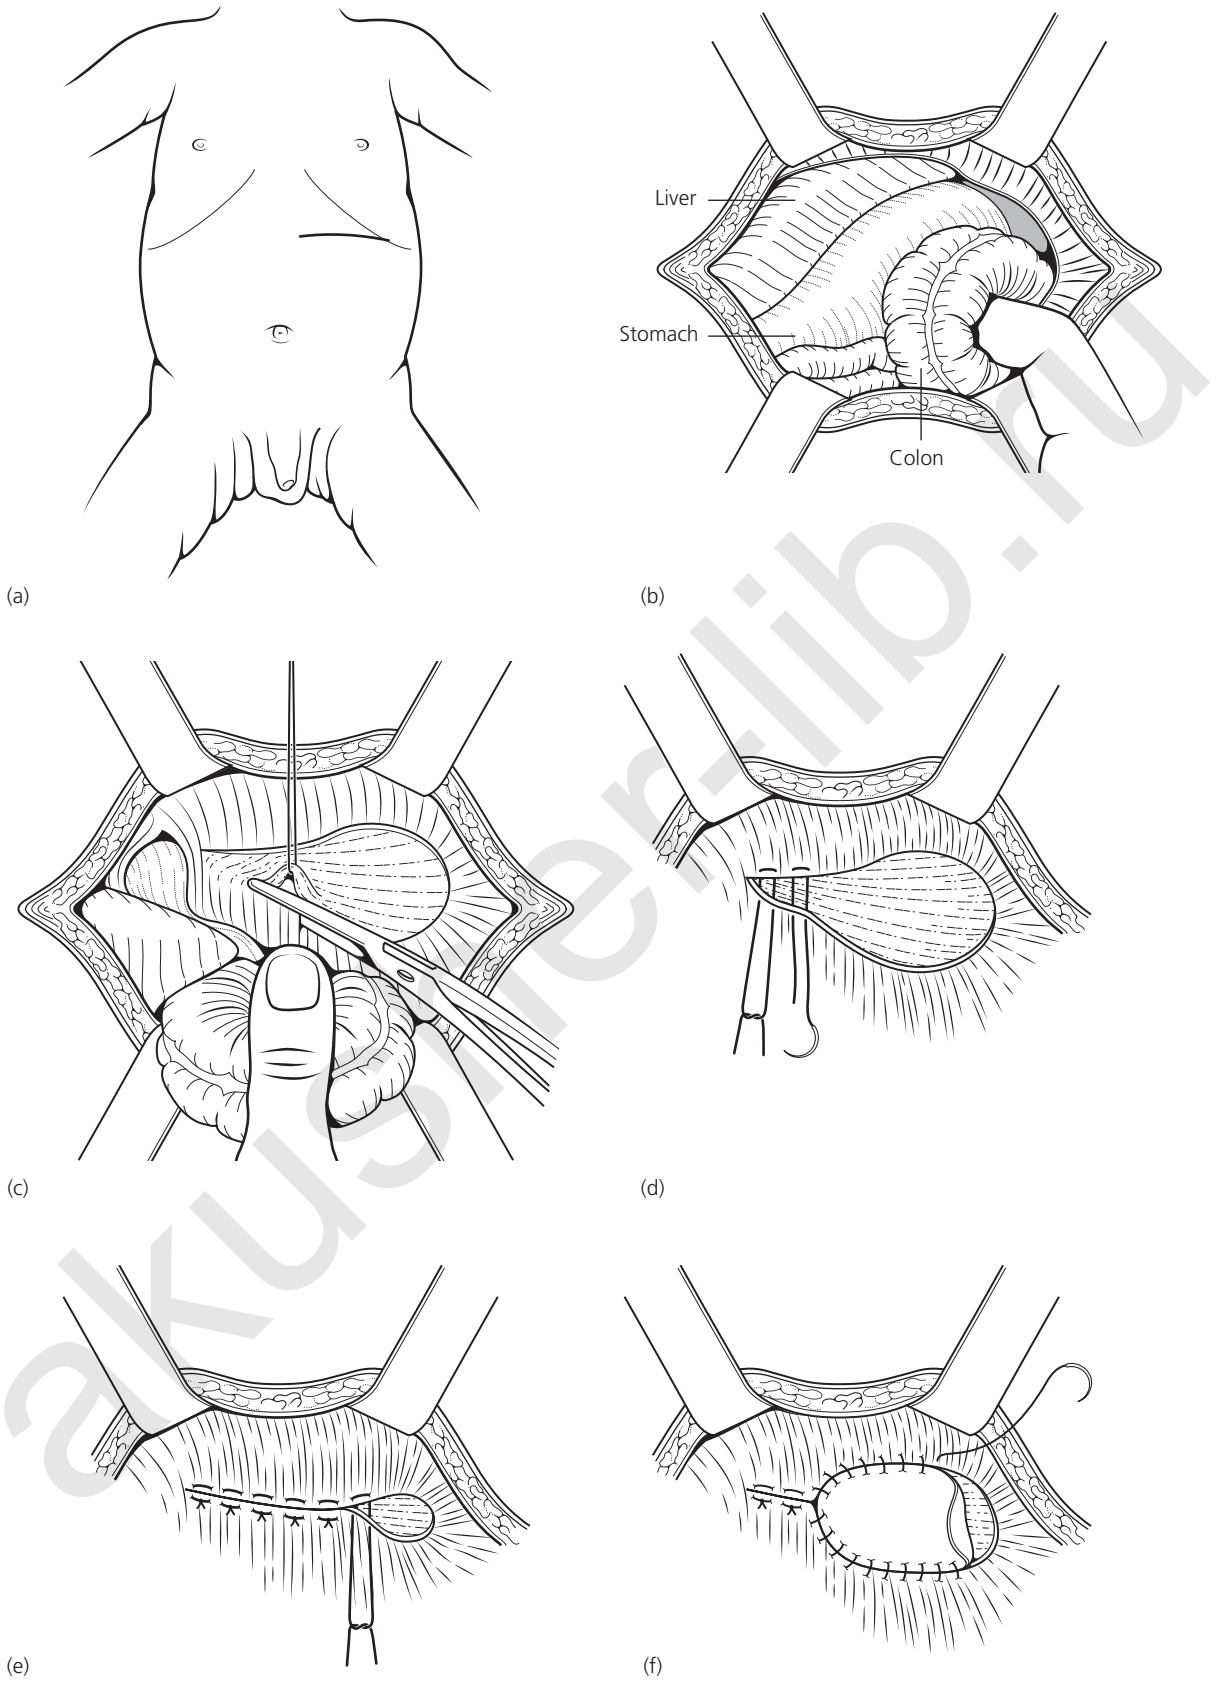

Figure 36.2 Operative repair of congenital diaphragmatic hernia (CDH). (a) A subcostal transverse muscle cutting incision is made on the side of the hernia. (b) The contents of hernia are gently reduced in the abdomen. (c) After inspecting diaphragmatic defect, posterior rim of the diaphragm is mobilized by incising the overlying peritoneum. (d, e) The defect is then closed by interrupted non-absorbable sutures. (f) Large diaphragmatic defect is closed by using Surgisis soft tissue graft.

ipsilateral lung. Most diaphragmatic defects can be sutured by direct sutures of the edges of the defect. Although the anterior rim of the diaphragm is usually quite evident, the posterior rim may not be immediately apparent and may require dissection for delineation. There is usually a layer of peritoneum running from the retroperitoneum over the lower edge of the defect. Division of this tissue usually allows visualization of the posterior edge of the diaphragm. The defect is closed by interrupted non-absorbable suture.

Sometimes, the posterior rim is absent altogether, in which case the anterior rim of the diaphragm is sutured to the lower ribs with either periosteal or pericostal sutures. In some cases, the defect is too large for primary closure, and prosthetic material is used. Currently, the most commonly used prosthetic material is Surgisis® soft tissue graft, which is incorporated into the adjacent tissue (Fig. 36.2f). An alternative to this approach is a muscle flap taken from the transversus abdominus, leaving the outer abdominal muscle layers intact. This technique should not be performed on patients on ECMO, or at risk of ECMO treatment, because of the risk of hemorrhagic complications. It also should be noted that the operations involving muscle flaps are too long and complex for critically ill patients and can lead to unsightly chest deformities. If the abdominal cavity is small, gentle stretching of the abdominal wall will enable safe closure in most patients. Whether a chest drain should be inserted prior to closure is controversial. The argument against the use of chest drain is in avoidance of barotraumas as it increases the transpulmonary pressure gradient.

Minimally invasive surgery has been argued to reduce the trauma and physiological disturbance of surgery. As endosurgical repair of CDH gains popularity, a systematic review and meta-analysis have recently observed that neonatal thoracoscopic CDH repair has greater recurrence rates and operative times, but similar survival and patch usage compared with open surgery.[51]

Postoperative treatment

Postoperative care should be performed in the same manner as preoperatively, with a close watch on fluid management, ventilatory support, and hemodynamic monitoring.[52] Some infants show improvement in oxygenation in the 'honeymoon period', but usually deteriorate 6–24 hours later. This deterioration is due to pulmonary hypertension and persistent fetal circulation with an increase in pulmonary artery resistance, elevated pulmonary artery pressure, and right-to-left ductal and preductal shunting leading to hypoxemia. Pulmonary hypertension is probably caused by multiple factors, such as increased abdominal pressure with impaired visceral and peripheral perfusion, limited diaphragmatic excursion, overdistension of the alveoli in the hypoplastic lungs with diminished alveolar-capillary blood flow, release of vasoactive cytokines, and deterioration in pulmonary compliance after surgical repair. Sudden deterioration in the patient's oxygenation status should raise the suspicion of pneumothorax. Infection complications including pneumonia and septicemia are not uncommon.

PRENATAL TREATMENT

A prenatal intervention that can reverse the lung hypoplasia might theoretically improve prognosis. Fetal surgery, with primary repair of the defect, was shown to be a promising way of dealing with pulmonary hypoplasia in experimental and initial clinical studies.[53,54] However, clinical application of anatomical fetal CDH repair was abandoned once it became clear that it was not possible in fetuses with liver herniation and that those without did not benefit from the intervention.[53,54]

A fetoscopic tracheal occlusion (FETO) was then developed as it became clear from experimental studies that lung growth can also be triggered by tracheal occlusion. The effect on lung growth by tracheal occlusion and retention of pulmonary fluid seems to be exerted by pulmonary stretch itself, which in turn causes upregulation of different growth factors.[55] Vascular endothelial growth factor (VEGF) has been shown to be upregulated by pulmonary stretch, and may contribute to pulmonary growth by increasing angiogenesis.[56] Insulin-like growth factor-I (IGF-I) gene expression is reduced in the lung parenchyma of lambs with surgically created CDH. IGF-I is, however, restored to normal or increased levels after tracheal ligation or postnatal lung distension.[57] A similar method of pulmonary stretch has been tried as a means of inducing postnatal lung growth in CDH infants. The lungs are then continuously distended with perfluorocarbon during ECMO treatment. Experimental as well as initial clinical results are promising.[58]

Sustained tracheal occlusion leads to a decreased number of type II pneumocytes and deficient surfactant production.[59] In sheep, cycles of 47 hours of tracheal occlusion and 1 hour of release yielded sufficient lung growth with normal morphology and type II cell count.[59] As yet, it is impossible to achieve this clinically, but the study proves that timing and duration of the occlusion period are crucial for the quality and response of airways and pulmonary vessels. All this leads us to the concept of tracheal occlusion in the late cannalicular phase with prenatal reversal.[60] Additional interventions such as corticosteroid or surfactant administration may improve postnatal lung function.

FETO has undergone further evolution, and currently a technique using one port, and the endoscopic placement of a tracheal balloon, is used.[61,62] In Europe, Deprest *et al.*[62] have performed FETO procedure percutaneously under epidural anesthesia in an average time of 20 minutes, and they have achieved survival rates of 50% compared to 9% for concurrent non-randomized patients with similar prognostic criteria. In their report, none of the patients has delivered before 37 weeks of gestation, a marked improvement compared to the 33 week average in a previous randomized controlled study in the United States reported by Harrison *et al.*[61] Interestingly, the European group has achieved the best results using balloon deflation by repeat tracheoscopy at 34 weeks gestation.[62] Prenatal release of the occlusion permits vaginal delivery and facilitates delivery closer to home, using standard neonatal therapy. The most common complication of FETO procedure is preterm premature rupture of the membranes (PPROM), which is probably iatrogenic in

nature.[63] PPROM does have an impact on gestational age at delivery and complicates balloon removal.[63] As FETO has the potential of increasing survival and reducing morbidity, this needs to be investigated in prospective randomized trials.

In order to deliver infants with fetal tracheal occlusion, a special method of delivery had to be developed, the *ex utero* intrapartum treatment procedure (EXIT). Cesarean section is performed with maximal uterine relaxation, and while keeping the infant on placental support, the upper airway can be instrumented. This method is useful as a means of delivering infants with other conditions affecting the upper airway as well, e.g. cystic hygroma of the neck or laryngeal atresia.[64]

PROGNOSIS

Although several centers have reported an increased survival rate using novel therapies, including ECMO,[35,44] the fact remains that the hidden mortality rate is high.[65] Since most centers are only aware of the cases that reach their center alive, pre- and perinatal mortality is usually not included. Recent population-based studies have reported that survival rates in CDH are around 55–70%.[1,2] Highly specialized centers report 80% and more, but discount the hidden mortality, mainly in the antenatal period. The high mortality and morbidity in CDH are mainly attributed to pulmonary hypoplasia and persistent pulmonary hypertension.[3,4]

It is of vital importance to recognize variables that predict pre- and perinatal mortality, since they will influence the information given to the family, as well as deciding eligibility to prenatal intervention. First, other lethal malformations, as well as chromosomal aberrations, should be excluded. In isolated left-sided CDH, herniation of the liver into the chest has been shown to be a predictor of high mortality, whereas survival is highly likely if the liver is not herniated into the thorax.[29,66] Furthermore, the LHR has been shown to adequately predict outcome in left-sided, 'liver-up' CDH. In a prospective series, an LHR <1.0 was associated with 100% mortality, whereas all patients with an LHR >1.4 survived.[30] Fetal MRI is a useful tool to measure lung volume and thereby to predict the severity of pulmonary hypoplasia.[31]

Several centers use preductal PaO_2 as a predictor of survival.[35] A study of computer-assisted analysis of the postoperative chest x-ray has been shown to predict pulmonary hypoplasia.[67] However, accurate preoperative predictors are needed in order to avoid placing patients with lethal pulmonary hypoplasia on ECMO.

LONG-TERM OUTCOME

Recent improvement in the treatment of infants with CDH has increased the survival of more severely affected infants. Long-term follow up of those patients has led to the recognition of pulmonary and extrapulmonary morbidities that were not previously recognized. Pulmonary morbidity is the most common and significant problem in CDH infants surviving beyond the neonatal period. Patients treated with ECMO or requiring patch repair of the diaphragmatic defect appear to have a higher risk of developing pulmonary morbidity.[68]

In CDH survivors, the severity of chronic lung disease may require prolonged ventilator support and tracheostomy.[68,69] Several follow-up studies have reported that CDH survivors suffer from recurrent respiratory tract infections in infancy and early childhood.[70,71] Neurodevelopmental abnormalities have been frequently described in CDH survivors. Developmental delay, motor, cognitive and behavioral disorders have been reported in patients with CDH.[72,73] Sensorineural fearing loss (SNHL) represents a peculiar form of neurological sequel in CDH survivors.[72,73] SNHL is found in CDH survivors treated with ECMO and without ECMO, suggesting that the use of ECMO is not the only predisposing factor for SNHL.[74] Because CDH survivors are exposed to a number of other potential predisposing factors, including the use of ototoxic medications and prolonged mechanical ventilations with high oxygen tensions, they are at high risk of developing SNHL.

A significant number of CDH survivors have shown gastrointestinal symptoms, including gastro-esophageal reflux (GER), failure to thrive (FFT, defined as weight <25th or 5th centile), and late bowel obstruction.[75,76] A review of the incidence of GER among CDH patients in different studies has suggested that nearly 40% of babies operated on for CDH will have symptomatic GER, half of which require antireflux surgery.[77] The most frequently reported predictor of antireflux surgery is the need of diaphragmatic patch repair.[68,78] Recurrence is more common in patients repaired with a prosthetic patch. Although most survivors beyond the neonatal period are able to lead a normal life, children with CDH should be followed up and assessed for respiratory status until adolescence.

Extracorporeal membrane oxygenation for neonatal respiratory failure

JEFFREY W GANDER AND CHARLES JH STOLAR

INTRODUCTION

Extracorporeal membrane oxygenation (ECMO) is a life-saving technology that uses partial heart/lung bypass for extended periods of time. It is a supportive modality, rather than a therapeutic tool, that provides gas exchange and perfusion for neonates with an acute, reversible respiratory or cardiac condition. During the time on ECMO, the patient's cardiopulmonary system is allowed to 'rest', thus being spared from the potentially deleterious effects of high FiO_2, high airway pressure, traumatic mechanical ventilation, and perfusion impairment. ECMO was first used in newborns in 1974. Since then, the Extracorporeal Life Support Organization (ELSO) has recorded approximately 28 000 newborns who have been supported with ECMO for a variety of cardiorespiratory disorders. The most common disorders in the newborn treated with ECMO are meconium aspiration syndrome (MAS), persistent pulmonary hypertension of the neonate (PPHN), congenital diaphragmatic hernia (CDH), sepsis, and cardiac support. Depending on the indication for ECMO, the outcome is varied, but overall, a survival rate of 80% has been reported for newborns treated in this high (>80%) mortality group.[1] This chapter discusses the selection criteria for ECMO in neonates and the management of these babies while on ECMO. It goes on to discuss ECMO for use in difficult clinical scenarios, such as CDH, and finally review outcome and follow up of neonates treated with ECMO.

SELECTION CRITERIA FOR NEONATAL ECMO

The selection criteria for newborns are based on historic experience from multiple institutions, patient safety, and mechanical limitations related to the biomedical devices.

Gestational age

The gestational age should be at least 34 weeks. In the early experience with ECMO, premature infants (<34 weeks' gestation) who were offered ECMO developed significant morbidity and mortality related to intracranial hemorrhage (ICH).[2] Despite refinement of ECMO techniques in the 1980s, premature infants continue to be at risk for ICH. This may be due to the fact that ependymal cells within the brain may not be fully developed in preterm infants, thus making them susceptible to intracranial bleeding. The incidence of ICH appears to be directly related to gestational age. Hardart *et al.*[3] reported a 22% incidence of ICH at 32 weeks versus 12% at 36 weeks. The systemic heparinization necessary to maintain a thrombus-free ECMO circuit also increases the risk of bleeding complications.

Birth weight

The birth weight should be nearly 2000 g as children under this weight present unique anatomical challenges to cannulation due to the limitation of cannula size. The smallest single-lumen ECMO cannula is 8 French (Fr) gauge. Flow through the tube is inversely related to length of the tube as well as directly related to the radius of the tube by a power of 4. If the vein is small, then the cannula will be small, resulting in flow that will be reduced by a 4th power. From historic experience, if the baby weighs less than 2 kg, then the difficulty of the placement of the cannula in conjunction with the inadequate flow from small catheters make ECMO in these small babies challenging.

Bleeding complications

The baby should have no active bleeding or major coagulopathy. Patients with uncorrectable coagulopathy, ongoing

uncontrollable bleeding, or sepsis and its associated coagulopathy are at high risk of bleeding complications while on ECMO. The need for continuous systemic heparin therapy while on ECMO adds to this risk of bleeding.[4] Therefore, prior to initiating ECMO, bleeding should be controlled.

Intracranial hemorrhage

The infant should not have an intracranial hemorrhage. ECMO candidates with a pre-existing intracranial hemorrhage may exacerbate the problem secondary to the use of heparin and altered cerebral blood flow while on ECMO. Infants with small interventricular hemorrhages (grade I–II) may be considered for ECMO on an individual case basis, but these cases should be closely monitored for worsening bleeding. Patients with previous intracranial bleeds, cerebral infarcts, and other risk factors (prematurity, coagulopathy, ischemic central nervous system injury, or sepsis) are particularly at high risk for severe neurologic consequences.[2,5] Pre-ECMO discussion with parents in this circumstance is especially important.

Reversible disease process

The baby should have a reversible lung disease and be supported by aggressive mechanical ventilation for no longer than 10–14 days prior to ECMO. Babies who have had prolonged exposure to high-concentration oxygen and positive-pressure ventilation develop bronchopulmonary dysplasia (BPD).[6] Recovery from this type of irreversible lung injury may take from weeks to months to occur, if at all. Support with ECMO can be beneficial for reversible lung disease over a relatively short period of time (2–3 weeks). However, even a lengthy ECMO course is unlikely to be sufficient to permit recovery of the irreversible fibrotic changes that occur to the lung following sustained barotrauma and/or oxygen toxicity. In addition, with a longer ECMO run, the chance of infection, bleeding complications, thromboembolic events, and mechanical failure increase.

In a retrospective case–control study which reviewed the records of ECMO patients over 66 months, patients with oxygen dependency at one month of age and radiographic evidence of BPD were compared to patients without these findings.[7] Patients with BPD were placed on ECMO at an older mean age than non-BPD patients (135 versus 50 hours old). The BPD group had longer mean ECMO courses as well (203 versus 122 hours). The authors suggest that risk of BPD from high levels of ventilatory support occur with as little as 4 days of assisted ventilation.

Coexisting anomalies

The baby should have no lethal congenital or chromosomal anomalies such as trisomy 13 or 18. ECMO is not intended to delay an inevitable death. Other treatable conditions, such as total anomalous pulmonary venous return (TAPVR) and transposition of the great vessels (TOGV), may initially manifest with respiratory failure. If possible, an echocardiogram should be rapidly obtained to determine the need for ECMO or cardiac surgery.

Bridge to diagnosis

Every effort should be made to establish a clear diagnosis before the initiation of ECMO. However, if that is not possible, then the diagnosis can be established during the course of ECMO. For example, pulmonary vein misalignment, a uniformly fatal anomaly of deficient alveolar capillaries and anomalous veins within the bronchoarterial bundles, presents with symptoms of persistent pulmonary hypertension unresponsive to treatment.[8] These children are often placed on ECMO. If the pulmonary hypertension is intractable despite support by ECMO, then the diagnosis of alveolar capillary dysplasia should be entertained.[9] The diagnosis is made via an open lung biopsy while on ECMO. If alveolar capillary dysplasia is confirmed, then withdrawal of ECMO support should occur. In addition, some important cardiac conditions such as TAPVR, TOGV, and intact septum, may present as respiratory failure, as mentioned above under Coexisting anomalies. These patients are occasionally placed on ECMO before an accurate diagnosis can be made. Once this is established, appropriate therapy should be instituted.

Failure of medical management

The baby must have first failed optimal medical management. This is often the most difficult criterion to elucidate. Different institutions have varying specialties, capabilities, and expertise. 'Optimal' medical management is a subjective term which may vary widely. Current optimal medical management may include pharmacologic support with vasodilator or vasoconstrictive agents, inotropic agents, sedatives, and analgesics. Ventilatory support usually begins with conventional strategies, but may change to include exogenous surfactant administration, induced respiratory alkalosis, hyperoxia, high positive expiratory-end pressure (PEEP), inverse I:E ratios, or high-frequency ventilation. Early use of steroids in the management of respiratory distress syndrome (RDS) has been proposed to decrease pulmonary inflammation, and achievement of metabolic alkalosis may be preferred to respiratory alkalosis.[10] The merits and demerits of all these treatment strategies are beyond the scope of this chapter.

Innovations in medical management have been developed, which have prevented ECMO in patients who otherwise meet the criteria for ECMO support. These innovations in management include high-frequency oscillatory ventilation, permissive hypercapnea with spontaneous ventilation and nitric oxide. In 1985, Wung *et al.*[11] used a non-traditional approach to the management of patients with persistent pulmonary hypertension. Hyperventilation and hyperoxia were not emphasized, and muscle relaxants were not used.

Permissive hypercapnea in conjunction with spontaneous ventilation was employed. In the series of 15 patients, a $PaCO_2$ of 50–80 mmHg and a PaO_2 of 40 mmHg were tolerated and low-pressure ventilator settings were employed to provide adequate chest wall excursion. These patients, who met institutional criteria for ECMO, survived with this medical approach alone.

Other, more objective criteria, have been established to quantify respiratory failure and aid in determining which infants should be placed on ECMO. High-pressure ventilator settings (peak inspiratory pressure (PIP) >40 cmH_2O, PEEP >7 cmH_2O, intermittent mandatory pressure (IMV) >100 and FiO_2 of 1.0) have correlated with mortality. In addition, studies have examined arterial oxygen pressure (PaO_2 <40 mmHg), alveolar-arterial oxygen gradient (A-aDO_2 >625 mmHg for 4 hours), and oxygenation index (OI >40) as predictors of mortality as well.[12–15] However, some have argued that the alveolar–arterial oxygenation gradient and oxygenation index should not be heavily weighted because these factors can be manipulated by ventilator settings.

CLINICAL MANAGEMENT OF NEONATES ON ECMO

Veno-venous versus veno-arterial ECMO

A decision is first made whether the infant would best be served with veno-venous (VV) or veno-arterial (VA) support. VV support delivers oxygen for respiratory indications. VV ECMO can be performed through a double-lumen catheter which is placed in the right internal jugular vein. The double-lumen catheter both drains deoxygenated blood and returns oxygenated blood to the right atrium. Double-lumen catheters of 12–15 Fr gauge are commonly used in the newborn. Bi-caval dual lumen cannulas have recently been designed for neonates. Deoxygenated blood is drained both proximally and distally on the cannula from the superior vena cava and inferior vena cava, respectively, and oxygenated blood is delivered through a single opening directed towards the tricuspid valve. These cannulas are constructed with Elast-Eon®, a combined polyurethane elastomer and silicone gel, which makes them resistant to kinking and thus improves flow characteristics. This is the primary advantage over the traditional VV cannulas which are prone to kinking. However, clinical outcomes between these two cannulas have not been studied.

As opposed to VV ECMO, VA ECMO not only delivers oxygen for respiratory failure but also provides circulatory support in the event of cardiac failure, difficulty weaning from cardiopulmonary bypass, or occasionally CDH anatomy. In these cases, VA support is provided by venous drainage of the right atrium through a cannula inserted in the internal jugular vein (Fig. 37.1). Oxygenated blood is returned through a cannula in the carotid artery. Patients who present with profound lactic acidosis, hypoxic ischemia, and end organ failure often have a component of cardiovascular collapse and may also require the circulatory support of VA as opposed to VV ECMO.

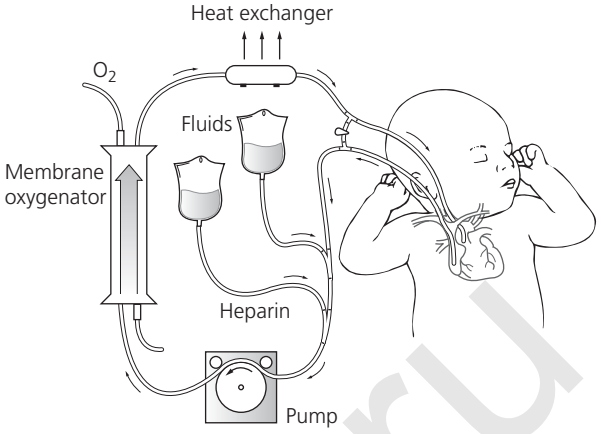

Figure 37.1 Schematic of completed veno-arterial extracorporeal membrane oxygenation (ECMO) circuit. Extrathoracic cannulation of the right atrium and ascending aorta allows venous drainage to a servo-controlled valley pump and arterial return directly to the heart and brain. Oxygenation and CO_2 removal is provided by a non-porous silicone membrane oxygenator. The blood is rewarmed before returning to the infant. All parenterally administered substances, such as heparin, fluids, blood products, and drugs are given directly into the circuit.

Cannula management

The preferred site for cannula placement is in the vessels of the right neck. The reason for this is that the femoral vessels are too diminutive for cannulation in a neonate. The internal jugular vein is accessed via an open procedure. During the open procedure, muscle relaxants are given to prevent the inadvertent aspiration of air into the vein. In the event of VA ECMO, the carotid artery is dissected and identified for catheter placement. After placement of the catheters and initiation of ECMO flow, the catheters are carefully secured with sutures to the blood vessel and skin (Fig. 37.2).

The position of the catheter is confirmed in two ways. First, a chest radiograph is performed, which can grossly demonstrate catheter position. The tip of the venous cannula should be located within the right atrium, while the tip of the arterial cannula should be located in the ascending aorta. The second mode of confirming cannula placement is cardiac echocardiography. The double-lumen catheter should be visualized within the right atrium, venting the return oxygenated blood through the tricuspid valve to minimize recirculation. If there is persistent difficulty maintaining flow due to poor venous withdrawal, the possibility of a catheter problem must be entertained and further imaging should be performed to confirm the proper position.

Prime management

The tubing of the ECMO circuit is initially circulated with carbon dioxide gas. This is followed by the addition of crystalloid and 25% albumin solution. The albumin coats the tubing to decrease its reactivity to circulating blood. The carbon dioxide gas dissolves into the fluid. Approximately 2 units of packed red blood cells are required for initial priming

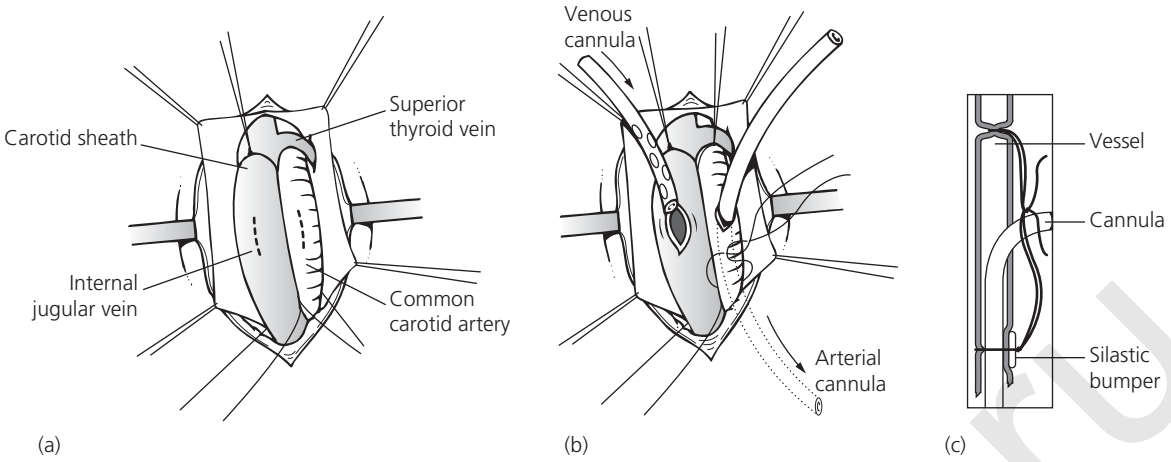

Figure 37.2 Details of the cannulation procedure. (a) The carotid sheath is opened with the sternocleiodomastoid muscle retracted laterally. This exposes the common carotid artery and internal jugular vein. (b) The infant is anticoagulated after the vessels are dissected and then ligated cephalad. A 10 Fr arterial cannula is passed into the ascending aorta by an arteriotomy. A 12–14 Fr venous cannula is passed into the right atrium by the venotomy. (c) The cannulas are fixed in position by ligation over a Silastic® bumper to facilitate removal. The two ligatures on each vessel are then tied together. After the incision is closed, the cannulas are also sutured to the mastoid process and connected to the ECMO circuit.

of the pump, which displaces the crystalloid and colloid in the circuit. One gram of calcium gluconate is added to minimize arrhythmias once going onto ECMO. Sodium bicarbonate and heparin are added to the circuit as well.

The initial pH, oxygen content, and carbon dioxide content of the circuit are then measured and adjusted to physiologic parameters. If the prime blood is acidotic, this may exacerbate the infant's condition; or, if the primed circuit has a low carbon dioxide content, this may cause metabolic problems for the neonate. Additionally, a heat exchanger warms the prime to normal body temperature. In summary, the primed circuit must be physiologically compatible with life prior to initiating ECMO to maximize support and prevent initial worsening of the child's condition.

Pump management

The goal of ECMO is to maintain adequate pump flow, which will result in good oxygen delivery to the tissues and organs. Oxygen delivery to the infant is dependent on the speed or rotations per minute (r.p.m.) of the roller pump as it non-occlusively propels the volume of blood in the 'raceway' (tubing within the roller pump housing). With VA ECMO, adequate perfusion and oxygen delivery can be monitored by the pH and PO_2 of a 'mixed venous' blood sample (pre-oxygenator blood sample). The flow of the roller pump should be adjusted to maintain a mixed venous PO_2 of 37–40 mmHg and saturation of 65–70%. With VV ECMO, the 'mixed venous' sample may not be a reliable indicator of perfusion as recirculation may produce a falsely elevated PO_2. Therefore, other indicators of poor perfusion should be followed: persistent metabolic acidosis, oliguria, seizures, elevated liver function tests, and hypotension. If oxygen delivery is found to be inadequate, then the r.p.m. of the pump may need to be increased to improve perfusion.

Roller pumps roll against the tubing to propel the blood towards the oxygenator. This area of contact is at risk for tubing rupture over time. To reduce the risk of rupture, the 'raceway' is advanced regularly after temporarily stopping the pump flow. Tubing rupture is a rare event, less than 1% of ECMO runs per year, due to modern materials such as Supertygon® (Norton Performance Plastics Corporation, Akron, OH, USA), a chemically altered polyvinyl chloride (PVC).[1]

Oxygenator management

The silicone membrane (envelope) oxygenator (Avecor, Minneapolis, MN, USA) is critical to the success of ECMO and long-term bypass. The mechanism of gas exchange occurs when blood in the tubing enters a manifold region and is distributed around the envelope of a silicone membrane lung. Oxygen flows through the inside of the membrane envelope in a countercurrent direction to the flow of blood. Oxygen diffuses across the silicone membrane into the blood as carbon dioxide is eliminated. The oxygenated blood drains into a manifold and is returned to the infant via a heat exchanger.

A thrombus may form in the oxygenator over time. As a thrombus extends, the membrane surface area is decreased, resulting in decreased oxygen and carbon dioxide transfer. This can lead to increased resistance to blood flow. The gaseous portion of the oxygenator may also develop obstructions, which may lead to air emboli. Long-term use may wear the silicone membrane, resulting in blood and water in the gas phase.

Most ECMO circuits measure a pre- and post-oxygenator pressure. The difference in these two pressures, the ΔP, can help determine when an oxygenator is failing. An elevated pre-oxygenator pressure with a stable post-oxygenator pressure, thus elevated ΔP, likely means that there is an obstruction to

blood flow in the oxygenator, often from thrombus. There is no absolute ΔP value that mandates replacement of an oxygenator. However, a rapid increase in this value with the anticipation of continued ECMO support should alert the practitioner to the need for replacement of the oxygenator. In addition, a larger oxygenator may also be required if the gas and blood flow rating of the old oxygenator are exceeded in order to maintain adequate perfusion.

Some centers have begun to use hollow-fiber oxygenators, such as the QuadroxD® oxygenator (Jostra Medizintechnik AG, Hirrlingen, Germany) for neonates. The oxygenator uses less priming volume (250 mL) and has a smaller surface area. The decreased surface area allows for more efficient gas exchange and reduces the potential for thrombus formation.[16] In addition, the resistance across the oxygenator is smaller than the silicone oxygenator, less than 100 mmHg. This may cause less disruption of red blood cells.

Volume management

While on ECMO, maintenance fluids for a term newborn under a radiant warmer are estimated to be 100 cc/kg/day. Water loss through the oxygenator may approach 2 cc/m^2/hour. For a baby weighing 3 kg, this would be about 10 cc/day. Fluid losses from urine, stool, chest tubes, nasogastric tubes, ostomies, mechanical ventilation, radiant fluid loss, and blood draws should be carefully recorded. Fluid management may become difficult in the baby on ECMO as fluid extravasates into the soft tissues during the early ECMO course. Therefore, meticulous recordings of the net fluid balance on ECMO should be maintained. Classically, the weight increases in the first 1–3 days as the patient becomes increasingly edematous. On the third day of ECMO, diuresis of the excess edema fluid begins, and can be facilitated with the use of furosemide. This diuretic phase is often the harbinger of recovery. In the event of renal failure on ECMO, hemofiltration or hemodialysis can be added to the ECMO circuit for removal of excess fluid and electrolyte correction. In a retrospective comparison of neonates on ECMO, use of hemofiltration was associated with shorter duration on ECMO and time on mechanical ventilation.[17]

Respiratory management on ECMO

Once the desired oxygen delivery is attained, the ventilator should be promptly weaned to avoid further oxygen toxicity and barotrauma. Such 'rest settings' have been studied and debated.[18] At the authors' institution, the FiO_2 is decreased to 0.21, PEEP to 5 cmH_2O, PIP to 20–25 cmH_2O, a rate of 12 breaths/minute and inspiratory time of 0.5 seconds if the infant's arterial and venous oxygenation are adequate.

If the baby remains hypoxic despite maximal pump flow, then higher ventilator settings may be temporarily required. Alternatively, hypoxic neonates on VV ECMO may need to be converted to VA ECMO for full cardiorespiratory support. On occasion, the chest x-ray will worsen in the first 24 hours independent of ventilator settings and improve after diuresis. As the patient improves on ECMO and the pump flow is weaned, ventilator settings are then modestly increased to support the baby off ECMO. In neonates, if the oxygen saturation is greater than 93%, the authors consider an FiO_2 of 0.4, PIP <28, PEEP of 5, and a rate <30 as adequate settings for a trial off ECMO.

In addition, during the course of ECMO, pulmonary toilet is essential to respiratory improvement and includes gentle chest percussion and postural drainage. Special attention should be made to the ECMO catheters and keeping the head and body aligned. Endotracheal suctioning is also recommended every 4 hours and as needed based on the amount of pulmonary secretions present.

Medical management

After the initiation of ECMO, vasoactive medications should be quickly weaned if the blood pressure remains stable. In the event of seizures, phenobarbital is usually given and maintained to prevent further seizures. In addition, gastrointestinal prophylaxis with an H_2-blocker, such as ranitidine, is instituted. Fentanyl and midazolam are usually administered for mild sedation, however the use of paralytics should be avoided. The baby's muscle activity is not only important for fluid mobilization of edema, but also for monitoring of neurologic activity.

At our center, infectious prophylaxis is provided by cefazolin, if no other antibiotics have been started. However, many neonates who are placed on ECMO are already on broad-spectrum antibiotics.

Due to the cannula and manipulation of the circuit at stopcocks, the risk of infection is a constant concern; therefore, strict observance to aseptic technique when handling the ECMO circuit should be maintained. Routine blood, urine, and tracheal cultures should be obtained to monitor for infection.

The caloric intake on ECMO should be maximized using standard hyperalimentation. For a newborn, total parenteral nutrition (TPN) should be started at 100 kcal/kg/day. Normally, this should be supplied as 60% carbohydrates (14.6 g/kg/day) and 40% fat (4.3 g/kg/day). Intralipid infusion may be used as a fat source, although there is some controversy with its use in the setting of severe lung disease. As a result, the percentage of fat in the hyperalimentation may be lowered. Amino acids may be added but must be considered in the setting of poor renal function and increasing blood urea nitrogen (BUN) levels. With normal renal function, approximately 2.5 g protein/kg/day should be provided in the TPN mixture.

Enteral nutrition is gaining acceptance in some centers. Initial concerns with feeding enterally on ECMO were that there was inadequate gut perfusion from the initial insult, which could lead to necrotizing enterocolitis when feeding was begun.[19] However, a retrospective study of 67 neonates supported with VA ECMO who were fed enterally, did not show any significant adverse effects.[20] While septic complications of enteral feeding appears to be low, many of these patients will have a gastrointestinal ileus. Of the previously mentioned 67 neonates, 21% had enteral feeding temporarily discontinued due to high gastric residuals.

Electrolytes should be closely monitored with potassium, calcium, and magnesium repleted as necessary. Sodium and phosphorus are usually not repleted as they are often provided in blood products and volume expanders.

Coagulation management

While on ECMO, the baby's hemoglobin is maintained at 15 g/dL to maximize the oxygen-carrying capacity of the blood. Platelet destruction during ECMO is anticipated and is secondary to the flow through the oxygenator and exposure to plastic surfaces. The platelet consumption should not exceed 0.5–3 units/day in neonates. In order to reduce the risk of bleeding during ECMO, the platelet count should be kept above 100 000/mm.[21] The authors recommend using 'hyperspun/concentrated' platelets to avoid the excess administration of fluid, and thus preventing further problems with volume overload and edema.

Heparin is initially administered as a bolus (100 units/kg) followed by a constant heparin infusion (30–60 units/kg/hour) to maintain a thrombus-free circuit. The level of anticoagulation is monitored by the activated clotting time (ACT). The heparin infusion is adjusted to maintain an ACT of 200–240 seconds. After decannulating, the heparin infusion is stopped and not reversed with protamine sulfate.

COMPLICATIONS ON ECMO

Mechanical complications

While hypovolemia is an important cause for poor venous return to the circuit and subsequent poor pump flow, other causes must be eliminated prior to volume infusion. These may include small venous catheter diameter, excessive catheter length, catheter kinks, improper catheter position, insufficient hydrostatic column length (i.e. patient height), and improper calibration or set up of the venous control module system. In addition, pneumothorax, cardiac tamponade, and abdominal compartment syndrome may need to be considered if there is no readily appreciated mechanical reason for poor venous return. After these causes have been excluded, small amounts of isotonic fluid (5–20 cc/kg) may then be introduced into the circuit to support higher pump flow rate. However, a large amount of volume infusion in conjunction with long-term muscle relaxants and venodilators can lead to anasarca, which in turn, can lead to poor chest wall compliance, compromised gas exchange and oxygen delivery. In some conditions, such as sepsis, there may be endothelial damage and capillary leakage, in which case anasarca may be unavoidable.

Neurologic complications

The most serious complications of the ECMO patient have been neurologic (e.g. learning disorders, motor dysfunction, cerebral palsy) and appear to be due to hypoxia and acidosis prior to ECMO. During the ECMO course, frequent neurological examinations should be performed, and paralytic agents should be avoided. The examination consists of evaluation of alertness and interaction, fullness of the fontanelles, reflexes, tone, spontaneous movements, eye findings, and presence of seizures. Intracranial hemorrhage is the most devastating complication on ECMO. Therefore, careful attention must be made to the rate of ECMO flow, rate of exchange of PCO_2, fluctuations in the ACT, and platelet count. Cranial ultrasounds should be performed every day to monitor ICH and after any major event, such as equipment malfunction, sudden worsening in oxygenation status, and pneumothorax. Electroencephalography (EEG) may also be helpful in the neurologic evaluation of the neonate.

Renal complications

Infants on ECMO may sustain acute tubular necrosis (ATN) marked by oliguria and increasing BUN and creatinine levels. ATN may extend into the first 24–48 hours of ECMO before improvement in urine output is seen. If the renal condition does not improve, poor tissue perfusion should be considered. A combination of inadequate ECMO flow rate, low cardiac output, and intravascular volume depletion from diuresis may lead to decreased renal function. If the infant remains in complete anuric renal failure and requires dialysis, a hemofiltration module can be added in series to the ECMO circuit to remove excess fluid and stabilize electrolyte abnormalities.

WEANING FROM ECMO

As the patient improves during the ECMO course, the flow of the circuit is weaned, based on improving postductal arterial and venous oxygenation. Neonates supported with VV ECMO should be weaned using the patient's SaO_2 as the SvO_2 will be artificially high from recirculation. Neonates supported with VA ECMO should be weaned using the patient's SvO_2. From starting flows as high as 150 cc/kg/minute, the flow is decreased to 30–50 cc/kg/minute while maintaining adequate perfusion. The ACT should be maintained at a higher level due to the lower flows to prevent thrombosis. If the baby tolerates the low flow, then the ECMO cannula (VV) or cannulas (VA) may be clamped while the ECMO circuit recirculates. The authors prefer to wean patients onto moderate conventional ventilator settings, i.e. IMV 20, FiO_2 0.4, PIP 25, and PEEP 5. Higher ventilator settings, though, may be tolerated if the risks of continuing ECMO outweigh those of discontinuing ECMO.

If the recirculation is tolerated, then decannulation is performed. As with the insertion, decannulation should be performed as a sterile surgical procedure. The patient should be placed in the Trendelenburg position and muscle relaxants should be administered to prevent air aspiration into the

vein. Prior to decannulation, vasoactive medication and hyperalimentation should be switched from the ECMO circuit to other vascular access. Once the catheter is removed, the vein is ligated and not repaired. This is also true for the artery in the case of VA ECMO.

ECMO IN INFANTS WITH CONGENITAL DIAPHRAGMATIC HERNIA

Neonates with CDH have abdominal viscera in the thoracic cavity, most commonly on the left side. This often leads to significant pulmonary hypoplasia and pulmonary hypertension. Pulmonary insufficiency can ensue, leading to hypoxemia, hypercarbia, and acidosis soon after birth; this can then lead to a vicious cycle of pulmonary vasospasm, pulmonary hypertension, right-to-left shunting of blood and worsening hypoxemia, hypercarbia, and acidosis. This cycle must be broken, if not medically, then with the assistance of ECMO. Medical management has improved greatly with the use of pulmonary vasodilators, such as tolazoline and inhaled nitric oxide.

If a fetus is antenatally diagnosed with a CDH, plans should be made for delivery in a medical center with ECMO capabilities in case of potential rescue therapy. There is no surgical indication or benefit to early delivery by Cesarean section. In the delivery room, intubation should be performed immediately after birth. The baby should then be transferred to a neonatal intensive care unit and started on mechanical ventilation to stabilize oxygenation and hemodynamics.

In the past, newborns with CDH have undergone repair as a surgical emergency. However, respiratory mechanics frequently worsen postoperatively, perhaps as a result of early repair.[22] In the 1980s, however, surgeons reported improved results with delayed surgery after postnatal medical stabilization.[23–28] A strategy of delayed repair in CDH patients after stabilization of respiratory and hemodynamic parameters with or without ECMO is the current standard of care.

Patient selection of newborns with CDH for ECMO support is particularly difficult. Neonates with CDH who present with overwhelming pulmonary hypoplasia that precludes gas exchange should not be offered ECMO. This group is characterized by the inability to attain a PaO_2 of 100 on an FiO_2 of 1.0 or a $PCO_2 < 50$. Their degree of pulmonary hypoplasia is incompatible with life and they would not be able to be weaned from ECMO. Appropriate candidates for ECMO will go through a 'honeymoon' period where they will maintain a $PaO_2 < 100$ on FiO_2 of 1.0 or a $PaCO_2 > 50$ for a period of time. Should they develop sustained hypoxemia ($PaO_2 > 40$), acidosis (pH > 7.2) or an alveolar arterial oxygen gradient < 600 for 10 hours, then ECMO should be instituted. This period of adequate gas exchange followed by deterioration suggests that these patients have a degree of reversibility of their pulmonary hypertension. Applying this criteria, 85% patients with a CDH supported on ECMO survived to discharge.[29]

OUTCOME AND FOLLOW UP OF NEONATES TREATED WITH ECMO

Mortality

Mortality statistics for neonates supported by ECMO are increasing according to the ELSO registry.[1] It is reasonable to extrapolate that improvements in ventilator strategies have increased the severity of illness of neonates placed onto ECMO. Severe respiratory failure from pulmonary hypertension has been a major cause for return hospitalization and late deaths, but mortality has remained specific to the primary diagnosis prior to ECMO.[1] For example, ECMO patients with the diagnosis of CDH have about a 50% mortality rate while the diagnosis of meconium aspiration syndrome has a mortality rate of about 5%.[1,30] For all diagnoses, the mortality rate for newborns placed on ECMO is about 20%.[1]

Of the infants who die on ECMO, about half die from severe bleeding complications. Another risk factor for mortality is a birth weight of < 2 kg. A retrospective study reviewed 300 newborns supported with ECMO, and the infants who weighed < 2.5 kg, although meeting the criterion of 2 kg, had a relative mortality risk of 3.45% compared to ECMO neonates with birth weights > 2.5 kg.[31]

Feeding and growth sequelae

After decannulation from ECMO, an important factor affecting neonatal intensive care unit (NICU) discharge is initiation of successful enteral feeding. Feeding problems have been reported in as many as one-third of ECMO-treated infants and varies in presentation.[32–34] These problems are due to a variety of possible causes which include interference from tachypnea, generalized central nervous system (CNS) depression, poor hunger drive, soreness in the neck from the surgical procedure, sore throat from intubation, poor oral–motor coordination, and manipulation or compression of the vagus nerve during the cannulation procedure.[34,35] Feeding problems also differ according to pre-ECMO diagnosis. For example, infants with CDH have a higher incidence of feeding difficulty than infants with MAS and RDS.[35–37] The CDH infants often have foregut dysmotility which leads to significant reflux, delayed gastric emptying, and feeding difficulties. Respiratory compromise and severe chronic lung disease also interfere with feeding. These babies may require prolonged nasogastric feeding or even a gastrostomy, fundoplication, and pyloroplasty to maintain adequate growth. However, ECMO infants generally do not have major long-term feeding complications.

Although normal somatic growth is most commonly reported, ECMO-supported children are more likely to experience problems with growth than normal controls. Head circumference below the 5th percentile occurs at a higher rate (10%) in post-ECMO children. Furthermore, poor head growth is associated with a major handicapping condition with a risk greater than 75% at five years of age.[38]

Although controversial, there have also been reports of macrocephaly, which follows a pattern of venous obstruction secondary to internal jugular vein ligation observed on neonatal neuroimaging.[38,39] Growth problems are most commonly associated with ECMO children who had CDH or residual lung disease.[36]

Respiratory sequelae

Significant respiratory problems are reported in ECMO survivors during the first two years of life, with a high rate of rehospitalizations for pulmonary conditions.[40,41]

Approximately 15% of infants supported with ECMO require oxygen at 28 days. By the age of five years, ECMO children were twice as likely to have a reported case of pneumonia as control children (25 versus 13%). Approximately half of the ECMO children with pneumonia were hospitalized compared to none of the control cases. Half of the cases of pneumonias in ECMO children occurred before one year of life compared to none in the control group. In addition, more than half of the ECMO rehospitalizations for pneumonia occurred within the first six months of life.

Of the ECMO-treated neonates, the primary diagnosis of CDH, in particular, has been found to be associated with chronic lung disease, defined by the need for bronchodilators, diuretics, or supplemental oxygen for the management of pulmonary symptoms. Specifically, the use of supplemental oxygen at discharge from the hospital has been reported in 22–80% of CDH patients.[37,42–44] Aggressive ventilator management and lung injury prior to initiating ECMO leads these children to develop bronchopulmonary dysplasia. Persistent oxygen requirements are due to pulmonary hypertension.

The age at the time of ECMO, correlating with the amount of time on mechanical ventilation prior to ECMO, is another factor associated with oxygen need past 28 days.[7] Neonates with severe respiratory failure had an 11.5-fold increased risk of bronchopulmonary dysplasia if ECMO was initiated at later than 96 hours of age. In addition, ECMO infants with birth weights of 2–2.5 kg have a greater risk for chronic lung disease than larger ECMO infants.[31]

Neurodevelopmental sequelae

Perhaps the most serious of post-ECMO morbidities is sensorineural handicap. Reports of neurodevelopmental outcome after one year of age have been published from multiple institutions. Among 540 ECMO survivors from 12 institutions, the total rate of sensorineural handicap (cerebral palsy, blindness, hearing impairment) is 6% on average, ranging from 2 to 18%.[38,45–57] Significant developmental delay among ECMO survivors is 9% on average, ranging from 0 to 21%. This is comparable to other critically ill neonates. For example, newborns with extremely low birth weights (<750 g) have a 15% rate of having major sensorineural handicap with 21% testing in the mentally retarded range.[58] Additionally, newborns with PPHN not supported with ECMO have an average sensorineural handicap rate of 23% (range 0–37%) among 162 survivors from eight institutions.[59–66]

At five years of age, 50% of children supported with ECMO as neonates had a normal neurologic outcome as defined by lack of a developmental delay, epilepsy, or cerebral palsy.[67] The remaining children had varying degrees of disability, most not being severe. The authors also found that low gestational age and low birth weight were significantly associated with a negative neurologic outcome. This further supports the notion that pre-existing factors contribute to negative neurologic outcomes rather than ECMO itself.

The underlying diagnosis prior to going onto ECMO may have a significant contribution to cognitive development. At an average age of 31 months at follow up, children with CDH supported by ECMO were more likely to have an abnormal cognitive status when compared to non-CDH ECMO survivors. Male gender and maternal education were also seen as risk factors.[55]

Auditory deficits are reported in more than 25% of ECMO neonates at the time of discharge.[68] The majority consists of mild–moderate deficit by brainstem auditory evoked response (BAER) testing which generally resolve over time. These auditory deficits may also be partly iatrogenic due to alkalosis secondary to furosemide administration or gentamicin ototoxicity. As a result, hearing screening is recommended at the time of NICU discharge. Examining data for 313 ECMO children from five centers shows an overall rate of 9% (range 4–21%).[38,50,52,54] This rate is not higher than that reported for non-ECMO PPHN children (23%, range 0–37%).[59–62]

Visual deficits in ECMO neonates are usually due to the immature retina in premature patients. This is uncommon in ECMO neonates weighing more than 2 kg. Concern about retinopathy of prematurity due to the hyperoxic condition of ECMO has not been borne out. Haney *et al.*[69] reported ocular findings in 16 of 85 ECMO neonates. These findings included vascular immaturity, vitreous and retinal hemorrhage, and optic nerve atrophy. However, not all infants were examined in this study and there may have been additional complications. Long-term sequelae were not reported, and non-ECMO controls were not tested.

Seizures, both clinical and electroencephalographic, are widely reported among ECMO neonates, ranging from 20 to 70%.[70–73] However, the timing and type of seizure activity is not consistent. In a group of five-year-old children previously supported with ECMO, only 2% had a diagnosis of epilepsy. Seizures in the neonate are associated with neurologic disease and poorer long-term outcome, including cerebral palsy and epilepsy.[74] According to one study, the handicap rate following neonatal seizures is 8%.[75] A predictive association between abnormal EEG and developmental status has been found, with only 18% of infants having normal EEGs with developmental delays; this is compared to 35% of infants with one abnormal EEG and 58% of ECMO infants with two or more abnormal EEGs.[71]

Neuromotor deficits range from a continuum of reports of mild hypotonia, gross motor delay, and asymmetry, to isolated cases of spastic quadraparesis. Although moderate hypotonia is not uncommon at discharge, it generally

improves over the next four to six months. However, these neuromotor findings are also seen in normal control children.[41] The incidence of severe non-ambulatory cerebral palsy is less than 5%.[38,45,50] These cases are generally accompanied by mental retardation, demonstrating a global insult to the brain. More commonly seen is a mild case of cerebral palsy in up to 20% of children supported with ECMO.

ECMO-supported neonates as a group most commonly function within the normal range.[38,45,47,50–57,76] The rate of major handicap appears to be stable across studies with an average of 11% (range 2–18%).

By the time of discharge, at approximately one month of life, ECMO infants still exhibit signs of general CNS depression, including lethargy, hypotonia, and weak primitive reflexes, an indication of moderate hypoxic–ischemic encephalopathy. By four months of age, ECMO infants typically function in the normal range defined by Bayley mental and motor scales. Residual hypotonia or mild asymmetry persists in about 25%. Mild motor delay usually accompanies the hypotonia. Significant neurological abnormalities and motor deficits (more than 2 s.d. below norm) are found in approximately 10–15% of affected individuals. By three years of age, the rate of handicap appears to be stable, but more subtle handicaps manifest at this age, such as learning disabilities, particularly with language and perceptual functioning.[34,77–79] By five years of age, a diagnosis of mental retardation (IQ <70, delay in social adaptive functioning) becomes more certain. In one five-year group, 11% of individuals studied were diagnosed as mentally retarded, most in the mild range with IQs of 50–70.

For ECMO children who had carotid artery cannulation and ligation, controversy remains over reconstruction of the artery. Baumgart *et al.* reported experience of 84 ECMO children who had carotid ligation and 41 who had right common carotid artery reconstruction.[80,81] Failure of the reanastomosis, defined by $>50\%$ occlusion or no flow, occurred in 25% of procedures. No significant differences were reported for occurrence of grade 3 and 4 hemorrhages, but 60% of the group reanastomosed had moderate to severe abnormalities on EEG, compared to 35% of the non-reconstructed group. Despite this, no differences were reported in the proportion of significant neurodevelopmental delays. An additional study of neonates with CDH supported by ECMO showed a 72% incidence of occluded or highly stenotic right common carotid artery, following reconstruction at two years of age. Similarly to previous studies, there was no significant difference in neurologic development when compared to controls.[82]

SUMMARY

Since the first use of ECMO in neonates in 1974, much has been learned about the treatment of infants with cardiac and respiratory disease. New, less invasive medication and techniques have been developed which have kept numerous babies from ECMO cannulation. Over the years, much has also been learned about ECMO; indications have been expanded and selection criteria honed. Currently, the successful treatment of a variety of neonatal respiratory diseases, such as meconium aspiration syndrome, persistent pulmonary hypertension of the neonate, and severe pneumonia can be achieved. ECMO may also be helpful in neonates with cardiac lesions and difficulty weaning from bypass. Difficult clinical scenarios, such as congenital diaphragmatic hernia and sepsis have also met with success through the use of ECMO. The criteria for ECMO candidates have been slowly fine-tuned to maximize survival rates and avoid unnecessary ECMO in infants with irreversible disease. Such criteria include early gestational age, low birth weight, coagulopathy, intracranial hemorrhage, lethal anomalies, and irreversible lung disease. In summary, any hypoxic infant who has a reversible pulmonary or cardiac condition, who is physically large enough for ECMO, and who has failed maximal medical therapy should be considered for ECMO. Meticulous attention and thorough documentation of each ECMO patient have improved knowledge about ECMO through the ELSO registry. With ECMO as a safety net, new therapies can be developed for this poor surviving group of newborns such that the ultimate success of ECMO will be its discontinuation.

Bronchoscopy in the newborn

STEPHEN M KIERAN AND JOHN D RUSSELL

INTRODUCTION

Bronchoscopy in the newborn is an important diagnostic and therapeutic tool.[1] Diagnosis of congenital laryngotracheal malformations and management of airway complications secondary to prolonged intubation are the two most common indications for pediatric bronchoscopy.[2] Bronchoscopy in children was first performed by Killian in 1895.[3] It was, however, associated with a high rate of complications due to poor visibility through small-diameter bronchoscopes, lack of a satisfactory light source, and difficulty maintaining ventilation during the procedure. Modern Hopkins lens systems' intense yet 'cold' light sources together with modern anesthetic techniques have facilitated safer examination of the airway in the newborn.[4,5] Pediatric flexible bronchoscopy was initiated in the mid 1970s, after Ikeda introduced the flexible bronchofibersope in 1968. Since then newer and smaller instrumentation and the addition of suction channels have enabled the bronchoscopist to examine the airway without significantly distorting the anatomy or the normal physiology and has largely superseded rigid bronchoscopy for diagnostic purposes in the lower airway.[6] The development of the pediatric fiberoptic nasendoscope, while not permitting a view of the trachea or bronchi, has dramatically changed airway endoscopy in the newborn. Infants, with stridor who are otherwise well, can have their larynx and upper airways examined at the bedside or the outpatient clinic. If a diagnosis of laryngomalacia is made, laryngoscopy and bronchoscopy under general anesthesia may not be required. However, the airway control and therapeutic ability of rigid bronchoscopy have not been replaced and it remains an important and potentially life-saving procedure.

RIGID BRONCHOSCOPY

Indications for rigid bronchoscopy

Rigid bronchoscopy can be performed for both diagnostic and therapeutic reasons. (Box 38.1). The commonest causes of stridor and airway obstruction in a neonate are laryngomalacia, subglottic stenosis (both congenital and acquired), and vocal cord paralysis.[7] Less common causes include laryngeal clefts, hemangiomas, and papillomas. Rigid bronchoscopy is the diagnostic procedure of choice in the management of airway obstruction. Most neonates with stridor will have laryngomalacia and can be diagnosed with fiberoptic laryngscopy in an outpatient setting. However, there are three clinical situations where neonates with stridor warrant rigid bronchoscopy: (1) the neonate with severe stridor and significant airway obstruction, who will require urgent bronchoscopy and airway support; (2) the neonate with initially stable but deteriorating stridor; (3) the neonate with mild or moderate stridor but with poor weight gain or difficulty in feeding, apnea, or cyanotic episodes. Adjuvant investigations may suggest a particular diagnosis, e.g. a vascular ring on barium swallow; however, endoscopy is needed to confirm this diagnosis. In neonates with recurrent aspiration rigid bronchoscopy is necessary to rule out a laryngotracheal cleft. Even if pathology is found in the larynx, it is important to complete a systematic assessment as about 70% neonates undergoing rigid bronchoscopy have more than one airway pathology.[4]

Box 38.1 Indications of rigid bronchoscopy

- Foreign body removal
- Evaluation of subglottic and tracheal pathology
- Management of severe upper airway obstruction (to provide a temporary airway and facilitate intubation)
- Management of massive hemorrhage and blood clots
- To remove benign tumors (recurrent respiratory papillomatosis)
- Endoscopic management of strictures, webs, granulation tissue
- Open airway surgery
- Re-expansion of consolidated/atelectatic pulmonary lobes

Instrumentation

A systematic assessment of the neonatal airway should be performed and includes laryngoscopy, tracheoscopy, and bronchoscopy. A wide range of equipment of varying sizes is required including laryngoscopes, bronchoscopes, telescopes, and telescopic forceps. The senior author's preference is for Karl Storz telescopes and the Lindholm–Benjamin laryngoscope. Suspension of the laryngoscope on a Mayo stand is essential for therapeutic procedures, freeing the surgeon's second hand (Fig. 38.1). The components of a modern bronchoscope are (Fig. 38.2):

Figure 38.1 Benjamin–Lindholm laryngoscope attached to a Mayo infant is receiving sevoflurane/oxygen via a nasopharyngeal tube.

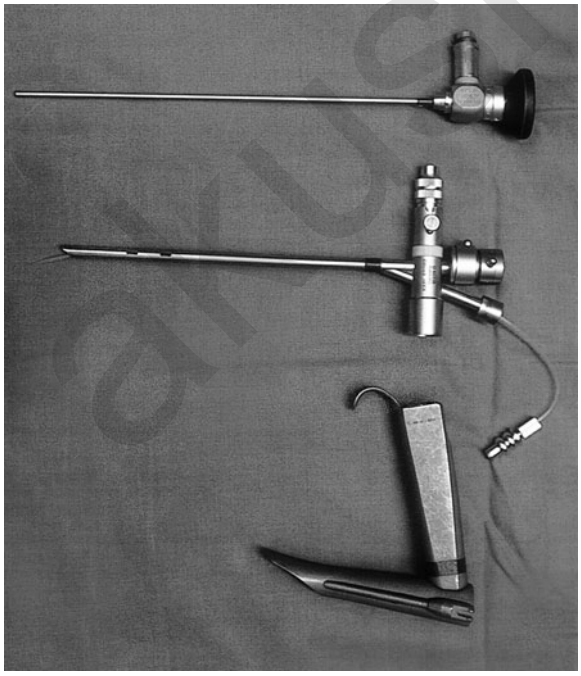

Figure 38.2 Equipment for rigid laryngobronchoscopy: 0° telescope (top); 2.5 mm ventilating bronchoscope (middle); Benjamin–Lindholm laryngoscope (bottom).

1. a closed gas system allowing connection to an anesthetic circuit
2. a rigid Hopkins rod telescope to allow distal illumination and vision
3. a side channel for the passage of suction catheters or flexible forceps.

The bronchoscopes range in size from 2.5 (outside diameter 4.0 mm) to 6.0 (outside diameter 8.2 mm). Sizes 2.5–3.0 are the most appropriate for neonates (Table 38.1).

Table 38.1 Diameter of rigid Storz bronchoscopes for newborns.

Length (cm)	Nominal size (mm)	Internal diameter (mm)	External diameter (mm)
20	2.5	3.2	4.0
20	3.0	4.2	5.0
26	3.0	4.2	5.0
20	3.5	4.9	5.7
26	3.5	4.2	5.0
30	3.4	4.9	5.7

Technique of rigid laryngobronchoscopy

Rigid laryngobronchoscopy requires general anesthesia. Modern techniques are versatile and controlled, allowing an unhurried and complete examination.[8] A full range of neonatal and pediatric laryngoscopes, bronchoscopes, and telescopes are essential. Modern 1 chip and 3 chip cameras allow magnification and excellent resolution of the image on screen of these tiny airways.

A spontaneous respiration technique is the anesthetic method of choice and has superseded transglottic jet ventilation. However, this technique is challenging to the anesthesiologist, requiring a balance as the patient must spontaneously breathe, while sedate enough to not develop laryngospasm or bronchospasm when instrumentation is introduced. Sevoflurane is, in most anesthesiologists' opinion, the anesthetic of choice. It allows a deep plane of anesthesia without causing respiratory arrest. The procedure should proceed in a systematic manner as outlined below.[9]

The neonate is anesthetized with a mixture of sevoflurane and oxygen via a face mask. The patient's chest is not covered with drapes so that respiration can be assessed. The surgeon sits at the head of the bed with the anesthetic machine positioned to the side in such a way that both the surgeon and the anesthesiologist should be able to read the patient's vital signs including oxygen saturation. The camera system's monitor should be positioned over the far end of the bed. The larynx is then briefly visualized using the laryngoscope and topical 4% lidocaine (0.5–2 mg/kg) applied (to prevent laryngospasm). An appropriately sized nasopharyngeal airway is inserted and the anesthetic agent is then provided via this route. Atropine may also be administered to prevent bradycardia and to dry up the secretions during the

assessment. A baby Lindholm laryngoscope is then inserted, by placing its tip in the vallecula, exposing the whole larynx. The scope is suspended on a Mayo table to avoid compression of the baby's chest or held with the non-dominant hand. The larynx is now examined using a 4 mm 0° Hopkins rod laryngeal telescope. Pathological conditions looked for in the larynx include: (1) laryngeal webs, (2) laryngeal cysts, (3) subglottic stenosis, and (4) hemangiomas. The mobility of the arytenoids is then assessed using a blunt laryngeal probe, which also allows palpation for small laryngeal clefts. Once the larynx has been thoroughly examined the telescope is passed into the subglottis and trachea. This allows a complete atraumatic inspection, easily passing to the carina. In order to examine the bronchi in detail one has to remove the laryngoscope and introduce an appropriately sized bronchoscope (Fig. 38.3). Turning the baby's head to the left allows entry through the right main bronchus and turning the head to the right allows entry into the left mainstem bronchus. On both the left and right sides, access to the upper lobe bronchus is the most challenging and may be aided by various dynamic maneuvers including flexing the infant's chin onto the shoulder and external pressure on the chest. The final part of the assessment is to examine the trachea and vocal cords as the baby is lightening up from the anesthetic. This is the only time when tracheobronchomalacia and vocal cord paralysis can be observed.

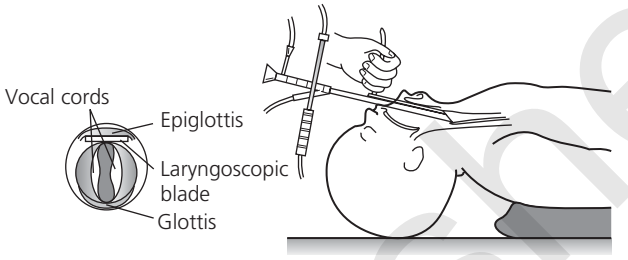

Figure 38.3 Under direct visualization of the larynx, the bronchoscope is introduced into the trachea.

Advantages of rigid bronchoscopy

The major advantage of rigid airway assessment is the excellent control of ventilation provided. This is of particular importance with the soft and collapsible neonatal airway. The rigid bronchoscope can also accommodate instruments, allowing therapeutic interventions to be performed endoscopically. Rigid bronchoscopy allows the lower airways to be inspected safely and in great detail while maintaining control over ventilation. Flexible bronchoscopy does not allow such control and in a small neonate or infant will cause significant, if not total airway obstruction. The image quality obtained by the rigid telescope is also superior to that obtained with the flexible fiberoptic bundles.

Complications of rigid laryngobronchoscopy

Despite the relative safety of modern rigid bronchoscopy, complications still occur with a complication rate of 2–4% reported. Safety is affected by the anesthetic technique (including intraoperative monitoring), the interventions performed during the endoscopy, availability of equipment, the expertise of the staff, and the condition of the patient.[5] Complications reported include laryngospasm, vocal cord trauma, subglottic edema, pneumothorax, pneumonia, hoarseness, hemorrhage, cardiac arrhythmia, and death. In Hoeve *et al.*'s series in 1993, a diagnosis of tetralogy of Fallot, undertaking biopsy or drainage, foreign body extraction, and tracheal stenosis were the main risk factors for complications. Interestingly, fewer complications occurred in the less than three months age group.[10]

FLEXIBLE BRONCHOSCOPY

Flexible bronchoscopy was first performed in the 1970s and since then newer and smaller scopes have enabled visualization of the airway of premature infants and neonates.[11] The advantages of flexible airway bronchoscopy are that examination of the distal lobar bronchi is less challenging than rigid bronchoscopy, that it can be performed as a day patient and requires little preparation except for no oral intake 4–6 hours preoperatively. Provided flexible bronchoscopy is performed by an experienced operator in a controlled setting, the procedure is very safe. Vauthy[6] reports over 10 000 flexible bronchoscopies with no mortality.

Indications for flexible bronchoscopy

Flexible bronchoscopy may be performed for diagnostic reasons in the neonate with mild stridor, unexplained wheezing, hemoptysis, chronic cough, persistent atelectasis, and persistent pulmonary infiltrates (Box 38.2). Flexible bronchoscopy is also increasingly performed in the neonatal intensive care unit (NICU).[12] Flexible bronchoscopy in the NICU can be performed via the existing endotracheal tube or tracheostomy (thus maintaining the airway) and negates the need to transfer the patient to the operating room. The bronchoscope can be used to check the position of the

Box 38.2 Indications for flexible bronchoscopy

Diagnostic
- Unexplained stridor
- Unexplained wheezing
- Hemoptysis
- Unexplained cough
- Persistent atelectasis
- Recurrent or persistent pulmonary infiltrates

Therapeutic
- To aid intubation
- Therapeutic bronchoalveolar lavage
- Brush biopsies
- Removal of airway secretions
- Diagnose and monitor after lung transplantation
- Transbronchial biopsy

endotracheal tube. Sudden respiratory deterioration in the NICU can be due to severe mucous plugging, atelectasis, granuloma formation, tracheitis, or tracheobronchomalacia. In these patients, flexible bronchoscopy may be both diagnostic and therapeutic, allowing careful direction of suction catheters to improve pulmonary toilet. Full-term infants tolerate flexible bronchoscopy with a 3.4 mm scope which has suction channels for insufflation of oxygen, suction and bronchial brushings, or bronchoalveolar lavage. Bronchoalveolar lavage aids the diagnosis of infection, gastro-esophageal reflux (detecting lipid laden alveolar macrophages) and the removal of mucous plugs.[13,14]

Technique of flexible bronchoscopy

Pediatric flexible bronchoscopy can be performed directly through the nose or mouth, via a face mask or laryngeal mask airway as well as through an endotracheal tube.[15] It is the authors' experience that the vast majority of patients require general anesthesia for flexible bronchoscopy. The neonate is placed on the table with the assistant providing oxygen via mask. The average diagnostic procedure lasts approximately 30 seconds and should be digitally recorded, so that the procedure can be reviewed. If performed as a day case post-procedure, the patient should be clinically observed for 1.5 hours and allowed to eat prior to discharge.

Common pitfalls for the unwary flexible bronchoscopist

CONCURRENT LESIONS

Children frequently have multiple airway abnormalities and these can often be missed due to the speed of the flexible assessment.

DIFFICULT NASAL PASSAGE

Nasal septal deviations or turbinate hypertrophy can lead to difficulty passing the flexible scopes. The use of a topical vasoconstrictor enables the nose to be entered in most cases. Wood,[16] in 1990, encountered only three patients in whom the transnasal passage of the flexible bronchoscope was not possible.

PHARYNGEAL HYPOTONIA

Patients with tracheostomies or who have reduced muscle tone because of neurologic disease often have pharyngeal hypotonia leading to an increase in the amount of secretions in the larynx, making visualization difficult.

Complications of flexible bronchoscopy

Complications of flexible bronchoscopy are generally minor and are reported to occur in 2–8% of cases.[17] Reported complications include laryngospasm, pneumothorax, epistaxis, bradycardia, and hemorrhage. Generally, high-risk patients are more likely to undergo rigid bronchoscopy as obstruction of a large proportion of the airway can lead to hypoxemia. It is also difficult to remove foreign bodies with a flexible scope. The relative contraindications to flexible bronchoscopy are: (1) hypoxemia, (2) respiratory distress, (3) hemorrhagic diathesis, (4) cardiac arrhythmia, and (5) a foreign body. All these problems increase the risk of complications with flexible bronchoscopy.

CONCLUSION

Modern rigid and flexible bronchoscopy in the newborn carried out by trained personnel is a safe, relatively atraumatic procedure with a low rate of serious complications. This is due to the advances in anesthesia, pharmacology, instrumentation, and camera technologies. Rigid and flexible bronchoscopy should be viewed as complementary and not competing mutually exclusive techniques. Both procedures should be in the armamentarium of the pediatric airway surgeon. There are advantages and disadvantages to each technique. It is to the neonate's advantage to have both types of endoscopes available so the procedure with the highest benefit-to-risk ratio can be employed.

Esophageal atresia and tracheo-esophageal fistula

PAUL D LOSTY, WAJID B JAWAID, AND BASEM A KHALIL

> To anastomose the ends of an infant's esophagus, the surgeon must be as delicate and precise as a skilled watchmaker. No other operation offers a greater opportunity for pure technical artistry
>
> Willis Potts 1950[1]

INTRODUCTION

Surgery for esophageal atresia (EA) is widely regarded as one of the most notable success stories in newborn surgery. Advances in neonatal intensive care have now led to greater than 95% survival for many babies treated in the modern era with increasing attention now focusing on morbidity, long-term clinical outcomes, and quality of life (QoL) in adult survivors. Recent noteworthy developments in EA management include minimally invasive thoracoscopic surgery and the deployment of the axillary skin crease thoracotomy pioneered by Bianchi. Expert opinion controversially dominates best practice with regard to pure long-gap esophageal atresia without fistula, medical versus surgical treatment of gastro-esophageal reflux (GER) disease, therapies for anastomotic stricture, and tracheomalacia. Applied embryology and molecular genetic studies continue to yield fascinating background into the etiology of EA and tracheo-esophageal fistula (TEF), with insightful contributions emerging from animal models sharing striking similarity to the human phenotype.[2,3]

HISTORY

The history of EA and TEF is well described in the literature.[2,3] The first survivors were not recorded until 1939 with Leven and Ladd achieving success with staged esophageal repair. Cameron Haight (an American surgeon working at Ann Arbor, Michigan) is fully credited with the first successful primary repair and survival of a 12-day-old female neonate. Reports from the UK soon followed with Franklin (1947) at the Hammersmith Hospital, London, Sir Denis Browne (1948) at Great Ormond Street Hospital, London, and Peter Paul Rickham (1949) at Alder Hey Children's Hospital in Liverpool recording equally good outcomes. Thereafter, improvements in survival were truly spectacular. By the 1980s, pediatric surgery centers worldwide were achieving survival approaching 85–90% in many newborns with mortality falling to less than 10%, thus defining a modern era of care.[2]

CLASSIFICATION

In 1929, Vogt proposed the first anatomical classification of EA and TEF, based on radiological and post-mortem findings.[4] A variety of surgical classifications were suggested as operative treatment became successful, the most frequently employed being attributed to Gross.[5] The most detailed classification, however, is credited to Kluth, and incorporates all described anatomical variants of EA and TEF.[6] However, from a practical viewpoint a working classification based on the frequency of each anomaly is of greatest value to the neonatal surgeon (Fig. 39.1).

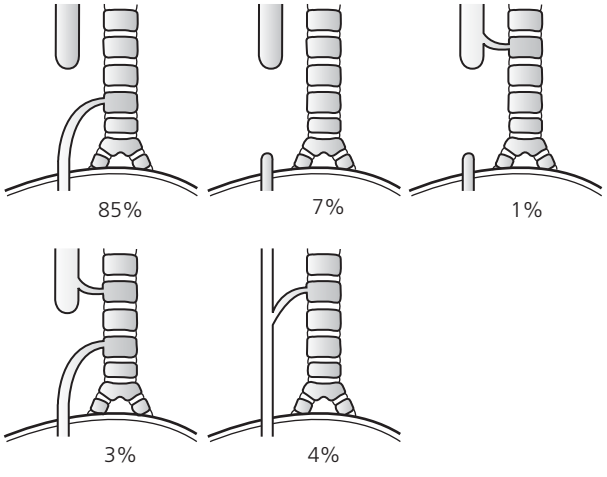

Figure 39.1 Classification and frequency of esophageal atresia (EA) and tracheo-esophageal fistula (TEF). EA and distal TEF, 85%; isolated EA, 7%; H-type TEF, 4%; EA with proximal and distal fistulas, 3%; EA and proximal fistula, 1%.

PROGNOSIS

Waterston's seminal paper describing the influence of pulmonary disease, birth weight, and associated congenital anomalies on outcome on newborns with EA-TEF provided an important historical basis for comparison of further refined better prognostic scoring systems.[7] It is now widely recognized that advances in neonatal intensive care have rendered the Waterston classification outdated. Spitz *et al.*,[8] in 1994, proposed a new risk categorization system based on birth weight and the presence or absence of congenital heart disease that is now widely accepted as applicable to the modern era [8] (Table 39.1). A Montreal classification system places greater emphasis on preoperative ventilator dependence and associated major anomalies as survival determinants.[9] Several studies report the negative influence of respiratory distress syndrome and pneumonia on outcome and the burden of aspiration events contributing to morbidity and late death following operative repair.[10,11] Variant anatomy also features as a risk factor(s) for favorable outcome with 'long gap' or 'pure' EA without fistula linked with significant morbidity including anastomotic leaks, stricture, increased requirement for fundoplication (and 'failure'/'redo' operations), and esophageal replacement procedures.[10,11,12]

Table 39.1 Spitz classification system

Group	Features	Survival
I	Birth weight >1500 g, no major cardiac	97%
II	Birth weight >1500 g, or major cardiac	59%
III	Birth weight >1500 g, and major cardiac	22%

EPIDEMIOLOGY

In the Liverpool region, the incidence of EA and TEF is 1 in 3300 live births.[13] The reported range varies from 1 in 2440 in Finland,[14] to 1 in 4500 both in Australia[15] and the US.[16] The sex ratio has been noted as equal by many authors, but others quote a slight male preponderance.[17] EA and TEF is more common in twin pregnancies. Exposure to teratogenic drugs during pregnancy has been implicated, and these include thalidomide, progesterone, and estrogen.[18]

GENETICS

The sporadic reports of vertical and transverse familial cases of EA and TEF suggest a polygenic hereditary etiology. The best estimate of risk of recurrence for parents of a single affected child is 0.5–2.0%, rising to 20% if another sibling is born with EA. The vertical transmission risk is 3–4%.[19]

A 10% incidence of non-specific chromosomal abnormalities (translocations, deletions, and duplications) has been noted. However, only trisomies 18 (Edwards syndrome) and 21 (Down syndrome) show any definite association with EA and TEF. Recognition of a syndrome suggestive of a major chromosomal abnormality in EA and TEF should prompt the urgent involvement of a clinical geneticist before corrective surgery is undertaken. EA and TEF have also been described in association with Feingold syndrome (autosommal dominant), Holt–Oram syndrome, DiGeorge sequence, polysplenia, and in babies with the Pierre Robin anomaly.[19]

ANIMAL MODELS

Significant contributions to our understanding of the embryology and genetic control of foregut development have evolved from basic laboratory research involving animal models of EA and TEF. The adriamycin rodent model was developed by Juan Tovar and colleagues in Madrid.[20] Timed pregnant rodents administered adriamycin (doxorubicin) in the prenatal period on gestational days 8 and 9 give rise to offspring with an EA-TEF variant phenotype.[20] These pups also demonstrate associated anomalies belonging to the VACTERL spectrum (denoting vertebral, anorectal, cardiac, tracheo-esophageal, radial/renal and limb anomalies).[21] A murine model of the VACTERL association has also been developed in mice with targeted deletions of the transcription factors Gli-2 and Gli-3 for the Sonic hedgehog (Shh) gene, which is pivotally linked with axial organogenesis. Gli-2–/–Gli-3–/– double mutants demonstrate the full phenotypic spectrum of the VACTERL syndrome confirming a crucial role for Shh in the genetic control of foregut development.[21,22]

EMBRYOLOGY

There is no unifying embryological theory which successfully explains all the anatomical variants of EA and TEF. The complete pathology has been demonstrated in the 5-week-old human embryo; therefore, causative factors must operate before this. In the developing embryo, the ventral aspect of the primitive foregut is destined to become the tracheobronchial tree. A median laryngotracheal groove develops in the ventral aspect of the foregut of the 23-day-old embryo. As the groove elongates with the growing esophagus, it is postulated that lateral epithelial ridges fuse to bring about foregut septation. While explaining the possible origins of tracheo-esophageal cleft and H-type variant EA fistula, caudocranial separation of the ventral trachea from the dorsal esophagus by a mesenchymal tracheo-esophageal septum clearly cannot adequately explain all variants of EA-TEF.

The finding of both an increased number of tracheal rings and a longer trachea in the adriamycin model of EA-TEF suggests localized abnormal proliferation and elongation of the ventral respiratory component of the common foregut tube. The preferential incorporation of tissue into the trachea may also result in esophageal discontinuity. The association of 13 pairs of ribs with long-gap TEF has also been used to strengthen the debate that abnormal forces, in this case hyper-somatization, result in a relative deficiency of tissue

which is preferentially absorbed into tracheal development at the expense of the esophagus.[23]

Further studies from the adriamycin model have shown that the notochord is also implicated in signaling activity to determine the fate(s) of neighboring cell populations. Shh protein, which is expressed in notochordal tissue, is thought to be pivotal in this dynamic signaling process.[24] Shh stimulates cell proliferation and inhibits apoptosis, via intermediary HOX gene expression. Shh binds to the cell surface protein 'Patched' (Ptc), which is upregulated by Shh, and thus limits the inductive capabilities of Shh. Ventral misplacement of the notochord may also result in an abnormal diffusion gradient for Shh and a localized imbalance of proliferation and apoptosis in the primitive foregut.

ASSOCIATED ANOMALIES

Associated anomalies are seen in over 50% of newborns presenting with EA and TEF.[2,25,26] Although some of these are relatively insignificant, a high proportion are life-threatening and significantly contribute directly to the morbidity and mortality of this condition. The early assessment of babies with EA-TEF should be prioritized with some urgency to address social, ethical, and surgical strategies relating to these coexistent anomalies. The incidence of these anomalies appears to be highest in newborns with pure EA without fistula and infants with orofacial clefts.[27] Babies born with EA-TEF have a higher incidence of prematurity than is seen in the normal population. Congenital heart disease (27%) is the commonest comorbid condition and probably has the greatest impact on survival. Aortic arch anomalies have been shown to occur frequently with 'long gap' EA-TEF variants. Other malformations include urogenital (18%), skeletal (12%), anorectal (12%), and gastrointestinal defects (9%) most notably duodenal atresia. The spectrum of associated anomalies encountered in 581 EA patients treated at Alder Hey Children's Hospital over four decades is shown in Table 39.2.

Several phenotypic variants have been described with EA-TEF babies. The VATER association,[27,28] now better referred to as the VACTERL sequence is defined by the presence of three or more anomalies. In a recent study from Alder Hey Liverpool, VACTERL associations were recorded in 19% of cases.[26] The CHARGE association refers to coloboma, heart disease, atresia choanae, retarded development, genital hypoplasia, and ear deformities with deafness. EA-TEF is also reported in the SCHISIS sequence, notably exomphalos, neural tube defects, cleft lip palate, and genital hypoplasia.[29–31]

Of interest, babies with EA and TEF have a higher than expected incidence of pyloric stenosis.[32] The almost universal association of gastro-esophageal reflux with EA may lead to delays in diagnosis if gastric outlet obstruction is not suspected. Tracheomalacia of variable severity is present in EA cases although the full spectrum of associated tracheobronchial and pulmonary abnormalities deserves further closer scrutiny. Significant anatomical tracheobronchial variant anomalies can be seen in 47% of infants undergoing bronchoscopy.[33] Pulmonary agenesis, foregut duplication cysts, congenital cystic adenomatoid malformations, and sequestered lobe have all been described in association with EA and TEF. Other rare foregut pathologies, such as laryngotracheo-esophageal cleft and congenital esophageal stenosis may coexist with EA and TEF.

Table 39.2 Abnormalities associated with esophageal atresia and TOF (Liverpool series 1953–97)[26,41]

Type	1953–97 (581 cases)
Cardiac	154 (27%)
Urogenital	105 (18%)
Skeletal	71 (12%)
Vertebral	64 (11%)
Anorectal	67 (12%)
Gastrointestinal	53 (9%)
Palate/laryngotracheal	44 (8%)
VASTERL[41]	25 (19%)

ANTENATAL PRESENTATION

Fetal diagnosis is now possible in cases of EA and TEF.[34] This may be clearly advantageous, as delivery can be planned at or near a specialist center with full neonatal surgical capability. Counseling is essential by a multidisciplinary team (obstetrician, pediatric surgeon, neonatologist) and a careful search for associated chromosomal or cardiac anomalies is important. The identification of a chromosomal abnormality may have implications for termination of pregnancy. Antenatal diagnosis of EA should theoretically reduce the likelihood of inadvertent feeding and aspiration pneumonitis. Despite the potential advantage of antenatal diagnosis, it is noteworthy that fetal ultrasonography selects an at-risk group of infants with a significantly worse prognosis.[35,36] The perinatal mortality (excluding termination of pregnancy) in a series from Newcastle, UK was reportedly 21%.[35] The classical sonographic features of EA and TEF in the fetus are absence of the stomach bubble and associated polyhydramnios.[37] Prenatal detection rates vary widely in fetal medicine centers (9–24%) and there appears to be a high rate of false-positive scans. Approximately 50% of all suspected cases on scanning are proven not to have EA after birth.[35]

CLINICAL PRESENTATION AND DIAGNOSIS

A newborn with EA is often noted to have difficulty clearing saliva. Episodes of coughing, choking, and even transient cyanosis may be observed shortly after birth. These signs are frequently overlooked and attempts to feed the infant result in immediate respiratory distress. The diagnosis is readily confirmed by the failure of passage of a firm nasogastric tube. A characteristic resistance is felt at the blind ending upper esophageal pouch, and the tube cannot be introduced into the stomach. A plain x-ray, which should include the chest and abdomen, demonstrates the nasogastric tube coiled in

the upper pouch. An associated TEF is confirmed by the presence of gas-filled intestinal loops below the diaphragm (Fig. 39.2). In isolated or pure EA, a featureless gasless abdominal x-ray is observed (Fig. 39.3). The presence of a double bubble on the abdominal film is highly suggestive of associated duodenal atresia (Fig. 39.4). A careful search for associated abnormalities is mandatory, specifically checking for patency of the anus. The cardiovascular system should be examined thoroughly to exclude a major congenital heart defect whose treatment may take priority over correction of the EA defect.

Figure 39.2 Chest x-ray film of a neonate with esophageal atresia and tracheo-esophageal fistula (TEF). Note the nasogastric tube coiled in the blind-ending upper esophagus. Air outlining intestinal loops below the diaphragm confirms the existence of a distal TEF.

Having established the diagnosis, i.v. fluids are commenced and a sump suction (Replogle) catheter introduced into the upper pouch to allow continuous aspiration of salivary secretions.[38] Alternatively, the upper pouch and oropharynx should be cleared of secretions by frequent intermittent suction. The infant is nursed in the supine or lateral position. Vitamin K should be administered intramuscularly after parental consent. Arrangements should be made for early transfer of the newborn to a neonatal surgical unit. Surgery is ideally performed within the first 24 hours following birth in an otherwise healthy baby, as pneumonitis is an ever-present risk from the aspiration of saliva and reflux of gastric acid through the lower pouch TEF.

Following admission to the neonatal surgical unit, the infant should be fully re-examined and radiology reviewed. The x-rays may be repeated with gentle downward pressure on the Replogle tube. On rare occasions, the authors have observed that a fine nasogastric tube may coil in an otherwise normal proximal esophagus, and the successful passage of the Replogle tube into the stomach prevents misdiagnosis and an unnecessary exploratory operation. In most instances, the diagnosis is fully established and an estimation of the length of the upper pouch on plain chest x-ray can give some idea as to the ease or difficulty of primary anastomosis. An echocardiogram should be performed prior to surgery as this will alert the surgeon and anesthetist to an underlying cardiac defect that may adversely influence prognosis, and may importantly, dictate the operative approach by identifying the side of the

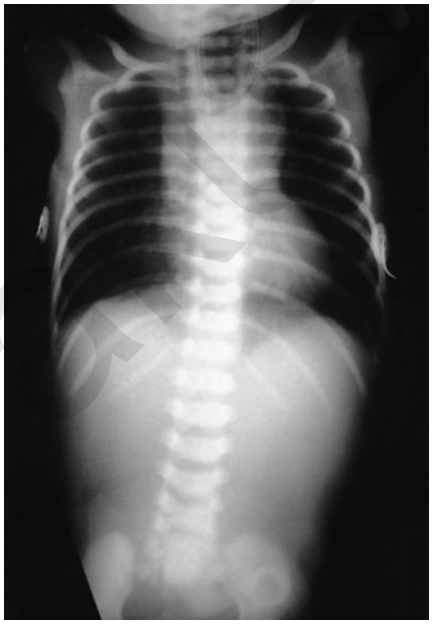

Figure 39.3 Case of 'pure' esophageal atresia without fistula. The nasogastric tube is lying coiled in the upper esophageal pouch. Absence of air-filled abdominal intestinal loops suggests that there is no distal esophageal fistula.

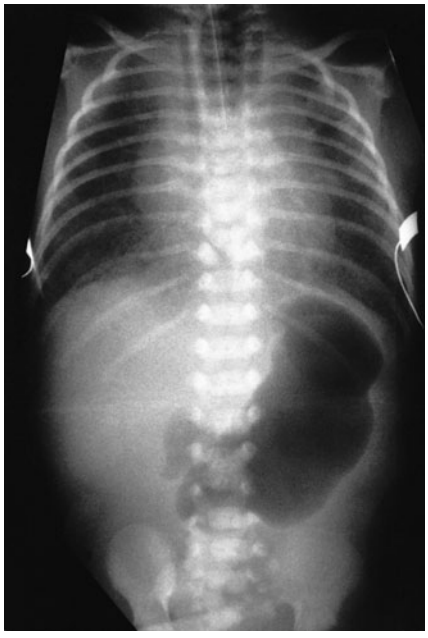

Figure 39.4 Esophageal atresia and tracheo-esophageal fistula with duodenal atresia. Nasogastric tube coiled in upper pouch. 'Double-bubble' appearance confirms duodenal atresia.

aortic arch. Blood should be taken for cross-match and a hematological and biochemical profile arranged preoperatively. Broad-spectrum antibiotics should be administered and i.v. fluids continued. Other investigations, notably whole-spine x-rays, renal and cranial ultrasonography can be deferred until after surgery. Contrast studies of the upper pouch to identify a rare upper pouch fistula have been superseded by preoperative bronchoscopy.

SURGICAL MANAGEMENT

Surgery for esophageal atresia is now usually performed as an elective procedure. Emergent operation rarely benefits the baby unless the surgeon is confronted with a 'high risk' ventilated neonate with severe respiratory distress and massive gastric distension with impending perforation where urgent transpleural fistula ligation is life saving (see below under Premature infant with RDS). It is common practice now for most surgical units to advocate preliminary rigid bronchoscopy after induction of general anesthesia when planning elective repair of EA and TEF. Depending on the infant's size, a 2.5–3.5 Fr neonatal bronchoscope (Storz) is used, as this permits the use of a suction catheter. Bronchoscopy allows confirmation of the diagnosis and in most cases will demonstrate the common variant fistula just proximal to the carina. Occasionally, a fistula may be seen arising at the level of the carina, or from one of the main bronchi. A careful search should be made to exclude an associated upper pouch fistula. The larynx should also be inspected to exclude a laryngotracheo-esophageal cleft.

Following bronchoscopy, an endotracheal tube is passed, taking care not to intubate the TEF. The infant is positioned for operation. In the classical operation, a right thoracotomy is planned with the baby in a lateral position, with the right arm raised across the head so that the scapula can be easily manipulated (Fig. 39.5). The neonatal surgeon may find the use of a headlamp and optical loupe magnification greatly facilitates the operation. A curved skin crease incision is made 1 cm below the angle of the scapula, extending from the anterior axillary line to the lateral margin of the erector spini muscles. Bianchi has also described a high axillary skin crease incision, which gives excellent cosmesis which we now increasingly deploy at Alder Hey.[39] The traditional Denis Brown vertical incision is least acceptable from an esthetic point of view. The anterior fibers of the latissimus dorsi are divided with electrocautery in the posterior aspect of the incision and the inferior digitations of the serratus anterior are separated from the ribs anteriorly. A retractor is used to lift the scapula off the chest wall, and the ribs are counted downwards from the second interspace. The chest is opened through the fourth interspace, dividing the intercostal muscle fibers using bipolar diathermy down to the level of the parietal pleura. The pleura is carefully separated from the ribs to commence an extrapleural dissection towards the fistula. The procedure is usually started with moist pledgets and, having developed the plane, may be continued by inserting a moistened gauze swab into the extrapleural space, sweeping the pleura away from the chest wall superiorly and inferiorly. Exposure is improved by introducing a Finochettio retractor for rib retraction. Great care is required with the dissection as it is particularly easy to create a pleural tear in the anterior aspect of the incision. If a significant pleural tear occurs during the dissection, it is probably wise to convert to a transpleural approach. The advantages of the extrapleural over the transpleural approach, include the possibility of avoiding a chest drain, and in the event of an anastomotic leak, the potential containment of contamination within the extrapleural space. The extrapleural exposure is completed by retracting the posterior mediastinal pleura forwards with a malleable retractor until the azygos vein is visualized as it enters the superior vena cava in the depths of the wound.

The azygos vein is mobilized and controlled with suture slings. The authors advocate temporary occlusion of the vein before ligation, as venous return to the heart may rarely be critically dependent on the azygos system. Provided this maneuver does not affect cardiac output, the azygos vein is ligated and divided as it enters the superior vena cava. Alternatively, some surgeons elect to preserve the azygos vein.[40] Once divided, the site of the fistulous communication between the trachea and the distal esophagus is usually readily apparent. Having confidently identified the distal esophagus, a vascular sloop is carefully passed around it. Traction on the sloop controls the fistula and enables its junction with the trachea to be located precisely. Although it is possible to suture ligate the fistula, the authors prefer to divide the fistula in stages and apply interrupted 5-0 or 6-0 monofilament prolene sutures to the tracheal component of the fistula. The distal esophagus is secured with a stay suture of the same material. The integrity of the TEF repair is evaluated by instilling saline into the thoracic cavity and requesting the anesthetist to exert positive airway pressure to ensure that no bubbles leak from the suture line. Occasionally, difficulty is encountered in identifying the distal esophagus, and it is quite possible to mobilize the descending aorta in the erroneous impression that this is the distal esophagus. The inexperienced operator may recognize the distal esophagus by following the vagus nerve as it courses distally, and by observing its rhythmic distension in time with ventilation.

Attention is then focused on the upper pouch, which is easily identified by requesting the anesthetist to push firmly on the Replogle tube. The upper pouch is usually a thick-walled bulbous structure, with a base readily identified by this maneuver. The upper pouch may be secured using a transfixion suture driven through the Replogle tube, which is used for traction during the mobilization of the upper pouch. Bipolar diathermy is ideal for this dissection, which should proceed to the thoracic inlet unless the gap is small. Mobilization is relatively easy except where the esophagus is closely applied to the trachea. Separation of this plane often requires sharp dissection, and should be performed with great care to avoid injury to the trachea. An upper pouch fistula may be identified at this stage, and should be repaired using 5-0 or 6-0 interrupted prolene sutures. The esophageal defect is closed with 5-0 or 6-0 interrupted polydioxanone sutures. Following full mobilization of the upper pouch it is usually possible to gauge whether a primary anastomosis is feasible. In most cases of EA with distal TEF, a primary

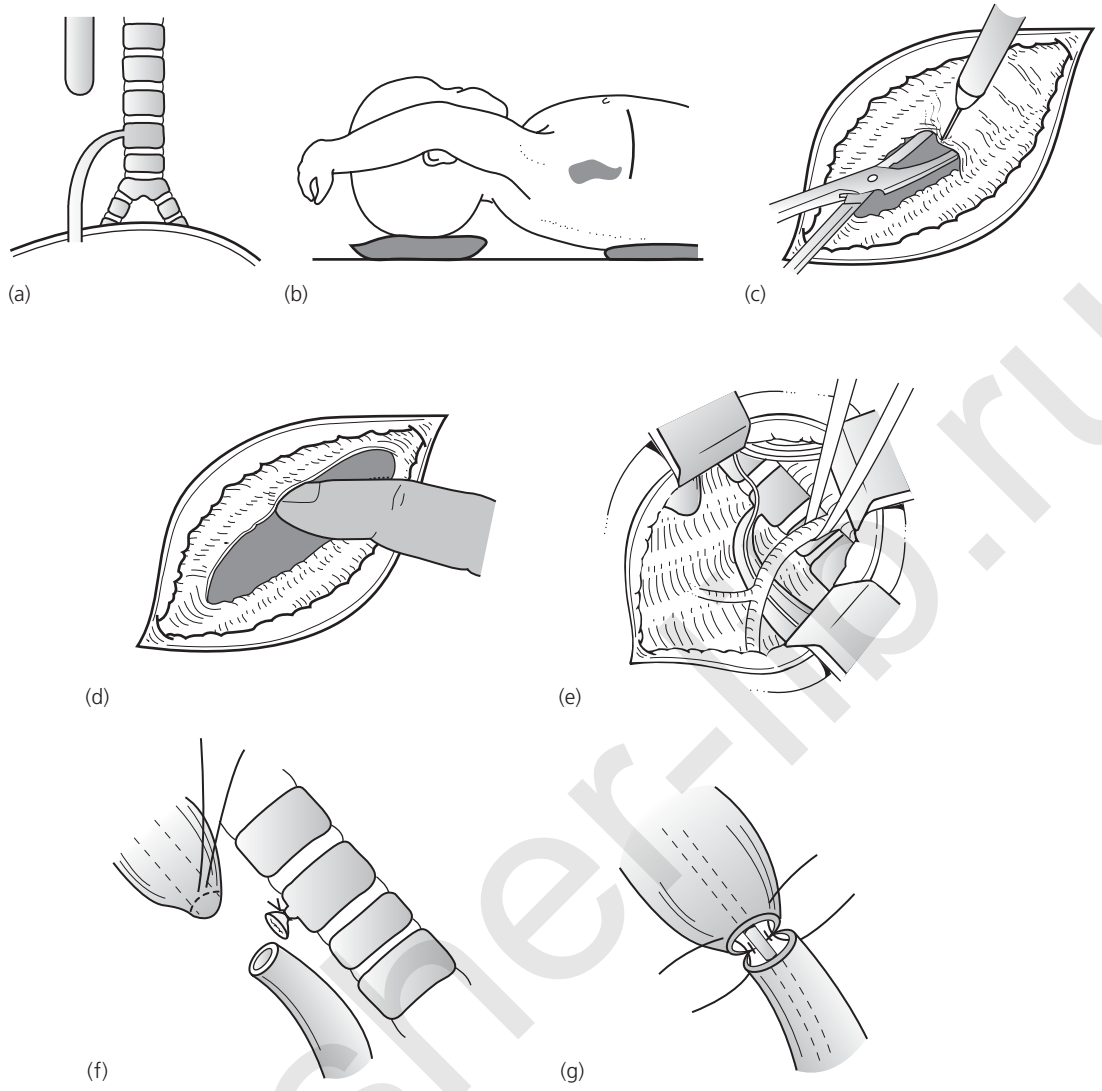

Figure 39.5 (a) The most frequent tracheo-esophageal anomaly. (b) Infant in lateral position prior to operation. Location of skin incision indicated. (c) Division of lateral thoracic and fourth space intercostal muscles. (d) Commencement of gentle stripping of parietal pleura from chest wall to develop extrapleural space. (e) Operative field when pleura and lung have been retracted medially. The azygos vein is easily seen. The other structures, i.e. the blind proximal esophageal pouch and the fistulous distal esophagus, with vagal fibers lying on its surface, will require some dissection, and are not as easily seen as is depicted in the diagram. (f) The fistula ligated and divided flush with trachea. (g) Lateral and posterior sutures and transanastomotic tube in place.

anastomosis is possible, although occasionally considerable tension is required to complete the repair.

The upper pouch is opened at its most distal extremity. The posterior wall of the anastomosis is commenced by placing two 5-0 or 6-0 polydioxanone sutures through all layers of the lateral margins of the distal esophagus, taking great care to avoid excessive tissue handling and trauma with tissue forceps. Sutures are completed by including all layers of the corresponding aspect of the upper pouch, so that the knot comes to lie on the inside. Before tying these sutures, two further posterior wall sutures are inserted. All are individually tied drawing the esophageal ends together. Having completed the posterior wall of the anastomosis, a 6–8 Fr fine bore nasogastric tube is passed by the anesthetist via the nose to the suture line, where it is grasped by the surgeon and carefully introduced into the lower esophagus and stomach. The anterior layer of the anastomosis is completed by laying the knots on the outside. Occasionally, generous mobilization of the lower pouch is also required to enable an anastomosis to be performed without excessive tension. Even when the gap seems too large to permit a primary anastomosis, this can sometimes be facilitated by creating either a Livaditis[41] myotomy of the upper pouch, or an upper pouch flap as described by Gough.[42] If the anastomosis is under tension, or has required one of these maneuvers, a chest drain is advisable. Under most circumstances where a satisfactory tension-free anastomosis has been completed without and where the extrapleural plane has been maintained, the authors, like others, consider a chest drain unnecessary.[43] The ribs are loosely approximated using absorbable pericostal sutures, and an anatomical closure of all muscle layers is performed. The chest drain, if present, should be attached to underwater drainage, and the patient transferred to intensive care for postoperative monitoring and ventilatory support.

Should additional surgical pathology be present, such as duodenal atresia or imperforate anus, these should be dealt with accordingly under the same anesthetic in the stable infant.

Long-gap EA with distal TEF

Rarely, the gap between the upper pouch and the distal esophagus is clearly too long to permit a primary anastomosis after division of the fistula, and full mobilization of both the proximal and distal esophagus. Under such circumstances, it is probably wise to proceed to cervical esophagostomy and feeding gastrostomy, accepting the need for esophageal replacement surgery at a later date.[2]

Right-sided aortic arch

Opinion is divided among pediatric surgeons regarding the optimal surgical strategy when a right-sided aortic arch is encountered. The incidence of right-sided arch in association with EA is 1.8–2.5%.[44,45] Chest x-ray may provide some clues. Preoperative echocardiography is at best 20% accurate in identifying this anomaly.[45] If the surgeon's suspicion remains high, magnetic resonance imaging should be arranged for definitive diagnosis. If a right-sided arch is identified from preoperative studies, experience from specialist centers advocate left thoracotomy. More commonly, the neonatal surgeon will encounter the anomaly unexpectedly in the course of the operation. The presence of a right-sided arch does not preclude a successful anastomosis in this situation, but the procedure is significantly more challenging as is evidenced by the 42% leak rate reported from Great Ormond Street Children's Hospital, London.[45] A trial dissection, including repair of the fistula, via right thoracotomy is appropriate, with completion of the esophageal anastomosis if this seems technically feasible.[46] Where significant difficulty is encountered with the dissection in preparation for the esophageal anastomosis, left thoracotomy is advisable following division of the fistula through the right or left chest as circumstances dictate. The second thoracotomy may be performed immediately or delayed, depending on the stability of the infant, and the experience of the surgeon.

PREMATURE INFANT WITH RDS

In premature babies with lung immaturity, emergency surgical intervention may become imperative if adequate ventilation is compromised by the TEF, resulting in abdominal distension and diaphragmatic splinting. The surgical priority is urgent division/ligation of the fistula via a transpleural approach to the anomaly. Should the infant's condition stabilize sufficiently after closure of the fistula, a primary repair of the esophagus is appropriate. Otherwise, a delayed repair is undertaken when the baby is stable. Sudden collapse due to gastric perforation is also a significant high risk event in these fragile babies. In such situations, emergent ligation of the fistula is a life-saving measure. Needle paracentesis with laparotomy, repair of the perforation, and feeding gastrostomy should follow.[47,48]

POSTOPERATIVE CARE

The infant should be nursed in the intensive care unit following repair of EA and TEF. Intravenous fluids and broad-spectrum antibiotics are continued. Weaning from ventilation need not be unduly prolonged in the stable infant with a satisfactory anastomosis. Where the anastomosis is under considerable tension, elective paralysis and ventilation for a period of 3–5 days is widely practiced.[49] It must be conceded, however, that there is no evidence base to support the claim that this technique favorably influences anastomotic healing.[50] There are some experimental data indicating that the level of tension in the anastomosis correlates with the severity of GER.[51] It is the authors' practice to commence all patients on H_2-antagonists (e.g. ranitidine) as prophylaxis against anastomotic stricturing potentiated by GER. A contrast esophagogram is optional after 5–7 days to evaluate the anastomosis, although major anastomotic leaks are clinically evident before this time. Minor (radiological) leaks are often seen on the postoperative contrast study. These are of no clinical significance and do not preclude the infant from being offered feeds.[52] In most cases, transanastomotic tube feeding can be commenced after 48 hours, and slowly increased as tolerated by the infant.

SURGICAL MANAGEMENT OF ISOLATED ('PURE') ESOPHAGEAL ATRESIA

The diagnosis of isolated EA without fistula is confirmed by the inability to pass a nasogastric tube, and a featureless 'gasless abdomen' on plain x-ray (Fig. 39.3). The absence of intestinal gas below the diaphragm, however, does not always completely exclude the presence of a distal fistula, as a small proportion of children may have a fibrotic connection between the lower pouch and the trachea, which does not readily permit the passage of air.[53]

Surgical management of these neonates is equally challenging and controversial. A majority of pediatric surgeons consider delayed primary anastomosis of the native esophagus the optimum approach. This strategy demands meticulous nursing care, physiotherapy, and careful attention to nutrition by supervised gastrostomy feeding. A prolonged period of hospitalization (6–12 weeks) is required to achieve this objective. Delayed primary esophageal anastomosis however, is associated with attendant morbidity, and further procedures to manage esophageal strictures and significant GER are commonly required.[54] The desire to preserve the infant's esophagus must be counterbalanced by the humility of knowing when to accept defeat, and to abandon the esophagus in favor of a replacement procedure. A feeding gastrostomy is created by minilaparotomy and special care should be taken to avoid injury to the small stomach in these babies with placement of the G-tube.[55] We do not advocate

an assessment of 'gap length' at the time of this operation and defer to a later session when the baby is more stable.

After a period of approximately 3 weeks, the extent of the gap can be assessed by fluoroscopy (Fig. 39.6). A radiopaque tube is pushed into the upper pouch and either contrast instilled via the gastrostomy, or a metal sound is introduced through the gastrostomy and directed via the esophageal hiatus into the distal esophageal stump. This procedure can be repeated at 2-week intervals, to assess whether the ends of the esophagus are sufficiently close to attempt delayed primary anastomosis.[56] A distance of less than two vertebral bodies separating upper and lower pouches is ideal. In practice, however, there is little to be gained by delaying restorative surgery beyond 12 weeks of age.

The operation of delayed primary anastomosis is essentially the same as has been described for EA and TEF. It is to be expected that the anastomosis may be created under considerable tension. The upper pouch should be fully mobilized to the thoracic inlet. The distal esophagus is frequently a primitive stump and not readily identified at thoracotomy without use of special aids. The surgeon can facilitate location of the distal esophageal stump by passing an illuminated neonatal gastroscope via the dilated G-tube tract site towards the esophageal hiatus. A brightly illuminated stump is easily identified in the depths of the thoracotomy wound. A stay suture (5-0 or 6-0 prolene) should be secured to the distal esophageal segment to aid mobilization and dissection. Some surgeons prefer passing metal sounds to identify the distal esophagus. The distal esophagus may be dissected to the diaphragmatic hiatus to help reduce tension on the anastomosis. A Livaditis myotomy or upper pouch flap may be helpful.[41,42,57–59] The authors prefer to perform a Livaditis myotomy over the inflated balloon of a Foley catheter passed by the anesthetist per-orally to the upper pouch. Extra length can be obtained by proceeding to laparotomy and creating a myotomy on the lesser curve as described by Scharli, or a Collis gastroplasty.[60,61] If a primary anastomosis is still not possible using these techniques, the options are a cervical esophagostomy and an esophageal replacement procedure at a later date. More often, a decision to convert to an immediate replacement of the esophagus is practiced provided the surgeon and team are sufficiently skilled. Options can include gastric transposition, a reverse gastric tube, colon replacement, or an operation regaining popularity, jejunal interposition.[2,62]

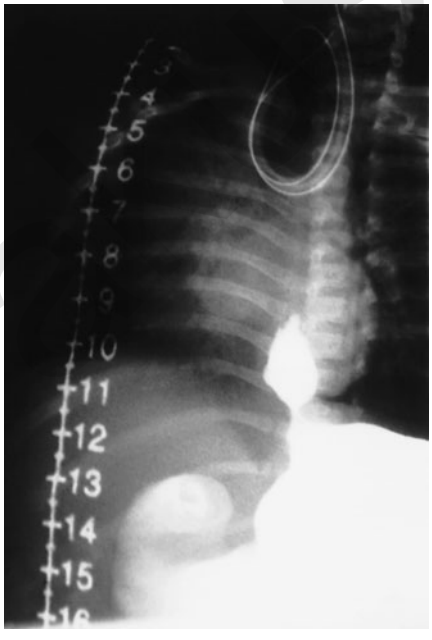

Figure 39.6 Gap assessment in a case of pure esophageal atresia. The scale bar represents gap length (cm).

Delays in restoring esophageal continuity have significant drawbacks. First, there is the ever-present risk of aspiration pneumonitis, and second, the inability to feed the infant via the normal oral route. Although the child's nutritional needs are met by gastrostomy feeding, the inability to establish oral feeds may lead to long-term feeding and speech problems. Spitz has recommended formally assessing the length of the gap when the gastrostomy is initially performed. A gap length less than six vertebral bodies (6 cm), would prompt him to abandon the esophagus and perform a cervical esophagostomy.[62] This approach of early cervical esophagostomy and delayed esophageal replacement permits early sham feeding, which theoretically promotes neuronal maturation and development of the learning skills needed for feeding and later speech acquisition.

A number of other innovative approaches to the operative treatment of long-gap EA have been described. True primary repair has been performed with reported gap lengths exceeding 5 cm. The hypothesis tested by Foker *et al.*[63] was that a well-constructed esophageal anastomosis can withstand considerable tension. The value-added technique for esophageal reconstruction (VATER) operation involves mobilizing the gastric fundus and performing a limited Thal fundoplication. At thoracotomy, the proximal stomach is drawn into the chest and a primary esophageal anastomosis is performed.[64] Staged neonatal colon esophagoplasty has also been described which involves the isolation of a short length of transverse colon based on the ascending branch of the left colic vessels at the time of open gastrostomy.[65] The conduit is positioned transhiatally in the posterior mediastinum to be retrieved at thoracotomy several days later, when continuity is restored.

Several well-established operations are available to restore gastrointestinal continuity in long-gap EA, where the infant's own esophagus has been abandoned.[62] Colonic or ileocolonic replacement was originally popularized by Waterston. The colonic conduit may be isoperistaltic (left colon based on the left colic vessels), or anteperistaltic (right colon based on the ileocolic vessels). The colon may be routed retrosternally, transmediastinally (via the hiatus), or through right or left chest cavities. Either pyloromyotomy or pyloroplasty is performed to promote gastric emptying. Cervical esophageal colonic anastomosis is prone to leakage. The colonic conduit tends to dilate, and kinking is common due to excessive tortuosity. Respiratory problems are seen due to recurrent aspiration.

The stomach may be utilized to create a neo-esophagus. A gastric tube esophagoplasty is fashioned from the greater curvature of the stomach, based on the left gastroepiploic (anteperistaltic) or right gastroepiploic arcades (isoperistaltic), and retrosternal, mediastinal, or thoracic routes may be used.[66]

The long suture lines of both the tube and new greater curve are prone to bleeding and leaking. Reflux is a problem and may predispose to anastomotic narrowing. However, dilatation and kinking are not encountered; reflux may be controlled by performing a posterior partial wrap fundoplication.

Gastric transposition has been advocated by Spitz and has the merit of simplicity.[62,67] The vascular supply is based on the right gastric and right gastroepiploic vessels, which allows full mobilization of the greater and lesser curvatures. After pyloroplasty, the stomach is passed through the mediastinum via the diaphragmatic hiatus and the esophagogastric anastomosis completed in the neck. Leakage from the anastomosis is reported in 12% of cases and strictures requiring periodic dilatation in a similar percentage of patients.[67]

Jejunal orthotopic interposition grafting has re-emerged as a useful technique for esophageal replacement following the encouraging reports from the Netherlands by Bax and colleagues.[68] Jejunal grafts do not dilate excessively and retain good peristalsis which may explain why GER does not appear to be problematic for these patients.[68,69]

H-TYPE TEF

H-type TEF is perhaps more accurately described as an N-type fistula as the track runs obliquely from trachea to esophagus. This is a rare anomaly comprising 4% of all EA-TEF variants.[2] Infants with H-type TEF usually present within the first month after birth, with a characteristic history of choking with feeds and cyanotic spells. Marked abdominal distension mimicking intestinal obstruction is an occasional presenting feature which the authors have encountered. Older children may have frequent chest infections with recurrent right upper lobe pneumonia due to aspiration.

Diagnosis may be established by a prone video esophagogram. In this study, contrast is injected through a nasogastric tube, which is slowly withdrawn from the esophagus. However, H-type fistulas may be missed in approximately half of all contrast studies. Where suspicion remains, bronchoscopy should be performed. At bronchoscopy, a size 4 Fr ureteric catheter is passed through the fistula into the esophagus to facilitate identification during subsequent neck dissection. A nasogastric tube is passed into the stomach, and broad-spectrum antibiotics commenced. A right transverse skin crease incision is marked a finger's breadth above the clavicle, before positioning the neck in extension with a sandbag placed under the shoulders. The sternomastoid is retracted laterally and, if necessary, its sternal head divided. The carotid sheath is mobilized after division of the middle thyroid vein. The ipsilateral recurrent laryngeal nerve should be identified and carefully preserved. Intraoperatively we have found that flexible bronchoscopy with a 2.2 mm instrument (Olympus) can aid precise identification by brightly illuminating the site of the fistula tract.[70] The esophagus is carefully dissected at this point and slung with vascular sloops both above and below the fistula. Caution should be taken with this maneuver, as the contralateral recurrent nerve is also vulnerable to injury at this point. Traction on the esophagus enables the fistula to be secured with stay sutures. After withdrawing the ureteric catheter (and 2.2 mm bronchoscope if deployed), the fistula is divided and the tracheal component repaired with 5-0 or 6-0 interrupted prolene sutures. The esophagus is closed with 5-0 or 6-0 polydioxanone sutures. Some authors recommend tissue interposition between esophageal and tracheal suture lines to prevent a recurrent fistula.

The infant should remain intubated and ventilated in the early postoperative period, as tracheal edema can result in progressive stridor.[71] The vocal cords should be checked on extubation, given the significant risk of recurrent nerve palsy. Nasogastric tube feeding may commence after 48 hours and oral feeds may be slowly introduced thereafter.

The Nd:YAG laser has also been successfully used to treat congenital H-type TEF. Repeated short duration pulses of laser light are used to coagulate the fistula.[72] Despite some success with this approach, the technique has not gained widespread acceptance, and open repair remains the gold standard. Complications following open surgery include recurrent laryngeal nerve palsy (both unilateral and bilateral), and rarely, recurrent fistula.

COMPLICATIONS AND SPECIAL CONSIDERATIONS

Anastomotic leak

The incidence of anastomotic leak following repair of EA and TEF ranges from 11 to 21%.[50,73] Major anastomotic disruption is uncommon and is usually manifested by early tension pneumothorax and gross salivary drainage from the chest drain. In these situations, it is rare for the anastomosis to be completely disrupted. Provided a transanastomotic tube is in place, it is usually possible to control the leak with an adequately sized chest drain. With good drainage, broad-spectrum antibiotics, and total parenteral nutrition, the esophagus will usually heal, although a prolonged period of chest drainage may be necessary. Some surgeons have used hyoscine patches in an attempt to 'dry up' the salivary leak. Others advocate early re-exploration (<48 hours), with direct repair of the esophagus if possible, and the establishment of satisfactory drainage.[13,74] This early re-operative approach may prove hazardous and further compromise a tenuous anastomosis. Where conservative management of a major leak proves unsatisfactory due to uncontrolled sepsis, the establishment of a cervical esophagostomy and a feeding gastrostomy are essential. This usually commits the child to some form of delayed esophageal replacement after recovery. It has been suggested that a clinical anastomotic leak predisposes to the development of an esophageal stricture.[75] While this association may seem logical, others have not been able to confirm such a correlation.[73]

GER

Significant GER occurs in 40–50% of children following repair of EA and TEF. GER may cause failure to thrive, can predispose to recurrent aspiration episodes, and may lead

to esophagitis and stricture formation.[2] Management of symptomatic GER initially entails aggressive medical therapy. Postural therapy and close attention to feeding regimes, with calorie supplementation of formula feeds, combined with the selective use of overnight continuous pump feeding by nasogastric tube and frequent small daytime bolus feeds may prove effective management strategies. Feed thickeners (e.g. Carobel) antacid preparations (e.g. Gaviscon), H_2-antagonists (e.g. ranitidine), proton pump inhibitors (e.g. omeprazole), and prokinetic agents (e.g. domperidone), may be used in various combinations if vomiting is significant. However, should such measures fail to control GER, surgical treatment may be the only option.

GER may contribute to recurrent aspiration episodes, with frequent symptoms of respiratory distress including tachypnea, apneic episodes, cyanosis, and x-ray evidence of patchy pneumonic changes. The differential diagnosis in this clinical setting also includes swallowing incoordination and respiratory distress due to significant tracheomalacia. It is not uncommon to see infants in whom all of these factors are operating to a variable degree. It is important not to overlook the possibility of a recurrent TEF as a cause of repeated episodes of respiratory distress, although the history of choking and cyanotic episodes during feeding is usually much more evident in infants with a recurrent fistula. The selective use of esophageal pH monitoring, contrast meal, bronchoscopy, and assessment of swallowing by video fluoroscopy, may assist in evaluating the contribution of GER and other pathologies to respiratory symptoms. Failure to control GER-related symptoms despite full medical therapy is an indication for fundoplication.

Fundoplication rates following surgery for EA vary widely between centers (6–45%), reflecting the differing enthusiasm for anti-reflux operations in this clinical setting.[2,76] There are several reasons for caution when considering fundoplication in EA patients. Dysphagia may be aggravated as a consequence of underlying esophageal dysmotility. Furthermore, fundoplication following EA has a higher failure rate (15–38%) than is generally seen in otherwise normal patients with isolated GER.[77] Some authors recommend a partial wrap (Thal) fundoplication, because of the lower incidence of postoperative dysphagia.[76] Despite these concerns, many pediatric surgeons prefer a short (1.5–2.0 cm) 360° floppy Nissen wrap for its proven effectiveness in reducing GER.[78] The high failure rate of fundoplication and the significant complications associated with surgical treatment of GER, demand vigilant follow up in this group of patients.

Anastomotic stricture

Reported definitions of esophageal stricture following repair of EA lack consistency. The incidence of symptomatic strictures requiring dilatation varies from 37 to 55%.[50,75] Some degree of anastomotic narrowing is seen in all postoperative contrast studies, but this is rarely of a sufficient degree to cause symptoms in the early postoperative period. Parents should be counseled to report symptoms of prolonged feeding, incomplete feeding, or associated respiratory difficulty. Contrast studies may be arranged. More often such symptoms reported by well-trained parents prompt us to arrange surveillance endoscopy to assess the caliber of the esophageal anastomosis. Balloon dilatation is our preferred method of treating symptomatic strictures. The radial dilating forces generated during balloon dilatation are considered to be less traumatic than the longitudinal shearing forces caused by conventional bougienage.[79] Balloon dilatation is performed under fluoroscopic control, by passing a guide wire through the stricture, over which a balloon dilator of appropriate size is introduced. Its position is confirmed by partially filling the balloon with contrast medium, so that 'waisting' due to the stricture is centrally located (Fig. 39.7). The balloon is then maximally inflated using contrast medium to dilate the stricture. A contrast esophagogram is performed after removing the balloon to ensure there has been no perforation. If a stricture requires repeated dilatations, GER should be fully investigated by a combination of an upper gastrointestinal contrast study, pH study, and endoscopy. Recalcitrant strictures may require repeated dilatations, fundoplication, and rarely formal resection at thoracotomy.

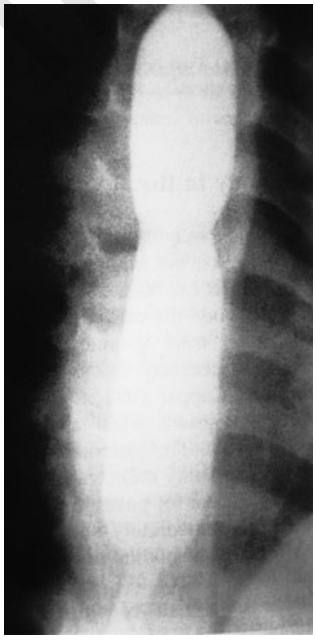

Figure 39.7 'Waisting' due to anastomotic stricture at balloon dilatation.

Tracheomalacia

Tracheomalacia is present to a variable degree in all patients with EA. It is thought to be responsible for the characteristic barking TEF cough.[2] Infants with tracheomalacia demonstrate expiratory stridor, which may result in episodes of desaturation, apnea, cyanosis, and bradycardia (often associated with feeding), and life-threatening so-called 'dying episodes'. Severe tracheomalacia may be evident in the early postoperative period, when it proves difficult to wean the infant from the ventilator.

Indications of the severity of tracheomalacia include ventilator dependency, respiratory distress characterized by stridor, and chronic carbon dioxide retention, and dying episodes. Full investigation for severe GER and recurrent TEF (see below) is advisable alongside evaluation of tracheomalacia, as aspiration secondary to GER and a recurrent fistula can mimic these symptoms. The extent of tracheomalacia is assessed by bronchoscopy under conditions of spontaneous respiration. The lumen of the trachea is significantly compressed anteroposteriorly and assumes a scabbard-like appearance during expiration due to tracheal cartilage deficiency. A further contribution is often made by the upper esophagus, which may bulge posteriorly into the airway. Tracheobronchomalacia can extend beyond the carina into the main bronchi.

As tracheomalacia can be self-limiting, surgical intervention is reserved for patients with life-threatening symptoms.[2] Treatment options include continuous positive airway pressure (CPAP), aortopexy, tracheostomy, and, more recently, tracheal stenting.[77,80] CPAP is a useful temporizing measure, but may be required for several weeks. Aortopexy is traditionally performed by anterior left thoracotomy through the third interspace. The left lobe of the thymus is excised to gain access to the root of the aorta taking care not to damage the phrenic nerve. Plegetted sutures incorporating reinforcing dacron squares are placed through the adventitia of the aortic root and the ascending aorta. The sutures are passed through the periostium of the manubrium and tied, hitching the aorta forwards, thereby relieving compressive forces on the trachea. Although this operation cannot resolve distal tracheobronchomalacia, it often provides immediate dramatic symptomatic relief. Failure of aortopexy may be an indication for tracheostomy, although some authors advocate tracheal stenting in this situation.[2,77,80]

Recurrent TEF

This complication is thought to occur in 5–15% of cases.[81] A recurrent TEF may result from an anastomotic leak, but the possibility of a missed upper pouch fistula should always be considered. Symptoms include recurrent chest infections and choking attacks during feeding. A high index of suspicion is required if the diagnosis is not to be overlooked. Chest x-ray may sometimes reveal an air esophogram. The initial investigation is prone video esophagography. If this study fails to demonstrate a fistula and the diagnosis remains strongly suspected, combined esophagoscopy and bronchoscopy should be performed. Rigid bronchoscopy is performed initially, and the site of the original fistula carefully examined. The fistula is gently probed with a ureteric catheter and methylene blue is carefully instilled into the fistula pit. Synchronous flexible esophagoscopy is performed to see if the dye can be seen entering the esophagus. Should this fail to demonstrate the fistula, an air/water test is a useful supplementary investigation. The esophagus is filled with water and positive pressure ventilation applied to the bronchoscope. Occasionally, bubbles of air can be seen emanating from the fistulous opening into the esophagus (Rintala, personal communication).

Several strategies have been described to deal with the recurrent TEF. The traditional approach is formal repair via right thoracotomy. At bronchoscopy, an attempt should be made to pass a fine ureteric catheter through the fistula into the distal esophagus. A flexible miniature bronchoscope (2.2 mm, Olympus) may be useful to navigate, cannulate, and brightly illuminate the fistula tract. The fistula is repaired using a similar strategy to that deployed for the H-type variant, i.e. isolation/slooping the esophagus repairing the fistula as described above under H-type TEF. Tissue interposition between suture lines is sometimes advisable in an attempt to reduce the chances of further fistula formation. A 10–22% risk of refistulation has been reported.[82] Other approaches have been described to treat recurrent TEF including diathermy fulguration of the fistula tract.[82] This technique has been refined using the Nd:YAG laser to obliterate the epithelial communication. Sclerosing agents, histoacryl, and fibrin glues have all been injected subepithelially to occlude fistulae. A recent review of endoscopic therapies reported an overall closure rate of 55% with several sessions required to effect cure. A study from Oxford concluded that formal surgical re-exploration remained the treatment of choice, except in high-risk patients.[81]

RECENT ADVANCES

Developments in minimally invasive surgery have now extended to the EA and TEF newborn population. In 2002, Rothenberg reported the technical feasibility of endoscopic repair in a personal series of eight newborns with EA-TEF ranging in weight from 2.1 to 3.4 kg.[83] This study followed the first pioneering operation of EA in a two-month-old infant in 1998. Collaboration from members of the International Pediatric Endoscopic Surgery Group (IPEG) promoted a 2005 multi-institutional analysis of thoracoscopic repair from centers in the US, Europe, and Hong Kong.[84] One hundred and four babies with common variant EA and TEF (excluding H-type and long-gap without fistula) were included. Of these, there were five (4.8%) conversions to open thoracotomy and a staged repair in one baby due to unforeseen long-gap EA-TEF. Twelve infants (11.5%) developed early leaks and strictures and 32% required esophageal dilatation(s). Survival in this selected population was 97% with three deaths recorded of which one was directly related to the EA-TEF repair on the 20th postoperative day. Additional operations were required for associated anomalies. These included duodenal atresia repair, imperforate anus surgery, aortopexy, and cardiac procedures. Twenty-five babies (24%) also underwent laparoscopic fundoplication for GER. In 2009, MacKinlay reported equally good outcomes in a study of 26 infants – 88% survival, 27% leak rate – all minor not requiring operation and 35% acquired strictures needing dilatation(s).[85] Long-term benefits from minimally invasive surgery include a reduction in musculoskeletal morbidity, notably winged scapula, and unsightly skin scarring. For pediatric surgery centers currently not offering advanced endosurgical repair, the axillary skin crease incision popularized by Bianchi provides an excellent alternative with good esthetic outcome and comparable reductions in skeletal morbidity.[39]

QUALITY OF LIFE AND LONG-TERM OUTCOME

The improved survival of babies born with EA and TEF has prompted a more detailed analysis of morbidity, with emphasis on long-term outcome data.[86] Several studies have examined respiratory function in EA children.[87–90] Symptoms of asthma and bronchitis are frequent, especially in the young child, and may persist into adolescence. Almost half of all children require future hospitalization due to ongoing respiratory morbidity. In a large, Melbourne series comprising 334 EA children, episodes of pneumonia were seen in 31% of children under the age of five, compared with 5% of those over 15.[89] The prevalence of annual attacks of bronchitis in these two age groups was 74 and 41%, respectively, with asthmatic symptoms reported in 40% of patients from each age range.[87] Spirometry studies have demonstrated both obstructive and restrictive abnormalities in over half the patients, and a similar proportion had a maximal working capacity below the normal range.[88] Tracheobronchial inflammation and airway narrowing have been demonstrated by bronchoscopy in one-third of patients, with histological evidence of inflammation in a further third.[89] It is plausible that abnormalities of bronchial anatomy, which are common in EA and TEF, may contribute to respiratory morbidity. Regular clinical assessment by a respiratory physician, with chest physiotherapy and aggressive antibiotic treatment for infective exacerbations is recommended. The contribution of aspiration episodes, whether due to esophageal dysmotility or GER, to respiratory symptoms, should be actively investigated. Recognition of the long-term respiratory morbidity associated with EA patients, prompted the establishment of a specialist TEF clinic at Alder Hey, which is staffed by pediatric surgeons, respiratory physicians, physiotherapists, and dieticians. This multidisciplinary team approach ensures that attention is focused on all aspects of the child's ongoing welfare. Other centers equally report the benefits to the child and family of this coordinated follow-up plan.

Esophageal dysmotility is a significant factor in long-term morbidity.[91] It is clearly implicated in many cases of food bolus impaction when endoscopy reveals no significant anastomotic narrowing. Less severe symptoms of dysphagia have been reported in 20% of adolescents[91] and in 48% of adults on long-term follow up. Esophageal manometry and fluoroscopy studies will demonstrate degrees of dysmotility in nearly all patients.[88] The dysmotility associated with EA may reflect intrinsic innervation abnormalities of the esophagus.[92] This may further contribute to respiratory morbidity through repeated 'silent' aspiration episodes.

GER may persist into adult life. Reported symptoms of heartburn and acid brash range from 18%[89] to 50%[88] in long-term follow-up studies. Clinical symptoms may underestimate the true incidence of GER as demonstrated by esophageal pH monitoring. An 8% incidence of Barrett's esophagus has been reported.[93] The relative risks of esophageal adenocarcinoma are uncertain although five cases have been recorded in the literature.[94,95] These observations highlight the importance of comprehensive long-term follow up with the pediatric surgeon's duty to ensure robust transitional care pathways for children as they become adolescents with transfer to adult medical and surgical services where indicated.

Various quality of life measures have been used to evaluate adults treated for EA and TEF. Using a Spitzer index and a gastrointestinal QoL index, it has been shown that adults who underwent primary anastomosis as newborns enjoyed an unimpaired quality of life. Quality of life measures were more favorable in patients who had native esophageal repair compared to colonic interposition.[86] Psychosocial assessment scores have further demonstrated more learning, emotional, and behavioral difficulties in EA adults than the general population.[96] Cognitive performance was also significantly impaired in a high risk group characterized by associated major congenital anomalies and/or the requirement for prolonged ventilation in the neonatal period.[90]

An energetic support group (TOFS), a UK-based charity was founded in 1982 for the benefit of children and parents. The organization with over 1000 members (www.tofs.org.uk) provides a useful resource of excellent information together with a handbook 'The TOF Child'.[97] With regular conferences attended by health care professionals and families, opportunities exist for exchange of knowledge and advice. The TOFS organization also raises valuable funds for research.[2] Similar valuable support networks exist in other European countries, e.g. KEKS in Germany.

Congenital esophageal stenosis

SHINTARO AMAE AND MASAKI NIO

INTRODUCTION

Difficulties in obtaining a differential diagnosis of congenital esophageal stenosis (CES) from achalasia and secondary esophageal stenosis, especially stricture due to reflux esophagitis,[1] have resulted in various clinical problems in its treatment. CES is defined as an intrinsic stenosis of the esophagus caused by congenital malformation of the esophageal wall architecture. This malformation may result from:

- tracheobronchial remnants in the esophageal wall;[2–16]
- fibromuscular thickening of the esophageal wall;[1,11,17–21]
- membranous mucosal diaphragm or web.[8,11,22–30]

Achalasia, inflammatory esophagitis, and stenosis caused by tumor or extrinsic compression of the esophagus should be excluded from this category. The localization of the stenosis varies with the type of pathology. Stenosis due to tracheobronchial remnants is the most common type of pathological anomaly, and is localized to the distal esophagus,[12] whereas fibromuscular thickening is generally found in the middle or lower portions of the esophagus.[11,21] Membranous webs are normally observed in the upper or middle levels of the esophagus.[11,26–30] In general, the stenotic area in cases with tracheobronchial remnants is usually localized, and that of fibromuscular stenosis varies from one to several centimeters in length with circular thickening of the esophageal wall. In almost all cases of membranous web, a single web is found in children;[26,28,30] however plural webs, termed multiple trachea-like rings, are observed in young adults.[31–33]

PATHOLOGICAL FEATURES

In the stenotic segment caused by tracheobronchial remnants, mature or immature cartilage, the seromucous tracheobronchial glands and ciliated epithelium are generally found microscopically. Tracheobronchial remnants are believed to be the result of failure in the normal separation of the embryonic respiratory tract from the foregut. In fibromuscular cases, circumferential proliferation of smooth muscle fibers with moderate fibrosis was revealed.[11,21,34] Singaram *et al.*[35] reported a significant reduction of myenteric nitrinergic neurons and fibers in the muscle layer of two young adults diagnosed with CES. Lack of submucosa[27] and loose, vascular connective tissue, and diffuse lymphocytes[26] were observed microscopically in specimens of membranous web.

CLINICAL FEATURES

CES is a rare condition that occurs in 1 in 25 000–50 000 live births.[1,11] Although the reason is unknown, the incidence of CES is higher in Japan than elsewhere.[8,36] There is no sex predisposition. The incidence of other anomalies in association with CES has been reported to be 17–33%.[11,36] For instance, the association of CES with congenital esophageal atresia,[9–11,18,19,24,37–42] cardiac anomalies,[11,24] intestinal atresia,[11,23] anorectal malformation,[10,36] chromosomal anomalies,[7,11,21,23] etc. has been reported in the literature. Surgeons should keep in mind the association of congenital esophageal atresia with distal CES due to tracheobronchial remnants.

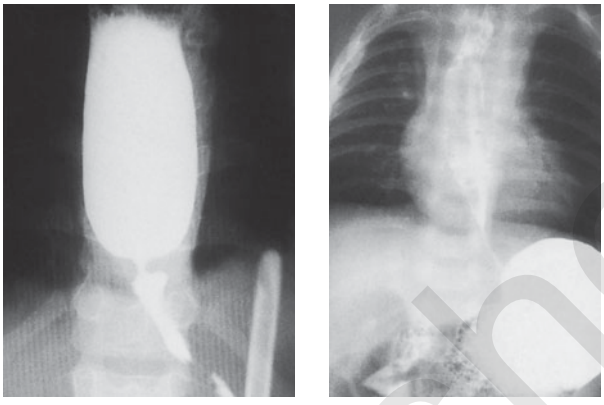
Symptoms of CES include vomiting or regurgitation, dysphagia, recurrent respiratory tract infections, and growth retardation. The onset of regurgitation coincides characteristically with the introduction of semi-solid and solid foods around the age of six months in patients with tracheobronchial remnants.[34] However, the development of symptoms rarely occurs in newborns.[25] In some patients, a foreign body in the esophagus may be the first symptom noted.[1]

DIAGNOSIS

Patients who develop the symptoms described earlier should undergo a barium swallow. Esophagograms show a tapered or abrupt narrowing of the esophagus in association with

various degrees of dilatation of the suprastenotic portion of the esophagus (Fig. 40.1). Most of the stenoses due to tracheobronchial remnants are present as an abrupt narrowing on the esophagogram, while fibromuscular stenosis usually shows a tapered narrowing.[40,42] Following surgery for the treatment of congenital esophageal atresia with or without tracheo-esophageal fistula (TEF), an esophagogram should be evaluated with great care to avoid failing to find a narrowing at the mid-distal esophagus. It was reported that 4.9–14% of TEF cases were associated with CES.[40,43,44] Esophagoscopy, manometric study, and pH monitoring are helpful tools for the differential diagnosis of CES from achalasia and secondary esophageal stricture due to gastro-esophageal reflux. Esophageal endoscopy can directly evaluate not only the stenotic area (Fig. 40.2) and the site of the gastro-esophageal junction but also the presence of esophagitis. The mucosa distal to the stenosis is normal in CES. In addition to esophagoscopy, endoscopic ultrasonography has been recently employed to evaluate the etiology of CES and is useful in deciding the strategy, either balloon dilatation or surgical treatment.[41,45,46]

In cases of CES, preoperative esophageal manometry demonstrates a normal pattern of the lower esophageal sphincter and a small high-pressure zone in the resting pressure profile (Fig. 40.3), which corresponds to the stenotic area of the esophagus (this small high-pressure zone disappears after corrective surgery). Moreover, an esophageal motility study reveals aperistalsis corresponding to the stenosis. pH monitoring revealed that significant positive reflux is not a feature in patients with CES in contrast to that seen in patients with gastro-esophageal reflux.



(a) (b)

Figure 40.1 Abrupt (a) and tapered (b) narrowing on esophagograms.

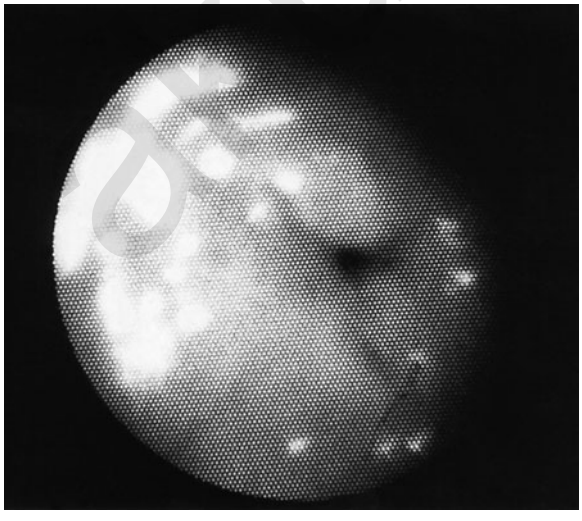


Figure 40.2 Endoscopic view of the stenotic portion of the esophagus.

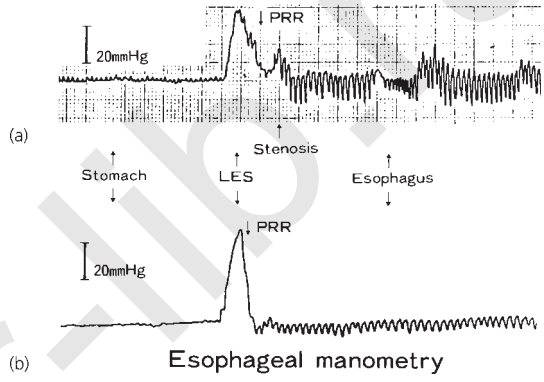

Figure 40.3 (a) Preoperative and (b) postoperative resting pressure profile of the gastro-esophageal junction and the esophagus in a case of CES with tracheobronchial remnants. A small high-pressure zone in the lower esophagus is noted and this disappeared after the corrective operation.

TREATMENT

The principles in the treatment of CES patients are the relief of the symptoms caused by esophageal stenosis and maintenance of the anti-reflux mechanism of the gastro-esophageal junction. This condition can be treated conservatively or by surgical intervention.

Balloon dilatation, as a conservative treatment, is the first choice of treatment for CES patients. Balloon dilatation should be tried not only for patients with tapered narrowing but also in patients with abrupt narrowing, when a balloon catheter can be passed safely through the stenotic area. We usually use the low-compliance (Rigiflex®) balloon catheter.[42] The effect of balloon dilatation varies with the type of pathology. Cases with membranous web of the esophagus and some cases of fibromuscular stenosis can be treated successfully by suitable dilatation.[11,26,28,29] Recently, successful treatment of membranous web using endoscopic instruments (electrocauterization, high-frequency-wave snare/cutter) have been reported.[47,48]

As a rule, when patients fail to respond to repeated (four to six times) attempts of bougienage, surgical intervention should be considered. Surgical resection of the stenosis followed by end-to-end esophageal anastomosis is a general surgical treatment for many cases with tracheobronchial remnants[6,8,10–16,36,39–42] and several cases with fibromuscular

thickening.[21,34] Circular myectomy was recently developed as the new surgical option to release the stenotic segment due to tracheobronchial remnant.[49,50]

Complications of treatment, as reported in the literature, are iatrogenic esophageal perforation by bougienage,[10,41] anastomotic stenosis, and leakage after surgical resection. In particular, iatrogenic esophageal perforation often requires an emergency operation. Circular myectomy is expected to prevent postoperative leakage and re-stenosis of esophageal anastomosis.[49,50]

PREOPERATIVE PREPARATION

Those patients who are undernourished should have their nutritional status corrected prior to surgery. Such patients may require total parenteral nutrition and/or enteral nutrition via a nasogastric tube or gastrostomy. Prior to the surgical procedure, it is essential that the surgeon knows the exact site and extent of the stenosis, and the distance from the gastro-esophageal junction. When the stenosis is situated in the distal portion of the esophagus, the authors always perform cineradiography and another special fluorographic procedure. In this procedure, first, a balloon catheter is inserted through the esophagus across the stenosis, and then barium is orally administered. Immediately following this, the balloon is inflated and pulled up. Adequate traction should position the balloon just below the stenosis allowing a clear image of the stenotic area (Fig. 40.4).

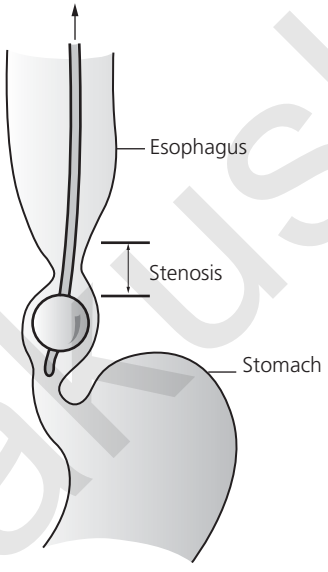

Figure 40.4 A special fluorographic examination for the evaluation of the exact site and extension of the stenosis. Stenosis is located between the dilated pouch of the esophagus and the balloon.

OPERATIVE PROCEDURE

Most cases of CES can be operated upon via the thoracic approach. However, when the stenosis is localized in the abdominal esophagus, the abdominal approach may be utilized. In a few cases of CES, complete resection of the stenotic segment using the thoracoscopic[51] or laparoscopic approach[52] has been reported. In the thoracic approach, right thoracotomy is employed for a stenosis in the middle portion of the esophagus, and left thoracotomy for a stenosis in the lower part of the esophagus. After exposing the esophagus, the authors insert a balloon catheter beyond the stenotic segment from the mouth to locate the stenotic segment. The balloon catheter is inflated and pulled up to confirm the lower margin of the stenosis. Following resection of the distal end of the stenosis, a sterile balloon catheter is passed through the stenotic area from the oral stump of the esophagus. The upper margin of the stenosis is decided by pulling down the catheter (Fig. 40.5).[42]

Complete removal of the stenotic area should be performed. Anastomosis should be made without tension. The use of single- or double-layer interrupted sutures using absorbable material is justified. The surgeons should, of course, pay attention to preservation of the phrenic and vagal nerves during surgery.

The possibility of simple excision of cartilaginous remnants and subsequent repair of the esophageal wall is limited.[5,11,42] Therefore, segmental resection with end-to-end anastomosis of the esophagus should be a standard procedure for patients with a stenosis in the mid or lower esophagus that is not close to the gastro-esophageal junction.

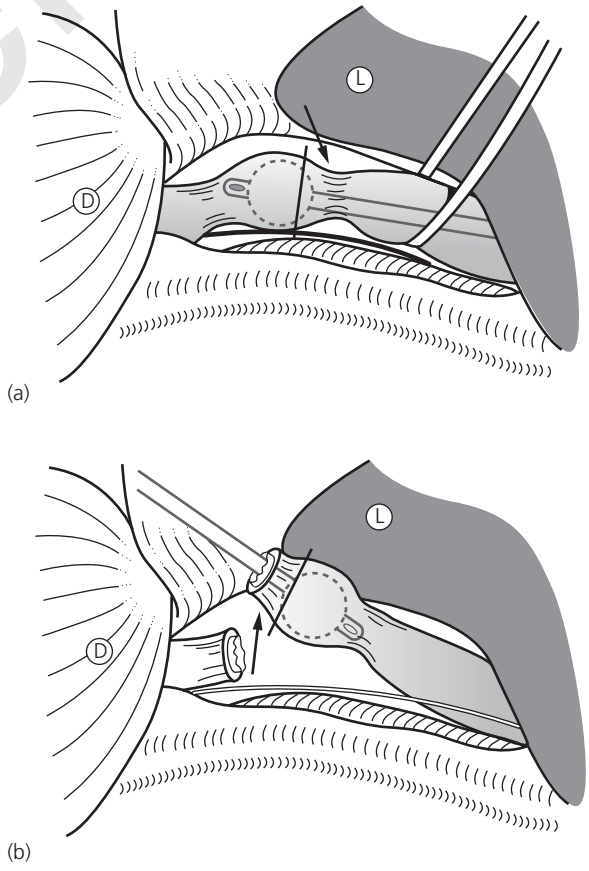

Figure 40.5 An intraoperative procedure by use of a Foley catheter to determine the (a) distal and (b) proximal sites of stenosis (arrows). (Solid line, resection line; D, diaphragm; L, lung.)

However, to prevent postoperative reflux, an anti-reflux procedure, for example a Nissen's fundoplication (Fig. 40.6) may be necessary, in addition to segmental resection, when the stenosis is situated close to the gastro-esophageal junction.[42] If the vagal nerve is severed by accident, a pyloroplasty should be performed. Patients with extensive fibromuscular stenosis necessitating resection of the esophagus of more than 3 cm may require esophageal replacement with a colon, jejunum, or gastric tube.

In circular myectomy, the stenotic segment is determined by pulling up and pushing down a balloon catheter inserted through the mouse. The muscular layer is incised to the mucosal layer at the lower and upper margins. Subsequently, the muscular layer is dissected circumferentially using sharp scissors or cautery (Fig. 40.7). The muscular layer is closed horizontally by interrupted absorbable sutures.[49,50]

Complications, such as an iatrogenic esophageal perforation following bougienage[10,53] and a leakage after segmental resection and reconstruction of the esophagus,[11] have been reported. Perforations and major leakages require surgical drainage, but minor leakages can be treated successfully by maintaining the patient on total parenteral nutrition. When gastro-esophageal reflux develops following simple resection and anastomosis, the anti-reflux procedure should be carried out.

Esophageal duplication cysts

DAKSHESH PARIKH AND MICHAEL SINGH

INTRODUCTION

Esophageal duplications and bronchogenic cysts are part of the spectrum of foregut malformations as both seem to have their origin in the primitive foregut.[1] Foregut duplication cysts in children account for up to one-third of mediastinal cysts and are one of the main differential diagnoses for posterior mediastinal tumors. In the literature, approximately 21% of gastrointestinal duplications are reported to be of esophageal origin.[2,3]

Esophageal duplication cysts are seen in close proximity to the esophagus. There may be associated duplications elsewhere in the gastrointestinal tract. Some of the esophageal duplications can be thoraco-abdominal in nature.[4,5] In contrast, bronchogenic cysts are more frequent and are closely associated with the tracheobronchial tree or within the lung parenchyma. Unlike bronchogenic cysts esophageal duplication cysts are commonly associated with vertebral anomalies. In the presence of a vertebral anomaly, rarely an intraspinal communication can be identified. This variant is called a neuroenteric cyst.[6]

ETIOLOGY

Esophageal duplications are thought to be a result of an aberrant dorsal foregut development during weeks 4–8 of gestation. One of the embryological theories implicates inappropriate canalization or failure of connection of the vacuoles as canalization of the gastrointestinal tract occurs to form a lumen. The other theory proposes a diverticulum occurring during the development of the gastrointestinal tract that may result in duplication with or without connection with the intestinal lumen. Both these theories fail to explain the various types of duplications occurring in the gastrointestinal tract. The split notochord theory in contrast can explain the association of vertebral anomalies with mediastinal duplications. The notochord is formed by the ingrowth of the mesodermal cells and separates from the endoderm. In the event of adhesion with the endodermal lining, it is drawn inside the spinal canal not allowing the spinal canal to close ventrally. It is possible that both ends of this connecting tract may remain open or closed on either side. The cephalic end may represent a fibrous cord, or connect to the cysts on either side, or disappear altogether as seen in most instances.[1]

PATHOLOGY

Esophageal duplications are described as cystic, tubular, or neuroenteric in nature. Over 60% of the esophageal duplication cysts are associated with the lower esophagus and the rest are identified within the upper and middle third of the esophagus. They generally have a thin wall of muscle coat and are in close proximity to the native esophagus or can be within the esophageal wall. Rarely some of the esophageal duplications can be simple epithelial lined cysts. The cysts can contain either a clear mucoid, brown, or blood-stained serous fluid. The majority do not communicate with the spinal canal or have an associated vertebral anomaly. Duplication cysts can have a wide variety of mucosal linings: squamous, gastric, pseudostratified, cuboidal, columnar, ciliated respiratory tract lining, or pancreatic cells.[4,5] A mixed epithelial lining within the cyst is commonly reported.[3,7,8] The symptomatic duplication may therefore bleed within the cyst or cause pressure symptoms onto the surrounding structures, such as trachea, esophagus, or fistulate.

PRESENTATION

The majority of esophageal duplication cysts present in early childhood and some are detected antenatally (Fig. 41.1a). In our experience of the antenatally detected, cystic thoracic lesions, approximately 5% of cases are subsequently diagnosed as foregut duplications. The majority of antenatally detected cases are asymptomatic at birth. Patients can present in infancy with: acute respiratory distress, stridor, dysphagia,

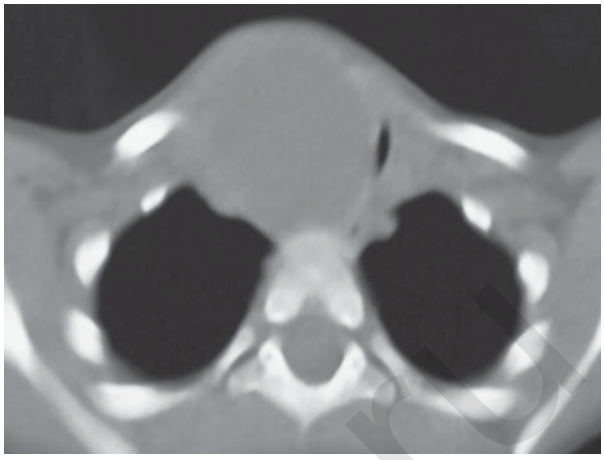
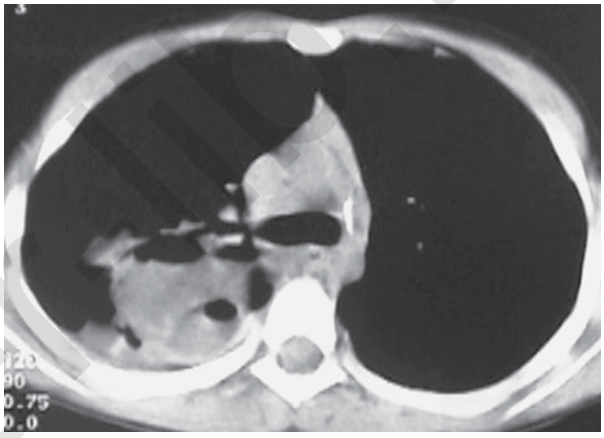
meningitis, and the sudden appearance of a cervical mass (Fig. 41.2a,b). Sudden death has been reported in some untreated cases where the most plausible explanation would be the rupture of the cyst into the tracheobronchial tree.[8,9]

Occasionally, duplications may be an incidental finding on chest x-ray (Fig. 41.3). The symptoms in older children are generally related to pressure on the surrounding structures. Esophageal compression causes dysphagia (Fig. 41.4b).



(a)



(b)

Figure 41.2 (a) Computed tomography (CT) scan demonstrating a large cervical esophageal duplication with tracheal compression and deviation, in a patient with acute stridor and sudden appearance of a cervical mass. (b) CT scan showing an infected duplication cyst with a fistula into the right upper lobe bronchus. This patient had recurrent pneumonia and developed a right upper lobe lung abscess seen on chest x-ray.

Tracheal compression results in stridor or respiratory compromise (Fig. 41.2a). These cysts may ulcerate, bleed, and rupture into the esophagus or tracheobronchial tree causing recurrent pneumonia, pain, hemoptysis. and lung abscess (Fig. 41.2b).[3,7,8] Both squamous cell carcinoma and adenocarcinoma in esophageal duplication cysts have been reported in adults.[10,11]

A high preoperative mortality (10%) has been reported in a large retrospective study.[8] The reported deaths are a consequence of exsanguinating bleeding into the esophagus, respiratory compromise, or septic complications.[8]

DIAGNOSIS

All antenatally diagnosed thoracic, cystic lesions must be investigated postnatally with contrast-enhanced computed tomography (CT) scan. A foregut duplication on CT scan is located in the posterior mediastinum in contact with the

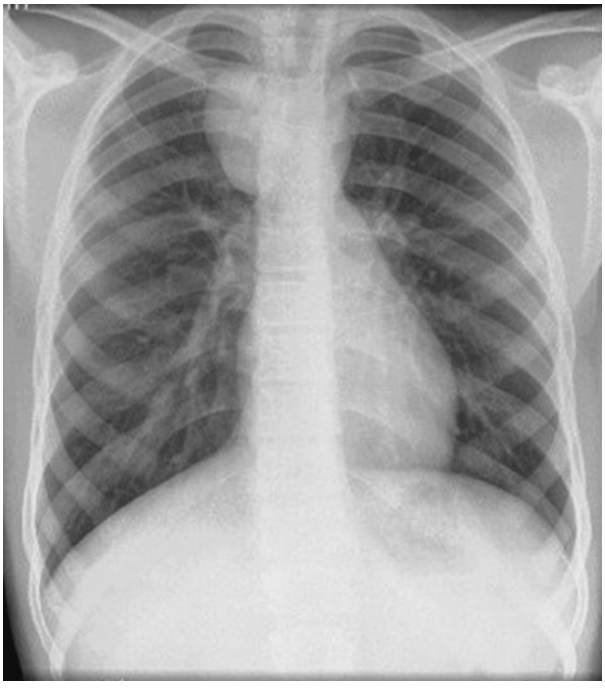


Figure 41.3 Incidental chest x-ray finding of a duplication cyst in a previously asymptomatic patient. This x-ray was done for blunt chest trauma. Subsequent investigation confirmed this to be an esophageal duplication.

esophagus or trachea. Typically, they are described as a low attenuation, homogenous cystic mass with a smooth border (Figs 41.4c and 41.5d).[12]

Plain x-ray may reveal a paravertebral, smooth round shadow. In symptomatic cases there may be a deviated or compressed trachea (Figs 41.2a and 41.4c). The plain x-ray is also useful in demonstrating associated vertebral anomalies (Fig. 41.5a).

In children presenting with dysphagia, a contrast swallow will demonstrate a smooth shadow compressing the esophagus (Fig. 41.4b). In the acute onset of stridor, a CT scan will show a cystic mass causing tracheal compression (Fig. 41.2a). The lower esophageal duplication cysts are likely to remain asymptomatic and can present in adulthood either on an incidental x-ray or with symptoms such as chest pain, dysphagia, or hematemesis (Fig. 41.5b). Magnetic resonance imaging (MRI) should be considered in the presence of vertebral anomalies for the diagnosis of an intraspinal component (Figs 41.1b and 41.5c). Upper gastrointestinal endoscopy and esophageal ultrasonography add little to the diagnosis of the esophageal cyst.

MANAGEMENT

Esophageal duplications warrant complete excision as incomplete excision inevitably results in a recurrence.[8] Antenatally diagnosed cases after investigation should be electively excised preferably with the thoracoscopic approach. In most instances, symptomatic cases are suitable for thoracoscopic resection with the exception of infected cases with fistulation (Fig. 41.2b). Thoracoscopic excision is being increasingly used for the management of esophageal duplication cysts.[13–15] The thoracoscopic approach has been shown to have lower opioid requirements, shorter duration of chest tube drainage and hospital stay.[14,15] Previous inadequate resection with recurrence may require an open approach for a complete resection.

Thoracoscopic resection
