# Preface

Most obstetricians and pediatricians would agree that the examination of the placenta often helps to explain an abnormal neonatal outcome. As early as in 1892, Ballantyne wrote,

*A diseased foetus without its placenta is an imperfect specimen, and a description of a foetal malady, unless accompanied by a notice of the placental condition, is incomplete. Deductions drawn from such a case cannot be considered as conclusive, for in the missing placenta or cord may have existed the cause of the disease and death. During intrauterine life the foetus, the membranes, the cord and the placenta form an organic whole, and disease of any part must react upon and affect the others.*

Similar thoughts were succinctly detailed in Price's (1950) discussion of his concept of the prenatal biases as they affected twins. His contribution also admonishes us that placental study is a *sine qua non* for a more perfect understanding of fetal development. Despite all this understanding of the past and appreciation for placental disease, great resistance still exists to perform the task of placental examination routinely. For many pathologists, therefore, the placenta has remained a mysterious organ.

This book had its beginning in 1967 when Shirley G. Driscoll and Kurt Benirschke wrote the volume on placental pathology for the *German Handbook of Pathology*, the "Henke-Lubarsch." Because there seemed to be a need for wider dissemination of the text, this book was reprinted by Springer-Verlag New York but soon became unavailable. Since then, a number of books on placental pathology have been written, in French, English, and German (Philippe, Baldwin, Fox, Lewis and Perrin, Lavery, Gall, Kraus et al., Naeye, Becker and Röckelein, Vogel, Kaplan, and Joshi), and much more interest has been accorded this so readily available but poorly studied organ. The journal *Placenta* has become a significant outlet for results from sophisticated placental studies. Regular trophoblast conferences are being held in Rochester, New York, and European and international meetings were organized. Much other new information has been obtained, and the continuing enigma of placental nonrejection has been tackled by numerous investigators. In addition, the availability of the placenta for biochemical study has stimulated many cell biologists and molecular biologists to use this organ as a convenient source of human tissue. Genetic information now adds to our understanding of the complexity of placental function and other issues. Also, because much interest is developing in comparative placentation, a new Web site may be found at <http://medicine.ucsd.edu/cpa>.

This fifth edition is being written because so many new findings have come from systematic study in the last few years that updating seemed necessary. Moreover,

there is a great need to have documentation for legal purposes as the placenta has become an important aspect of medicolegal adjudication of circumstances around the time of birth. The organization of the previous edition also left some topics uncovered that are now being corrected. Many changes have been made throughout the book. Not only was the text updated, but also a more complete index was created, the order of chapters is presented more logically, and tables are presented more usefully. The text was written with MSWord. A complete set of diskettes with the references can be made available from the authors, if the reader desires.

I (K.B.) am indebted to many people, foremost to my wife for her understanding and patience with me and with this task; the publishers and many of its staff members have been gracious and patient; my colleagues at the university, and other persons who have all helped gather data, are gratefully acknowledged. Many students and colleagues have graciously read most chapters and they have made many helpful suggestions and corrections, for which I am appreciative. There are some colleagues, however, whose inspiration have helped more than others: Marjorie Grafe; the dysmorphologists Kenneth L. Jones, his wife Marilyn, and their numerous fellows as well as neonatologist Frank Mannino; and ultrasonographer Dolores Pretorius, who continues to challenge me and requires that I provide explanations for perinatal deaths and abnormalities. Having examined all placentas of all deliveries in the institutions with which I was affiliated over the past five decades, I have gathered a large amount of material to digest. Most of all, however, I am grateful to Dr. Geoffrey Altshuler, Oklahoma City, for many stimulating discussions and endless patience with me and his friendship.

P.K. gratefully acknowledges the scientific cooperation of many former and present coworkers: Mario Castellucci, Ayse Demir, Hans-Georg Frank, Hitoshi Funayama, Gabriele Gaus, Berthold Huppertz, Mahmed Kadirov, Sonja Kertschanska, Gaby Kohnen, Georg Kosanke, Azizbek Nanaev, Frank Reister, and the late Gertfried Schweikhart. Many of my data are based on their material, their findings, and their ideas. Also, many colleagues and friends from other laboratories have contributed by discussion and by offering technical help. In this respect I am particularly grateful to Ramazan Demir, Gernot Desoye, Jean-Michel Foidart, John Kingdom, Hubert Korr, Rudolf Leiser, Peter Ruck, Hobe Schröder, Tullia Todros, and the late Elizabeth Ramsey. In many cases it is virtually impossible to differentiate between their and my ideas.

These chapters do not only require scientific inspiration but also much artistic, technical, and secretarial work. The artistic help of Wolfgang Graulich and the photographic assistance of Gaby Bock as well as of Helga Kriegel are gratefully acknowledged. The histologic and electron-microscopic pictures are based on material processed by Marianne von Bentheim, Barbara Ihnow, Michaela Nicolau, Lian Shen, and Uta Zahn. Perfect secretarial assistance was provided by Jutta Ruppert.

The collaboration of all these coworkers and friends was the basis for my contribution. Last but not least, I am very much indebted to my wife for her support and understanding.

## Examination of the Placenta

### Macroscopic Examination

Most placentas are normal, as are most babies. Therefore, an examination of all placentas may not be warranted, although this has been advocated repeatedly. Practical guidelines, including indications for the examination have been published by the College of American Pathologists (Langston et al., 1997). This reference describes in tabular form the major abnormalities and their association with clinical features. Booth et al. (1997) inquired what reasons constituted the submission of a placenta for examination and found, regrettably, that it was cesarean section delivery. This is hardly a good reason, as will be seen. A large number of surgical deliveries are repeat sections and have little impact on perinatal problems for which placental examination might be useful. Altshuler and Hyde (1996), on the other hand, found that 92% of placentas for which an examination was requested by obstetrician or neonatologist had relevant pathology. Salafia and Vintzileos (1990) made a strong plea for the study of all placentas by pathologists. We concur with this view, as the sporadic examination does not provide sufficient training for young pathologists and it does not allow the “routine” pathologist to obtain sufficient background knowledge as to what constitutes a truly normal placenta. Another reason for the examination of all placentas is today’s litigious climate; it makes study of placentas highly desirable (see Chapter 26). Furthermore, it has been shown repeatedly that a placental examination is needed to understand the causes of perinatal deaths. This was demonstrated, especially for stillbirths, by the study of Las Heras et al. (1994). The most important lesions were found in the umbilical cord (18%), with inflammatory lesions being second. Altshuler (1999) wrote a searching essay on the placenta-related epidemiology from his vast experience in these matters. Because placentas differ widely in shape, size, and in appearance, the novice must become familiar with this spectrum of placental shapes. To do so, a large number of placentas must be examined routinely. In

hospitals with large numbers of deliveries, however, it may be prudent to select placentas for examination by the pathologist.

### Storage

To facilitate the practice of saving placentas for a week, storage is required so that placentas are available when needed. The American College of Obstetricians and Gynecologists (ACOG), on the other hand, has suggested, surprisingly, that the routine study of the placenta is not warranted (ACOG, 1991), a decision with which we strongly disagree. Placentas should **not** be frozen prior to examination, as this obliterates the most useful histologic characteristics and makes even the macroscopic examination more difficult. We believe that formalin fixation has a similar unwanted effect. It is best to store the delivered placentas in containers, such as plastic jars. We have found ice cream cartons, made from Styrofoam, the most convenient and least expensive. Cardboard containers absorb the fluids, and the placentas tend to stick to them. These containers can also be readily labeled and stored in a refrigerator at 4°C. In this state, the placenta is preserved for a meaningful examination for many days. Autolysis is minimal. We cannot agree with the opinion of Naeye (1987) that this storage causes significant artifacts that render a subsequent examination difficult. Indeed, the immediate fixation of the organ in formalin, recommended by others (Bartholomew et al., 1961) as a good means to evaluate the extent of infarction, makes the placenta more difficult to evaluate critically, aside from the storage problems, expense, and odor. Prior fixation also makes tissue culture, bacteriologic examination, and other procedures more difficult or impossible. For maximal convenience, it is a good idea to have a refrigerator with seven shelves, labeled Monday through Sunday, and to discard the normal placentas from one shelf when the next similar weekday arrives. In this way, all placentas from problem births will be available for study.

The placenta loses some weight during storage. In part, the loss is due to evaporation, but most weight is lost by leakage of blood and serum occasioned by the weight of placental tissue resting on other portions. The quantity of weight loss depends on the length of storage and the degree of edema, but the edema is not great in the normal placenta. It is most significant in the edematous placentas of hydrops. We have observed a 180-g fluid extravasation from a 740-g placenta within 1 day from a hydropic placenta. The freshly examined placenta is thus softer, bloodier, and thicker than one that has been stored. On the other hand, it must be noted that the placenta gains weight when it is stored in formalin, particularly during the first day of fixation. Not all organs increase in weight uniformly after such fixation, as the detailed report by Schremmer (1967) specified. The placenta, according to this author, gains between 0.7% and 23.0%, with an average of +9.9%. It is among the organs with the largest deviations in weight gain after fixation. Our own findings are summarized in the graph shown in Figure 1.1.

## Selection

Placentas from all prematurely delivered infants and all twins should be examined routinely, at least macroscopically, and many of them require histologic study as well. In addition, many circumstances arise during the first few days of life of an infant where the neonatologist is interested in placental findings. These often help to clarify whether a particular disease had a prenatal onset. Furthermore, there are some maternal conditions that warrant placental examination, for example preeclampsia, the condition known as lupus anticoagulant, diabetes, fever, and many more. In our routine study of placentas, the obstetricians and neonatologists alert us as to which placentas they believe warrant more scrutiny, and thus

perhaps 5% to 10% of all placentas undergo histologic examination in our hands.

## Photography

A photographic record is often desirable and is useful for many purposes. Most pathology laboratories are equipped with cameras that can take Kodachrome color pictures, which are then valuable for teaching purposes. It has been our experience, however, that colors tend to disappear, and certainly these photographs cannot generally be retrieved years later when they may be of interest in litigation or review of material. Nowadays, digital photography has become such a routine procedure and storage of the digital images has become so easy that much more photography of specimens is desirable and practiced. The photographic task is generally quickly accomplished. Colleagues have often been amused by this recommendation, but they agree that a good picture is worth a lot of words, especially when it comes to litigation.

## Examination

Detailed protocols for the examination of the placenta have been presented in the past (Snoeck, 1958; Benirschke, 1961a,b; Gruenwald, 1964; Fox, 1997). Some protocols were designed to allow an unbiased examination of the placenta and record keeping by the many different medical centers of the Collaborative Study so that, ultimately, correlations could be made regarding fetal outcome. Our routine procedure now is to select for histologic study those that appear abnormal or whose perinatal circumstances demand such an examination. The selection process just outlined has been helpful, and we have rarely missed a placenta that was of importance. Other recommendations for a "triage" of placental study and other

FIGURE 1.1. Weight gain of placenta (trimmed, without cord or membranes) after formalin fixation.

FIGURE 1.2. Instruments found to be most practical for the placental examination: scissors, forceps, “dipstick” to measure the thickness of placental tissue, and a long, stiff knife.

ramifications come from a joint conference held in 1990 (Travers & Schmidt, 1991). That volume provides useful information on many aspects of placental pathology.

The tools for the examination are simple (Fig. 1.2). They consist of a ruler, a long and sharp knife, a toothed forceps, a pair of scissors, and a scale. Our ruler is permanently mounted over the cutting board, thus enabling rapid measurement of the length of the umbilical cord and the placenta's diameter. A butcher's scale with removable bucket that weighs items up to 2 kg is also available. The long knife, best obtained from a butcher supply house, is sharpened just before examination.

The placenta is removed from its container. At this time one often perceives rather characteristic odors. For instance, when a mother has recently eaten garlic, the intense smell of its diallyl sulfides is readily apparent. Also, in infected placentas the fetid smell of *Escherichia coli* and the rather sweeter smell of *Listeria monocytogenes* can be distinguished by an experienced pathologist. Storage in the refrigerator enhances the growth and hence the recognition of these organisms.

The shape of the placenta is then ascertained by stretching it flat on the cutting board. Is it normally round or oval? Are there accessory (succenturiate) lobes? Is a question now answered? One finds that, during the delivery, the membranes have generally inverted over the maternal surface (Schultze procedure) and rarely are they found in the position they held in utero (Duncan) (Pritchard et al., 1985). They are then inverted by the examiner so that they assume the in utero configuration, and one next ascertains the completeness of the membranes. It is also noted at this time if the tear that allowed the infant to escape from its membranous enclosure extends to the edge of the placenta or if free membranes extend beyond the edge. If there is **any** margin of intact membranes, this placenta could not have been a placenta previa, provided it was from a vaginal delivery. If the edge of the membranous tear is far from the placental border (often the case with circumvallate placentas), a fundal

position can be deduced. Torpin and Hart (1941) made the point that when the minimally disturbed sac is immersed in a bucket of water the sac assumes the configuration of the uterus, and that its position before birth can be reasonably accurately determined by this study. At this time it is prudent to inspect the color and appearance of the fetal surface of the placenta. Normally it is shiny, and the subjacent blood is seen as a clear blue hue, particularly in the immature organ. When chorioamnionitis is present, the membranes become opaque by the interposition of leukocytes, and the surface usually loses its sheen. Greenish discoloration betrays either meconium (slimy) or hemosiderin deposition.

Next the membranes are cut off the edge of the placenta with the knife. If one anticipates making sections of the placenta for histologic study, it is wise to follow a routine protocol for doing it, as it enhances subsequent interpretation. Therefore, it is recommended that one get used to doing it one way, once and for all. It is preferable to cut the membranes off in such a manner that one knows the point of rupture; then, when sections are made, the membrane roll is prepared in such a fashion that the point of rupture is in the center of the roll with the amnion inward (Fig. 1.3). This method of preparing a roll of membranes (the “jelly roll”), in order to obtain a maximum amount of membranes with decidua capsularis, was first described by Zeek and Assali (1950). In immature placentas, there may be a large amount of decidua, and it is often ragged. In more mature organs the decidua atrophies and often it degenerates. Occasionally, one finds an intrauterine device in this decidua capsularis, usually at the edge of the placenta and associated with old clot and debris (Figs. 1.4 and 1.5). Frequently, there are areas of brown to green discoloration in the membranes that are from former hemorrhages, or they may have been induced by amniocentesis.

In many placentas that come from patients after labor, in contrast to those after cesarean section, the amnion is disrupted or sheared off the underlying chorion. In fact,

FIGURE 1.3. Rolling of membranes for fixation and later sectioning. It is best to prepare them in a standardized fashion, for example, amnion inside, starting at the site of rupture and pro-

ceeding toward the edge of the placenta, as shown at left. A segment is then taken from a well-rolled portion (center) and is fixed for a day (right) before trimming.

FIGURE 1.4. Edge of the placenta (right) with an intrauterine device embedded in degenerating decidua (partly removed) and old blood clot.

FIGURE 1.5. Intrauterine devices at the placental margin at term (left) and in a slightly immature (right) pregnancy. Note the attending hemorrhagic degeneration of the adjacent tissues.

the amnion may be totally detached. Often, though, there is milky, white vernix caseosa that has dissected underneath the amnion; it is readily moved about by pressure. It has no significance. Moreover, the membranes near the edge of the placenta frequently contain the remnant of the yolk sac, a small white to yellow oval disk that is located underneath the amnion. The yolk sac of early stages of development can now be visualized ultrasonographically. Measurements have shown that the size of the yolk sac is variable, and that it is not a useful prognosticator of fetal well-being (Reece et al., 1988). Occasionally, one sees remnants of tiny vessels traversing from it to the insertion of the cord, or even within the cord.

The color of the membranes is noted, as are the surface characteristics. A slimy feeling is often the result of meconium discharge, as is a green color. The length of time of meconium discharge can be estimated by the presence of green discoloration in different layers. When it is only in the amnion, this suggests a short time interval; when meconium is found also in the chorion after the amnion is stripped off, a longer interval has passed since discharge (Miller et al., 1985). We found that after 1 hour the meconium macrophages are visible within the amnion; after 3 hours they may be seen in the chorionic membrane. At even later times it reaches the decidua capsularis. Greenish or brownish discolorations in immature placentas are more often due to blood breakdown products (hematoidin, hemosiderin) following hemolysis, rather than due to meconium. Hemosiderin can be stained with the Prussian blue method for iron, and the bilirubin of meconium stains (poorly) with bile stains. The very immature fetus cannot discharge meconium, lacking the hormonal maturation for intestinal propulsion (Lucas et al., 1979). The surface of the membranes, the amnion, is normally shiny. Around the insertion of the cord, one may find squamous metaplasia in the form of concentric nodules that are hydrophobic (Fig. 1.6). They are normal

features. Amnion nodosum, usually represented by a finely granular, dull appearance of the amnionic surface, correlates with oligohydramnios. One must be cognizant of whether the amnion is present at all and, if not, whether amnionic bands exist. Also, often some blood has dissected underneath the amnion during delivery or especially when fetal blood has been aspirated for diagnostic tests from the fetal surface blood vessels.

The placenta is next measured, and then the cord is examined. Is it central, eccentric, marginal, or membranous (velamentous) in its insertion? What is its length, and is it spiraled? We now believe that the length of the umbilical cord is determined primarily by fetal movements and that excessive spiraling implies unusual fetal motions (Moessinger et al., 1982). There may be a genetic component to the spiraling and the length, as the umbilical cords of some animals have different and consistent lengths; but this characteristic is so far unknown for human umbilical cords. Are there knots, thrombi, or discolorations? Can any other unusual features be detected? The cord is then severed from the bulk of the placenta, and its cut surface is studied at several locations. The most important observation to be made here is whether there are three vessels and if other unusual features are present. A single umbilical artery (SUA) is the commonest abnormality. One must also appreciate that there is almost always an anastomosis (Hyrtl's anastomosis) between the two umbilical arteries, which is usually found near the point of insertion on the placental surface (Priman, 1959). Thus, counting the number of vessels is best done farther away from the insertion. When a velamentous insertion of the cord is found, the examiner must pursue the ramifications of the fetal vessels after they leave the site of cord insertion, at times finding thrombi, and particularly in membranous vessels. These vessels may be disrupted, as in vasa previa, and acute exsanguination of the fetus is common in such circumstances.

FIGURE 1.6. Squamous metaplasia of amnion in concentric patches, usually found near the insertion of the umbilical cord. The plaques are water-repellent.

The weight of the remaining disk is ascertained. It is generally useless to know the weight of the entire organ, including cord and membranes. Correlations with fetal weight and development can be made only by knowing the “net” weight of placental tissue (Walker, 1954; Gruenwald & Minh, 1961). Excessive amounts of maternal, retroplacental clots must also have been removed before weighing. Note again that the weight of formalin-fixed placentas is greater than that of fresh organs (Fig. 1.1) (Schremmer, 1967). Variations in normal placental weight are common. They reflect mostly the length of storage and the amount of fetal blood content.

When studying the fetal surface of the placenta, one notes its color and the possible presence of granular excrescences. Most importantly, however, one must carefully inspect the fetal vessels, which are carried in the chorion; the amnion has no blood vessels. In nearly all placentas, one can recognize the fetal arteries as those vessels that cross over the veins (Hyrtl, 1870; Bacsich & Smout, 1938; Boe, 1953; Crawford, 1962). It will be observed that the terminal branches of arteries dip singly into a cotyledon; and next to it, a vein emerges to return the blood to the cord (Fig. 1.7). One often finds thrombi in these vessels in placentas of abnormal newborns. They appear as white-yellow streaks on the vessel’s surface and are usually not completely occlusive. When they are, an area of hemolysis is often seen adjacent to the thrombosis. Thrombi may also calcify. They must be sampled for histologic study.

The fetal surface of the mature placenta is often described as being “bosselated” or “tessellated,” meaning that tiny white elevations are present underneath the chorion, giving the surface a mosaic, irregular pattern. These protrusions represent accumulations of fibrin in the intervillous space and they increase in number with advancing maturity. Larger patches of fibrin also exist; at

times they have a liquefied center, but they are assumed to be of little significance (Geller, 1959). In our experience, however, larger subchorionic thrombi are abnormal and occasionally associated with fetal growth restriction. Cysts from the subchorionic extravillous trophoblast cells (“X-cells”) may bulge on the surface and contain a clear, slightly viscid mucoid substance. At times it is discolored with blood. Finally, the insertion of the membranes is observed. Was it at the edge, or was there a ring of “circumvallation”?

When the placenta is turned over then, thus exposing the maternal surface, the first need is to identify possible areas of abruptio placentae. When an abruption is fresh, one may not be able to differentiate it from the normally present postpartum maternal blood clot that adheres. Within a few hours, though, the blood dries, becomes firmer and stringy, and then changes color to brown and eventually it may become greenish. In such cases, the placenta underneath the clot is usually infarcted or it is at least compressed. Abruptios are common, and most are clinically silent. Most are located at the margin of the placenta; and on occasion one finds old clot behind the membranes. Calcification on the maternal surface is then sought: small yellow-white granules in the decidua basalis and septa. Calcifications vary a good deal in quantity; they are usually found only in mature organs. The quantity has no clinically important correlations (Fujikura, 1963a,b; Jeacock et al., 1963), but clinicians have paid much attention to the recognition of calcification. It may be detected by sonography and has served as a method to “grade” (age) the placenta (Fisher et al., 1976). This is rarely done now as it has not been found to be helpful. At this point one also observes the cotyledons, the major subdivisions of the placental tissue. They increase in size and differentiation with advancing gestation, being absent early. One needs to ascertain now whether all of the

FIGURE 1.7. Entrance of fetal vessels on the chorionic plate into the cotyledon. One artery (large arrowhead) brings the fetal blood; the vein (small arrowhead) next to it returns it to the fetus.

placental “floor” is present or whether there are missing cotyledons. If no cotyledonary subdivisions exist in the mature placenta, then the floor is often too thick and it may be infiltrated with an excess amount of fibrin. This condition is known as maternal floor infarction (MFI) and is best noted at this time (Naeye, 1985).

Long, parallel cuts are now made with the long knife and, most importantly, the color of the villous tissue is observed. The red color of the villous tissue is almost wholly determined by its content of fetal blood. Thus, a congested placenta (as in maternal diabetes, for instance) is dark, and that of an anemic, hydropic, exsanguinated, or erythroblastotic fetus is pale, and it is usually also much more friable. Such a placenta is also commonly thicker, 3 to 5 cm, in contrast to the normal placenta, which averages 2.0 to 2.5 cm at term.

It is normal to find “holes” in the center of many placental cotyledons (Fritschek, 1927). Such holes were filled, *in vivo*, with maternal blood and represent the areas of first blood distribution into the intervillous space from the maternal injection jet. Intervillous thrombi, often located in these spaces, may be dark when fresh; alternatively, they are composed of layered white fibrin when older. The intervillous thrombi differ from infarcts in that they displace villous tissue. Furthermore, infarcts are granular in contrast, because they are composed of dead villous tissue. Fresh infarcts are red, and older ones are yellow to white. When sectioning the placenta, one also finds that the intercotyledonary septa contain some calcium, and often they contain some cystic spaces filled with trophoblastic secretion, the same clear mucoid material as contained in surface cysts. They too arise from extravillous trophoblast cells. Occasionally, one encounters round tumors of a solid nature, chorioangiomas. “Gitterinfarcts” or “Netzinfarcts,” because they appear to form a network of fibrin, accompany maternal floor infarction. They may be prominent, appear as dense fibrin patches throughout the organ, and have great clinical significance. It is a good practice to estimate the total amount of infarction and to record it; in fact, it is ultimately of some importance and may have medicolegal implications in infants with growth retardation. Single marginal infarcts are common and do not correlate with either fetal or maternal conditions. Other lesions are occasionally seen. Thus, some lesions that appear grossly as “infarcts” may turn out to be choriocarcinoma on histologic study (Driscoll, 1963).

## Placentas of Multiple Births

Placentas of multiple births are important records for infants and pediatricians alike, and they are routinely examined. A recording of the membrane relation between twins, triplets, and so on is mandatory. For meaningful analysis it is necessary that the umbilical cords be labeled

with sutures or clamps by the obstetrician, in the order of births. The most important decisions to be made in examining placentas of multiple births are (1) the number of membranes that divide the sacs (two or four) and (2) the types of vascular anastomoses that are generally present only in monochorionic twin placentas (Schatz, 1886). Fraternal (dizygotic) twins essentially *always* have diamnionic/dichorionic (DiDi) placentas. Fused placentas, however, are not always monochorionic. They may be DiDi and they may be diamnionic/monochorionic (DiMo). Finally, there may be no “dividing membranes” between the fetuses, as in the monoamnionic/monochorionic twin placenta (MoMo). All monochorionic twin placentas belong to monozygotic (MZ; identical) twins. The time at which MZ twins separated one from another during the early embryonic stages presumably determines the type of placentation that ultimately develops, and this can thus be estimated from an examination of the membrane relation. It is easiest, but not necessarily best, to separate the dividing membranes from each other. If there are four distinctive leaves, it is a DiDi placenta, whereas if only two membranes are apposed it is a DiMo placenta. Equally readily, the diagnosis of a DiDi twin placenta is made by ascertaining that the dividing membranes are opaque and contain remnants of old vessels or other debris (old decidua, degenerated villi). Also, in DiDi placentas one usually finds a ridge at the site where the membranes meet over the placenta. It is caused by the buckling of tissues from the collision of the two expanding placental tissue masses. The dividing membranes of DiMo placentas, in contrast, are transparent. The diagnosis of membrane relationship is easiest and most permanently established by a histologic section of a membrane roll of this tissue, or by a T-shaped section that includes this area (Fig. 1.8).

The location of the cord insertion is especially important in twin placentas, as it is much more frequently marginal or membranous than in singletons; this may reflect some problems in early placental development. Moreover, the absence of one umbilical artery (single umbilical artery, SUA) is more common in multiple births (Heifetz, 1984).

After the membrane relation is established, the “vascular equator,” that is, the area where the two chorionic vascular districts meet, is examined. In DiDi placentas, there is **never** a confluence of fetal blood vessels; if one were found, it would be exceptional and would be the basis for the exceedingly rare blood chimerism in fraternal twins. It must be cautioned here that ascertainment of a DiDi relation does *not* make the diagnosis of fraternal twins. Approximately one third of identical twins have this placentation (discussed in greater detail in Chapter 25). In monochorionic placentas (DiMo, MoMo), there are almost always some anastomoses, particularly in the prematurely delivered placentas. These anastomoses have

FIGURE 1.8. Preparation of a “T section” of the meeting point of the dividing membranes in twin placentas.

a great influence on the well-being of the developing fetus (Benirschke, 1961b; Bejar et al., 1988). They take three forms: artery to artery (AA), vein to vein (VV), and artery to vein (AV). The latter is doubtless the most important and is the basis for the twin-to-twin transfusion syndrome (TTTS). It must here be remembered that arteries lie on top of veins and that they are thus readily identified macroscopically. An arteriovenous (AV) anastomosis carries the blood of one twin, through a cotyledon in a one-way direction, from one twin to the other. Often the various types of anastomoses coexist, and the consequences for fetal development may be different depending on the arrangements that are present. When in doubt, one injects the vessels in question with colored water or milk, all being readily available in obstetrical suites. Only the most sophisticated studies require injection with plastics (Panigel, 1962). Injection of vessels has presented some problems for novices. First it must be remembered that most placentas have suffered some disruption during delivery, especially the immature twin placentas. Thus, only small, selected districts should be injected, and this should be done only after the umbilical cords have been cut off in order to reduce resistance. Before injecting one should seek to identify by careful inspection those areas that seem most profitable for the injection study. Large interarterial anastomoses (common) may be identified by one's ability to push blood back and forth from one side to the other. When one attempts to demonstrate the areas that reflect shared cotyledons, as in the transfusion syndrome, one best uses a 20-mL syringe and a large (15-gauge) blunt needle. This is inserted into an arterial branch a short distance away from the prospective site and gradually one then fills the area with water or milk. The cotyledon will first rise and, when completely filled, it will empty into the vein that drains the cotyledon. It is also advisable to make a drawing or photograph of the anastomotic arrangements among

multiple placental vascular districts, just to have them available for the record.

Examination of the maternal surface and of other parameters of the placentas of twins follows that of the regular protocol. It must be borne in mind that when the blood content of twins differs considerably it may be reflected in the macroscopic placental examination as well. One portion of such a twin placenta may be severely congested and larger, with the other being pale and smaller. This condition is present when only one AV anastomosis exists. Here, in the classical mechanism of the transfusion syndrome, one twin constantly loses blood through this one-way AV shunt, whereas the other becomes plethoric. Usually, it leads to hydramnios, premature birth, and disparate birth weights of these “identical twins.” It must be recognized, however, that differences in neonatal hemoglobin content of monochorionic twins may also occur acutely, when large AA and VV anastomoses exist. Thus, after the delivery of one twin, the other twin may “bleed” through anastomoses if the cord of the delivered twin is not promptly clamped. Likewise, when one such twin dies in utero, significant shifts of blood may occur from the live twin through such large anastomoses into the relaxed vascular bed of the deceased twin. Finally, it is our practice to dissect the two halves of the twin placenta at the site of the vascular equator in order to determine the placental weight of each twin. Higher multiple births are handled the same way.

### Fixation

The pathologist is used to fixing tissues for histologic study in 10% formalin solution (a 1:10 dilution of the commercial 40% formaldehyde) and there is no need to make an exception with the placenta. For **routine histopathology** we prefer Bouin's solution, however, because it makes embryonic and placental tissue considerably

harder and allows one to trim the tissue more readily before embedding. After a membrane roll is made with the help of the forceps, it is also much easier to trim this jelly roll when Bouin's solution, rather than formalin, has been used. Bouin's solution is made by preparing a saturated solution (1.2%) of picric acid in water and adding 40% formaldehyde solution and glacial acetic acid in proportions of 15:5:1. After overnight fixation, the tissue is ready to be trimmed. The solution has the additional benefit of decalcifying fetal tissues. Prolonged storage of tissues in Bouin's solution makes them very hard.

Carnoy solution is a useful alternative if immediate fixation is required directly after delivery and if obstetricians refuse the use of formaldehyde in the vicinity of the delivery room. This fixative is composed of 60mL absolute ethanol, 30mL chloroform, and 10mL glacial acetic acid. It guarantees good structural preservation, provided that the thickness of the tissue blocks does not exceed 3 to 4mm.

Many other fixatives have been used. Jiricka and Preslickova (1974) made a detailed study of seven solutions and evaluated the effect for the staining characteristics with different dyes. They found that none is ideal for all purposes, so the fixative must be chosen that gives the best results for a specific reason. The authors presented this information in tabular form, and the article must be consulted if optimal results are to be obtained.

Ideally, the sectioned slices, when Bouin-fixed, are immersed in a saturated lithium carbonate solution before embedding. This step is not absolutely required, but it helps to remove extraneous pigments. Moreover, some intervillous blood is lysed, and pigments derived from blood ("formalin pigment," acid hematin) are more frequently present when lithium carbonate is omitted. Note, however, that occasionally the use of Bouin's fixation is disadvantageous. For instance, Altshuler and Hyde (1985) reported that infection with fusobacteria was less readily appreciated after Bouin's fixation than when formalin was used. Furthermore, Bouin's solution is not useful for fixation when the purpose is to conduct immunohistochemical or in situ hybridization studies (Gleich, personal communication, 1989). Today many **immunohistochemical studies** can be carried out on paraffin sections, such as the demonstration of most cytoskeletal proteins, extracellular matrix molecules, and several proliferation markers (Frank et al., 1994). For all these purposes we suggest the fixation in 4% neutral buffered formaldehyde solution for a maximum of 24 hours followed by paraffin embedding not exceeding 60°C. Possible flow cytometry is also more readily done with such material.

Another important issue is the manner of tissue handling prior to fixation. The time and the mode of cord clamping (Bouw et al., 1976), the ischemic period before onset of fixation (Voigt et al., 1978; Kaufmann, 1985), as well as the composition of the fixative (Kaufmann, 1980)

may well influence the distention of the fetal vascular bed and the width of the intervillous space (see tables in Chapters 15, 17, 18, and 19). We recommend particularly for all studies concerning the pathology of the fetoplacental vessels (e.g., in cases with Doppler high resistance index) that a strictly standardized sampling and fixation protocol be used. If this is not done, false impressions of such conditions as chorangiosis may be obtained.

Other techniques may also require special handling, as for instance in the studies by Becker and Bleyl (1961) on toxemia. They employed fluorescence microscopy of villi to understand their different composition in this disease.

It is the recommended practice to save at least one section of umbilical cord, a membrane roll, and three pieces of placental tissue for histologic examination. Of course, having more sections of umbilical cord available for histological study is ideal, as an inflammatory response, thrombi, and other features are not always uniformly distributed throughout the length of the umbilical cord. Preparing more than one piece of placental tissue for histologic study is also desirable because so many areas of the placenta show histologic variations. Thus, one can much better determine the existence of inflammatory lesions and is less apt to overlook changes that are not ascertained macroscopically. Moreover, one must obtain sections from the more normal portions of the placenta as well. Although the pathologist is used to sampling abnormal areas for histologic study, it is not desirable to take only abnormal areas of the placenta. Indeed, almost all infarcts are histologically alike, and since they also have a typical macroscopic appearance, they are rarely worth the trouble of histologic study, except that the sections provide verifiable evidence of the existence of infarcts. It is much more important to save normal-appearing placental tissue for microscopy. One must sample both the fetal and maternal surfaces in order to include some fetal surface blood vessels. Because it is generally impossible to anticipate from macroscopic inspection whether chronic villitis and many other lesions exist, it is better to preserve too much than too little in the fixative. It goes without saying that unusual-appearing areas must also be sampled.

For histologic examination, we prefer the hematoxylin and eosin (H&E) stain. On many occasions, however, it is useful to employ special stains, such as elastica preparations, bacterial and spirochete stains, periodic acid-Schiff (PAS) preparations, and specific immunohistochemical stains that disclose the presence of viruses (e.g., cytomegalovirus and herpes antigens) as well as specific proteins [e.g., human chorionic gonadotropin (hCG), human placental lactogen (hPL), major basic protein (MBP), cytokeratin, vimentin, fibrin, proliferation markers] (see Chapter 3). These tests have given much insight into the distribution of various placental tissue components, the

### Special Procedures

The placenta can serve as a good source of tissue for **chromosome analysis**. This is especially true when the fetus is macerated. One proceeds best by disinfecting the amnion with some alcohol and then stripping the amnion off a portion of placental surface. For the purpose

of taking the biopsy from chorion, sterile instruments are recommended. A small piece of chorion, ideally with a bit of fetal surface vessel, is best for the purpose of establishing a tissue culture. The biopsies are placed into tissue culture medium with antibiotics and transferred to the laboratory. Touch preparations of amnionic surface or from the undersurface of the amnion may be useful for the **identification of bacteria or leukocytes**. It is of parenthetic interest that Jauniaux and Campbell (1990) showed that many structural abnormalities of the placenta can already be anticipated from sonography.

## 2

# Macroscopic Features of the Delivered Placenta

The full-term, delivered placenta is, in more than 90% of the cases, a disk-like, flat, round to oval organ. In nearly 10% it has abnormal shapes, such as placenta bilobata, placenta duplex, placenta succenturiata, placenta zonaria, and placenta membranacea (Torpin, 1969). The average diameter is 22 cm, the average thickness in the center of the delivered organ 2.5 cm, and the average weight 470 g (see Chapter 28, Table 28.1). The respective measurements show considerable interindividual variation and strongly depend on such factors as the mode of birth, timing of cord clamping (see Chapter 28, Table 28.8), and time elapsed between delivery and examination.

### Fetal Surface

The **fetal (chorionic or amnionic) surface**, facing the amnionic cavity, has a glossy appearance because of the intact epithelial surface of the amnion. This membrane covers the **chorionic plate**, including the **chorionic vessels**. The latter branch is a star-like pattern positioned centrifugally from the cord insertion over the fetal surface (Fig. 2.1, left). Where arteries and veins cross, the arterial branches are usually closer to the amnion; they cross the veins on their amnionic aspect. Wentworth (1965) reported that only about 3% show the opposite condition. According to Boyd and Hamilton (1970), the superficial position of one or few venous branches at points of arteriovenous crossing is not unusual.

In the vicinity of the larger chorionic vessels, the chorionic plate normally has an opaque appearance because an increased number of collagen fibers accompany the vessels. Those areas of the chorionic plate located between the chorionic vessels are mostly transparent and are dark lilac to black because maternal blood in the intervillous space shines through. Opaque spots (bosselations) or large opaque areas independent of chorionic vessels usually point to large subchorionic deposits of Langhans' fibrinoid.

Near the **placental margin**, where the most peripheral branches of the chorionic vessels bend vertically toward the marginal villous trees, the transparency of the chorionic plate decreases, resulting in a largely incomplete, opaque **subchorial closing ring** that is a result of increased amounts of cytotrophoblast and collagen fibers (see Chapter 9). It connects the placenta with the membranes. In the case of a particularly broad and prominent subchorial closing ring, the specimen is called a placenta marginata. A placenta circumvallata is formed when the closing ring is peripherally undergrown by villous trees. In such cases, it does not represent the outermost margin of the placenta; rather, the membranes insert superficially from the fetal surface of the placenta.

**Placental shape and cord insertion** are sometimes regarded as structurally impressive but functionally unimportant parameters. Becker (1989) stressed that both are influenced by the intrauterine position of the placenta. According to Schultze (1887), the location of the cord insertion represents the epicenter of implantation. Eccentric or marginal cord insertion thus points to an eccentric implantation on the anterior or posterior uterine wall, which causes asymmetrical development of the organ for mechanical and nutritional reasons.

### Maternal Surface

The **uterine (maternal) surface** of the placenta is opaque, as it is an artificial surface originating from laminar degenerative processes within the **junctional zone** that led to the separation of the organ. This separation process subdivides the junctional zone between placenta and uterine wall into

- the **basal plate**, which is attached to the placenta and represents the maternal, uterine surface of the organ; and
- the **placental bed**, which remains in utero.

FIGURE 2.1. Apical (left) and basal (right) views of a freshly delivered, mature human placenta. Note the slightly eccentric insertion of the umbilical cord, which is the most usual location. The chorionic arteries (white because of postpartum injection

of milk) cross over the corresponding veins (dark). The basal surface (right) is subdivided into placental lobules of varying size by an interrupted net of dark grooves.  $\times 0.4$ .

The basal plate and the maternal surface of the placenta could not be identified before placental separation in the in situ specimens that were fixed before the onset of labor (see Chapter 4, Fig. 4.7). It is composed of a heterogeneous mixture of trophoblastic and decidual cells embedded into prevailing amounts of extracellular debris, fibrinoid, and blood clot.

An incomplete system of grooves subdivides the basal surface of the placenta into 10 to 40 slightly elevated areas

called **maternal cotyledons** (lobes or lobules) (Fig. 2.1, right; Fig. 2.2). Internally, these grooves correspond to the **placental septa**, folds of the basal plate, which project into the intervillous space (see Fig. 4.7). In histologic sections, the septa can often be seen to be indented at their basal surfaces. It is likely that these grooves and the respective basal indentations of the septa are the postpartal results of tearing at sites of minor mechanical resistance, as the basal central parts of the septa are often characterized by

FIGURE 2.2. Basal view of the placenta, drawn in combination with a radiograph of the same placenta after injection of a radio-paque medium into the fetal vessels. The borderlines of the placental lobules (maternal cotyledons, red stippled) are marked by red lines corresponding to the grooves. The radiographic projections of 29 villous trees are represented by blue stippled areas. This combination demonstrates a fairly good harmony of villous trees and maternal lobes. One to three villous trees (fetal cotyledons) are projected on one lobe (maternal cotyledon). (Source: Kaufmann & Scheffen, 1992, with permission; based on photographs by Boyd & Hamilton, 1970.)

necrotic zones, clefts, and local pseudocysts. Despite their possibly artifactual genesis, the grooves delineate the lobes and mark the position of the septa. As is described in Chapter 9, the septa must not be misunderstood as separating structures that subdivide the intervillous space into chambers; rather, they are irregular pillars or short sails that only trace the lobular borders.

The lobes show fairly good harmony with the position of the **fetal cotyledons**. From the chorionic plate at term, 60 to 70 villous stems arise, each branching into one villous tree (or fetal cotyledon) (see Fig. 4.7 and Chapter 7, Fig. 7.18). Thus, according to Boyd and Hamilton (1970) and Kaufmann (1985), each lobe is occupied by one or several villous trees. When a radioangiograph of the villous trees is projected onto a basal view of the same placenta (Fig. 2.2), the borderlines of the lobes usually coincide with the borderlines of single villous trees or small groups of trees. Small marginal lobes are likely to be occupied by only a single villous tree and thus correspond to what Schuhmann and his group (1981) described as representing a **placentone**.

## The Terms **Fetal Placenta** and **Maternal Placenta**

In describing human placentation, terms such as **fetal placenta** and **maternal placenta** must be avoided because they are misleading and often cause misinterpretation. This point may become important as soon as morphologically inexperienced biochemists, endocrinologists, and others isolate respective parts of the organ, then place trust in their putative and designated origin, and draw functional conclusions.

A typical example is the questionable interpretation that maternal tissues (decidua) may produce human placental lactogen (hPL). The basal plate, often erroneously referred to as “**maternal placenta**,” is not exclusively composed of maternal cells but rather represents a colorful mixture of trophoblastic (fetal) and endometrium-derived (maternal) cells. And only the fetal, trophoblastic cells secrete hPL.

A corresponding warning is necessary regarding the placental bed. It is often thought to represent only the maternal remains of the placental site after separation of the placenta. Trophoblastic streamers deeply invade the endometrium, however, and even penetrate the myometrium. They remain in utero long after delivery and can be found as fetal admixtures in the placental bed.

The term “fetal placenta” is also inappropriate. With the possible exception of central parts of the chorionic plate, there are no placental structures for which the pure fetal composition can be ensured. The marginal zone of the chorionic plate contains decidua, and the same is true for parts of the cell islands and septa. Because the latter may be attached to the villous trees, one is never certain that preparations of it are devoid of maternal tissues, even if we disregard maternal blood and fibrinoid deposits that are partly maternal blood clot products.

## Microscopic Survey

For the beginner in placental histology and histopathology, paraffin sections of the organ look confusing because they contain not only a broad variety of differently structured villi but many nonvillous structures as well. This chapter introduces those basic histologic features that leap to the eye when inspecting a paraffin section and thus provides a quick orientation for the inexperienced reader. For this purpose we have selected a collection of conventional photographs from routine histologic sections, of routine quality. Labeling of the figures is explained in the text. For further reading concerning the various structures, we refer the reader to later chapters. For quantitative data, see Chapter 28, Table 28.1.

Ideally, the routine histologic examination of the human placenta requires vertically oriented sections that cover all placental structures from the chorionic plate, via the intervillous space down to the basal plate (Figs. 3.1 and 3.2). Such sections are easily obtained from most second and third trimester placentas, as well as from the rare in situ specimens obtained by hysterectomy in the first trimester (Fig. 3.1). Tissue biopsies from legal interruptions are in most cases less ideal for good survey pictures; usually the basal plate together with neighboring tissues such as septa, anchoring villi, and cell columns are either absent or at least difficult to identify because they are destroyed and mixed up among the villi.

### Typical Histologic Features of the First Trimester Placenta

Complete and well-preserved survey sections of the first trimester placenta, such as this vertical section of an in situ specimen from the 6th week postmenstruation (p.m.) (Fig. 3.1A), cover the following structures: chorionic plate (Fig. 3.1B), intervillous space surrounding the placental villi (Fig. 3.1C–F), cell islands (Fig. 3.1G), and the basal plate (Fig. 3.1J–M) from which a septum (Fig. 3.1H) protrudes into the intervillous space; some anchoring villi are

connected via cell columns to the septum (Fig. 3.1H) or to the basal plate (Fig. 3.1I).

In Figure 3.1A, the **intervillous space** (see Intervillous Space as Related to the Villous Trees in Chapter 7) is the diffuse space that is surrounded by the chorionic plate on the one side and the basal plate on the other. From the 13th week on, it contains ample maternal blood, the volume of which increases to about 100 to 200 mL at term. Up to the 12th week p.m. only little maternal blood has been found in the intervillous space; limited maternal circulation of the intervillous space is probably caused by intraluminal plugs of trophoblast cells within the uteroplacental vessels (see Basal Plate in Chapter 9). The maternal blood flows around the villous trees, cell islands, septa, and fibrinoid deposits. In early pregnancy, the mean width of the intervillous space (between neighboring villi) usually amounts to several hundred micrometers.

In Figure 3.1B, the histologic specimens of the first trimester **chorionic plate** (see Chorionic Plate in Chapter 9) is devoid of amnion as this membrane is only superficially attached to the chorionic plate and is usually removed during preparation. Occasionally, pieces of amnion can be found curled up or upside down somewhere at the section's margin. As it is a regular constituent of most third trimester survey sections, the chorionic plate is discussed in the next part of this chapter (see Typical Histologic Features of the Third Trimester Placenta; Fig. 3.2A,B).

If the amnion is missing, as it is in this case, the surface of the chorionic plate (toward the fetus) is covered by an inconspicuous, incomplete layer of mesothelium. It follows a thick layer of chorionic mesoderm in which the chorionic branches of the umbilical vessels are embedded. Toward the intervillous space, the surface is covered in the early stages by a layer of syncytiotrophoblast, which with progressing pregnancy is replaced by fibrinoid (Fig. 3.2C).

Figure 3.1C: The tree-like arranged placental villi arise from the chorionic plate and protrude into the

intervillous space, the villous trophoblastic surface being bathed directly by maternal plasma or blood. The trophoblastic surface of the villi is composed of an outer continuous layer of **villous syncytiotrophoblast** beneath which is a discontinuous layer of **villous cytotrophoblast** (Langhans' cells) (see Villous Cytotrophoblast in Chapter 6). The villous cytotrophoblast represents the proliferating stem cells for the syncytiotrophoblast that forms the decisive maternofetal transport barrier. The relative number of Langhans' cells decreases toward term.

The stroma of the villi is composed of the **fetal vessels**, which are embedded in a mixture of fixed connective tissue cells, macrophages, and connective tissue fibers. Throughout the first 2 months of pregnancy, **nucleated red blood cells** are a regular finding inside the fetal villous vessels (see Nucleated Red Blood Cells in Chapter 12).

In Figure 3.1D, very early in gestation, the **central stems** of the villous trees show signs of fibrosis around larger central vessels that gradually achieve the structural characteristics of arteries and veins. The superficial stromal layer has an unfibrosed, reticular appearance (see Development of Stem Villi in Chapter 7; also see Figs. 7.4 and 8.3 to 8.6). Arrows indicate the syncytial sprouts (Fig. 3.1F). Before the 8th week p.m., even the largest villi show a homogeneous mesenchymal stroma that is mostly not fibrosed and is devoid of the reticular structure; arteries and veins are absent also (see Figs. 8.1 and 8.2).

Figure 3.1E: Most of the large, bulbous villi of the first and second trimesters are the **immature intermediate villi** with reticular stroma and without stromal fibrosis. The fixed connective tissue cells surround channel-like spaces within the reticular stroma (Fig. 3.1J; see Immature Intermediate Villi in Chapter 7). These channels contain stromal macrophages (Hofbauer cells) that are easily identifiable by their rounded shape and their vacuolated or granular cytoplasm (see Hofbauer Cells in Chapter 6).

In Figure 3.1F, the peripheral branches of the immature intermediate villi are the **mesenchymal villi** (see Mesenchymal Villi in Chapter 7). They usually have diameters of 60 to 200  $\mu$ m, are characterized by a dense cellular stroma, and do not possess many fetal vessels or collagen fibers. Peripherally, the mesenchymal villi extend into **syncytial sprouts** (see Development of the Mesenchymal Villi in Chapter 7), representing syncytiotrophoblastic, multinucleated structures. Very often the sprouts appear as dark cross sections (Fig. 3.1D) that seemingly do not contact villous surfaces.

Syncytial or trophoblastic sprouts are the first steps in the formation of new villi. They are invaded by mesenchymal stroma and by fetal capillary sprouts and thus transform into mesenchymal villi. Later, the mesenchymal villi grow in size and achieve the typical structure of

immature intermediate villi (see Development and Fate of Immature Intermediate Villi in Chapter 7). For a description of the structural aspects of syncytial knotting and sprouting, see Syncytial Knotting in Chapter 15; for histopathologic significance see Control of Villous Development in Chapter 7, and Chapter 14.

In Figure 3.1G, a **cell island** as globular accumulation of extravillous trophoblast cells adheres to several villi (see Cell Islands in Chapter 9). They are directly continuous with villous cytotrophoblast in places where the villous syncytiotrophoblast is interrupted. Parts of the surfaces of these islands may be covered with plaques of syncytiotrophoblast. The extravillous trophoblast cells are usually embedded in matrix-type fibrinoid (see the following discussion, and Fibrinoid in Chapter 9). Cell islands are the still proliferating remainders of the free-floating primary villi from early pregnancy stages that never have been excavated by villous stroma.

In Figure 3.1H, a placental septum protrudes as veil-like extension of the basal plate into the intervillous space. They are rudimentary walls that are unable to completely subdivide the intervillous space into separate chambers. Structurally they show the same composition as the basal plate, as they contain mostly extravillous trophoblast cells and sometimes also some decidual cells. Very often, anchoring villi can be seen attached to the septa. In this stage of pregnancy they belong to the mesenchymal or immature intermediate type of villi. Cross sections of tips of septa look like cell islands and can be confused with the latter. For further information see Septa and Cell Islands in Chapter 9.

Figure 3.1I: **Anchoring villi** are peripheral villi that are connected to the basal plate or placental septa (see Fig. 3.1H) via cell columns. They stabilize the position of the villous trees in the maternal intervillous bloodstream. For development see Early Villous Stages in Chapter 5. **Cell columns** are the trophoblastic feet of the anchoring villi. In early stages of pregnancy they consist of several layers of proliferating extravillous cytotrophoblast serving as a proliferative source of villous as well as of basal plate cytotrophoblast (see Extravillous Trophoblast in Chapter 9).

Figure 3.1J: The **basal plate** is the bottom of the intervillous space and represents that part of the maternofetal junctional zone that adheres to the delivered placenta (see Basal Plate in Chapter 9). The basal portion of the maternofetal junctional zone, which adheres to the myometrium and remains in utero after delivery, is called the placental bed. The basal plate is composed of an admixture of extravillous trophoblast cells, various endometrial stromal cells, decidual cells, uteroplacental vessels, and endometrial glands, all embedded in ample fibrinoid that makes up the glossy to fibrillar ground substance.

FIGURE 3.1. Typical features of the first trimester placenta as seen in paraffin sections following hematoxylin and eosin (H&E) staining. All specimens are from the 6th week postmenstruation (p.m.), except when otherwise stated. For details, see the text. A: Vertical survey section of an in situ specimen, 6th week p.m. The marked frames refer to the following detailed pictures.  $\times 20$ . B: Chorionic plate. v, vein; arrowheads, mesothelium; me, chorionic mesoderm; arrows, incomplete layer of syn-

cytotrophoblast.  $\times 100$ . C: Surface of an immature intermediate villus with trophoblast and a fetal vessel (V) containing nucleated red blood cells. s, syncytiotrophoblast; arrowheads, cytotrophoblast.  $\times 400$ . D: Transitional form of an immature intermediate villus to become a stem villus (18th week p.m.). a, artery; v, vein; r, reticular stroma; fs, fibrous stroma; arrows, sprouts.  $\times 100$ . E: Immature intermediate villus showing characteristic reticular stroma with macrophages (arrowheads).  $\times 400$ .

FIGURE 3.1. F: Mesenchymal villus (m) arising from an immature intermediate villus (i) and extending into syncytial sprouts (ss).  $\times 400$ . G: Cell island (ce) attached to some villi.  $\times 100$ . H: Placental septum (ps) connected to a villus (av) by a cell column (cc).  $\times 200$ . I: Anchoring villus (av) connected to the basal plate by a cell column (cc).  $\times 200$ . J: Surface of the basal plate showing extravillous trophoblast cells (arrowheads) embedded in fibrinoid (10th week p.m.).  $\times 100$ . K: Deep part of

the basal plate showing a uteroplacental vein (uv) surrounded by extravillous cytotrophoblast (ec) and decidua (dc) (37th week p.m., similar to the first trimester situation).  $\times 140$ . L: Multiple cross sections across a spiral artery (sa), the wall of which is replaced by fibrinoid (arrowheads).  $\times 100$ . M: Endometrial glands (eg) of the junctional zone embedded in endometrial stroma (es).  $\times 200$ . For further details see the text.

**Extravillous trophoblast cells** (see also Fig. 3.1K) is the summarizing term for all trophoblast cells located outside the villi—in the chorionic plate, cell islands, septa, basal plate, cell columns, and membranes. Apparent inhomogeneities within the population are mostly the result of different stages of proliferation and differentiation. Those cells resting on the basal lamina facing the chorionic mesoderm (chorionic plate, membranes) or the villous stroma (cell columns, cell islands) are the proliferating stem cells (Langhans' cells), whereas the nonproliferating extravillous trophoblast cells, which have lost contact to the basal lamina represent more highly differentiated, invasive daughter cells of the former (see Extravillous Trophoblast in Chapter 9). Histologically, extravillous trophoblast cells appear as rounded to polygonal or spindle-shaped cells that may be isolated or grouped in strings; they differ from decidual cells in that, in paraffin sections, most of the cell bodies show nuclear cross sections (see Figs. 3.1K and 3.2L).

In Figure 3.1K, **decidual cells** are enlarged endometrial stromal cells that have elongated, partly branched bodies. Neighboring decidual cells are usually arranged in parallel, resulting in a peculiar histologic appearance. All the cellular sections in one area have the same shape, which is round, ellipsoid, or longitudinal (see Fig. 3.2L), depending on the sectional angle. Because the cell body is elongated, cross sections of the ovoid nuclei are rarely found (see Decidua in Chapter 9). **Uteroplacental veins** are endothelial tubes, surrounded by few regressive medial and adventitial cells, embedded in decidua and extravillous trophoblast cells; the latter rarely invade the venous walls and never the venous lumina (see Uteroplacental Vessels in Chapter 9).

In Figure 3.1L, **uteroplacental arteries (spiral arteries)** traverse the basal plate in spiral turns and connect the maternal uterine arteries to the intervillous space. Because of their shape, usually several cross sections are found close together (see Uteroplacental Vessels in Chapter 9). In contrast to the uteroplacental veins, the endothelial lining of the uteroplacental arteries is largely replaced by intravascular trophoblast, a special form of extravillous trophoblast. These cells may form large plugs that narrow or even occlude the arterial lumen (not shown). Arterial media and also the adventitia are replaced by trophoblast cells and fibrinoid, the latter substance also forming the immediate surrounding of most arteries.

In Figure 3.1M, in the depth of the basal plate, remainders of **endometrial glands** can be found. These are regular findings throughout the first 2 months of pregnancy, forming round to star-shaped lumina lined by cubical epithelium. They are surrounded by endometrial stroma or decidualized endometrial stromal cells. In subsequent stages of pregnancy, the glands disintegrate and only degenerative epithelial remainders may be found (see Decidua in Chapter 9).

## Typical Histologic Features of the Third Trimester Placenta

Third trimester sections of the placenta, such as this vertical survey section of a mature placenta (Fig. 3.2A), are more difficult to examine as the villi are smaller and often stick so closely together that it is difficult to find the intervillous space in between. This section covers the chorionic plate (Fig. 3.2C), including the amnion (Fig. 3.2B), different types of villi (Fig. 3.2D–G), fibrinoid deposits in various locations (Fig. 3.2C,F,H–L), anchoring villi with rudimentary cell columns (Fig. 3.2I), cell islands (Fig. 3.2J), septa (Fig. 3.2K), and the basal plate (Fig. 3.2L).

In Figure 3.2A, in contrast to the first trimester situation, the width of the **intervillous space** is highly variable with large “subchorionic lakes” below the chorionic plate and narrow intervillous clefts between the terminal villi. In the normal term placenta, the mean width of the clefts including the subchorionic lakes is between 16 and 32 mm (see Intervillous Space as Related to the Villous Trees in Chapter 7). A generally much wider intervillous space indicates deficiency of terminal villi as in persisting villous immaturity (e.g., rhesus incompatibility) and in cases of excessive nonbranching angiogenesis (e.g., early-onset intrauterine growth restriction, early-onset IUGR) (see Chapter 15). A generally much tighter intervillous space is usually correlated with increased numbers of highly branched terminal villi as, for example, in cases of excessive branching angiogenesis (e.g., late-onset IUGR, often combined with preeclampsia) (see Chapter 15).

Figure 3.2B: The **amnion** covers the chorionic plate toward the amniotic cavity. It consists of a single layer of cubical to columnar cells that participate in the turnover of the amniotic fluid (see Amnion in Chapter 11). Seemingly multilayered segments of the amniotic epithelium represent oblique or tangential sections across the surface in most cases. In addition, nearly 50% of mature placentas also possess foci of real squamous metaplasia of the amniotic epithelium that may become up to 15 cellular layers in thickness (see Amnion in Chapter 11). Underneath the amniotic epithelium is a thin layer of amniotic mesoderm (about 15 to 30 mm in thickness). It is only loosely connected with the next layer, the chorionic mesoderm, via the spongy or intermediate layer, a reticular zone showing larger clefts (Fig. 3.2C). Because of unstable connection, the amnion may start gliding or may even become lost during preparation.

In Figure 3.2C, the third trimester **chorionic plate** is a multilayered structure. It consists of the spongy layer with numerous clefts, followed by the compact layer of chorionic mesoderm that is separated from the Langhans' fibrinoid stria by a rudimentary basement membrane. On the lower side of this basement membrane, highly variable amounts of extravillous cytotrophoblast can be

found. During early pregnancy they form a complete and usually multilayered stratum; in later pregnancy, this layer becomes rarefied. Some of the cells deeply invade the fibrinoid (see Chorionic Plate in Chapter 9). Attached to or embedded into the fibrinoid one finds numerous stem villi, representing the first branches of villous trunci branching off from the chorionic plate nearby (see upper third of Fig. 3.2A). The chorionic plate represents the cover of the intervillous space, which follows directly below.

Figure 3.2D: The villous trees measure 1 to 4 cm in diameter. Their central branches are made up of **stem villi** (see Chapter 7, Fig. 7.26). These are the large-caliber villi that range from 80 to several thousand micrometers in diameter (see Stem Villi in Chapter 7). The highest concentration of stem villi and the largest calibers are found near the chorionic plate. Histologically, they are characterized by one or several arteries and veins or arterioles and venules with clearly visible muscular walls and are surrounded by a fibrous stroma that contains few paravascular capillaries (see Paravascular Capillary Net of Stem Villi in Chapter 7). Near term, the trophoblastic cover is focally or largely replaced by fibrinoid (see Perivillous Fibrinoid in Chapter 6). This process is more pronounced in larger stem villi.

In Figure 3.2E, immature forerunners of the stem villi, the **immature intermediate villi** can be seen. They are easily identifiable by their large caliber and their pale staining. Larger arteries and veins are usually absent, as are larger amounts of collagen fibers. The prevailing structure within the stroma is a reticularly arranged loose connective tissue with few fetal vessels. It is composed of net-like arranged fixed connective tissue cells that surround round spaces, the so-called stromal channels (see Immature Intermediate Villi in Chapter 7), which contain the Hofbauer cells (macrophages) (see Hofbauer Cells in Chapter 6). The latter are characterized by their rounded cell body and their numerous vacuoles or lysosomes.

Immature intermediate villi are the dominating villous type in early pregnancy (Fig. 3.1D,E). At term pregnancy, they usually persist in small groups (<10% of the total villous volume) in the centers of the villous trees. They are absent in hypermature placentas and their number is increased with persisting immaturity of the placenta (see Persisting Villous Immaturity and Rhesus Incompatibility in Chapter 15).

In Figure 3.2F, **mature intermediate villi** are slender, multiply curved branches of stem villi that exhibit diameters ranging from 60 to about 100  $\mu$ m. They differ from stem villi by the absence of both stromal fibrosis and fetal stem vessels (arterioles and venules) with a media identifiable by light microscopy. Their stroma is composed of slender fetal capillaries embedded into a loose connective tissue that is rich in cells but poor in fibers (see Mature Intermediate Villi in Chapter 7). Longitudinal

sections of mature intermediate villi are easily identifiable, whereas cross sections can easily be confused with terminal villi (see the following discussion).

Figure 3.2G: **Terminal villi** are the grape-like terminal side branches of the mature intermediate villi (see and Terminal Villi in Chapter 7 and Fig. 7.10). Their diameters range from 40 to about 80  $\mu$ m. The dominating structures within the loose stroma are sinusoidally dilated and highly coiled fetal capillaries (see Sinusoids of Terminal Villi in Chapter 7). Typically, they bulge against the trophoblastic surface and transform this into extremely thin vasculosyncytial membranes that are devoid of nuclei.

The terminal villi, together with mature intermediate villi, represent the main exchange area of the third trimester placenta. Mature intermediate villi with slender capillaries and terminal villi with dilated sinusoids are easily discernible in placentas following early cord clamping and immediate fixation. Placentas that were fixed late after delivery and have lost larger amounts of fetal blood show the collapse of sinusoids, so that the terminal villi can no longer be discriminated from mature intermediate villi, which have slender capillaries.

A typical cross-sectional feature of terminal villi, and to a certain degree also of other villous types, is the **syncytial knotting** (Tenney-Parker changes). This designation is the usual term applied to an increased appearance of seemingly polypoid trophoblastic outgrowths at the villous surfaces and to the trophoblastic bridges connecting neighboring villi. Only a small percentage of respective structures represents real trophoblast protrusions and real bridges in the third trimester (see Syncytial Knotting in Chapter 15). Rather, the vast majority are flat sections across trophoblastic surfaces of irregularly shaped and branched villi. Toward term, as well as under hypoxic conditions, the outer shape of terminal villi becomes more irregular, thus increasing the chance of trophoblastic flat sectioning (syncytial knotting).

In Figure 3.2H, **fibrinoid** is an acellular, intensely staining, eosinophilic material that is mostly related to the intervillous space (Fig. 3.2C,D,F,H). When it replaces the trophoblastic cover of villi, as shown in this figure, it is called perivillous fibrinoid. In other villi, it may replace the stroma beneath a largely intact trophoblastic surface (intravillous fibrinoid, villous fibrinoid necrosis; Fig. 3.2F). Other sites of fibrinoid deposition are a prominent fibrinoid layer below the chorionic plate (Langhans' fibrinoid, Fig. 3.2C), a corresponding layer at the surface of the basal plate (Rohr fibrinoid, Fig. 3.2I,L), the Nitabuch fibrinoid in the depth of the maternofetal junctional zone (Fig. 3.2L), and the extracellular matrix of cell islands (Fig. 3.2J) and septa (Fig. 3.2K).

Despite the fact that fibrinoid appears to be homogeneous histologically, it is composed of two completely different materials: (1) **fibrin-type fibrinoid** (see

FIGURE 3.2. Typical features of the third trimester placenta as seen in paraffin sections following H&E staining. All specimens are from the 40th week p.m. For details see the text. A: Vertical survey section. The marked frames refer to the following detailed pictures.  $\times 10$ . B: Amnion. ae, amnionic epithelium; am, amnionic mesoderm; sl, spongy layer.  $\times 120$ . C: Chorionic plate,

covered by the amnion. lf, Langhans' fibrinoid stria; arrows, basement membrane; cm, chorionic mesoderm; ivs, intervillous space.  $\times 60$ . D: Peripheral stem villus. fs, fibrous stroma; a, artery; v, vein; arrowheads, syncytiotrophoblast.  $\times 180$ . E: Two immature intermediate villi (i) surrounded by some mature intermediate and terminal. villi.  $\times 180$ .

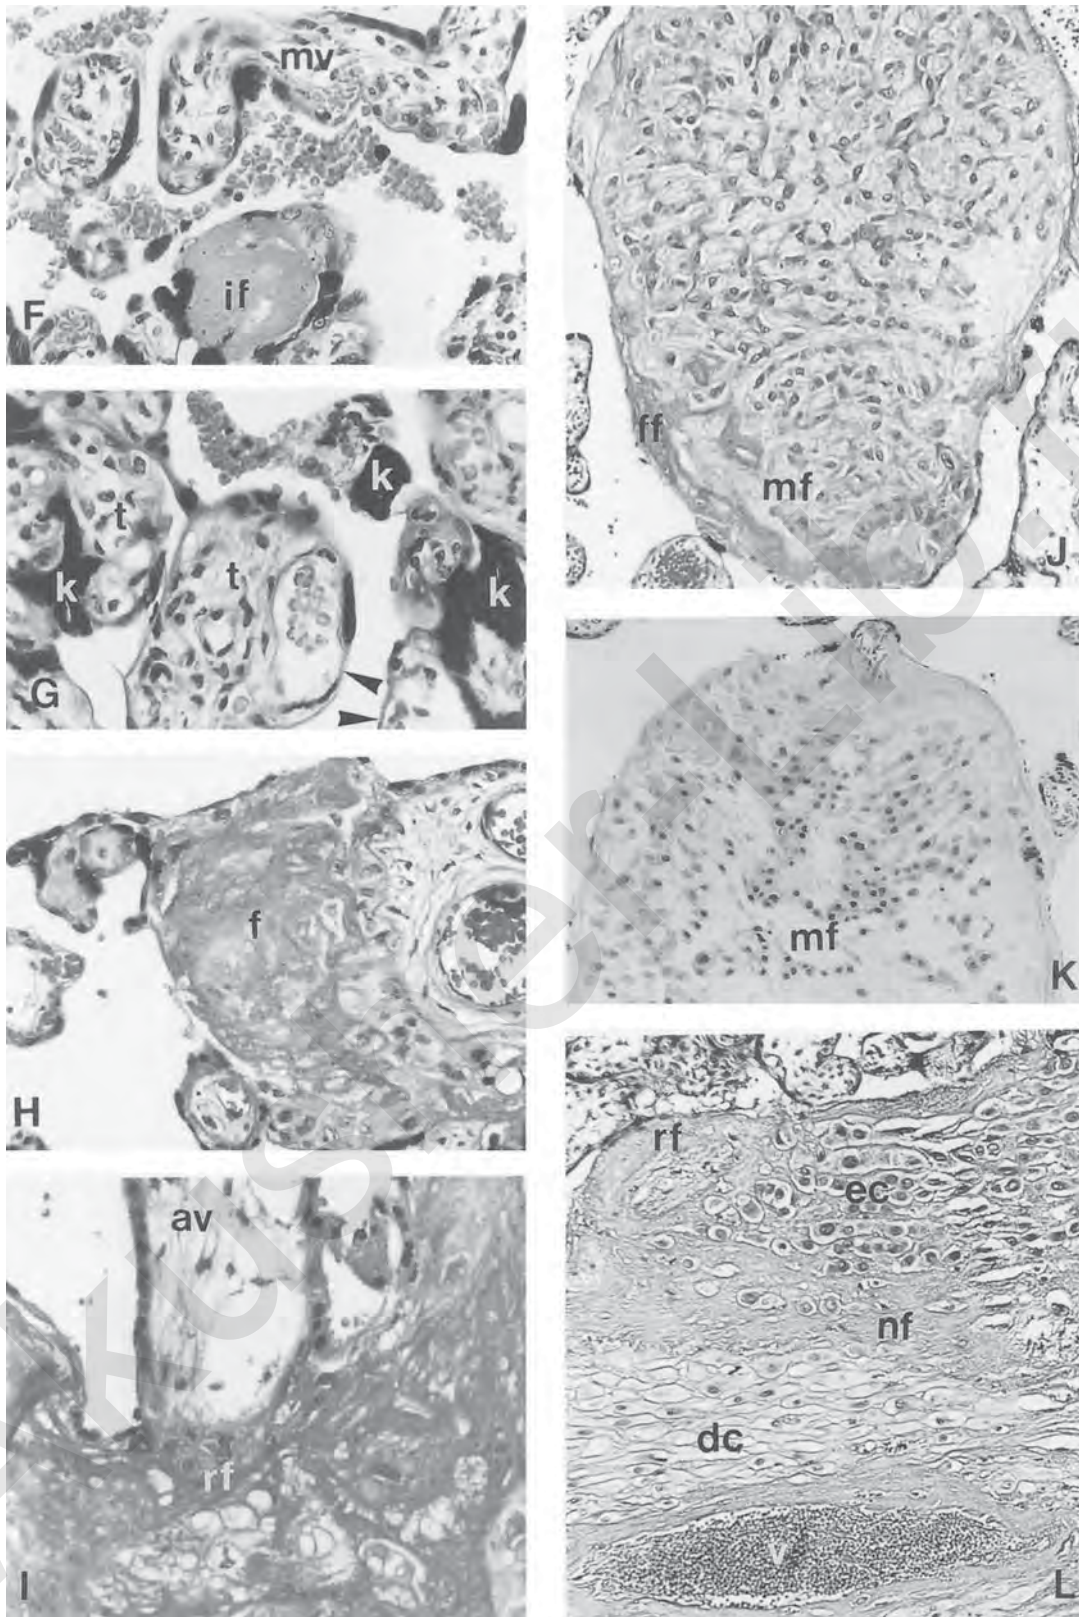

FIGURE 3.2. F: A longitudinally sectioned mature intermediate villus (mv) together with some terminal villi and a villous fibrinoid necrosis (if).  $\times 180$ . G: A group of terminal villi (t) showing considerable syncytial knotting (k).  $\times 360$ . H: A small stem villus, the trophoblastic cover of which is partly replaced by a thick plug of perivillous fibrinoid (f).  $\times 180$ . I: An anchoring villus (av),

connected to the basal plate by Rohr fibrinoid (rf) as the originally connecting cell column has vanished.  $\times 180$ . J: Cell island. mf, matrix-type fibrinoid.  $\times 90$ . K: Tip of a placental septum.  $\times 90$ . L: Basal plate with obvious layering. rf, Rohr fibrinoid; nf, Nita-buch fibrinoid; dc, decidua cells; ec, extravillous cytotrophoblast; v, vein.  $\times 90$ . For further details see the text.

Fig. 3.5C), a blood clotting product that is free of extravillous trophoblast cells and usually in contact with the intervillous space; and (2) **matrix-type fibrinoid** (see Fig. 3.5D), which embeds varying numbers of extravillous trophoblast cells and is itself a secretory product of these cells. Both substances may be deposited close together or separately (see Fibrinoid in Chapter 9).

Figure 3.2I: With the increasing development of free-floating villi that takes place in the course of the last trimester, **anchoring villi** become less prominent. They are still connected to the basal plate or to septa by **cell columns** (see Fig. 3.1H,I). As the proliferative activity of the columnar cytotrophoblast slows down, the cells are rarefied to one layer that is sometimes even incomplete. In some cases, extravillous trophoblast may be completely replaced by matrix-type fibrinoid so that the stroma of the anchoring villus directly borders Rohr's fibrinoid of the basal plate. Some cell columns maintain their proliferative activity and thus act as growth zones for the anchoring villi as well as for the basal plate, even near term (see Extravillous Trophoblast in Chapter 9).

Figure 3.2J: **Cell islands** increase in size throughout pregnancy by means of the continuous proliferation of their extravillous trophoblast cells. Also, the amount of fibrinoid embedding these cells increases steadily by apposition of fibrin-type fibrinoid from the intervillous space and by secretion of matrix-type fibrinoid from the trophoblast cells. Large cell islands may contain central cavities, or "cysts." They must be considered the result of degeneration of trophoblast cells and subsequent liquefaction. Occasionally, cell islands may contain some decidual cells in addition to extravillous trophoblast cells. Such islands can be interpreted either as cross sections of placental septa or as disrupted parts of such. For an understanding of their development see Early Villous Stages in Chapter 5; for the structure, see Cell Islands in Chapter 9.

Figure 3.2K: **Placental septa** are the result of folding of the basal plate, probably supported by tension of anchoring villi (see Septa in Chapter 9). They are rudimentary pillar-shaped structures, insufficient to subdivide the intervillous space into separate chambers. They are attached to the basal plate at their base (Fig. 3.2A) and are usually composed of extravillous trophoblast and decidual cells, both embedded in much fibrinoid. Sometimes large cysts, similar to those of the cell islands, can be found (see Cysts and Breus' Mole in Chapter 9). These sites of minor mechanical resistance during delivery usually give rise to deep basal tears of the placenta, the grooves delineating the placental lobes (see Chapter 2, Figs. 2.1 and 2.2). The septal tips (Fig. 3.2K) are composed mostly of extravillous trophoblast and matrix-type fibrinoid and are surrounded by fibrin-type fibrinoid. Their cross sections are hardly distinguishable from cell islands.

Only in a few exceptional places is the **basal plate** of the term placenta as clearly layered as depicted in Figure 3.2L, showing a superficial stria of Rohr fibrinoid, followed by extravillous cytotrophoblast, a layer of Nitabuch fibrinoid, and a compact decidual layer. In the latter, an uteroplacental vein is embedded. In most cases, however, there is no clearly defined fetomaternal border but rather extravillous cytotrophoblast, decidual cells, uteroplacental vessels, and glandular residues intermingled with ample fibrinoid and having no identifiable order (see Basal Plate in Chapter 9). In such cases, immunohistochemical markers may facilitate orientation (see the following discussion). For a consideration of the uteroplacental vessels and intraarterial trophoblast, see the description of the first trimester placenta, above.

#### IMMUNOHISTOCHEMICAL MARKERS

Structural orientation in histologic sections can be considerably facilitated by immunohistochemical markers. Some of those may even be applied to paraffin sections, provided that the tissue has been fixed with formalin only. We prefer fixation in a 4% neutrally buffered formaldehyde solution (10% formalin solution) for a maximum of 24 hours and at temperatures below 60°C during the paraffin embedding. Correspondingly prepared paraffin blocks may be used even years later for many immunohistochemical reactions (intermediate filaments, extracellular matrix proteins, proliferation markers, etc.).

The following immunohistochemical reactions may be useful for routine histologic examination of placental paraffin sections. All of them work with human material; some even cross-react with the respective molecules in several animal placentas.

**Anticytokeratin** stains epithelial structures such as amnionic epithelium, villous syncytio- and cytotrophoblast, and extravillous cytotrophoblast. In particular, for the discrimination between extravillous cytotrophoblast (Fig. 3.3A; also see Figs. 3.5A and 3.7A) and decidual cells (Fig. 3.3B; also see Fig. 3.5B) or intraarterial trophoblast (Fig. 3.3A) and maternal endothelium (Fig. 3.3C), it is a useful marker. We prefer a "pan-cytokeratin" antibody directed against cytokeratins 10, 17, and 18, which stains all cellular epithelial elements and additionally myofibroblasts and some vascular smooth muscle cells. Syncytiotrophoblast is only partly stained. Anticytokeratin 7 is a more specific trophoblast marker that does not cross-react with contractile mesenchymal cells. This antibody reproducibly stains villous and extravillous cytotrophoblast, but rarely villous syncytiotrophoblast or multinucleated trophoblastic giant cells.

**Antivimentin** stains all mesenchyme-derived cells, such as connective tissue cells, macrophages, decidual cells, smooth muscle cells, and endothelial cells. We use it as control on paraffin sections that are parallel to those stained for cytokeratin. Placental cells should be positive either for cytokeratin (epithelial origin, such as trophoblast, amnion, gland cells) or vimentin (mesenchymal origin, such as connective tissue, deciduas, smooth muscle cells endothelium). It is a useful tool to identify decidual cells (Fig. 3.3B; also see Fig. 3.5B) as opposed to extravillous trophoblast cells (Fig. 3.3A; also see Fig. 3.5A) or to discriminate maternal endothelium from intraarterial trophoblast (Fig. 3.3C).

**Anti-factor VIII-related antigen** (the former anti-von Willebrand factor) is a marker that is largely specific for most endothelial cells. Application of this antibody provided proof that the intervillous space in the adjacency of venous openings is lined by maternal endothelium (Fig. 3.3C). It does not always work on paraffin sections. The much more reliable marker for endothelial cells in paraffin sections is **anti-CD 34** (the monoclonal antibody QBend10) which detects a

FIGURE 3.3. Serial sections of a superficial part of the mature basal plate bordering the intervillous space (IVS) and showing a colorful mixture of extravillous trophoblast cells with decidual cells as well as a uteroplacental vessel (V). Immunohistochemistry using three different marker antibodies allows easy discrimination of cell types. A: Anticytokeratin, an epithelial marker, binds to evenly spread extravillous trophoblast cells as well as to the trophoblast cell lining of the uteroplacental vessel (brown). The surface of the basal plate remains unstained. B: Antivimentin, a mesenchymal marker, stains the decidual cells

(brown) as well as the endothelial lining of the basal plate (arrowheads). The luminal lining of the uteroplacental vessel (V) remains unstained since it consists of trophoblast rather than of endothelium. C: Staining with antibodies to factor VIII-related antigen, an endothelial marker, reveals that the surface of this part of the basal plate is covered by (maternal) endothelium (brown, arrowheads). All other cellular constituents of the basal plate including the luminal lining of the uteroplacental vessel remain unstained.  $\times 230$ . (Courtesy Dr. Sonja Kertschanska, Aachen.)

FIGURE 3.4. Endothelial markers facilitate identification of fetal capillaries within placental villi. A: Hematoxylin and eosin staining of term placental villi allows easy identification of villous shapes and of the trophoblastic surface. Discrimination of stromal components such as fibroblasts, macrophages,

and endothelium is largely impossible. B: The antibody QBend10 (anti-CD34) specifically stains endothelial cells (brown) of the villous vessels and enables easy discrimination of the fetoplacental vessel bed. Term placenta.  $\times 145$ .

cell surface marker specific for endothelium and its progenitor cells (Fig. 3.4).

**Antifibrin** can be used as a specific marker for fibrin-type fibrinoid as a blood clotting product (Fig. 3.5C). Specific detection of fibrin can only be achieved when an antibody is available (e.g., Immunotech, clone E8) that does not cross-react with the nearly universally present fibrinogen.

**Anti-oncofetal fibronectin BC-1** (directed against the III-7 domain of oncofetal fibronectins containing the EDB sequence) and **FDC-6** (directed against the O-glycosylated III-CS region of oncofetal fibronectins) are specific markers for matrix-type fibrinoid as shown for BC-1 in Figure 3.5D. Different from other fibronectin antibodies, they cross-react with neither fibrin-type fibrinoid nor connective tissue.

**Anti- $\gamma$ -smooth muscle actin** in placental tissues is largely specific for vascular smooth muscle cells and myofibroblasts. It is a useful tool to identify the vessel walls of fetal villous arteries and arterioles as well as of veins and venules. It may be used as marker for different types of stem villi (Fig. 3.6A) and their immature forerunners, the immature

intermediate villi, as both villous types are the only villi having these stem vessels.

The more easily available **anti- $\alpha$ -smooth muscle actin** (Fig. 3.6B) has a staining pattern that is largely comparable to anti- $\gamma$ -smooth muscle actin. The antibody detects, however, also earlier stages of myofibroblast differentiation and vascular pericytes. As the latter are also present in mature intermediate and terminal villi, this antibody is less useful for the discrimination of different villous types.

**Anti-CD68** and **anti-CD14** (antibody leuM3) (see Chapter 6, Fig. 6.27) are the most consistent immunohistochemical markers of macrophages, the Hofbauer cells. They detect monocyte differentiation antigens. Application of these antibodies to placental villi demonstrates that a much larger share of villous stromal cells are in fact macrophages (see Fig. 6.27) than had been expected from ultrastructural and enzyme histochemical studies. Like most antibodies directed against cell-surface receptors, these antibodies preferably should be applied to unfixed cryostat sections. However, with some care they may also work on paraffin sections.

FIGURE 3.5. Serial sections of a cell column of the first trimester placenta. A: Anticytokeratin stains the villous trophoblastic surface as well as extravillous trophoblast (brown, ec) that forms a compact layer at the border to the anchoring villus (av) and invades the basal plate (below). dc, decidual cells. B: Antivimentin staining of a parallel section reveals that most of the basal plate cells are of mesenchymal origin (decidual cells, brown). The trophoblast cells (slender blue nuclei) invade the decidual layer. Also villous stromal cells (above)

are of mesenchymal origin and therefore are immunostained. C: Antifibrin binds to a deposit of fibrinoid (fibrin-type fibrinoid, reddish, ff) that is closely related to the intervillous space and devoid of extravillous trophoblast cells. D: In contrast, anti-oncofetal fibronectin (antibody BC-1) binds to the reticular fibrinoid deposits (matrix-type fibrinoid, brownish) around the invading extravillous trophoblast cells and decidua cells.  $\times 105$ . (Courtesy of Dr. Hans-Georg Frank, Aachen.)

FIGURE 3.6. A: Anti- $\gamma$ -smooth muscle actin specifically stains smooth muscle cells (brown) of arteries/arterioles (a) and veins/venules (v) of stem villi as well as highly differentiated myofibroblasts (arrowheads), which are characteristic for the extra-vascular stroma of only the largest stem villi (>300  $\mu$ m caliber). The stroma of mature intermediate (m) and terminal villi (t) remains unstained. The trophoblastic cover of the villi appears

blue from nuclear counterstaining with hematoxylin.  $\times 165$ . B: The closely related  $\alpha$ -smooth muscle actin can be detected immunohistochemically in media smooth muscle cells of an arteriole (brown, ao), in stromal myofibroblasts (brown), and additionally in vascular pericytes (p) identifiable by their characteristic spider-like shapes.  $\times 1080$ . (Courtesy of Dr. Gaby Kohnen, Aachen.)

FIGURE 3.7. Serial paraffin sections of a cell column (brown) connecting an anchoring villus (above, av) to the basal plate (bottom, bp). The comparison of anticytokeratin staining of the extravillous cytotrophoblast (brown in part A) with MIB-1 staining of proliferating trophoblast cells (brown in part B) reveals that only extravillous trophoblast cells located close to the basal lamina separating cell column and anchoring

villus undergo mitosis. In contrast, those invasive daughter cells (arrowhead in A) that have left the cell column and deeply invaded the basal plate are no longer proliferative (unstained in B). In conclusion, those cells resting on the basal lamina are the proliferating stem cells of all extravillous trophoblast cells.  $\times 150$ . (Courtesy of Dr. Gaby Kohnen, Aachen.)

The antibodies **Ki-67**, **MIB-1**, and **anti-PCNA** (clones PC10, 19A2, 19F4) bind to nuclear proteins that are expressed in proliferating cells. Ki-67 is only applicable on cryostat sections. MIB-1 is its analogue for carefully fixed paraffin sections; it can be applied also on cryostat sections. Anti-PCNA can be used only for paraffin material. Ki-67/MIB-1

binds only to cells in the mitotic cycle. Because of its longer biologic half-life PCNA (proliferating-cell nuclear antigen) can also be detected in cells that have already left the cell cycle up to 24 hours earlier. These antibodies are useful markers to distinguish proliferating stem cell populations from differentiated ones and identifying growth zones (Fig. 3.7)

# 4

## Placental Types

Throughout pregnancy, the viviparous vertebrates develop a system of membranes that surround the fetus. The apposition or fusion of these fetal membranes with the uterine mucosa, for purposes of maternofetal physiologic exchange, initiates the formation of the placenta. To put it differently, the fetus is surrounded by the fetal membranes, to which it is connected by the umbilical cord (Fig. 4.1). The sac of membranes lies in the uterine cavity and has contact with the endometrium over almost its entire surface. The maternofetal contact zone, thus provided by membranes and endometrium, represents the placenta.

This nonspecific definition points to the great **structural and functional variability of the organ**. There is probably no other organ that exhibits such a large degree of species differences as the placenta. When comparing species, the outer shape and inner structure can vary to such a degree that nonplacentologists who are familiar with the structure of only the human placenta probably cannot identify any other type as a placenta at all. There is only one structural component that all placental types have in common, namely, the existence of two separate circulatory systems—the maternal system and the fetal system. Under normal conditions, the vessels of both systems remain separated by several tissue layers throughout pregnancy. Even the origin of these separating tissue layers, making up the so-called placental barrier or interhemal membrane, varies. These may be derived from fetal tissues such as (1) the blastocyst wall (trophoblast), which following fusion with the fetal mesenchyme is called the chorion; (2) the allantois, which is the extracorporeal embryonic urinary bladder; or (3) the yolk sac, an extracorporeal vesicular extension of the gut (Fig. 4.2). Each of these membranes is complemented by the amnion, which forms a second, fetally derived, membranous sac surrounding the embryo. In some cases, these fetal constituents are complemented by maternal tissues, that is, remainders of the endometrium.

The placenta is unique among all other organs in that it conducts the **functional activities** of most fetal organs

(except the locomotor apparatus and the central nervous system) from its early beginning on throughout its development. The following fetal functions are partially or completely accomplished by the placenta during pregnancy as a substitute for still immature embryonic and fetal organs:

1. Gas transfer (later the function of the lung)
2. Excretory functions, water balance, pH regulation (later the function of the kidney)
3. Catabolic and resorptive functions (later the function of the gut)
4. Synthetic and secretory functions of most endocrine glands
5. Numerous metabolic and secretory functions of the liver
6. Hematopoiesis of the bone marrow (during early stages of pregnancy)
7. Heat transfer of the skin
8. Immunologic functions (to a largely unknown degree)

It is very unlikely that these numerous functional requirements can be fulfilled by a phylogenetic development of an identical structural solution for all species, as species exhibit tremendous variation in size, length of pregnancy, litter size, and living conditions. The logical result of this situation has been the development of numerous placental types, differing from each other with respect to outer shape, kind of maternofetal interdigitation, structure of the maternofetal barrier, and maternofetal blood flow interrelations. As a basis for a better understanding of the human placenta, we present only a brief overview of the so-called **allantochoorial placentas**. This group comprises all those placentas that develop from the blastocyst wall and become fetally vascularized from the allantois, the embryonic bladder (see Fig. 4.2). This placental type is the most common among mammals and is also represented in the human. For more detailed information we refer to the fundamental monographs on comparative

FIGURE 4.1. A placenta is formed when the fetal membranes (blue, central figure) come into close contact by apposition or fusion with the endometrial lining (red, left figure) of the uterus. This theoretically most simple type of a placenta, namely a

placenta diffusa with a smooth contact area as shown on the right figure, is not known to exist. (Source: Modified from Kaufmann, 1981, with permission.)

FIGURE 4.2. Synoptic representation of the fetal membranes (black, blue) that may contribute to the formation of a placenta. Maternal tissues are colored red and brown. The trophoblast (blue), as derivative of the blastocyst wall, together with the fetal mesenchyme (gray, dotted), forms the chorion, which is the main exchange membrane of most mammals. The chorion does not develop its own vessels but rather becomes vascularized either by the allantois (black) ( $\rightarrow$  chorioallantoic placenta) or by the yolk sac (black) ( $\rightarrow$  choriovitelline placenta). In some species, the chorion is replaced locally by the yolk sac (black) ( $\rightarrow$  yolk sac placenta). The amnion (black) is unvascularized and never replaces the chorion; rather, it serves as an additional, inner membrane that separates the chorion or yolk sac from the amniotic fluid.

placentology by Björkman (1970), Steven (1975), Ramsey (1982), and Mossman (1987), and to the reviews by Wimsatt (1962), Enders (1965), and Kaufmann (1981).

Among the numerous possibilities for classifying the allantochorial placentas (Amoroso, 1952; Wimsatt, 1962; Steven, 1975; Kaufmann, 1981; Ludwig 1981; King, 1982; Ramsey, 1982; Mossman, 1987; Dantzer et al., 1988), the following characteristics proved to be the most successful for characterizing the organ structurally and, to a limited degree, functionally:

1. Outer shape and surface extension around the chorionic sac
2. Kind and intensity of interdigitation of maternal and fetal tissues
3. Number, kind, and structure of tissue layers separating maternal and fetal blood
4. Spatial arrangement of maternal and fetal vessels or of blood flow directions, respectively

It is impossible to cite here the vast comparative placentologic literature covering the various placental types. Rather, for each placental type or for each group of animals, we refer to one or two detailed publications that may serve as characteristic illustrations.

## Placental Shapes

The extent of maternofetal and fetomaternal transfer depends largely on the size of the maternofetal contact area available for exchange (Kaufmann, 1981; Ludwig, 1981; Schröder, 1982). The smooth contact area of the chorion (derivative of the blastocyst wall, and outer layer of the fetal membranes) with the endometrium seems to be insufficient to meet the fetal demands, even if the contact is established over the entire surface of the chorionic sac (as depicted in Fig. 4.1). This placental type does not exist in mammals. Rather, all mammals increase the placental exchange area by interdigitation of the opposing maternal and fetal tissue surfaces. In most cases, the surface enlargement by interdigitation is so intense that enough exchange surface can be provided even if interdigitation takes place only on a limited surface area of the chorionic sac. This interdigitating part is called the **placenta**, whereas those parts of the chorionic sac that maintain a more or less planar apposition to the uterine surface are called smooth chorion, chorion laeve, paraplacenta, or simply outer **fetal membranes**. Each animal order or suborder has a typical shape and surface extension of its placenta.

In the light of phylogeny, it is interesting to note that most of these typical placental shapes have been observed as more or less rare malformations in the human as well. It is still a matter for discussion, however, whether placental shapes of certain animal orders and the respective

human malformations are really comparable results of placental development rather than mere products of external similarity in shapes.

In comparative placentology the following placental shapes have been defined:

- Maternofetal interdigitation extending over the entire surface of the chorionic sac is called **placenta diffusa** (placenta membranacea) (Fig. 4.3). This type is seen in Perissodactyla (Amoroso, 1952), Cetacea (Wislocki & Enders, 1941), Suidae (MacDonald & Bosma, 1985), Tylopoda (Ramsey, 1982), and some lower primates (Ramsey, 1982). According to Torpin (1969), it may occur rarely in the human as well (see Chapter 13). In all other cases, maternofetal interdigitations are locally restricted and highly concentrated.
- Many such spot-like regions of intense maternofetal interdigitations, such as those in ruminants (Björkman, 1969), are called **placenta cotyledonaria** or placenta multiplex (Fig. 4.3). To our knowledge, a corresponding malformation has not been described for the human.
- In carnivores (Björkman, 1970), Sirenia (Wislocki, 1935), Hyracoidea (Mossman, 1937), and Proboscidea (Mossman, 1937), the placenta forms a ring-like zone in the chorionic sac surrounding the fetus like a girdle, the **placenta zonaria**, placenta annularis, or girdle-like placenta (Fig. 4.3). The incidence of a corresponding kind of maldevelopment in the human is much less than 0.1%. It has been interpreted as a result of implantation in the uterine cervix, where the fetal membranes establish intense contact with the uterine wall in a ring-like fashion (Torpin, 1969).
- Several lower and higher primates (Luckett, 1970; Ramsey, 1982), as well as the *Tupaia* (Kaufmann et al., 1985; Luckhardt et al., 1985) as a possible phylogenetic link between insectivores and lower primates, develop two disk-like areas of intimate contact, the **placenta bidiscoidalis** (Fig. 4.3). In the human it is represented by the placenta duplex (0.1%). Incomplete subdivision of the placental disk in the human is described as placenta bilobata or placenta bipartita (2–8%). The placenta succenturiata in the human (0.5–1%) shows an asymmetrical complete or incomplete subdivision into a large and a small disk. All three types of placental malformation in the human have been described as being a result of lateral implantation in the corner between the anterior and posterior walls of the uterus (Torpin, 1969).
- The highest degree of concentration of maternofetal interdigitation is realized in the **discoidal placenta** (Fig. 4.3), which provides only a single disk-like zone of intimate maternofetal contact. This most common type of placenta exists in rodents (Enders, 1965; Kaufmann & Davidoff, 1977; Ramsey, 1982), the great apes (Ludwig & Baur, 1971), and the human (Boyd & Hamilton, 1970).

FIGURE 4.3. Instead of the smooth contact area shown in Figure 4.1, all known placental types show interdigitations between maternal (red) and fetal (blue) components. Depending on the

extent of these interdigitations, several placental shapes are described. For details see text. (Source: Modified from Kaufmann, 1981, with permission.)

## Types of Maternofetal Interdigitation

If that part of the surface area of the chorionic sac in which maternofetal interdigitation takes place is reduced, it must be compensated for by an increased intensity of the interdigitations. This results in five different types of maternofetal interdigitation:

- The simplest form of interdigitation, consequently, is combined with the large-surfaced diffuse placenta: It is called the **folded type of placenta** (Fig. 4.4A) and is characterized by poorly branching, ridge-like folds of the chorion that fit into corresponding grooves of the uterine mucosa. Examples are seen in the pig (MacDonald & Bosma, 1985) and some lower primates (Ramsey, 1982) that have a diffuse placenta.
- A generally similar but more complex construction is typical for the **lamellar type of placenta** (Fig. 4.4B). This type is found in the carnivores (Leiser & Kohler, 1984). In this case, the ridges multiply branch into complicated systems of slender chorionic lamellae, oriented
- in parallel to each other and separated by correspondingly branching endometrial folds.
- Even more exchange surface per placental volume is provided by a tree-like branching pattern of the chorion, resulting in the placental villous tree. The villi fit into corresponding endometrial crypts or are directly surrounded by maternal blood. This **villous type of placenta** (Fig. 4.4D) exists in ruminants (Steven, 1975; Kaufmann, 1981) and in higher primates (Boyd & Hamilton, 1970; King & Mais, 1982).
- An intermediate stage between the lamellar and the villous condition is represented by the **trabecular type of placenta** (Fig. 4.4C). It has been described for some platyrrhine monkeys, such as *Callithrix* (Luckett, 1974; Merker et al., 1987). This placental type is characterized by branching folds from which leaf-like and finally finger-like villi branch off.
- The most common and most effective kind of interdigitation can be found in the **labyrinthine type of placenta** (Fig. 4.4E). It has been described so far only in placentas that have a discoidal or bidiscoidal shape. It is the

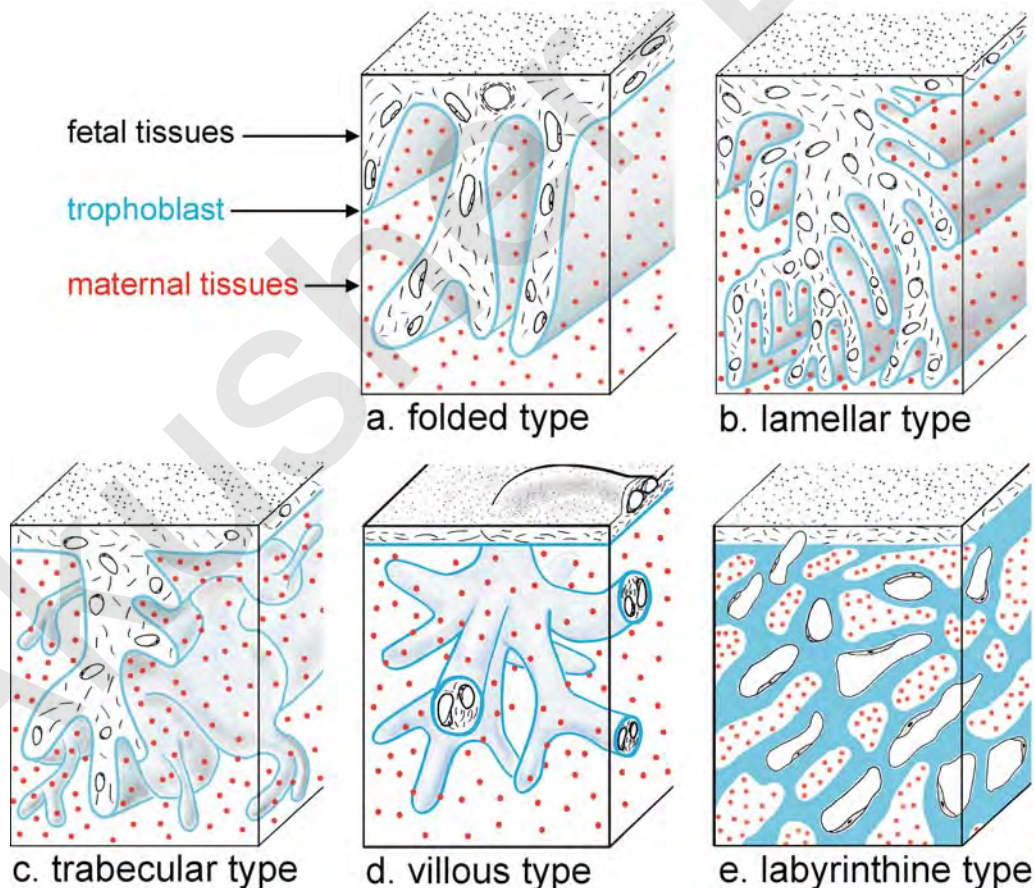

FIGURE 4.4. Types of interdigitation between maternal and fetal tissues. Maternal tissue or maternal blood (red); fetal trophoblast (blue); fetal capillaries and fetal connective tissue (black).

For details, see text. (Source: Modified and extended from Kaufmann, 1981, with permission.)

typical interdigitation for the placentas of rodents (Kaufmann & Davidoff, 1977), lagomorphs (Mossman, 1937), insectivores (Malassine & Leiser, 1984), bats (Wimsatt & Enders, 1980), and some lower monkeys (Ramsey, 1982; Kaufmann et al., 1985; Mossman, 1987). As the characteristic feature, a tissue block of trophoblast is penetrated by web-like channels that are filled with maternal blood or fetal capillaries.

## Maternofetal Barrier

The two preceding systems of classification are merely structurally descriptive ones. Grosser (1909, 1927) initiated a more functional system of classification, describing structure and composition of the so-called placental barrier. This system was later extended by Enders (1965). Although often criticized because it fails to consider structural variation within the same placenta, this system still has its merits, “if for no other reason than that it serves as a ready reminder of the different components that need to be analyzed before drawing functional conclusions” (King, 1982). The terms **maternofetal barrier** and **placental barrier** are traditional descriptions of the tissue layers separating maternal and fetal circulations in the placenta. These terms are still in use despite the fact that they are somewhat misleading (King, 1982). Increasing knowledge of placental physiology has taught us that synthetic, secretory, and transport functions of the placenta are as important aspects of this organ as the barrier role, separating the maternal and the fetal circulations.

As an alternative, the term **interhemal membrane** is in use because it avoids any functional connotation for the separating layers. However, the use of the term **membrane** for a complex layer composed of several cells, rather than for the unit membrane of a cell, is also misleading.

The following types of maternofetal barrier have been classified:

- In the most complete case of a placental barrier—in the Artiodactyla (Wooding et al., 1980), the Perissodactyla (Amoroso, 1952; Ramsey, 1982), and some prosimians (Mossman, 1987)—the fetal chorion directly faces the intact endometrial epithelium. The blastocyst did not invade the endometrium, but only remained attached to it. This condition is called the **epitheliochorial placenta**. Maternal and fetal blood is separated by six tissue layers (Fig. 4.5): maternal capillary endothelium, maternal endometrial connective tissue, and maternal endometrial epithelium, and three layers of fetal origin—trophoblast, chorionic connective tissue, and fetal endothelium. From the six layers, the trophoblast or the maternal epithelium may fuse syncytially.

Sometimes even hybrid syncytia are formed by fusion of trophoblastic (fetal) and uterine epithelial (maternal) cells, as in ruminants (Wooding, 1992).

- By stepwise removal of maternal tissue layers the maximum barrier, consisting of six layers, can be reduced during invasion of the blastocyst. If invasion stops after destruction of the uterine epithelium, the **syndesmochorial placenta** (Fig. 4.5) is obtained. Originally, sheep and goats were said to possess this type. More recently, the existence of this five-layer barrier has been refuted (Kaufmann, 1981; Ramsey, 1982). Sheep and goats seem to display an epitheliochorial or synepitheliochorial condition (Wooding, 1992; Wooding et al., 1980), like all other Artiodactyla.
- Deeper invasion with subsequent removal of endometrial connective tissue, establishing a direct apposition of trophoblast and maternal endothelium, results in the development of the **endotheliochorial placenta** (Fig. 4.5). This placental barrier is characteristic for all carnivores (Björkman, 1970), and it is represented in some insectivores (Malassine & Leiser, 1984), lower primates (Kaufmann et al., 1985), and bats (Ramsey, 1982).
- As the next and final step of invasion, the maternal vessels are eroded and finally completely destroyed by the invasive trophoblast. The trophoblastic surfaces now directly face the maternal blood. The respective placental type is called the **hemochorial placenta** (Fig. 4.5). It has been described, for instance, for all rodents and lagomorphs, for some insectivores, bats, and Sirenia, and for the higher primates including the human (Enders, 1965; Ramsey, 1982). Depending on the number of trophoblastic epithelial layers, Enders (1965) has proposed a more detailed subdivision into **hemotrichorial** (rat: Enders, 1965; mouse: Björkman, 1970; hamster; Carpenter, 1972), **hemodichorial** (beaver: Fischer, 1971; rabbit: Enders, 1965; human in the first trimester: Boyd & Hamilton, 1970), and **hemomono-chorial** (caviomorph rodents, e.g., the guinea pig: Kaufmann & Davidoff, 1977; human placenta at term: Boyd & Hamilton, 1970).
- Some authors (see Wimsatt, 1962) have described less common types of placentas in insectivores and bats in which even fetal tissue components are subjected to destruction, resulting in **endothelioendothelial** and even **hemoendothelial** conditions. In most cases, these descriptions have not been based on ultrastructural studies and thus need to be corroborated.

Generally speaking, maternofetal and fetomaternal diffusional transfer depend on the thickness of the separating layers, whereas the number and kind of the layers of the barrier influence facilitated transport, active transport, and vesicular transfer. This statement, however, does not imply that all layers to the same extent contribute to the **barrier function**. When stating that three to six tissue layers make up the placental barrier, this does not necessarily mean that a corresponding number of cells must

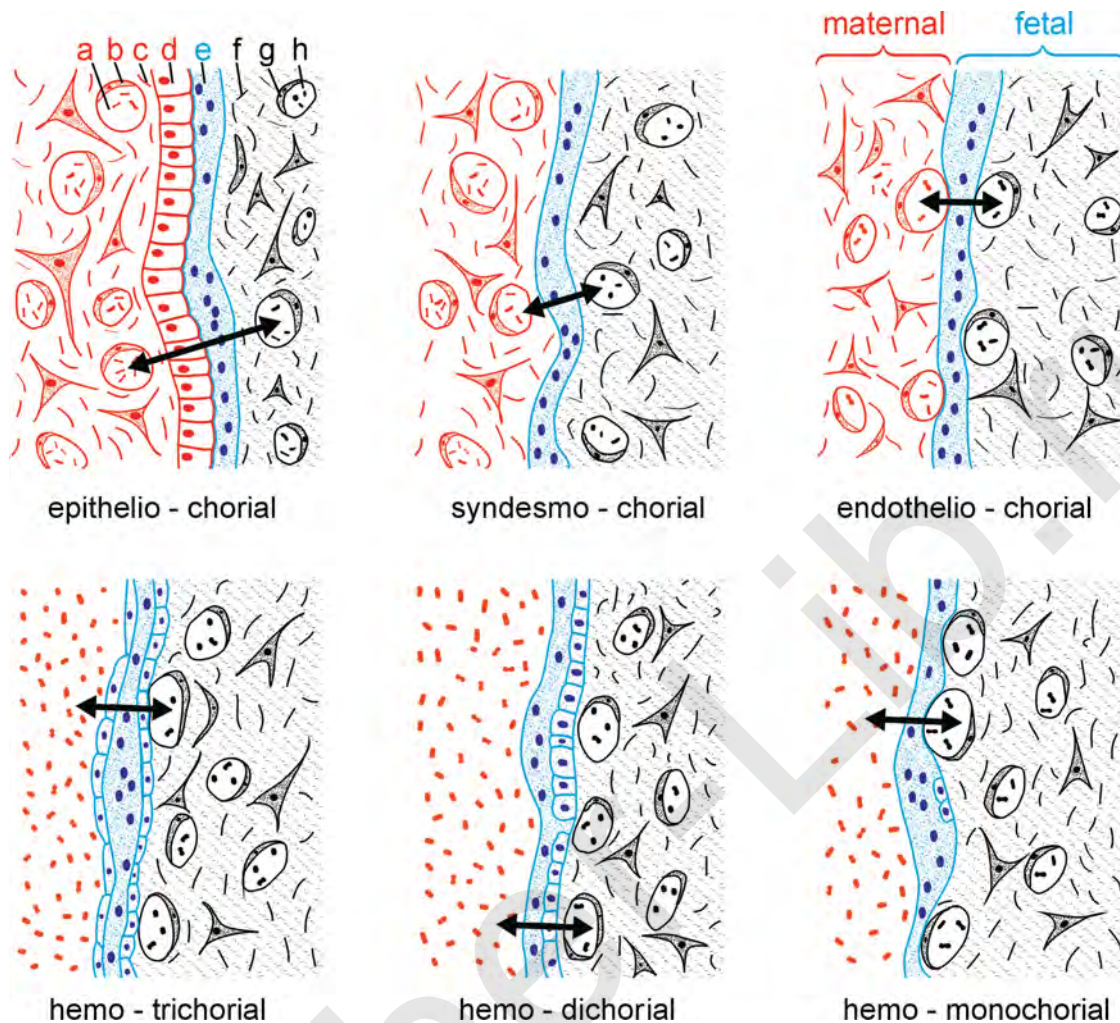

FIGURE 4.5. Tissue layers of the maternofetal barrier according to the Grosser classification. a, maternal blood (red dots); b, maternal endothelium (red); c, endometrial connective tissue (red); d, endometrial epithelium (red); e, trophoblast (blue); f, fetal connective tissue (black); g, fetal endothelium (black); h, fetal blood (black dots). The fetal components of the placental barrier (e–g) are collected under the term **chorion**. The maternal components are reduced step by step until the chorion comes into direct contact with the maternal blood

(a, red dots). The trophoblast (blue), normally consisting of a syncytium (e), may be covered on one side (hemodichorial) or on both sides (hemotrichorial) by cytotrophoblast. In most species, the trophoblast fuses syncytially. In some species, mostly those with epitheliochorial placentation, either the maternal epithelium fuses syncytially instead of the trophoblast, or both epithelia remain cellular. For further details, see text. (Source: Modified and extended from Kaufmann, 1981, with permission.)

be passed transcellularly by each transported molecule. This situation is only mandatory for the trophoblast, which in most species with invasive implantation is a syncytium that can be passed only transcellularly by transport mechanisms such as diffusion, facilitated transfer, active transport, and vesicular transfer. In both connective tissue layers, however, transport may easily take place paracellularly by diffusion. For smaller molecules, the same is valid for the uterine epithelium (so far as it is cellular in nature) and for both endothelia. These epithelial and endothelial linings offer limited paracellular transfer to small molecules along the lateral intercellular clefts. As a consequence, the syncytiotrophoblast in most placentas, including that of the human, is the decisive barrier that limits or supports transplacental transfer processes.

According to Fick's law of diffusion, **exchange efficiency**, that is the net amount of substance crossing the membrane, depends (*inter alia*) on the concentration difference of the substance across the mem-

brane, as well as on the area and thickness of the membrane. Thus, reduction of the distance between maternal and fetal blood is of decisive importance for the maternofetal diffusional exchange. It makes the Grosser classification valuable for determining diffusional efficiency of the organ. It is, however, important to note that this is valid only for passive diffusion (oxygen, carbon dioxide, water) (Schröder, 1982; Faber & Thornburg, 1983). For most transport mechanisms, the product of exchange surface available and the activity of the uptake mechanisms (carrier molecules, enzymes, and receptors for active and vesicular transport) are the limiting factors, not the barrier thickness. The latter situation is comparable to an escalator, the capacity of which is limited by width and speed rather than by length. It is valid for transplacental transport processes, such as facilitated diffusion (e.g., glucose), active transport (e.g., ions and many amino acids), and vesicular transport (peptides, proteins, lipids). As a consequence, we must conclude that

the applicability of the Grosser classification is limited to the interpretation of the capacity of the placenta for passive diffusion. The findings by Dantzer et al. (1988) make it likely that primarily the fetal demands determine placental size during transplacental oxygen diffusion.

## Maternofetal Blood Flow Interrelations

Similar advantages but also similar limitations as discussed for the Grosser classification are valid for the placental classification according to the geometric arrangement of maternal and fetal capillaries or blood flows in the exchange area (Bartels & Moll, 1964; Faber, 1969; Moll, 1972, 1981; Martin, 1981; Schröder, 1982; Faber & Thornburg, 1983; Dantzer et al., 1988). The relative efficiencies of various types of the following theoretical exchanges for the diffusion of, for example, oxygen, have been calculated. Physiologists have defined several theoretical models of diffusional exchangers and calculated their efficiency for diffusional transfer. The results have been compared with real structural and functional findings in various mammals:

- The **concurrent flow exchanger** (Fig. 4.6) is the most inefficient system. Its fetal and maternal capillaries are thought to be arranged in parallel, having identical blood flow directions. Obviously it is not represented in placentas of mammals (Martin, 1981).
- Also, with the **countercurrent flow exchanger**, maternal and fetal capillaries are arranged in parallel but with blood flow in opposite directions (Fig. 4.6). This is the most effective vascular arrangement for passive diffusion. It is nearly perfectly realized in the placentas of all rodents (Kaufmann & Davidoff, 1977; Dantzer et al., 1988) and lagomorphs (Mossman, 1926). Accordingly, these animals exhibit small placentas compared to their fetal weight (fetoplacental weight relations up to 20:1).
- The remaining theoretical and real exchange systems have an intermediate position between concurrent and countercurrent exchangers regarding their efficiency. Among them, for placentology the most important ones are the **simple crosscurrent flow** (Fig. 4.6) (carnivores: Leiser & Kohler, 1984; Dantzer et al., 1988), **double crosscurrent flow** (Fig. 4.6) (lower primates: Luckhardt et al., 1985; pig: Dantzer et al., 1988).
- Last but not least also the **multivillous flow exchanger** (Fig. 4.6) (ruminants: Dantzer et al., 1988; higher primates and human: Moll, 1981) have an intermediate position regarding efficiency.

The importance of this classification system for the fetal oxygen supply is stressed by the fact that the animals showing a less efficient vessel arrangement have a poorer fetoplacental weight relation at term (pig: 9:1; cat: 8:1; human: 6:1) compared to the highly effective, small rodent placentas (up to 20:1) (Dantzer et al., 1988).

FIGURE 4.6. Idealized arrangement of the fetal (lilac arrows) and maternal (red arrows) bloodstreams of different placental exchange types, according to, Faber (1969), Moll (1972), and Martin (1981). The intensity of blue color in the venous limbs of the fetal vessel loops (upper right vessel of each single drawing) illustrates the efficiency of the various exchangers in diffusional exchange (for example, oxygen). For further details, see text. (Source: Dantzer et al., 1988, with permission.)

## Placental Types and Phylogeny

The foregoing systems of placental classification have been accused of being merely structurally descriptive but functionally more or less irrelevant, since both

“primitive” and “highly developed” placentas produce healthy offspring. This reproach is supported by several facts:

- The pig seems to have one of the most primitive placentas possible: a diffuse, epitheliochorial, folded, crosscurrent placenta (Dantzer et al., 1988).
- By contrast, the guinea pig placenta is thought to be one of the most highly developed ones, belonging to the discoidal, labyrinthine, hemomonochorial, counter-current type (Kaufmann & Davidoff, 1977).

The seemingly primitive pig placenta, however, guarantees embryonic development as satisfactorily as does the highly sophisticated guinea pig placenta for its embryos; and probably nobody would state that the reproductive qualities of the guinea pig are superior to that of the pig. One therefore must be careful when describing a placenta as “primitive” or “highly developed.” Independent of the simplicity or complexity of their structure, all placentas fulfill their biologic tasks, when necessary compensating for missing complexity simply by increased mass, as this is the case when comparing pig and guinea pig.

Schröder (1993) has stressed another interesting view to explain the phylogenetic variabilities of placental sizes and efficiencies:

- Animals with a rather short gestational period as compared to neonatal weight have relatively **large daily fetal growth rates**. If such species want to produce their large fetuses within a short time with a small placenta (e.g., myomorph rodents), their choice of placental type is restricted to the high-efficiency type, such as labyrinthine and hemochorial with countercurrent flow.
- With **low daily fetal growth rates**, however, it does not really matter which placental type and efficiency are available to the species; all grades of efficiencies are possible ranging from the villous, synepitheliochorial, multivillous sheep placenta, via the villous, hemomonochorial, multivillous human placenta, to the labyrinthine, hemomonochorial, countercurrent capybara placenta.

Unquestioned is the importance of the classification systems when looking for **in vivo models for the human**. The delivered human term placenta has been easily available for many kinds of research. For nearly all in situ studies, however, we need animal experiments. The only placentas that are directly comparable to those of the human are the placentas of the great apes. For several reasons (expense and protection of rare species) they provide no real alternatives for placental research. Thus,

one has to work with laboratory animals with placentas that are largely different from those of the human. The classification systems described here provide a certain orientation regarding differences and similarities between the various animal models and the human placenta. Moreover, as stated by King (1982), they remind us that we must take into consideration the differences before drawing functional conclusions.

When inspecting Table 4.1, one realizes that there is no evident relationship between placental classification and taxonomy. Some orders such as the carnivores, lagomorphs, and rodents seem to be homogeneous regarding placental structure. Others, such as insectivores and primates, may even give us the impression that several animals have acquired their respective placental types by chance. Perhaps this is the result of the special situation of the placenta, which has been developed for single use over a limited life span. Most placentas show considerable excess capacity, which makes a considerable difference when evaluating efficiency. It is an important consideration in pathology: The human placenta, which compared to the fetus, is rather large, can compensate for 50% tissue degeneration, and perhaps even more, without severe disturbance of pregnancy. In animals with relatively small placentas compared to their fetus, such as the guinea pig or the tupaia, fetal death is the normal result as soon as only a small amount of placental parenchyma is destroyed (Van der Heijden, 1981).

## Human Placenta

According to these classification systems, the human placenta is discoidal, villous, and hemochorial in structure. The arrangement of its maternal and fetal blood flows is in accord with the multivillous type of exchange system.

These basic structural characteristics are realized by the following design: The human placenta at term is a local, disk-like thickening of the membranous sac (Fig. 4.7) that is achieved by splitting the membranes into two separate sheets, the chorionic plate and the basal plate (Fig. 4.7). Both sheets enclose the intervillous space, as cover and bottom. The intervillous space is perfused with maternal blood, which circulates, without its own vessel wall, directly around the trophoblastic surfaces of the placental villi. The villi are complex tree-like projections of the chorionic plate into the intervillous space. Inside the villi are fetal vessels that are connected to the fetal circulatory system via the chorionic plate and the umbilical cord. At the placental margin, the intervillous space is obliterated so that the chorionic plate and the basal plate fuse with each other and thus form the chorion laeve.

TABLE 4.1. Placental classification at term in various animal orders

Order/species	Placental shape	Fetomaternal interdigitation	Placental barrier	Fetomaternal blood flow interrelations	Neonatal/placental weight ratio
<b>Marsupialia</b>					
Opossum	Discoidal	Folded	Epitheliochorial	—	—
<b>Insectivora</b>					
Sorex	Discoidal	Labyrinthine	Endotheliochorial	—	—
European mole	Discoidal	Labyrinthine	Endotheliochorial	—	—
Pacific mole	Diffuse	Labyrinthine	Hemochorial	—	—
<b>Primates</b>					
Tupaia	Bidiscoidal	Labyrinthine	Endotheliochorial	Double cross-current	18:1
Galago	Diffuse	Folded	Epitheliochorial	—	—
Marmoset	Bidiscoidal	Trabecular	Hemomonochorial	Multivillous	—
Rhesus monkey	Bidiscoidal	Villous	Hemomonochorial	Multivillous	—
Great apes	Discoidal	Villous	Hemomonochorial	Multivillous	—
Human	Discoidal	Villous	Hemomonochorial	Multivillous	—
<b>Chiroptera</b>					
Microchiroptera	Discoidal	Labyrinthine	Endotheliochorial	—	—
Molossidae	Discoidal	Labyrinthine	Hemodichorial	—	—
<b>Lagomorpha</b>					
Rabbit	Discoidal	Labyrinthine	Hemodichorial	Countercurrent	6:1
Hare	Discoidal	Labyrinthine	Hemodichorial	—	—
<b>Rodentia</b>					
Guinea pig	Discoidal	Labyrinthine	Hemomonochorial	Countercurrent	20:1
Chinchilla	Discoidal	Labyrinthine	Hemomonochorial	Countercurrent	30:1
Hamster	Discoidal	Labyrinthine	Hemotrichorial	Countercurrent	—
Beaver	Discoidal	Labyrinthine	Hemodichorial	—	—
Mouse	Discoidal	Labyrinthine	Hemotrichorial	Countercurrent	—
Rat	Discoidal	Labyrinthine	Hemotrichorial	Countercurrent	10:1
<b>Cetacea</b>					
Dolphin	Diffuse	Villous	Epitheliochorial	—	—
<b>Carnivora</b>					
Dog	Zonary	Lamellar	Endotheliochorial	—	—
Cat	Zonary	Lamellar	Endotheliochorial	Simple cross-current	8:1
Bear	Zonary	Lamellar	Endotheliochorial	—	—
Hyena	Zonary	Villous/labyrinthine	Hemomonochorial	—	—
<b>Sirenia</b>					
Manatee	Zonary	Labyrinthine	Hemochorial	—	—
<b>Pholidota</b>					
Pangolin	Diffuse	Villous	Epitheliochorial	—	—
<b>Proboscidea</b>					
Elephant	Zonary	Villous	Endotheliochorial	—	—
<b>Hyracoidea</b>					
Hyrax	Zonary	Labyrinthine	Hemochorial	—	—
<b>Edentata</b>					
Sloth	Discoidal	Labyrinthine	Endotheliochorial	—	—
Armadillo	Discoidal	Villous	Hemochorial	—	—
<b>Perissodactyla</b>					
Horse	Diffuse	Villous	Epitheliochorial	—	—
Rhinoceros	Diffuse	Villous	Epitheliochorial	—	—
<b>Artiodactyla</b>					
Pig	Diffuse	Folded	Epitheliochorial	Double cross-current	9:1
Alpaca	Diffuse	Folded/villous	Epitheliochorial	—	—
Sheep	Cotyledonary	Villous	Epitheliochorial	Multivillous	10:1
Goat	Cotyledonary	Villous	Epitheliochorial	Multivillous	10:1
Cow	Cotyledonary	Villous	Epitheliochorial	Multivillous	—

The data were assembled from the following publications: Wimsatt (1962), Enders (1965), Björkman (1970), Starck (1975), Ramsey (1982), Mossman (1987), Dantzer et al. (1988).

FIGURE 4.7. The mature human placenta in situ is composed of the chorionic plate (CP) and the basal plate (BP) surrounding the intervillous space (IVS) as cover and as bottom, respectively. The fetally vascularized villous trees project from the chorionic plate into the intervillous space and are directly surrounded by the maternal blood that circulates through the intervillous space. The loose centers of villous trees, arranged around the maternal arterial inflow area, are frequent features. M, myometrium; CL, chorion laeve; A, amnion; MZ, marginal zone between placenta and fetal membranes, with obliterated intervillous space and ghost villi; \*, cell island, connected to a villous tree; S, placental septum; UC, umbilical cord. # Early Development of the Human Placenta

For many years, understanding placental pathology was thought to demand only a limited knowledge of implantation and early placental development, because disturbances of these early steps of placentation seemed to cause abortion rather than affecting placental structure and function. Increasing experience with assisted fertilization, however, has taught us that an increased percentage of these cases show impaired fetal and neonatal outcome such as an increased incidence of intrauterine growth retardation and retroplacental hematoma, as well as increased perinatal mortality (Beck & Heywinkel, 1990). The causal connections are still unknown, although the authors give some arguments that placental causes must be considered. It must be speculated that improper conditions during implantation handicap early development and finally result in the inappropriate functioning of the fetoplacental unit.

Basic information concerning early development may be of increasing importance and thus is presented in this chapter. The pathologically interesting interactions between the site of implantation and the shape of the placenta are considered in Chapter 13.

## Prelacunar Stage

According to the general definition of the placenta given earlier, the development of the placenta begins as soon as the fetal membranes establish close and stable contacts with the uterine mucosa, that is, as soon as the blastocyst implants. To deal with the molecular mechanisms of implantation in detail would be beyond the scope of this chapter. For this purpose we refer the reader to the literature (Loke et al., 1995; Yoshimura et al., 1995, 1998; Aplin, 1996, 2000; Rao & Sanfilippo, 1997; Simon et al., 1998; Bentin-Ley & Lopata, 2000; Loke & King, 2000; Sunder & Lenton, 2000; Merviel et al., 2001a,b; Lindhard et al., 2002).

The first step of implantation is called apposition. In the human it takes place around day 6 to 7 postcoitus (p.c.) (day 1 p.c. = the first 24 hours after conception). During this stage, the implanting blastocyst is composed of 107 to 256 cells (Hertig, 1960; Boyd & Hamilton, 1970). It is a flattened vesicle, measuring about  $0.1 \times 0.3 \times 0.3$  mm in diameter. Most of the cells make up the outer wall (**trophoblast**) surrounding the blastocystic cavity (Fig. 5.1A). Generally speaking, the trophoblast is the forerunner of the fetal membranes, including the placenta. The inner cell mass, a small group of larger cells that form the **embryoblast**, is apposed to the inner surface of the trophoblastic vesicle. The embryo, umbilical cord, and amnion are derived from these cells. Moreover, both embryoblast-derived mesenchyme and embryoblast-derived blood vessels contribute to the formation of the placenta.

In most cases, the blastocyst is oriented in such a way that the embryonic pole (that part of the blastocyst bearing the embryoblast at its inner surface) is attached to the endometrium first (Boyd & Hamilton, 1970). Accordingly, this part of the circumference is also called the implantation pole. Rotation of the blastocyst in such a way that the embryonic pole and the implantation pole are not identical results in abnormal cord insertion. Thus, in moderate cases we find an eccentric or marginal insertion of the cord; in severe cases a velamentous cord insertion may be the consequence (see Chapter 12). The usual implantation site is the upper part of the posterior wall of the uterine body, near the midsagittal plane. According to Mossman (1937, 1987), this region is homologous with the antimesometrial wall of a bicornuate uterus, where primary attachment takes place in most mammals.

In all species, implantation is introduced by attachment of the apical plasma membranes of the blastocystic trophoblast to the apical plasma membranes of the uterine epithelium. This phenomenon has been described by Denker (1990) as a cell biologic paradox because

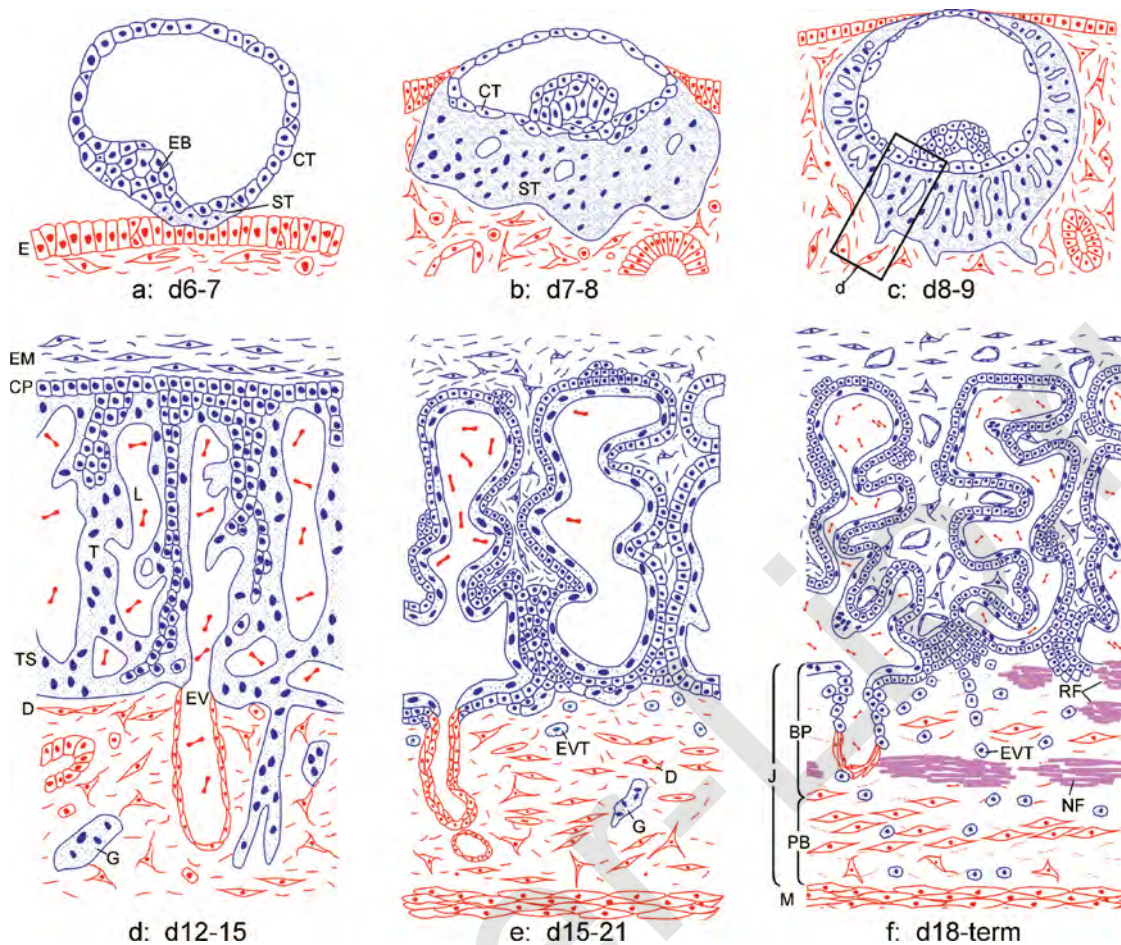

FIGURE 5.1. Simplified drawings of typical stages of early placental development. a,b: Prelacunar stages. c: Lacunar stage. d: Transition from lacunar to primary villous stage. e: Secondary villous stage. f: Tertiary villous stage. Note that the basal segments of the anchoring villi (e,f) remain merely trophoblastic, finally forming cell columns. All maternal tissues are in red, and all fetal tissues are in lilac. Fibrinoid of mixed, maternal, and fetal origin are in lilac. E, endometrial epithelium; EB, embryo-

blast; CT, cytotrophoblast; ST, syncytiotrophoblast; EM, extra-embryonic mesoderm; CP, primary chorionic plate; T, trabeculae and primary villi, L, maternal blood lacunae; TS, trophoblastic shell; EV, endometrial vessel; D, decidua; RF, Rohr's fibrinoid; NF, Nitabuch's or uteroplacental fibrinoid; G, trophoblastic giant cell; EVT, extravillous cytotrophoblast; BP, basal plate; PB, placental bed; J, junctional zone; M, myometrium. (Source: Modified from Kaufmann & Scheffen, 1992, with permission.)

apical plasma membranes of epithelia are normally known to be nonadhesive. Adhesiveness is a normal quality of basolateral epithelial plasma membranes, which are thus attached both to each other and to their basal laminae.

The blastocyst and the endometrium show this usual epithelial behavior throughout the entire preimplantation phase so long as the blastocyst moves in the fallopian tube and uterine cavity. Apical adhesiveness of both epithelia, the trophoblast and endometrium, is apparently achieved for only a short, specific phase, which has been called the implantation window (Psychoyos, 1988). This phase is used for attachment of the blastocyst. To find or to generate this window is the most important prerequisite for successful implantation following in vitro fertilization.

With the noninvasive types of implantation, the epitheliochorial placentation (e.g., pig, horse, some ruminants), implantation is arrested at the stage of attachment. Invasion with destruction of either epithelial surface does not follow. In contrast, in most mammals more intimate types of maternal-fetal contacts are established by invasion. In the human, implantation is also an invasive process. Knowledge of structural details, however, is largely lacking, as appropriate human material is rare and is usually poorly preserved when it is available. Numerous studies in animals have revealed the existence of three types of invasive implantation (Schlafke & Enders, 1975; Denker, 1990):

1. **Displacement type.** This type is observed in rodents. The blastocyst is attached to the apical plasma membrane of the uterine

epithelium. These cells degenerate thereafter and detach from the basal lamina. The subsequent penetration of the basal lamina is initiated by the underlying decidual cells, rather than by penetrative activities of the trophoblast itself.

2. **Fusion type.** The apical plasma membrane of the attached trophoblast fuses with the apical membranes of the uterine epithelial cells and forms a mixed syncytium, derived from maternal and trophoblastic cells. This syncytium then actively penetrates the basal lamina and endometrial connective tissue, and finally it erodes the maternal blood vessels. This mode of invasion has been described for the rabbit. According to Larsen (1970), it may also be present in the human.

3. **Intrusive type.** This type is the usual one in carnivores. Small extensions of syncytiotrophoblast intrude into the intercellular clefts between the uterine epithelial cells, opening the intercellular junctions between the epithelial cells. At the same time, new junctions between trophoblast and uterine epithelium are formed. In some species, even a local formation of mixed syncytia composed of maternal and trophoblastic origin has been observed. Based on the results of investigations by Larsen (1970), this mechanism of implantation may also pertain for the human.

Lacking respective human findings, further structural details and mechanisms of the implantation process are not discussed here. For this purpose, we refer the reader to the comparative anatomy literature (for reviews, see Finn, 1977; Denker, 1977, 1990; Pijnenborg et al., 1981; Denker & Apelin, 1990).

During attachment and after invasion of the endometrial epithelium, the trophoblastic cells of the implanting embryonic pole of the blastocyst show increased proliferation that results in a double-layered trophoblast (Heuser & Streeter, 1941). The outer of the two layers, directly facing the maternal tissue, is transformed to a **syncytiotrophoblast** by fusion of neighboring trophoblast cells. The remaining cellular components of the blastocyst wall, which have not yet achieved contact to maternal tissues, remain temporally unfused and are called **cytotrophoblast** (Fig. 5.1A). Throughout the following days and with progressive invasion, additional parts of the blastocyst surface come into close contact with maternal tissues, followed by trophoblastic proliferation with subsequent fusion. The mass of syncytiotrophoblast increases and achieves considerable thickness at the implantation pole, as the cytotrophoblast lying underneath continues to proliferate and fuses syncytially. The mass increases further by expanding over the surface of the implanting blastocyst as implantation progresses. At the implantation pole, this is not a smooth-surfaced mass; rather, it is covered with branching, finger-like extensions that deeply invade the endometrium. This first stage, lasting from day 7 to day 8 p.c., during which time the syncytiotrophoblast (except for its basal extensions) is a rather solid mass, was defined as representing the prelacunar period by Wislocki and Streeter (1938).

The syncytiotrophoblast has lost its generative potency during fusion. The cytotrophoblast acts as a stem cell that guarantees growth of the trophoblast by continuous proliferation, with subsequent fusion (see Chapter 6). The syncytiotrophoblast is formed by cellular fusion (i.e., syncytium), rather than by nuclear division without subse-

quent cytoplasmic division (i.e., plasmodium). Therefore, Bargmann and Knoop (1959) suggested that the term **plasmodiotrophoblast** (often used in the literature) be abandoned and replaced by **syncytiotrophoblast**.

The syncytiotrophoblast is a continuous system, not interrupted by intercellular spaces, and composed of neither individual cells nor individual syncytial units. Terms such as **syncytial cells** and **syncytiotrophoblasts**, which are widely used in the literature, are inappropriate. The few available reports that point to the existence of vertical cell membranes that subdivide the syncytium into syncytial units (e.g., Tedde et al., 1988 a,b) have an accidental rather than a real basis (see Chapter 6).

## Lacunar Stage

On day 8 p.c., small intrasyncytial vacuoles appear in the increasing syncytiotrophoblastic mass at the implantation pole. The vacuoles quickly grow and become confluent, forming a system of **lacunae** (Fig. 5.1B,C). The separating lamellae and pillars of syncytiotrophoblast are called the **trabeculae**. Their appearance marks the beginning of the lacunar or trabecular stage of placentation, which lasts from day 8 to day 13 p.c. Lacuna formation starts at the implantation pole. With advancing implantation, the syncytiotrophoblastic mass expands over the entire blastocystic surface. In all those places where it exceeds a certain critical thickness, new lacunae become evident, so that the lacunar system extends all over the blastocyst within a few days.

This process lasts until day 12 p.c., when the blastocyst is so deeply implanted that the uterine epithelium closes over the implantation site (Boyd & Hamilton, 1970). At this time, the outer surface of the blastocyst is completely transformed to syncytiotrophoblast. At its inner surface, it is covered by a locally incomplete layer of cytotrophoblast. Because trophoblastic proliferation and syncytial fusion have started at the implantation pole, the trophoblastic wall is considerably thicker at this point compared to the antiimplantation pole. This difference in thickness is never made up by the thinner parts during the subsequent developmental steps. The thicker trophoblast of the implantation pole is later transformed to the placenta, whereas the opposing thinner trophoblastic circumference only initially attempts to establish the same structure; later it shows regressive transformation to the smooth chorion, the membranes. All data of placental development given in this volume refer to the situation at the implantation pole.

Lacunar formation subdivides the trophoblastic covering of the blastocyst into three layers (Fig. 5.1C,D): (1) primary chorionic plate, facing the blastocystic cavity; (2) lacunar system together with the trabeculae; and (3) trophoblastic shell, facing the endometrium.

The **primary chorionic plate** is composed of a more or less continuous stratum of cytotrophoblast, which in some places is double- or even triple-layered. Toward the lacunae, the cytotrophoblast is covered by syncytiotrophoblast (Fig. 5.1D). On day 14 p.c., mesenchymal cells spread around the inner surface of the cytotrophoblast layer. There they transform to a loose network of branching cells, the **extraembryonic mesenchyme**. In the older literature, this mesenchyme had been thought to be of trophoblastic origin (Hertig, 1935; Wislocki & Streeter, 1938; Hertig & Rock, 1941, 1945, 1949). When reevaluating the Carnegie collection of early human ova, Luckett (1978) found proof that these primitive connective tissue cells were derived from the embryonic disk. Later, Luckett's findings were supported by Enders and King (1988), who studied the mesenchymal development in early macaque development.

Below the primary chorionic plate is the **lacunar system**. The lacunae are separated from each other by septa or pillars of syncytiotrophoblast, the trabeculae (Fig. 5.1C). Originally, these trabeculae were merely syncytiotrophoblastic in nature. Around day 12 p.c., however, they are invaded by cytotrophoblastic cells (Fig. 5.1D), which are derived from the primary chorionic plate. Within a few days the cytotrophoblast spreads over the entire length of the trabeculae. Where the peripheral ends of the trabeculae join together, they form the outermost layer of the trophoblast, the trophoblastic shell (Hertig & Rock, 1941; Boyd & Hamilton, 1970). In the beginning, this is a merely syncytiotrophoblastic structure, but as soon as the cytotrophoblast reaches the shell via the trabeculae (about day 15 p.c.), the former achieves a more heterogeneous structure (Fig. 5.1E). The syncytiotrophoblast establishes the bottom of the lacunae. It is followed by a more or less complete and sometimes multilayered zone of cytotrophoblast. Below the latter and facing the endometrial connective tissue, one again can find discontinuous syncytiotrophoblastic elements.

During the early stages of implantation, erosion of the maternal tissues occurred under the lytic influence of the syncytial trophoblast. Now the appearance of proliferating and migrating cytotrophoblast at the bottom of the shell starts **trophoblast invasion**, a key event during implantation and placentation that is responsible not only for further invasion of the blastocyst but also for adaptation of the maternal vessels to pregnancy conditions and for anchorage of the developing placenta (Boyd & Hamilton, 1970; Pijnenborg et al., 1981; Enders, 1997). In the course of this process, numerous syncytial elements can be observed far removed from the trophoblastic shell, in the depth of the uterine wall. Boyd and Hamilton (1970) suggested that they were remnants of the originally merely syncytiotrophoblastic shell. More recent publications have provided evidence that these so-called syncytiotrophoblastic or multinuclear giant cells are

derived from invading cytotrophoblast that later fused (Park, 1971; Robertson & Warner, 1974; Pijnenborg et al., 1981).

The endometrial stroma undergoes remarkable changes throughout this process. The presence of eroding trophoblast, by being a mechanical irritant and by hormonal activity, causes the endometrial stromal cells to proliferate and to enlarge, thus giving rise to the **decidual cells** (Kaiser, 1960; Dallenbach-Hellweg & Sievers, 1975; Welsh & Enders, 1985). Further structural and functional details are presented in Chapter 9.

The invasive activities of the basal syncytiotrophoblast from day 12 p.c. on cause disintegration of the maternal endometrial vessel walls. Blood cells, leaving the leaky capillaries at that time, are found inside the lacunae (Boyd & Hamilton, 1970). The detailed mechanisms of this phenomenon are still a mystery of early implantation. Studies on rabbit implantation showed subepithelial capillary coiling and dilatation as the initial process, resulting in increased capillary permeability and stromal edema (Hafez & Tsutsumi, 1966; Finn, 1977; Hoos & Hoffman, 1980). This is followed by disintegration of the walls of capillary loops, a process that is likely to be induced by the trophoblast nearby (Larsen, 1961; Denker, 1980; Steven, 1983). At the same time, the disintegrating capillaries are surrounded by the basally expanding syncytiotrophoblast, which replaces the capillary walls in stepwise fashion (Leiser & Beier, 1988). It thus forms new lacunae.

In the next developmental step, the newly formed lacunae fuse with the already preexisting lacunae and thus establish the maternal perfusion of the entire lacunar system. Further invasion of the trophoblast, with progressive incorporation of the capillary limbs down to their arteriolar beginnings and their venular endings, provides the anatomic basis for the final formation of separate arterial inlets into the lacunar system as well as venous outlets.

Throughout the first steps of development, the maternal blood in the lacunae, which is propelled only by capillary pressure, moves sluggishly. With deeper invasion of the endometrium, the spiral arteries are also eroded, resulting in a higher intralacunar blood pressure and in the first real maternal circulation of the placenta.

Note that these views are based largely on studies performed in animals with labyrinthine placentas. Morphologic (Hustin et al., 1988) and clinical studies in the human (Doppler ultrasound, endoscopy) (Schaaps & Hustin, 1988) have suggested that efficient maternal blood flow in the normal human placenta is established only after the 12th week of pregnancy (see Chapter 9). This finding is surprising, in particular because the structural processes of lacuna formation look similar to those in labyrinthine placentas. Further studies are required to solve this problem.

## Early Villous Stages

Shortly after the first appearance of maternal erythrocytes in the lacunae, on about day 13 p.c., increased cytotrophoblastic proliferation with subsequent syncytial fusion in the trabeculae takes place. As a result, not only can longitudinal trabecular growth be observed but also blindly ending syncytial side branches form and protrude into the lacunae (Fig. 5.1D,E). With increasing length and diameter, these **primary villi** are invaded by cytotrophoblast. Both processes mark the beginning of the villous stages of placentation. Further proliferative activities, with branching of the primary villi, initiate the development of primitive **villous trees**, the stems of which are derived from the former trabeculae (Fig. 5.1E). When the latter keep their contact to the trophoblastic shell, they are called **anchoring villi**. At the same time, the lacunar system, by definition, is transformed into the **intervillous space**.

Only 2 days later mesenchymal cells derived from the extraembryonic mesenchyme layer of the primary chorionic plate begin to invade the villi, transforming them into **secondary villi** (Fig. 5.1E). Within a few days, the mesenchyme expands peripherally to the villous tips and near the basis of the anchoring villi (Wislocki & Streeter, 1938; Hertig & Rock, 1945; Boyd & Hamilton, 1970).

The expanding villous mesenchyme does not reach the trophoblastic shell, which during these early stages of placentation remains free of fetal connective tissue. Rather, the basal segments of the trabeculae persist until the late stages of pregnancy on the primary villous stage, consisting of clusters of cytotrophoblast that are surrounded by a thin and partly incomplete sheet of syncytiotrophoblast. These cytotrophoblastic feet of the trabeculae or anchoring villi (Fig. 5.1E,F) are called **cell columns**. They are places of longitudinal growth of anchoring villi as well as sources of extravillous trophoblast (see Chapter 9). A similar phenomenon can be found in some free-floating villi. If the villous tips are not invaded by villous mesenchyme, they also persist on the primary villous stage as merely trophoblastic structures. Thus, briefly, cytotrophoblast shows nearly explosive proliferation transforming the villous tips into **trophoblastic cell islands** (see Chapter 9). The function of these cell islands is still uncertain.

The earlier theories of an additional in situ delamination of mesenchyme from villous cytotrophoblast (Hertig, 1935; Wislocki & Streeter, 1938; Hertig & Rock, 1945) have been refuted by Dempsey (1972), King (1987), and Demir et al. (1989). Their electron microscopic studies, performed on human and rhesus monkey placentas, showed that cytotrophoblast and villous mesenchyme are always clearly separated from each other by a complete basal lamina, which is never transgressed by a delaminat-

ing cytotrophoblast that might transform to mesenchyme, as was once thought to be the case.

With a few days' delay and beginning between days 18 and 20 p.c., the first **fetal capillaries** can be observed in the mesenchyme. They are derived from hemangioblastic progenitor cells (see Chapter 6, Fig. 7.21), which locally differentiate from the mesenchyme (King, 1987; Demir et al., 1989). The same progenitor cells give rise to groups of **hematopoietic stem cells**, which are always surrounded by the early endothelium and are thus positioned within the primitive capillaries (Fig. 7.22e). The appearance of cross sections of capillaries in the villous stroma marks the development of the first **tertiary villi**. Until term, all fetally vascularized villi (comprising most of the villi) can be subsumed under this name. Henceforth, only cell columns and cell islands, as well as transitory developmental stages of new villous formation (trophoblastic and villous sprouts), correspond to primary or secondary villi. At about the same time the fetal vascularization of the villi begins, the fetally vascularized allantois (Fig. 5.2) reaches the chorionic plate and fuses with the latter. Allantoic vessels develop into the chorionic plate and, according to Benirschke (1965), even into the larger villi. There they come into contact with the locally formed intravillous capillary segments. A complete fetoplacental circulation is established around the beginning of the 5th week p.c., as soon as enough capillary segments are fused with each other to form a regular capillary bed. Intravascular hematopoiesis can be observed during the following weeks, restricted to newly sprouting villi with de novo produced capillaries in most cases.

The expansion of the early villous trees takes place in the following way (Castellucci et al., 1990): at the surfaces of the larger villi, local cytotrophoblast proliferation with subsequent syncytial fusion causes the production of syncytial (trophoblastic) sprouts (see Chapter 7, Fig. 7.12). These sprouts are structurally comparable to the early primary villi and are composed of only trophoblast. Most of the syncytial sprouts degenerate again, probably the result of inappropriate local conditions; only some are invaded by villous mesenchyme and are thus transformed into the so-called villous sprouts (see Fig. 7.13). They correspond structurally to the secondary villi of the first steps of placentation. Formation of fetal vessels within the stroma (see Figs. 7.22 and 7.14), with subsequent growth in length and width, is characteristic of the transformation into new mesenchymal villi. Along their surfaces, new sprouts are again produced. (For further details, see Chapter 7.)

Assuming that there is already an intervillous circulation in the human placenta, fetal and maternal blood come into close contact with each other as soon as an intravillous (i.e., fetal) circulation is established. The two bloodstreams are always separated by the **placental barrier** (see Fig. 6.1D), which is composed of the follow-

FIGURE 5.2. Semithin section across embryo and placenta of the 4th week after conception. Underneath the embryo (E) one can identify the connective stalk (CS) as precursor of the cord, the yolk sac (YS), and a small amniotic vesicle (AV). The chorionic cavity is surrounded by the chorionic plate (CP); from the latter,

numerous placental villi protrude into the surrounding intervillous space (IVS). The basal plate is missing in this specimen, as it remained in utero, attached to the endometrium.  $\times 9.5$ . (Source: Kaufmann, 1990, with permission.)

ing layers: (1) a continuous layer of syncytiotrophoblast covering the villous surface and thus lining the intervillous space; (2) an initially (first trimester) complete, but later (second and third trimesters) discontinuous layer of

cytotrophoblast (Langhans' cells); (3) a trophoblastic basal lamina; (4) connective tissue; and (5) fetal endothelium, which is surrounded only by an endothelial basal lamina in the last trimester.

Throughout the subsequent periods of development, the tertiary villi undergo a complex process of differentiation that results in various villous types that differ from each other in terms of structure and function (see Chapter 7). This differentiation process is paralleled by qualitative and quantitative changes of the placental barrier: The syncytiotrophoblast is reduced in thickness from more than 20 mm to a mean of 3.5 mm. The cytotrophoblast is rarefied and, at term, it can be found in only 20% of the villous surface. The mean villous diameter decreases because the newly formed villous types are generally smaller than those preceding. Because of this latter process, the intravillous position of the fetal capillaries comes closer to the villous surface with advanced maturation. In many places, the capillary basal lamina may even fuse with that of the trophoblast (see Fig. 6.7A), thus considerably reducing the barrier in thickness and number of layers.

In summary, all these factors result in a reduction of the mean maternofetal diffusion distance from 50 to 100 mm in the second month to between 4 and 5 mm at term. The evident functional and pathogenetic importance of these phenomena makes it advisable to discuss the villous differentiation in more detail in Chapter 7.

# Basic Structure of the Villous Trees

M. Castellucci and P. Kaufmann

Nearly the entire maternofetal and fetomaternal exchange takes place in the placental villi. There is only a limited contribution to this exchange by the extraplacental membranes. In addition, most metabolic and endocrine activities of the placenta have been localized in the villi (for review, see Gröschel-Stewart, 1981; Miller & Thiede, 1984; Knobil & Neill, 1993; Polin et al., 2004).

Throughout placental development, different types of villi emerge that have differing structural and functional specializations. Despite this diversification, all villi exhibit the same basic structure (Fig. 6.1):

- They are covered by **syncytiotrophoblast**, an epithelial surface layer that separates the villous interior from the maternal blood, which flows around the villi. Unlike other epithelia, the syncytiotrophoblast is not composed of individual cells but represents a continuous, uninterrupted, multinucleated surface layer without separating cell borders (Fig. 6.1C; see Fig. 6.21, and Chapter 7, Fig. 7.11).
- Beneath the syncytiotrophoblast is an interrupted layer of **cytotrophoblast**, which consists of single or aggregated cells, the Langhans' cells, which are the stem cells of the syncytiotrophoblast; they support the growth and regeneration of the latter.
- The **trophoblastic basement membrane** separates syncytiotrophoblast and cytotrophoblast from the stromal core of the villi.
- The **stroma** is composed of varying numbers and types of connective tissue cells, connective tissue fibers, and ground substance.
- Additionally, the stroma contains **fetal vessels** of various kinds and calibers. In the larger stem villi, the vessels are mainly arteries and veins; in the peripheral branches, most fetal vessels are capillaries or sinusoids.

## Syncytiotrophoblast

### Syncytium or Multinucleated Giant Cells?

The syncytiotrophoblast is a continuous, normally uninterrupted layer that extends over the surfaces of all villous trees as well as over parts of the inner surfaces of chorionic and basal plates. It thus lines the intervillous space. Systematic electron microscopic studies of the syncytial layer (e.g., Bargmann & Knoop, 1959; Schiebler & Kaufmann, 1969; Boyd & Hamilton, 1970; Kaufmann & Stegner, 1972; Schweikhart & Kaufmann, 1977; Wang & Schneider, 1987) have revealed no evidence that the syncytiotrophoblast is composed of separate units. Rather, it is a single continuous structure for every placenta. Only in later stages of pregnancy, as a consequence of focal degeneration of syncytiotrophoblast, fibrinoid plaques may isolate small islands of syncytiotrophoblast from the surrounding syncytial continuum; this happens mainly at the surfaces of chorionic and basal plates. Therefore, terms such as *syncytial cells* and *syncytiotrophoblasts*, widely used in experimental disciplines, are inappropriate and should be avoided. Their use points to a basic misunderstanding of the real nature of the syncytiotrophoblast.

Where the syncytiotrophoblast due to degenerative processes is interrupted, the gap is filled by fibrin-type fibrinoid (see Chapter 9). A few reports (Tedde et al., 1988a,b) have pointed to the existence of **vertical cell membranes** that seemingly subdivide the syncytium into syncytial units. These extremely rare findings have an accidental rather than a real basis. They represent the likely results of a syncytiotrophoblastic repair mechanism (Figs. 6.1, 6.2B, and 6.3). That is, after syncytial rupture, apical and basal plasmalemmas fuse at either side of the

FIGURE 6.1. Basic morphology of human placental villi. A: Simplified longitudinal section across the uterus, placenta, and membranes in the human. The chorionic sac, consisting of placenta (left half) and membranes (right half), is black. B: Peripheral ramifications of the mature villous tree, consisting of a stem villus (1), which continues in a bulbous immature intermediate villus (3); the slender side branches (2) are the mature interme-

diante villi, the surface of which is densely covered with grape-like terminal villi (4). C: Highly simplified light microscopic section of two terminal villi, branching off a mature intermediate villus (right). D: Schematic electron microscopic section of the placental barrier, demonstrating its typical layers. (Source: Modified from Kaufmann, 1983, with permission.)

FIGURE 6.2. Remains of cell membranes in the syncytiotrophoblast result from two mechanisms: fusion of neighboring villous surfaces forming bridges and repair of disrupted syncytial surfaces. A: As a first step of formation of syncytial bridges between adjacent villi, the opposing microvillous membranes interdigitate. The identical initial step occurs as a first step of wound repair when the disrupted ends of syncytiotrophoblast become covered by microvillous membranes, which subsequently come into contact and interdigitate.  $\times 14,500$ . B: Follow-up stage of that depicted in part A. The interdigitating syncytial surfaces

have largely lost their microvilli and now establish a smooth intercellular cleft bridged by numerous desmosomes that vertically traverse the syncytiotrophoblast. (See the survey picture in Figure 6.3.)  $\times 11,000$ . C: As the next step of repair, the newly developed separating cell membranes show disintegration (arrows) so that the newly formed intrasyncytial cleft becomes focally bridged by syncytioplasm. After complete disintegration of membranes and desmosomes, the syncytial villous cover is again continuous.  $\times 13,800$ . (Source: Cantle et al., 1987, with permission.)

wound, thus avoiding further loss of syncytioplasm. Afterward, either a fibrinoid plug closes the wound, or the disconnected parts of the syncytium again come into close contact to form a lateral intercellular cleft bridged

by desmosomes. Later, fusion occurs by disintegration of the separating membranes (Fig. 6.2). Transitory stages of this process may be misinterpreted as borders of syncytial units.

FIGURE 6.3. Survey electron micrograph of the section shown in Figure 6.2B demonstrates that in intermediate stages of syncytial repair the villous syncytial trophoblast can be traversed by vertical “intercellular” clefts connecting the intervillous

space (IVS) with the connective tissue core (CO) of the villi. Such intrasyncytial membranes must not be misinterpreted as stable intercellular clefts subdividing the syncytium in smaller syncytial units.  $\times 7000$ .

Many authors have described **remainders of intercellular junctions** within the syncytiotrophoblast (Carter, 1963, 1964; Boyd & Hamilton, 1966; Burgos & Rodriguez, 1966; Metz et al., 1979; Reale et al., 1980; Wang & Schneider, 1987). Some investigators have interpreted these junctions as vestiges of a former cellular state of the syncytium or as proof of recent cytotrophoblastic contribution to the syncytiotrophoblast (Carter, 1963, 1964; Boyd & Hamilton, 1966). In a systematic study of these junctions, Metz et al. (1979) as well as Reale et al. (1980) have described zonulae and maculae occludentes that were mostly located in apical membrane infoldings, as well as numerous isolated desmosomes, without contact to any surface membranes. The structural evidence has been supported by recent immuno-histochemical data that show zonula occludens type 1 (ZO-1) as well

as occludin in the apical part of syncytiotrophoblast (Marzioni et al., 2001). The authors of the publications considered above hypothesized that these junctions represent stages of several dynamic processes: for example,

- remainders of cytotrophoblastic fusion with the overlying syncytium,
- establishment of intervillous contacts by partial or complete syncytiotrophoblastic surface fusion,
- repair of syncytial disruption, or
- decomposition of temporary surface invagination of the syncytiotrophoblast.

The syncytiotrophoblast must be seen as a highly dynamic layer that is qualified for ameboid movements. Disconnection with subsequent re-

fusion and the formation of invaginations and bridges seem to be regular phenomena.

We not only find the ultrastructural remains of this process but also can easily observe it in vitro; when we (1) carefully trypsinize villi from full-term placentas, (2) remove mesenchymal cells by means of CD9-antibodies, (3) remove cytotrophoblast by means of a hepatocyte growth factor-activator-inhibitor (HAI-1) antibody (Pötgens et al., 2003), and (d) let the remaining isolated tissues adhere on culture dishes, we obtain a nearly pure population of mononucleated fragments of syncytiotrophoblast. These small CD105-positive mononucleated trophoblast elements, which result in large numbers during any attempt of trophoblast isolation, should not be misinterpreted as cytotrophoblast (Pötgens et al., 2003), even though they are cytokeratin-positive and each adherent syncytial fragment is surrounded by a plasmalemma (Huppertz et al. 1999). Within 1 or 2 further days of culture, the fragments start re-fusion, then again forming islands of syncytiotrophoblast.

## Syncytial Plasmalemmas and Microvilli

With deference to the intentions of this chapter, we consider here only briefly some aspects of the plasma membranes of the syncytiotrophoblast. Sideri et al. (1983) have pointed to differences between the syncytiotrophoblastic brush-border membrane (BBM; facing the maternal blood) and the basal plasma membrane (BPM; facing adjacent cytotrophoblast or the basal lamina) of the syncytiotrophoblast. Both plasmalemmas exhibit different densities of intramembranous proteins. Vanderpuye and Smith (1987) presented a useful review of the relevant data. Later studies have confirmed these differences between BBM and BPM. They showed that receptors for calcitonin (Lafond et al., 1994) and calcitonin gene-related peptide (Lafond et al., 1997), as well as muscarinic (Pavia et al., 1997) and transferrin receptors (Verrijt et al., 1997) are different in number, affinity, and distribution of their subtypes in BBM and BPM. In addition, some G-protein subunits (Mabrouk et al., 1996) and protein kinase C isoforms (Ruzycky et al., 1996) showed different distributions in the two membranes.

Microvilli nearly completely cover the syncytiotrophoblastic surface and represent an enormous maternofetal contact zone (see Fig. 6.14). At term, the presence of microvilli multiplies the total villous surface area of about 12 m<sup>2</sup> (see Chapter 28, Table 28.5) by a factor of about 7.67 (Teasdale & Jean-Jacques, 1986; see also Mayhew, 1985). Because of their localization at the maternal-fetal border, the microvilli have engendered much immunologic and cell biologic interest. Two summarizing articles provide details (Smith et al., 1977; Truman & Ford, 1984).

Morphologic studies of microvillus structure and its functional significance have been published by Boyd et al. (1968b), Herbst and Multier (1970), Wainwright and Wainwright (1974), Truman et al. (1981), King (1983), Al-Zuhair et al. (1983, 1987), Mazzanti et al. (1994), and Jaggi et al. (1995). Most of the histochemical studies concerning the composition of the microvillous membrane focused on the glycocalyx. They describe its polysaccharide composition and discuss the immunologic relevance of the polysaccharides (Bradbury

et al., 1969, 1970; Rovasio & Monis, 1973; Liebhart, 1974; Martin et al., 1974; Okudaira & Hayakawa, 1975; Nelson et al., 1976; Wada et al., 1977, 1979; Kelley et al., 1979; King, 1981; Wasserman et al., 1983a,b; Fisher et al., 1984; Parmley et al., 1984; Maubert et al., 1997). Various lectin-binding sites have been described by Whyte (1980), Gabius et al. (1987), Hoyer and Kirkeby (1996), and Lang et al. (1994a,b).

Cytochemical demonstration of **membrane-bound enzymes** studied in the transmission electron microscope (TEM) comprise alkaline phosphatase (Hempel & Geyer, 1969; Borst et al., 1973; Hulstaert et al., 1973; Kameya et al., 1973; Jemmerson et al., 1985; Matsubara et al., 1987c), galactosyltransferase (Nelson et al., 1977),  $\alpha$ -amylase (Fisher & Laine, 1983), protein kinases (Albe et al., 1983), Ca-ATPase (Matsubara et al., 1987b), cyclic 3,5-nucleotide phosphodiesterase (Matsubara et al., 1987d), 5-nucleotidase (Matsubara et al., 1987a), and nicotinamide adenine dinucleotide phosphate diaphorase (Matsubara et al., 1997).

The analysis of **surface receptors involved in transplacental transfer** has achieved even more importance for our understanding of transplacental transport (King, 1976; Ockleford & Menon, 1977; Wood et al., 1978a,b; Galbraith et al., 1980; Johnson & Brown, 1980; Brown & Johnson, 1981; Green & Ford, 1984; Malassine et al., 1984, 1987; Alsat et al., 1985; Parmley et al., 1985; Bierings, 1989; Yeh et al., 1989; for a review see Alsat et al., 1995).

The vast literature on **receptors for hormones and growth factors** has been discussed repeatedly (Adamson 1987; Blay & Hollenberg, 1989; Ohlsson, 1989; Mitchell et al., 1993; Alsat et al., 1995) and cannot be reviewed here. For further reading on some particular subjects we refer the reader to the following publications: insulin receptor (Nelson et al., 1978; Jones et al., 1993; Desoye et al., 1994, 1997); insulin-like growth factor II (IGF-II) (Daughaday et al., 1981; Nissley et al., 1993); interleukin-6 receptor (Nishino et al., 1990); parathyroid hormone receptor (Lafond et al., 1988); vascular endothelial growth factor (Cheung, 1997); calcitonin receptor (Lafond et al., 1994); calcitonin gene-related peptide (Lafond et al., 1997); and colony-stimulating factor and its receptor (CSF-1R: Adamson, 1987; Aboagye-Mathiesen et al., 1997).

Special attention has been paid to the epidermal growth factor receptor (EGFR) a gene-product of the proto-oncogene *c-erbB-1* (Rao et al., 1984, 1985; Chegini & Rao, 1985; Maruo & Mochizuki, 1987; Maruo et al., 1987, 1996; Morrish et al., 1987, 1997; Chen et al., 1988; Yeh et al., 1989; Mühlhauser et al., 1993; Evain-Brion and Alsat, 1994), and the closely related proto-oncogene product *c-erbB-2* (Mühlhauser et al., 1993; Lewis et al., 1996; Aboagye-Mathiesen et al., 1997):

- Epidermal growth factor receptor is present in the syncytiotrophoblast as well as in the villous and extravillous cytotrophoblast (Bulmer et al., 1989; Ladines-Llave et al., 1991; Mühlhauser et al., 1993). Its ligand, epidermal growth factor (EGF) is detectable in amniotic fluid, umbilical vessels, and placental tissue (Scott et al., 1989). Maruo et al. (1996) found evidence that it is expressed by syncytiotrophoblast. The question of placental production sites is still open. Morrish et al. (1987) have pointed out that this growth factor induces morphologic differentiation of trophoblast together with increased production of human chorionic gonadotropin (hCG) and human placental lactogen (hPL) in vitro. It obviously has no effect on trophoblast proliferation (Maruo et al., 1996).
- Structurally related to the EGF receptor is the gene product of the proto-oncogene *c-erbB-2*. It represents the only member of the HER receptor family that neither has a direct and specific ligand nor has it kinase activity (for review, see Casalini et al., 2004). Rather, it seems to play a major coordinating role since the other receptors of the HER family act by heterodimerization with *c-erbB-2* upon activation by their specific ligand. It seems to be important in human cancer. In some types of malignant tumors, *c-erbB-2* protein product

and EGFR are both overexpressed, and this correlates with a reduction in patient relapse-free interval and with overall survival (Slamon et al., 1987; Wright et al., 1989). These data suggest that the two receptors may contribute to the development and maintenance of the malignant phenotype. Interestingly, in the human placenta, which shares some aspects with invasive tumors, this coexpression is present in villous syncytiotrophoblast, which, however, and contrary to invasive tumor cells, is nonproliferative; on the other hand, in the proliferating cells of the extravillous trophoblast, only EGFR is expressed, whereas *c-erbB-2* characterizes the differentiating and no longer proliferating cells (Mühlhauser et al., 1993).

## Syncytiotrophoblastic Cytoskeleton

Ockleford et al. (1981b) have speculated that in addition to the skeletal structures of the villous stroma there must be other mechanical factors responsible for the maintenance of the complex shape of the villi. They described a superficially arranged complex system of intrasyncytial filaments that largely occupies the superficial layer of the syncytiotrophoblast. They suggested the term **syncytioskeletal layer** for this zone. Numerous other authors have contributed to our knowledge of the syncytial cytoskeleton as well (Vacek, 1969; Scheuner et al., 1980; Ockleford et al., 1981a,c; King, 1983; Khong et al., 1986; Beham et al., 1988; Mühlhauser et al., 1995; Berryman et al., 1995).

The **syncytial cytoskeleton** is composed of actin, tubulin, and intermediate filament proteins as cytokeratins and desmoplakin (Ockleford et al., 1981b; King, 1983; Beham et al., 1988; Mühlhauser et al., 1995; Berryman et al., 1995). The microtubules are arranged in a coarse, open lattice-like network that is oriented parallel to the syncytial surface. They are intermingled with microfilaments that form an apparently disordered meshwork. Actin filaments interact with ezrin, and microfilaments of this meshwork pass into the microvilli, where they display a distinct polarity, with their S1 arrowheads pointing away from the microvillous tips.

Different from intestinal microvilli, the rootlets of the microvillous filaments are short and interact with other filaments of the terminal web almost immediately after emergence from the microvilli. The overall impression of this system, reported by King (1983), is that of a poorly developed terminal web. Beham et al. (1988) and Mühlhauser et al. (1995) found immunohistochemical evidence for the presence of cytokeratin and desmoplakin in the apical zone. The presence of the latter intermediate filament protein is in agreement with the occasional appearance of desmosomes in this zone. Both intermediate filaments were also found in the basal zone of the syncytioplasm (Beham et al., 1988), where King (1983) also detected actin.

## Specialized Regions of the Villous Surface

Dempsey and Zergollern (1969) and Dempsey and Luse (1971) have subdivided the syncytiotrophoblast into three

zones: an outer absorptive zone in which organelles related to vesicular uptake are accumulated as well as large parts of the cytoskeleton (syncytioskeletal layer; Ockleford et al., 1981b), a middle secretory zone containing most organelles, and a basal zone with few organelles. Structural changes and variations in the thickness of the middle zone are responsible for regional specializations that become evident in the second half of pregnancy.

During earlier stages of pregnancy, the syncytiotrophoblast is a mostly homogeneous layer with evenly distributed nuclei (Boyd & Hamilton, 1970; Kaufmann & Stegner, 1972). The distribution of cellular organelles is homogeneous and does not suggest a marked structural and functional differentiation inside this layer. From the 15th week on, this situation gradually changes (Kaufmann & Stegner, 1972). At term, structural diversification results in a highly variable pattern of mosaic areas of different structure and histochemical attributes (Amstutz, 1960; Fox, 1965; Burgos & Rodriguez, 1966; Hamilton & Boyd, 1966; Schiebler & Kaufmann, 1969; Alvarez et al., 1970; Dempsey & Luse, 1971; Kaufmann & Stark, 1973; Martin & Spicer, 1973b; Kaufmann et al., 1974b; Jones & Fox, 1977) (Figs. 6.4 to 6.6). This mosaic pattern, however, lacks sharp demarcations because all specialized areas are part of one single continuous syncytium.

Several types of syncytiotrophoblast can be classified regarding the thickness of the syncytiotrophoblast, the distribution of its nuclei, the kind and number of its organelles, and its enzymatic activities. As will be dealt with later in this chapter, these specialized regions of syncytiotrophoblast obviously correspond to different stages of the trophoblastic apoptosis cascade, which starts with syncytial fusion resulting in thick nucleated syncytiotrophoblast with ample rough endoplasmic reticulum and ends with extrusion of syncytial knots containing apoptotic nuclei.

## Syncytiotrophoblast with Prevailing Rough Endoplasmic Reticulum

Syncytiotrophoblast with prevailing rough endoplasmic reticulum in early stages of pregnancy is the only type of syncytiotrophoblast. At term, it is still the most common type. Its thickness varies between about 2 and 10  $\mu\text{m}$ , depending on whether it contains nuclei or is devoid of them. The surface is covered by more or less densely packed microvilli. In addition to vesicles and all types of lysosomes, numerous mitochondria, Golgi fields, and ample rough endoplasmic reticulum characterize the cytoplasm. After conventional postpartum fixation, the latter is vesicular (Figs. 6.2 and 6.3) (Boyd et al., 1968a). With optimal fixation, as from aspiration biopsy during cesarean section from a placenta in situ that is still being maternally perfused (Schweikhart & Kaufmann, 1977),

A

B: 17 beta-steroid DH

FIGURE 6.4. A: Simplified drawing of a cross section of a terminal villus demonstrating the structural variability of its syncytiotrophoblastic cover. B: Semithin section demonstrating the histochemical activity of  $17\beta$ -hydroxysteroid dehydrogenase (black). As a prominent indicator of syncytiotrophoblastic spe-

cialization, this enzyme has maximum activity in and around a syncytial lamella (arrowhead) covering villous cytotrophoblast (ct). Note the close relationship between cytotrophoblast,  $17\beta$ -steroid dehydrogenase-positive trophoblast and fetal capillary (c).  $\times 800$ . (Source: Kaufmann et al., 1974b, with permission.)

the rough endoplasmic reticulum is composed of slender cisternae oriented in parallel (Fig. 6.7A). The degree of dilatation depends on the delay of fixation (Kaufmann, 1985).

Several publications have presented structural aspects of this type of syncytiotrophoblast (Boyd et al., 1968a; Dempsey & Zergollern, 1969; Schiebler & Kaufmann, 1969; Dempsey & Luse, 1971; Martin & Spicer, 1973a; Ockleford, 1976). The functional interpretation is based on enzyme histochemical data. Most enzymes found, are related to energy metabolism (Fig. 6.5). In addition, relevant activities of glutamate dehydrogenase,  $\alpha$ -glycerol-phosphate dehydrogenase, nonspecific esterase, acid phosphatase, alkaline phosphatase, nicotinamide adenine dinucleotide phosphate diaphorase, and proteases were found (Wielenga & Willingham, 1962; Wachstein et al., 1963; Velardo & Rosa,

1963; Lister, 1967; Hoffman & Di Pietro, 1972; Hulstaert et al., 1973; Kaufmann et al., 1974b; Gossrau et al., 1987; Matsubara et al., 1997). The immunohistochemical proof of  $11\beta$ -hydroxysteroid dehydrogenase was interpreted as an enzymatic barrier, preventing maternal glucocorticoids from passing into the fetal circulation where they might have adverse effects (Yang, 1997). In addition, superoxide dismutase and xanthine oxidase were detected in the syncytiotrophoblast and were thought to be involved in degrading superoxide, thus playing a role in the maintenance of uterine quiescence (Myatt et al., 1997; Telfer et al., 1997; Watson et al., 1997). These studies make it likely that this type of syncytium is involved in more complex active maternofetal transfer mechanisms, including catabolism and resynthesis of proteins and lipids.

Immunocytochemical studies have provided evidence that **synthesis of proteo- and peptide hormones** takes place here. These include:

FIGURE 6.5. Semithin section with histochemical demonstration of lactate dehydrogenase. The enzyme activity is bound to the vicinity of syncytial nuclei, whereas syncytium devoid of nuclei does not exhibit enzyme activity.  $\times 420$ . (Source: Schiebeler & Kaufmann, 1981, with permission.)

FIGURE 6.6. Transmission electron microscopic section of a terminal villus. Note that the structural specialization of the syncytiotrophoblast depends on its spatial relation to the fetal capillaries (C). In nearly all places where the capillaries bulge against the villous surface, the syncytiotrophoblast is attenuated to thin lamellae (vasculosyncytial membranes) devoid of nuclei. The nuclei accumulate between the lamellae and form syncytial knots.  $\times 1350$ . (Source: Castellucci & Kaufmann, 1982a, with permission.)

- human chorionic gonadotropin (hCG) (Dreskin et al., 1970; Hamanaka et al., 1971; Genbacev et al., 1972; Kurman et al., 1984; Beck et al., 1986; Frauli & Ludwig, 1987c; Morrish et al., 1987; Sakakibara et al., 1987; Hay, 1988);
- human chorionic somatotropin (hCS) or hPL (Kim et al., 1971; De Ikonoff & Cedard, 1973; Dujardin et al., 1977; Kurman et al., 1984; Beck et al., 1986; Fujimoto et al., 1986; Morrish et al., 1988; Jacquemin et al., 1996);
- other human growth hormones (hGHs) such as hGH-V and hGH-N (Liebhaber et al., 1989; Alsat et al., 1997), human prolactin (hPRL) (Bryant-Greenwood et al., 1987; Sakbun et al., 1987; Unnikumar et al., 1988);
- oxytocin (Unnikumar et al., 1988);
- leptin (Masuzaki et al., 1997; Senaris et al., 1997; Castellucci et al., 2000a);
- erythropoietin (Conrad et al., 1996);
- corticotropin-releasing hormone (CRH) (Warren and Silverman, 1995);
- parathyroid hormone-related protein (PTHrP) (Dunne et al., 1994; Emly et al., 1994);

- b-endorphin and b-lipotropin (Laatikainen et al., 1987);
- pregnancy-specific glycoprotein (Zhou et al., 1997); and
- various placental proteins such as SP1 (Gosseye & Fox, 1984; Beck et al., 1986).

### Syncytiotrophoblast with Prevailing Smooth Endoplasmic Reticulum

Syncytiotrophoblast with prevailing smooth endoplasmic reticulum are small spot-like areas, dispersed in the syncytiotrophoblast equipped with rough endoplasmic reticulum (Figs. 6.4A, 6.7, and 6.8), and showing gradual transitions to the latter. They are usually equipped with mitochondria of the tubular type. The structural similarity to endocrine cells active in steroid metabolism (Gillim et al., 1969; Crisp et al., 1970) is striking. Focally increased activities of 3 $\beta$ -hydroxysteroid dehydrogenase and

FIGURE 6.7. A: Transmission electron micrograph of syncytiotrophoblast with well-developed rough endoplasmic reticulum, probably active in protein metabolism. IVS, intervillous space; S, syncytiotrophoblast; CT, cytotrophoblast; E, fetal endothelium.  $\times 14,000$ . (Source: Schiebler & Kaufmann, 1981, with permission.) B: Electron micrograph of syncytiotrophoblast with well-developed smooth endoplasmic reticulum. Such areas are probably involved in steroid metabolism.  $\times 14,800$ .

lium.  $\times 14,000$ . (Source: Schiebler & Kaufmann, 1981, with permission.) B: Electron micrograph of syncytiotrophoblast with well-developed smooth endoplasmic reticulum. Such areas are probably involved in steroid metabolism.  $\times 14,800$ .

FIGURE 6.8. A: Transmission electron micrograph of a thin syncytiotrophoblastic lamella covering villous cytotrophoblast (CT). The syncytiotrophoblast of this type is well equipped with dense bodies and vesicles. As can be deduced from its enzymatic activity, such areas are probably involved in endocrine activity.  $\times 22,000$ . B: Transmission electron micrograph of a thin syncytiotrophoblastic lamella covering cytotrophoblast (CT). This lamella is devoid of microvilli and dense bodies. Its cytoplasm is characterized only by vesicles. Following enzyme histochemical reactions (see Fig. 6.4B), it exhibits high activities of  $17\beta$ -hydroxysteroid dehydrogenase and thus participates in steroid metabolism.  $\times 14,500$ .

tiotrophoblastic lamella covering cytotrophoblast (CT). This lamella is devoid of microvilli and dense bodies. Its cytoplasm is characterized only by vesicles. Following enzyme histochemical reactions (see Fig. 6.4B), it exhibits high activities of  $17\beta$ -hydroxysteroid dehydrogenase and thus participates in steroid metabolism.  $\times 14,500$ .

17 $\beta$ -hydroxysteroid dehydrogenase in just these areas (Fig. 6.4B) underline the assumption that these are steroidally active areas (Kaufmann & Stark, 1973; Kaufmann et al., 1974b).

### Vasculosyncytial Membranes

Vasculosyncytial membranes or epithelial plates (Figs. 6.4A, 6.6, and 6.9) were first identified by Bremer (1916) and later defined in more detail by Amstutz (1960). They are thin syncytiotrophoblastic lamellae, measuring 0.5 to about 1  $\mu$ m in thickness; free of nuclei and poor in organelles, they are directly apposed to sinusoidally enlarged parts of the fetal capillaries (Schiebler & Kaufmann, 1969; Fox & Blanco, 1974). One can conclude from the structural features that the expanding fetal sinusoids bulge against the villous surface and completely displace the syncytial nuclei as well as most of the syncytial organelles. Capillary basement membrane and trophoblastic basement membrane may come into such close contact that they fuse (Figs. 6.1 and 6.9A). In agreement with the view, that pressure by the sinusoids displaces the syncytial nuclei, accumulations of nuclei and organelles may be observed directly lateral to the vasculosyncytial mem-

branes; they are called syncytial knots (Figs. 6.4A, 6.6, and 6.10A).

**Function:** Some further findings are helpful for the functional interpretation. The density of microvilli at the surface of the vasculosyncytial membranes is sometimes considerably reduced (Fig. 6.9) (Leibl et al., 1975; however, compare King & Menton, 1975). There is some evidence that some growth factors particularly involved in angiogenic processes, such as placental growth factor (PlGF) (Khaliq et al., 1996) and hepatocyte growth factor (HGF) (Kilby et al., 1996), are particularly expressed in and around vasculosyncytial membranes. High activities of hexokinase and glucose-6-phosphatase were found histochemically, whereas enzymes of the energy metabolism are largely inactive (Fig. 6.5). With respect to structure and enzymatic equipment, we conclude that these areas are especially involved in diffusional transfer of gases and water as well as in the facilitated transfer of glucose.

Slightly thicker vasculosyncytial membranes are equipped with more organelles. In addition, they show hydrolytic enzymes such as alkaline phosphatase (Kameya et al., 1973), 5-nucleotidase, and adenosine triphosphatase (ATPase) (Schiebler & Kaufmann, 1981). These sites are presumably concerned with active transfer (e.g., amino acids, electrolytes) rather than serving merely passive transfer processes.

When one is studying optimally fixed terminal villi of the term placenta, the vasculosyncytial membranes amount to 25% to 40% of the villous surface (Sen et al., 1979), depending on the maturational status of the villi. After delayed fixation this value may be considerably smaller because of fetal vascular collapse and trophoblastic shrinkage (see Chapter 28, Tables 28.6 and 28.9) (Voigt et al., 1978).

FIGURE 6.9. A: Transmission electron micrograph of a vasculosyncytial membrane. Note the extremely thin syncytial lamella that extends over the fetal capillary (C), the former being characterized by only a few organelles and a reduced number of microvilli.  $\times 4800$ . B: Scanning electron micrograph of a vasculosyncytial membrane comparable to that depicted in part A. It

is viewed here from the intervillous space (black) at the villous surface. The protrusion of the villous surface caused by the underlying capillary is clearly visible. It is largely devoid of microvilli.  $\times 3300$ . (Source: Schiebler & Kaufmann, 1981, with permission.)

FIGURE 6.10. A: Transmission electron micrograph of a syncytial knot characterized by clustered nuclei that are rich in condensed chromatin, suggesting an apoptotic character.  $\times 5000$ . (Source: Cattle et al., 1987, with permission.) B: Electron micrograph of a sprout-like structure that shows obvious signs of degeneration. The nuclei exhibiting condensed chromatin point to an earlier stage of apoptosis, whereas dissolution of plasma-lemma and cytoplasm suggest necrotic events. This combination of two contrasting kinds of cellular death (secondary necrosis)

can often be found in syncytiotrophoblast.  $\times 5100$ . C: Transmission electron micrograph of a syncytial sprout from a mature placenta that, because of its appearance, is likely to represent a tangential section of the villous surface (see Chapter 15, Figs. 15.1 to 15.5). Most knots and sprouts observed in the mature placenta belong to this type of sectional artifact and should be called syncytial knotting or Tenney-Parker-changes.  $\times 4600$ . (Source: Schiebler & Kaufmann, 1981, with permission.)

## Syncytial Lamellae Covering Langhans' Cells

The syncytial lamellae covering Langhans' cells are comparable to the vasculosyncytial membranes in structure and thickness. In most cases, they are direct continuations of the vasculosyncytial membranes, as the thin syncytial lamellae of the latter extend from the bulging capillaries to the neighboring bulging Langhans' cells (Figs. 6.4 and 6.8). They are normally characterized by increased numbers of dense bodies (lysosomes? secretory granules?) found in both the syncytiotrophoblast and the underlying cytotrophoblast. Histochemically, they often show an intense reaction for 17 $\beta$ -hydroxysteroid dehydrogenase (Fig. 6.4B) (Kaufmann & Stark, 1973; Kaufmann et al., 1974b).

**Function:** These zones start developing at about the 15th week post-menstruation (p.m.), in parallel to the development of vasculosyncytial membranes and fetal sinusoids. It may be helpful for the functional interpretation that from the same date onward also the maternal plasma concentrations of 17 $\beta$ -hydroxysteroid dehydrogenase and the maternal urinary estriol excretion increase (see Kaufmann & Stark, 1973).

## Syncytial Knots, Sprouts, and Bridges

Syncytial knots, sprouts, and bridges are a very heterogeneous group of syncytiotrophoblastic specializations, all of which have remarkable accumulations of nuclei in common (Hamilton & Boyd, 1966; Boyd & Hamilton, 1970) (see Chapter 15). Since their number increases in many pathologic placentas, they have raised much interest and caused much speculation. The interpretation comprises local hyperplasia of the syncytium (Baker et al., 1944); the results of trophoblastic degeneration (Tenney & Parker, 1940; Merrill, 1963); structural expression of placental insufficiency (Becker & Bleyl, 1961; Kubli & Budliger, 1963; Werner & Bender, 1977); structural expression of ischemia, hypoxia, or hypertension (Wilkin, 1965; Tominaga & Page, 1966; Alvarez, 1970; Alvarez et al., 1972; Gerl et al., 1973); and the results of fetal malperfusion of placental villi (Fox, 1965; Myers & Fujikura, 1968).

Studies by Küstermann (1981), Burton (1986a,b), Cantle et al. (1987), and Kaufmann et al. (1987a) have provided evidence that

- the vast majority of these structures are in fact results of tangential sectioning of the villous surfaces ( $\rightarrow$  **syncytial knots**, **syncytial buds**, and most **syncytial bridges**).
- There is, however, a limited amount of true syncytiotrophoblastic outgrowth, representing the first steps of villous sprouting ( $\rightarrow$  **syncytial sprouts**).
- Other true aggregations of syncytial nuclei represent sites of extrusion of aged, dying nuclei ( $\rightarrow$  **apoptotic knots**).

**Syncytial knots** are characterized by a multilayered group of aggregated nuclei that bulge only slightly on the trophoblastic surface. If they exhibit the same structural and histochemical features as the surrounding syncytiotrophoblast, they are likely to be only representations of tangential sections (syncytial knotting, Tenney-Parker changes; see Chapter 15). The vast majority of nuclear aggregates within the placenta are such syncytial knots.

Boyd and Hamilton (1970) have described islands of multinuclear syncytiotrophoblast located in the villous stroma and referred to them as **syncytial buds** or "stromal trophoblastic buds." It is very likely that these also are tangential sections of indenting villous surfaces or places of villous branching (Küstermann, 1981). Therefore, the old question whether these trophoblastic elements may "invade" fetal vessels (Salvaggio et al., 1960; Boyd & Hamilton, 1970) is no longer relevant.

There has been intense discussion concerning **syncytial bridges**, which began with their first description by Langhans (1870) and continued with reports by Stieve (1936, 1941), Ortmann (1941), Peter (1943, 1951), Hörmann (1953), Schiebler and Kaufmann (1969), Boyd and Hamilton (1970), Kaufmann and Stegner (1972), and Jones and Fox (1977). Most are sectional artifacts that must be interpreted as the results of tangential sectioning of villous branchings (see Chapter 15, Figs. 15.1 to 15.6) (Küstermann, 1981; Burton, 1986a; Cantle et al., 1987). Placentas with tortuously malformed villi, such as those in maternal anemia or severe preeclampsia, may exhibit so many bridges in histologic sections that a net-like appearance is achieved (see Figs. 15.15 and 15.16). In light of these findings, one may argue that reports on villi, arranged as a three-dimensional network (Stieve, 1941; Schiebler & Kaufmann, 1981) have been three-dimensional misinterpretations of tangential sections of tortuous villi. The famous diagram of the human placenta with villi in a net-like arrangement by Stieve (1941) was refuted by Peter (1951), based on reconstructions of wax plates.

Only the studies of Burton (1986a,b, 1987) and Cantle et al. (1987) made clear that there are real bridges in addition to those of artifactual genesis (Fig. 6.11). Hörmann (1953), Kaufmann and Stegner (1972), Jones and Fox (1977), and Cantle et al. (1987) presented evidence that real bridges are the result of fusion of adjacent villous surfaces that occur as soon as these come into prolonged intimate contact. Intermediate stages can be found as soon as slender intercellular gaps are formed between neighboring villous surfaces and become bridged by desmosomes. Later, the separating membranes disintegrate, causing the formation of a real syncytial bridge. Using radioangiographic and morphologic methods, vascularization of such bridges has been observed resulting in fetal intervillous vascular connections (Peter, 1951; Lemtis, 1955; Boyd & Hamilton, 1970). Unlike Stieve

FIGURE 6.11. A: Transmission electron micrograph of a syncytial bridge connecting two neighboring villi.  $\times 1500$ . (Source: Cantle et al., 1987, with permission.) B: Scanning electron micrograph of a syncytial bridge similar to that depicted in Figure 6.11A demonstrates that not all bridges seen in sections are artifacts

and caused by tangential sectioning. Such real bridges are probably caused by local contacts of neighboring villous surfaces with subsequent syncytial fusion.  $\times 890$ . (Source: Cantle et al., 1987, with permission.)

(1941), who postulated a net-like fetal vascular system that connects all villi, the authors cited provided evidence that such connections are rare exceptions. Whether the syncytial bridges have any mechanically supporting effects on the villous tree or are accidental structures without significance is a matter of speculation.

**Apoptotic knots** are structurally similar, but are characterized by more densely packed nuclei, separated from each other by slender strands of cytoplasm that is devoid of most organelles. The small nuclei show a more or less condensed chromatin (Fig. 6.10A) (Martin & Spicer, 1973b; Jones & Fox, 1977; Schiebler & Kaufmann, 1981) and sometimes even evidence of apoptotic or aponecrotic nuclear changes (Huppertz et al., 1998, 2002) (see following discussion on Trophoblast Differentiation and Apoptosis Cascade). The surrounding cytoplasm usually exhibits degenerative changes.

Martin and Spicer (1973b) as well as Dorgan and Schultz (1971) demonstrated that the life span of syncytiotrophoblast is limited (see Quantitation of Trophoblast Turnover, below, for calculations of syncytial life span). Thus, the presence of local degenerative changes caused by normal aging must be expected. Based on such views, Martin and Spicer (1973b), Jones and Fox (1977), Schiebler and Kaufmann (1981), and Cantle et al. (1987) described syncytial nuclear accumulations as sites where

aged syncytial nuclei are accumulated and later pinched off together with some surrounding cytoplasm (Fig. 6.10; see also Fig. 6.18). Huppertz et al. (1998) provided evidence that the nuclei of such sprouts represent various stages of apoptosis, thus suggesting that trophoblastic “sprouting” in fact is the syncytiotrophoblastic correlate of the formation of apoptotic bodies. We suggest the term **apoptotic knotting** (see Trophoblast Differentiation and Apoptosis Cascade).

Iklé (1961, 1964), Wagner et al. (1964), and Wagner (1968) found such segregated parts of the syncytiotrophoblast in the maternal uterine venous blood. According to Iklé’s calculations in pregnancy weeks 6 and 20, about 150,000 such sprouts per day were shed into the maternal circulation. Syncytiotrophoblast fragments are nearly exclusively found in uterine venous blood, rather than in other peripheral veins (Wagner et al., 1964). This finding suggests that most of these deported sprouts are eliminated by phagocytosis in the lung; however, to our best knowledge this process has not yet been analyzed in detail. Excess shedding leading to pulmonary embolism has been reported by Schmorl (1893), Marcuse (1954), and Atwood and Park (1961).

Larger, mushroom-like aggregates of syncytial nuclei are historically called **syncytial sprouts** (Figs. 6.10B and 6.12) (Langhans, 1870; Boyd & Hamilton, 1970). In the

past, this term has been applied for all mushroom-like or drumstick-shaped multinucleated syncytial protrusions. Meanwhile the term should no longer cover those structures, which are merely sectional artifacts caused by flat-sectioning of villous surfaces (Küstermann, 1981; Burton, 1986a; Cante et al., 1987) (see the discussion of syncytial knots earlier in this section). Rather it should be restricted to those protrusions that represent true expressions of villous sprouting. They can be identified by large, ovoid, loosely arranged nuclei that possess little heterochromatin and never show signs of apoptosis. The nuclei are surrounded by ample free ribosomes and well-developed rough endoplasmic reticulum. During early pregnancy (Fig. 6.1; see Chapter 7, Fig. 7.12), true syncytial sprouts are regular findings. In term placentas, they are found only in small groups on the surfaces of immature intermediate and mesenchymal villi in the centers of the villous trees.

From studies of villous development (Castellucci et al., 1990c, 2000b) it has become evident that sprouts of this type are really an expression of villous sprouting. Their concentration in the centers of the villous trees is in agreement with Schuhmann's (1981) view that the centers are growth zones for the villous trees.

In conclusion, when observing accumulations of syncytial nuclei in sections of placental villi, three different types of genesis should be considered:

1. In all stages of pregnancy, and in particular in the third trimester placenta, nearly all syncytial bridges and buds as well as many knot-like and sprout-like structures are results of **flat sectioning across syncytiotrophoblastic surfaces**. We suggest the term **syncytial knotting** or **Tenney-Parker changes** (see Three-Dimensional Interpretation of Two-Dimensional Sections in Chapter 15).

FIGURE 6.12. A: Scanning electron micrograph from the 8th week postmenstruation (p.m.) of gestation, showing local accumulations of mushroom-like true syncytial sprouts arising from broad villous protrusions. The latter probably represent the initial steps of the formation of new villi; they are common features in the early placenta but are rare at term.  $\times 180$ . (Source: Cante et al., 1987, with permission.) B: Semithin section from

the 9th week of gestation, showing two true syncytial sprouts, comparable to those depicted in part A. Note the unevenly dispersed nuclei and compare with the aggregated and pyknotic nuclei of the apoptotic knots and Tenney-Parker changes depicted in Fig. 6.10.  $\times 870$ . (Source: Cante et al., 1987, with permission.)

2. In all stages of pregnancy, a minority of knot-like and sprout-like structures characterized by nuclei with highly condensed chromatin, partly showing typical apoptotic annular chromatin condensation, are sites of **shedding of apoptotic nuclei** into the maternal circulation. The term **apoptotic knotting** is recommended (see Trophoblastic Apoptosis, below, and Chapter 15).

3. Throughout the first half of pregnancy, a limited number of syncytial sprouts are early stages of real **trophoblastic sprouting**; these are characterized by loosely arranged, large ovoid syncytial nuclei. In later pregnancy they are extremely rare. Only for these structures do we suggest the term syncytial sprouting (cf. Development of Mesenchymal Villi in Chapter 7; see also Chapter 15).

### Transtrophoblastic Channels

The syncytiotrophoblast is thought to be an uninterrupted maternofetal barrier composed of two plasmalemmas with an intermediate layer of syncytial cytoplasm. Therefore, every substance passing the syncytiotrophoblast from the maternal to the fetal circulation was thought to do so under the control of this syncytiotrophoblast layer. The existence of pericellular pathways is still unacceptable to many placentologists. Exchange of respective data during a 1986 workshop on transtrophoblastic channels, held at the second meeting of the European Placenta Group in Rolduc/Aachen, caused considerable controversy lasting until today.

Transport experiments by Stulc et al. (1969) provided the first evidence for the existence of water-filled routes, so-called pores or channels, across the rabbit placenta. Their radius was calculated to be approximately 10 nm. This finding has been confirmed for the guinea pig placenta by Thornburg and Faber (1977) and by Hedley and Bradbury (1980).

However, it took several years to find the structural correlates. Application of lanthanum hydroxide as an extracellular tracer via the maternal or fetal circulation resulted in the demonstration of membrane-lined channels in the isolated guinea pig placenta (Kaufmann et al., 1987b, 1989), in the postpartally perfused human placenta (Kertschanska & Kaufmann, 1992; Kertschanska et al., 1994, 1997), and in the rat placenta (Kertschanska et al., 2000). These channels have a luminal diameter from 15 to 25 nm and extend as winding, branching structures from the apical or basal surface into the syncytiotrophoblast. Because of their winding structure, they have never been traced in full length across the trophoblast. The release of the tracer into the maternal circulation, when applied via the fetal circulation and vice versa, makes it likely that at least some of these channels pass the syncytiotrophoblast in full length.

**Function:** The functional meaning of the transtrophoblastic channels has been elucidated by further experiments. In the fully isolated, artificially perfused guinea pig placenta, hydrostatic and colloid osmotic forces cause fetomaternal fluid shifts (Schröder et al., 1982). Fetal venous pressure elevation of 5 to 17 mmHg was enough to shift 30% to 50% of the arterial perfusion volumes into the maternal circulation. We detected, ultrastructurally, initially slender and later bag-like dilated channels that passed the syncytiotrophoblast in full length, as routes for the fluid shift (Kaufmann et al., 1982). As soon as the fetal venous pressure was reduced to normal values, the fluid shift ceased and the bag-like channels disappeared. These experiments have been successfully repeated in the isolated human placental lobule (Kertschanska & Kaufmann 1992; Kertschanska et al., 1997). The reversibility of the events refuted the possibility that the channels were of traumatic origin. The only possible explanation is the existence of channels that can be dilated under condition of pressure increase. It is likely that the channels traced with lanthanum hydroxide are identical to those dilated experimentally under the conditions of fluid shift and those postulated in transfer experiments by the physiologists mentioned (for review, see Stulc, 1989). Similar basal invaginations or intrasyncytial vacuoles such as those found under the experimental conditions of fluid shift are sometimes observed in freshly delivered human placentas. It is still open to question if this phenomenon is an expression of active fetomaternal fluid shift during labor.

Functionally, the transtrophoblastic channels are possible sites of transfer for water-soluble, lipid-insoluble molecules with an effective molecular diameter of about 1.5 nm (Thornburg & Faber, 1977; Stulc, 1989). Under the conditions of fetomaternal fluid shift caused by fetal venous pressure increase or fetal decrease of osmotic pressure, they may dilate to such an extent that all molecules, independent of size and solubility, may pass (Kaufmann et al., 1982; Schröder et al., 1982; Kertschanska & Kaufmann, 1992; Kertschanska et al., 1994, 1997).

Another functional aspect may be important. The embryo and fetus have problems of eliminating surplus water. Simple renal filtration with subsequent urination does not necessarily solve this problem, as the urine is delivered into the amniotic fluid and is still inside the fetoplacental unit. On the other hand, excessive fetal hydration causes an increase of fetal venous pressure and a decrease of fetal osmotic pressure. Both factors have been experimentally proved to dilate channels, allowing fetomaternal fluid shift and equilibration of the surplus water. Thus, pressure-dependent dilatation and closure of the channels may act as an important factor in fetal osmoregulation and water balance.

### TROPHOBLASTIC BLEBBING

When studying the syncytiotrophoblastic surface of human placental villi by electron microscopy, many authors have reported the existence of fungiform, membrane-lined protrusions of the apical syncytioplasm. These are largely or completely devoid of organelles. Their diameter normally ranges from 2  $\mu$ m to about 15  $\mu$ m (Ikawa, 1959; Hashimoto et al., 1960a,b; Arnold et al., 1961; Geller, 1962; Rhodin & Terzakis, 1962; Lister, 1964; Nagy et al., 1965; Strauss et al., 1965; Herbst et al., 1968, 1969; Knoth, 1968; Kaufmann, 1969). Numerous studies have shown that these protrusions are not a specific feature of syncytiotrophoblast but, rather, common features of most epithelia and sometimes of other cellular types (for review, see Kaufmann, 1975a). They are produced under degenerative conditions (Kaufmann, 1969; Stark & Kaufmann, 1971, 1972) and are likely to correspond to "blebs" observed during apoptotic processes (for review, see Kerr et al., 1995). Blockage of glycolysis by several enzyme inhibitors results in increased development of blebs; experimental substitution of glycolysis below the point of blockage results in suppression of their formation (Kaufmann et al., 1974a; Thorn et al., 1974). Hypoxia or experimental blockage of oxidative phosphorylation does not induce their production (Thorn et al., 1976).

After the protrusions have reached a certain size, they are pinched off into the maternal circulation. The only pathologic importance attributed to the blebs is related to placental infarction. Pronounced production of plasma protrusions in the guinea pig placenta was induced by experimental blockage of glycolysis, which led to obstruction of the maternal placental blood spaces by massive blebbing (Kaufmann, 1975b). The disintegration of the blebs induced blood clotting. The result was experimental infarction. Similar events have been described for the human placenta (Stark & Kaufmann, 1974). Assuming that this experimentally induced trophoblastic blebbing also is related to apoptotic events. The underlying molecular mechanism of blood clotting may be a phosphatidylserine flip in the respective plasmalemma from the inner to the outer leaflet. Externalization of phosphatidylserine was shown to be an early apoptotic event that initiates the coagulation cascade (see Molecular Mechanisms of Syncytial Fusion, below).

## Villous Cytotrophoblast (Langhans' Cells)

The villous cytotrophoblast forms a second trophoblastic layer beneath the syncytiotrophoblast. During early pregnancy, this layer is nearly complete (Fig. 6.13) and later becomes discontinuous (see Figs. 6.10A and 6.23A and

Chapter 28, Table 28.3). In contrast to earlier reports that described the villous cytotrophoblast to be absent from the mature placenta (Hörmann, 1948; Clavero-Nunez & Botella-Llusia, 1961), it is now well established that the Langhans' cells persist until term. In the mature placenta, they can be found beneath 20% of the villous syncytiotrophoblast (see Chapter 7, Fig. 7.11); the exact figure depends on the villous type, the kind of tissue preservation, and the pathologic state of the organ (see Table 28.6).

One should not deduce from these figures that the number of Langhans' cells is decreasing toward term. When one multiplies the relative numbers (percentages) of Langhans' cells per volume of villous tissue (Table 28.6) with the villous weights (g) per placenta (Table 28.2) during the 12th week p.m. and compares them to the term placenta, one arrives at surprising results. The total amount of Langhans' cells in the 12th week p.m. is about 2g, as opposed to 12g at term. In addition, stereologic studies have shown that the absolute number of cells increases steadily until term (Simpson et al., 1992). The real situation is that as the villous surface rapidly expands, the cytotrophoblast cells become widely

FIGURE 6.13. Semithin section showing two opposing villous surfaces, from the 9th gestational week p.m. Underneath the thick syncytiotrophoblast (S) are nearly complete layers of cytotrophoblast. Its varying staining intensities indicate different stages of differentiation from undifferentiated, proliferating

cytotrophoblast (arrow) to highly differentiated cytotrophoblast with signs of syncytial fusion (interrupted arrows). Some of the cytotrophoblastic cells are obviously degenerating (double arrow).  $\times 1270$ . (Source: Kaufmann, 1972, with permission.)

separated and thus less numerous in sectioned material. This change has important consequences for maternofetal immunoglobulin transfer, because unlike the syncytiotrophoblast and endothelial cells, cytotrophoblast cells do not express Fc- $\gamma$  receptors (Bright & Ockleford, 1993). Transport of immunoglobulins, therefore, may become possible only in later pregnancy when the cytotrophoblastic layer becomes incomplete.

Earlier authors (Spanner, 1941; Stieve, 1941) considered a syncytiotrophoblastic origin of the Langhans' cells. Ortmann refuted this as early as 1942. He pointed out that formation of a syncytium must be regarded as differentiation from cellular precursors, and as an irreversible process. Richart (1961) presented the first proof for this assumption using  $^3\text{H}$ -thymidine incorporation to demonstrate the absence of DNA synthesis from syncytiotrophoblastic nuclei while it was, however, present in cytotrophoblastic nuclei. Galton (1962), who simultaneously carried out microspectrophotometric DNA measurements of trophoblastic nuclei, supported these data. The cytotrophoblastic contribution to the formation of syncytiotrophoblast has been generally accepted since the detailed ultrastructural evaluation of human placental villi from early pregnancy until full term also structurally demonstrated this process (Boyd & Hamilton, 1966). Hörmann et al. (1969) reviewed the vast literature of subsequent studies in much detail; the early autoradiographic findings were supported and extended by many authors (Pierce & Midgley, 1963; Fox, 1970; Weinberg et al., 1970; Kim & Benirschke, 1971; Geier et al., 1975; Kaufmann et al., 1983). The authors found that  $^3\text{H}$ -thymidine is incorporated only into the cytotrophoblastic nuclei, never into those of syncytiotrophoblast (see Fig. 6.20A). This fact excludes nuclear replication within the syncytiotrophoblast. Moe (1971), who described mitoses of syncytiotrophoblastic nuclei following in vitro

application of colchicine, has published the only conflicting results. Because no one ever has reproduced these results, they must be regarded as misinterpretation.

### Cytotrophoblast Cell Types

During all stages of pregnancy, most of the Langhans' cells possess light microscopic and ultrastructural features that clearly distinguish them from overlying syncytiotrophoblast, the characteristic features of **undifferentiated, proliferating stem cells** (Fig. 6.14). Studies on cyclin D3-expression (DeLoia et al., 1997) suggest that about 50% of these cells are in the cell cycle. Occasional mitoses,  $^3\text{H}$ -thymidine incorporation, and Ki-67/MIB-1 positivity demonstrate that these are proliferating stem cells (Tedde & Tedde-Piras, 1978; Arnholdt et al., 1991; Kohnen et al., 1993; Kosanke et al., 1998). Another about 40% of cells displays the same undifferentiated phenotype but is immunonegative for cyclin D3. This subset very likely represents  $G_0$ -cells.

The cells display an ultrastructurally undifferentiated phenotype with a large euchromatic nucleus and few cell organelles (Kaufmann, 1972; Martin and Spicer, 1973b) (Fig. 6.13). The cytoplasm contains a well-developed Golgi field, few mitochondria, few dilated rough endoplasmic cisternae, and numerous polyribosomes (Figs. 6.14 and 6.15A) (Schiebler & Kaufmann, 1969; Kaufmann, 1972; Martin & Spicer, 1973b). Histochemically, enzymes

FIGURE 6.14. Transmission electron micrograph of mature placenta shows an undifferentiated cytotrophoblastic cell (CT) lying underneath a thin syncytiotrophoblastic lamella (S). During

all stages of pregnancy, most of the villous cytotrophoblast belongs to this type of proliferating or resting stem cell.  $\times 9800$ . (Source: Schiebler & Kaufmann, 1981, with permission.)

FIGURE 6.15. A: Transmission electron micrograph of mature placenta shows highly differentiated Langhans' cell (CT), shortly before its syncytial fusion with the neighboring syncytiotrophoblast (S). Note the ultrastructural similarity of the two.  $\times 7400$ . B: Even after syncytial fusion with complete disappearance of the separating cell membranes, the area of the original

cytotrophoblast (CT) can be clearly distinguished from the overlying syncytium (S) because of the marked difference in density of cell organelles. Note the accumulation of mitochondria and endoplasmic reticulum transferred into the syncytium by this kind of organellar transplantation into the syncytium.  $\times 14,700$ .

of the aerobic and anaerobic glycolysis revealed only low activities (see Fig. 6.22) (Kaufmann & Stark, 1972; Kaufmann et al., 1974b).

A few Langhans' cells show **higher degrees of differentiation**, expressed by large amounts of free ribosomes, rough endoplasmic reticulum, and mitochondria (Fig. 6.15A). This finding has usually been interpreted as signs of differentiation toward a later syncytial state (Boyd & Hamilton, 1966; Hörmann et al., 1969; Schiebler & Kaufmann, 1969; Kaufmann, 1972). By light microscopy, these cells may show staining patterns similar to those of syncytiotrophoblast (Fig. 6.13). The enzymes of the

aerobic and anaerobic glycolysis (see Fig. 6.22A) express increasing activities.

As soon as the cytotrophoblast reaches an electron density that is comparable to that of the neighboring syncytium, the first signs of **syncytial fusion** may be observed (Boyd & Hamilton, 1966; Hörmann et al., 1969; Kemnitz, 1970; Kaufmann, 1972; Kaufmann et al., 1977a). Only in severely damaged areas of the villous trees are Langhans' cells observed with an organellar density exceeding that of the overlying syncytiotrophoblast (Figs. 6.16 and 6.17) (Kaufmann et al., 1977a). Syncytial fusion begins with the disintegration of separating cell membranes (Fig. 6.18).

FIGURE 6.16. Transmission electron micrograph of mature placenta shows that the highly differentiated cytotrophoblast (CT) sometimes fails to fuse with the neighboring syncytiotrophoblast (S). Because it lacks regeneration, the latter shows obvious signs of degeneration, such as vesicular hydrops of most organ-

elles, absence of ribosomes, and disintegration of the plasma-lemma. Because of continuous differentiation, the nonfusing cytotrophoblast has an unusually large accumulation of organelles. Similar pictures can be seen in extravillous cytotrophoblast, which also lacks syncytial fusion.  $\times 16,800$ .

FIGURE 6.17. Survey transmission electron micrograph showing a villus in preeclampsia. If the cytotrophoblast (CT) fails definitely to fuse syncytially, the syncytiotrophoblast (S) degenerates, as demonstrated in Figure 6.16. As a final stage, the syncytiotro-

phoblast may locally disappear so that hypertrophic cellular trophoblast makes up the villous surface and directly borders the intervillous space (above). In this case, the villous stroma (below) also exhibits severe degenerative changes.  $\times 2800$ .

FIGURE 6.18. Cytotrophoblastic contribution to the regeneration of the villous syncytiotrophoblast. As soon as the syncytiotrophoblast shows its first signs of degeneration (loss of ribosomes—blue; degranulation of rough endoplasmic reticulum—blue), the cytotrophoblast begins to proliferate. Some of the daughter cells start differentiation and develop large numbers of organelles. At the same time the initiation stages of apoptosis are started in the cytotrophoblast and the phosphatidylserine flip takes place, which induces syncytial fusion. After disintegration of the separating membranes, the newly formed cytotrophoblast organelles together with high amounts RNA and proteins are transferred into the syncytium and thus regen-

erate the latter. Apoptosis inhibitors (Bcl-2, Mcl-1) expressed in the cytotrophoblast and transferred into the syncytiotrophoblast by syncytial fusion, temporarily block progression of the apoptosis cascade. The freshly incorporated nucleus can easily be identified for a certain period because of its size and low quantity of heterochromatin. As soon as the syncytial organelles degenerate again, this process starts anew. In this way, large numbers of trophoblastic nuclei accumulate in the syncytiotrophoblast. They are clustered as syncytial knots, protrude as sprout-like structures, and finally are pinched off into the intervillous space. (Source: Modified from Kaufmann, 1983, with permission.)

Contractor et al. (1977) have studied this process in detail in the human and Firth et al. (1980) in the guinea pig. The fusion seems to be initiated by establishment of gap junctions that bridge the intercellular space. Connexin 43 is under discussion as the responsible gap junction molecule in the human (Malassine et al., 2003). In vitro data suggest that hCG plays a major role in the stimulation of gap junction communication during human trophoblast fusion and differentiation (Cronier et al., 1997). It is proposed that the major role of the gap junctions is to bring the adjacent plasma membranes into close contact to become the starting points for cell fusion. Experimental studies in pseudopregnant rabbits have shown that the formation of a uterine epithelial syncytium, characteristic for implantation in this species, is also introduced by formation of gap junctions; they establish intercellular coupling and finally induce dissolution of the membranes (Winterhager, 1985). As a second step, plasma bridges between syncytium and cytotrophoblast are formed. From the gap junctions, this process spreads over the contact surface between Langhans' cell and syncytiotrophoblast. According to Contractor (1969) and Contractor et al. (1977), increased numbers of secondary lysosomes are actively involved in disintegration of the plasma membranes.

**Freshly fused syncytiotrophoblast** can easily be identified by electron microscopy, enzyme histochemistry, and immunohistochemistry (Figs. 6.15B and 6.18; also see Fig. 6.22B). They are characterized by a compact area of accumulated mitochondria, rough endoplasmic reticulum, and free ribosomes. These structures surround a large, ovoid nucleus rich in euchromatin. Such nuclei still may show immunoreactivity for proliferating-cell nuclear antigen (PCNA), a protein related to DNA polymerase  $\delta$  and usually expressed in proliferating cells (Kohnen et al., 1993); the molecule has a half-life of about 24 hours and may thus persist from the last mitosis, via syncytial fusion, to the syncytial state. Its presence in syncytiotrophoblast must not be misinterpreted as a sign of proliferative activity of the latter.

In accordance with the ultrastructural appearance of freshly fused syncytiotrophoblast, maximal activities of all enzymes of aerobic and anaerobic glycolysis have been shown (Kaufmann & Stark, 1972). The density of organelles and the activities of enzymes considerably exceed that of the overlying syncytiotrophoblast. The density of organelles and enzyme activities decrease soon with spreading over the neighboring parts of the syncytium. Even then, the "new" syncytial area can easily be detected by the unusual size of its nucleus.

According to the results of Martin and Spicer (1973b), the nuclei are the most reliable indicators for the syncytial "age," which is the time elapsed since the syncytial fusion. Prevalence of small, densely stained, obviously pyknotic syncytial nuclei together with reduced numbers

of Langhans' cells indicate degenerative changes of the syncytiotrophoblast because of reduced syncytial fusion.

In early stages of pregnancy, also degenerating villous trophoblast cells are regular findings. Between pregnancy weeks 6 and 15, Burton and coworkers (2003) found 0.49% Langhans' cells showing **secondary necrosis** (aponecrosis; abortive forms of apoptosis) and 5.97% Langhans' cells characterized by **primary necrosis**.

#### NEMATOSOMES

Nematosomes are spherical to ovoid, membrane-free organelles with a diameter of about 1  $\mu\text{m}$  (Fig. 6.19). They consist of helically arranged central strands of filaments to which small electron-dense conglomerates are attached. The latter are thought to consist of storage forms of RNA (Grillo, 1970; Ockleford et al., 1987). Many authors have described nematosomes as regular features of undifferentiated Langhans' cells. They have also been found within other embryonic tissues and in neurons, but never in syncytiotrophoblast. The most detailed review of the relevant literature is that by Ockleford et al. (1987).

Regarding their potential role as RNA storage, studies of apoptosis in villous trophoblast may be of interest. It has been shown that apoptosis is already initiated in cytotrophoblast prior to fusion. Syncytiotrophoblast is already in an advanced stage of apoptosis (Huppertz et al., 1998). In apoptotic tissues transcription is gradually downregulated, and there is evidence that large amounts of RNA already transcribed in the cytotrophoblast are "transplanted" into the syncytium by syncytial fusion. Nematosomes may represent one of such storage forms. No evidence has thus far been found of any relationship between nematosomes and overt gestational pathology and between nematosomes and virus infections in the placenta (Ockleford et al., 1987).

#### Endocrine Activities of the Villous Cytotrophoblast

In addition to their role as trophoblastic stem cells, endocrine activities have been attributed to the cytotrophoblast. Repeatedly, it has been suggested that Langhans' cells are the source of hCG.

Two arguments have been stressed: the number of Langhans' cells and their proliferative activity seem to parallel the urinary and serum levels of hCG (Gey et al., 1938; Wislocki & Bennett, 1943; Tedde & Tedde-Piras, 1978); trophoblast cultures continue to produce hCG when only cytotrophoblast survives (Stewart et al., 1948). The first deduction is inconclusive, as only the relative rather than the absolute amount of villous cytotrophoblast is so impressive in early pregnancy. As discussed earlier, the absolute number of Langhans' cells increases steadily until term. Also, the second deduction is not convincing. Cytotrophoblast behaves differently under culture conditions; here it acquires stages of differentiation that are not reached in vivo (Nelson et al., 1986; Kao et al., 1988).

Midgley and Pierce (1962), Dreskin et al. (1970), Hamanaka et al. (1971), and Kim et al. (1971) described hCG immunoreactivities mainly within the villous syncytiotrophoblast. Outside the villi, in extravillous tissues where syncytial fusion is rare, extravillous trophoblast locally synthesizes this hormone (see Chapter 9). Gaspard et al. (1980) were the first to point out that  $\alpha$ -hCG and  $\beta$ -hCG

FIGURE 6.19. A,B: Transmission electron micrographs of undifferentiated villous cytotrophoblast in a human placenta at term. The cells show typical nematosomes consisting of helically

arranged strands of filaments to which small electron-dense bodies are attached. The structures resemble coiled strings of beads. A:  $\times 8400$ ; B:  $\times 20,500$ .

under certain conditions can be found also in the villous cytotrophoblast. The  $\beta$ -hCG subunit, however, was detected in cytotrophoblast only underlying heavily damaged syncytium.

Molecular studies by Hoshina et al. (1982, 1983, 1984) and Kliman et al. (1986, 1987) produced evidence that the ability to secrete hCG and hPL is related to the level of trophoblastic differentiation. Boime et al. (1988) proposed a model for hCG and hPL expression that associates subsequent activation of  $\alpha$ -hCG,  $\beta$ -hCG, and hPL genes at different stages of differentiation. Under normal in-vivo conditions,  $\alpha$ -hCG is expressed and secreted directly before fusion,  $\beta$ -hCG immediately following fusion, and hPL slightly later. Following discussion with the authors, we suggest, however, that this cascade of gene activation is not tied to the syncytial fusion itself but rather to the process of trophoblastic differentiation. Under normal in vivo conditions, syncytial fusion takes place at the time of  $\alpha$ -hCG expression. In pathologic conditions ( $\beta$ -hCG expression by cytotrophoblast; reported by Gaspard et al., 1980), in tissue culture, and

under normal conditions in extravillous cytotrophoblast, syncytial fusion but not the sequence of gene expressions may be delayed or completely inhibited.

Only a few reports have considered additional secretory activity of the villous cytotrophoblast. Nishihira and Yagihashi (1978, 1979) reported the production of **somatostatin** in Langhans' cells. Somatostatin is an inhibitor of adenohypophyseal hormones, such as growth hormone and thyroid-stimulating hormone (TSH). These authors discussed a suppressive role of somatostatin on hCG and hPL production by the syncytiotrophoblast.

Other peptides with alleged origin in the villous cytotrophoblast are **corticotropin-releasing factor (CRF)** (Petraglia et al., 1987; Saijonmaa et al., 1988), **gonadotropin-releasing hormone** [GnRH, placental luteinizing hormone releasing factor (LRF)] (Khodr & Siler-Khodr, 1978), neuropeptide Y (NPY) (Petraglia et al., 1989), and inhibin (Petraglia et al., 1987). Reevaluation of the latter two papers (Petraglia et al., 1987, 1989) and repetition of the experiments in cooperation with the author revealed, however, that inhibin and NPY immunoreactivities were

clearly localized in the villous capillary walls, and only certain inhibin subunits were found in the trophoblast, too. Korhonen and coworkers (1991) arrived at similar conclusions. In later publications, Petraglia et al. (1991, 1992) have specified their findings for the various inhibin subunits. Regulatory effects of inhibin on the hCG secretion are discussed by Petraglia et al. (1987, 1990) and by Petraglia (1991).

## Trophoblast Turnover and Syncytial Fusion

As already discussed above, syncytiotrophoblast lacks  $^3\text{H}$ -thymidine incorporation and consequently nuclear replication (Richart, 1961; Galton, 1962; Pierce & Midgley, 1963; Fox, 1970; Weinberg et al., 1970; Kim & Benirschke, 1971; Geier et al., 1975; Kaufmann et al., 1983; Huppertz et al., 1999). Therefore, syncytiotrophoblast cannot grow by itself. Rather, syncytial growth and surface expansion throughout pregnancy depend on continuous incorporation of cytotrophoblast by syncytial fusion. As we will show below, syncytial fusion does not only fulfill the syncytiotrophoblastic needs for growth, but rather has additional functional importance.

### Quantitation of Trophoblast Turnover

This becomes evident when one compares for an average near-term placenta (1) the number of proliferating trophoblast cells (Kosanke et al., 1998) with (2) the weight gain of syncytiotrophoblast in the respective period (see Tables 28.2 and 28.3). It must be pointed out that the following calculations are partly based on very rough assumptions. The resulting data should be used as very preliminary clues only:

- In the last month of pregnancy, placental villi are covered with a mean of 90 g of trophoblast, 77.5 g of which are syncytiotrophoblast and 12.5 g cytotrophoblast.
- Assuming a mean volume for a villous trophoblast cell to be  $1400\mu\text{m}^3$ , 12.5 g of cytotrophoblast correspond to  $9 \times 10^9$  villous trophoblast cells.
- The trophoblastic surface per placenta at term amounts to about  $12\text{m}^2$  (see Table 28.5), and per  $10,000\mu\text{m}^2$  of surface, 70 trophoblast mitoses take place within 4 weeks (Kosanke et al., 1998). From this, we calculate  $3 \times 10^9$  villous trophoblast mitoses per day and per placenta.
- A low percentage of postmitotic trophoblast cells may degenerate (assumption, 15–20%). We furthermore suppose that the absolute number of villous trophoblast cells is kept largely constant throughout the last trimester (Table 28.3). It follows that about  $2.5 \times 10^9$  of

the trophoblast cells produced daily by mitosis, subsequently will fuse syncytially; this corresponds to a daily generation rate of 3.5 g of new syncytiotrophoblast.

- The weight gain of villous syncytiotrophoblast in the last month of pregnancy is 10 to 11 g. That equals a daily rate of syncytiotrophoblast growth of about 0.4 g.
- Accordingly, only 0.4 g of the daily generated 3.5 g of syncytiotrophoblast are required to cover the daily expansion of the syncytial surface.
- The remaining about 3.1 g, which are generated in excess of the daily growth rate, are shed again as syncytial knots into the maternal circulation. This figure nicely fits to data presented by Iklé (1964); he found a daily shedding rate of about 150,000 “sprouts” (apoptotic knots). Assuming nearly round structures with a mean diameter of 15 to  $20\mu\text{m}$ , this equals 1.5 to 3.5 g.
- We know from the structural features described above, that not freshly included nuclei but rather the oldest nuclei are shed as syncytial knots. Based on a total of 77.5 g of syncytiotrophoblast at term, a shedding rate of 3.1 g/day suggests an average of 25 days between inclusion of a cytotrophoblast nucleus by syncytial fusion and its extrusion via a syncytial knot.
- Accordingly, syncytiotrophoblast generated once, does not live until the end of pregnancy. Rather, the cytotrophoblast is incorporated for a transient period of 25 days only, after which the aged remains of the cells (nuclei and some surrounding cytoplasm) are again extruded by syncytial knots into the maternal.

### Why Does Syncytiotrophoblast Survival Depend on Syncytial Fusion?

The importance of syncytial fusion for survival of syncytiotrophoblast is stressed by several observations. The life span of syncytiotrophoblast in culture without syncytial incorporation of cytotrophoblast is limited. Assuming that isolated syncytiotrophoblast has already a mean age of 12.5 days, its complete structural disintegration should be in the same range of nearly 2 weeks. Its functional death happens much earlier: in vitro, syncytiotrophoblast without cytotrophoblastic fusion shows steeply decreasing hormonal production rates within some days and finally dies (Castellucci et al., 1990a; Crocker et al., 2004). Similarly, maximal villous cytotrophoblast proliferation without syncytial fusion, as observed in severe hypoxia in vitro, was accompanied by syncytial degeneration (Fox, 1970). From experimental studies in the rhesus monkey placenta (Panigel & Myers, 1972), it has become evident that loss of villous cytotrophoblast and degenerative changes of the syncytiotrophoblast are usually associated.

Downregulation of transcription following syncytial fusion very likely is the major reason for the limited life span of syncytiotrophoblast. To test this hypothesis,  $^3\text{H}$ -uridine incorporation into villous trophoblast was studied. The resulting data resembled the results of  $^3\text{H}$ -thymidine incorporation studies. This RNA precursor was mostly incorporated into the nuclei of cytotrophoblast and stromal cells (Fig. 6.20B) (Kaufmann, 1983; Kaufmann et al., 1983; Huppertz et al., 1999). Syncytiotrophoblast did not show  $^3\text{H}$ -uridine incorporation levels detectable by autoradiography. Meanwhile, the lack of transcription in syncytiotrophoblast has also been proven specifically for some genes. These include the apoptosis inhibitor *bcl-2* (Huppertz et al., 2003), the protease caspase 8 (Black et al., 2004), and the anion transporter *OAT4* (Black et al., 2004). Downregulation of transcription is a widespread phenomenon after induction of apoptosis (Owens et al., 1991; Leist et al., 1994; Kockx et al., 1998). This does not necessarily imply lacking transcription of all proteins; rather transcription is focused on few genes that are essential for safe execution of apoptosis.

If this were true for the majority of genes in the syncytiotrophoblast, the latter regarding survival and functional activity would depend on continuous supply with cytotrophoblastic RNA through syncytial fusion of cytotrophoblast. In this case, not the rather low requirements of growth expansion of syncytiotrophoblast, but rather the much higher demands of RNA would define the rate

of syncytial fusion. One may object that messenger RNA (mRNA) due to universally available ribonuclease (RNase) has an extremely short half-life, which would not be in agreement with mRNA supply only by cellular fusion. On the other hand, the human placenta is the richest known source for the RNase inhibitor (RNasin) (Blackburn & Gavilanes, 1980), which blocks RNA cleavage and thus helps stabilizing mRNA. Moreover, the nematosomes characteristic for the human trophoblast and which are thought to consist of storage forms of RNA (Grillo, 1970; Ockleford et al., 1987) may present means for the preservation of RNA between syncytial fusion and utilization for translation within the syncytiotrophoblast.

In conclusion, it is not only the mass of trophoblast that is required for growth; rather, we suspect that fusion takes place to transfer “consumables” not synthesized in the syncytium itself (e.g., RNA), from the cytotrophoblast into the syncytiotrophoblast to maintain its functional capacity. Only with this continuous regeneration by fusion syncytiotrophoblast is kept functionally active.

### Trophoblastic Differentiation and Apoptosis Cascade

Programmed cell death (apoptosis) as opposed to accidental cell death (necrosis) is characterized by typical ultrastructural signs such as annular chromatin condensa-

FIGURE 6.20. A:  $^3\text{H}$ -thymidine incorporation into the villous trophoblast. The black silver grains indicate active DNA synthesis. They have accumulated only over the cytotrophoblastic nuclei (big black spots in the center). The syncytiotrophoblast shows no signs of DNA synthesis.  $\times 1400$ . (Courtesy of Dr. W. Nagl.) B:  $^3\text{H}$ -uridine incorporation into the villous trophoblast. Similar to

$^3\text{H}$ -thymidine incorporation,  $^3\text{H}$ -uridine, as a precursor of RNA, is mostly incorporated into the cytotrophoblast (fine black grains), indicating that RNA metabolism in the syncytiotrophoblast is downregulated by apoptotic events but fully active in the cellular trophoblast.  $\times 1400$ . (Courtesy of Dr. W. Nagl.)

tion, loss of microvilli, cytoplasmic dehydration, and membrane blebbing, but preservation of organelle integrity (for review, see Kerr et al., 1995). These features have been observed since the early periods of electron microscopy also in villous syncytiotrophoblast; however, their interpretation and designation as apoptosis took place considerably later. This delay was partly because the term **programmed cell death (apoptosis)** seemed to be not applicable to a tissue, which represents an **acellular**, syncytial continuum.

With a delay of about 25 years, a series of studies of various aspects of apoptosis suggested that villous syncytiotrophoblast undergoes a closely related process of programmed death that involves most but not all the classic features of apoptosis. Aspects studied in the placenta comprise Fas and FasL expression (Runic et al., 1996; Bamberger et al., 1997; Uckan et al., 1997); expression of the tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) receptors p55 and p75 (Yui et al., 1996); Bcl-2 expression (Castellucci et al., 1993c; LeBrun et al., 1993; Sakuragi et al., 1994; Kim et al., 1995; Lea et al., 1997; Marzioni et al., 1998); DNA degradation (TUNEL test) (Yasuda et al., 1995; S.C. Smith et al., 1997a; Kokawa et al., 1998); and annular chromatin condensation (Nelson, 1996).

In a series of studies, different stages of the apoptotic cascade were correlated with differentiation, syncytial fusion, and degeneration of villous trophoblast (Huppertz et al., 1998, 1999, 2001, 2002, 2003; Huppertz & Kaufmann, 1999; Black et al., 2004). In summary, the data suggested that apoptosis starts as early as in the cellular stage of trophoblast differentiation and subsequently is involved in a series of events (Fig. 6.18):

- The p55 receptor for TNF- $\alpha$ , a major inducer of apoptosis, is expressed by villous cytotrophoblast (Yui et al., 1994, 1996). Caspase-8, a so-called initiator caspase that starts the apoptosis cascade becomes activated already in the cellular stage of trophoblast (Huppertz et al., 1999). Moreover, inhibitor proteins (Bcl-2 and Mcl-1) as well as inactive proforms of some of the molecular machinery of later steps of the cascade (pro-caspase-3, inactive transglutaminase) are available in these cells (Huppertz et al., 1998).
- The start of these early stages of the apoptosis cascade seems to be responsible for trophoblast cells leaving the cell cycle and entering the differentiation pathway (for review, see Huppertz et al., 2001). In vitro data by McKenzie et al. (1998) revealed that interactions between (1) increased expression levels of the cyclin-dependent kinase (Cdk) inhibitor Kip1, (2) inactivation of Cdk2, (3) downregulation of cyclin E, and (4) accumulation of active (hypophosphorylated) retinoblastoma gene product (pRb) are responsible for blockage of the S phase of cytotrophoblast and the cells' entrance into the differentiation pathway. This happens only to a small percentage of cells. In a variety of other cells, it was shown that Bcl-2 induces the cells to enter a quiescent G<sub>0</sub>/G<sub>1</sub> state and thereby reduces proliferation (Vairo et al., 1996; O'Reilly et al., 1997). Furthermore, Mazel et al. (1996) have shown that elevated levels of Bcl-2 lead to an increase of hypophosphorylated retinoblastoma gene product (pRb), which according to McKenzie et al. (1998) was responsible for blockage of the cell cycle.
- Moreover, the endogenous retroviral envelop protein ERV-3 Env is under discussion because it may commit trophoblast cells to cell cycle arrest (for details, see below) (Rote et al., 2004).
- In some of the cells, which had left the cell cycle and had reached higher levels of differentiation, the flip of phosphatidylserine (PS flip) from the inner to the outer plasmalemmal leaflet occurs (Huppertz et al., 1998). Different molecular steps lead to the PS flip: (1) the activation of initiator caspase-8; (2) the caspase-8-mediated activation of slow floppases or fast scramblases, both of which actively translocate negatively charged phosphatidylserine from the inner to the outer plasmalemmal leaflet; (3) the caspase-8-mediated inactivation of flippases (translocases), which normally would counteract outward flipping of PS from the inner to the outer plasmalemmal leaflet. The net effect of all three processes together is the accumulation of phosphatidylserine in the outer plasmalemmal leaflet (for review, see Huppertz et al., 2001). This PS flip seems to be a prerequisite for syncytial fusion of trophoblast cells (in vitro data by Lyden et al., 1993; Adler et al., 1995; Katsuragawa et al., 1997).
- Consequently, our data suggest that early, but still reversible, stages of apoptosis in highly differentiated trophoblast cells initiate syncytial fusion; parallel expression of the inhibitory proto-oncogene products Bcl-2 and Mcl-1 for 3 to 4 weeks prevents irreversible progression of the apoptotic cascade.
- Inhibition of the apoptosis starter caspase-8 in vitro blocked syncytial fusion and thus demonstrated the importance of these initiation stages of apoptosis for the fusion process.
- Following syncytial fusion, irreversible progression of apoptosis is blocked, so long as sufficient amounts of members of the Bcl-2 family of proteins (Bcl-2: Marzioni et al., 1998; Huppertz et al., 2003; Mcl-1: Huppertz et al., 1998) are present in the syncytiotrophoblast. The data moreover suggest that either the inhibitory protein itself or its mRNA is transferred from the cytotrophoblast into the syncytium by syncytial fusion (Huppertz et al., 2003).
- In apoptotic cells, transcription of mRNA is typically reduced; this was also shown for syncytiotrophoblast (Kaufmann et al., 1983). The RNA of the latter is likely to be transplanted from the cytotrophoblast by syncytial fusion, rather than being synthesized in the syncytium itself (Fig. 6.20B). The data imply that this is also valid for Bcl-2 and Mcl-1 mRNA (Huppertz et al., 2003).
- Consequently, prevention of irreversible apoptotic damage depends on syncytiotrophoblastic availability of inhibitory members of the Bcl-2 protein family; this in turn depends on syncytial fusion of trophoblast cells in regular, but still unknown, intervals.
- As long as fresh cytotrophoblast is incorporated into villous syncytiotrophoblast, syncytial apoptosis does not progress generally but rather only focally. These apoptotic foci in the syncytiotrophoblast are characterized by several features (Huppertz et al., 1998, 1999, 2002): focal loss of immunoreactivities for Bcl-2 and Mcl-1; PS flip; leakiness of the syncytial plasmalemma for propidium iodide; activation of caspase-3; degradation of nuclear proteins such as PARP (poly ADP-ribose polymerase) (involved in DNA repair), lamin B (an intrinsic nuclear pore protein), and topoisomerase IIa (involved in condensation of chromosomes); translocation of TIAR (T-cell restricted intracellular antigen-related protein) (involved in biogenesis and translation of mRNA) from the nucleus to the cytoplasm; activation of transglutaminase II beneath the apical plasmalemma where it prevents loss of proteins through the increasingly leaky membrane.
- The final steps of syncytiotrophoblastic apoptosis comprise DNA degradation with TUNEL positivity and annular chromatin condensation of the nuclei. In most cases, these features are restricted to nuclei in syncytial knots and sprouts, indicating that the apoptotically damaged nuclei are focally accumulated (Fig. 6.21) before shedding into the intervillous space (Yasuda et al., 1995; Nelson, 1996; Huppertz et al., 1998, 2002).

FIGURE 6.21. Schematic representation of trophoblast turnover and trophoblastic apoptosis at the villous surface. Cytotrophoblast nuclei surrounded by high concentrations of ribosomes (blue) are transferred into the syncytiotrophoblast by syncytial fusion. In the course of about 3 weeks the syncytially incorporated nuclei undergo apoptotic changes, accompanied by loss of RNA and degranulation of the surrounding cytoplasm (the density of blue point shading represents density of ribosomes). Finally, the nuclei are accumulated and extruded by apoptotic

knotting and shedding. The remaining syncytiotrophoblast is void of nuclei and corresponds to the thin syncytial lamellae of vasculosyncytial membranes and to syncytial lamellae covering villous cytotrophoblast. New syncytial fusion of differentiating cytotrophoblast supplies the syncytiotrophoblast with fresh nuclei, new ribosomes and other organelles. These cyclic events at the villous surfaces are the basis of regional specializations of villous syncytiotrophoblast.

- Interestingly, most of the final steps of apoptosis with accumulation of apoptotic nuclei were observed at or close to villous tips, suggesting that flux of nuclei during the process of apoptosis is a unidirectional process from the villous base to its tip, comparable to that in intestinal villi.
- Since caspase-3 upon activation in the syncytiotrophoblast among others cleaves also cytoskeletal components such as cytokeratins (Huppertz et al., 1998, 2002; Kadyrov et al., 2001), the loss of cytoskeletal anchorage of nuclei may facilitate their movement along the villi and their accumulation at the villous tips. As force causing this unidirectional nuclear movement, one may discuss maternal blood flow in the surrounding intervillous space.
- We never found breakdown of nuclei with formation of typical apoptotic bodies in the syncytiotrophoblast. Rather, accumulated apoptotic and preapoptotic nuclei, surrounded by some cytoplasm and a plasmalemma, are shed as so-called syncytial knots or sprouts. We prefer the term **apoptotic knots**. It is assumed that these are further degraded in the lung (Iklé, 1964; Wagner et al., 1964), presumably by alveolar macrophages (Huppertz et al., 1998), a process that has not yet been studied. The role of this trophoblast deportation for the pathogenesis of preeclampsia is under discussion (Johansen et al., 1999; Huppertz et al., 2002).

Taken together, the above data suggest, that a prolonged form of apoptosis drives the stages of trophoblast differentiation and trophoblast turnover:

1. Initiation stages of apoptosis are responsible for the trophoblast cell's exit from the cell cycle and for its entrance into the differentiation pathway.
2. Activation of the apoptosis initiating caspase-8 induces the phosphatidylserine flip, which is a key signal for syncytial fusion.
3. Upon syncytial fusion, excess expression of apoptosis inhibitors blocks further progression of the apoptosis cascade for 3 to 4 weeks (mean 25 days, see above). Throughout this period, the syncytiotrophoblast fulfills its functions as maternofetal transport barrier and as metabolic center of the placenta.
4. Throughout these 4 weeks of retarded apoptosis so-called differentiation stages of syncytiotrophoblast are driven by apoptotic mechanisms that finally result in the

mosaic pattern of different types of syncytiotrophoblast (see above): Caspase-3 mediated degradation of the cytoskeleton enables nuclear accumulation producing (1) nuclear knots and (2) syncytial lamellae (e.g., vasculosyncytial membranes) void of nuclei. Apoptosis-related continuous loss of RNA leads to degranulation of rough endoplasmic reticulum to the benefit of smooth endoplasmic reticulum.

5. Finally, massive restart of the cascade with activation of endonucleases by caspase-3 induces DNA breakdown and nuclear condensation. This results in extrusion of about 3 g of apoptotic knots per day, consisting of apoptotic nuclei with some surrounding aged syncytioplasm well sealed in plasma membranes.

## Molecular Mechanisms of Syncytial Fusion

There are two different types of syncytial fusion of human trophoblast (for review, see Pötgens et al., 2002):

- **Cell-cell fusion** is limited to the periimplantation period and involves trophoblast cells of the blastocyst. As soon as implantation is completed, trophoblast cells do not fuse any longer with each other.
- Rather, extension of the already existing syncytiotrophoblast from now onward takes place by **cell-syncytium fusion**.

One of the critical aspects of all studies on trophoblast fusion is that nearly all in situ studies describing the localization of the various molecules involved are performed on placental villi, and thus on cell-syncytial fusion. By contrast, in vivo models based on trophoblast cells or analogs study cell-cell fusion. Since cell-cell fusion is restricted to implantation and seems to be blocked in subsequent placentation, it is very unlikely that the molecular mechanisms of both events are identical (Pötgens et al., 2002). If this holds true, we also cannot be sure that data obtained on cell-cell fusion in vitro can easily be transferred to such obtained on cell-syncytium fusion in vivo. Several contradictions among the results of both approaches must possibly be explained in this way.

### Phosphatidylserine Flip as Fusion Signal

Phosphatidylserine is well accepted as a key player in the syncytial fusion process (for review, see Huppertz et al., 2001). It normally prevails in the inner plasmalemmal leaflet. This asymmetry is maintained by flippases (translocases), which translocate spontaneously outward flipping PS molecules back to the inner leaflet. Accumulation of larger amounts of PS in the outer plasmalemma (PS

flip) is the consequence either of degradation of these **flippases** by **caspase-8** or of caspase-8-mediated activation of slow **flippases** and fast **scramblases**, both of which actively translocate phosphatidylserine from the inner to the outer plasmalemma leaflets. Antibodies directed against externalized phosphatidylserine blocked trophoblast fusion in vitro (Adler et al., 1995; Katsuragawa et al., 1997; Rote et al., 1998). The same holds true for the prevention of the PS flip by inhibition of its enzymatic starter, caspase-8 (Black et al., 2004). Also immunohistochemically, the PS flip was shown in fusion-stages of trophoblast cells (Huppertz et al., 1998, 1999).

On the other hand, the PS flip is a ubiquitous phenomenon among apoptotic cells throughout the body (Martin et al., 1995; Bevers et al., 1996); however, most of these cells do not fuse syncytially. Rather, syncytium formation is a strictly regulated event, which in the human occurs only between cells of the same lineage (trophoblast cells, myoblasts, and osteoclasts). This suggests that not only the PS flip, but also additional tissue-specific cell surface signals are required for fusion. Their presence avoids heterofusion with cells of other lineages. Several such fusogenic membrane proteins are currently under discussion (see below). Most of them, however, are continuously expressed in those cells, which are destined to undergo fusion, also in phases of their lives in which they do not fuse. Consequently, a second acute fusion signal is required, which is activated as soon as the cell has reached a degree of differentiation sufficient for syncytial fusion. We suggest that the phosphatidylserine flip may serve as this acute fusion signal.

### Junctional and Adhesion Molecules as Fusion Mediators

The formation of gap junctions was shown to precede syncytial fusion (Firth et al., 1980). Therefore, junctional molecules such as connexins are candidates as fusogenic molecules. Antisense inhibition of **connexin 43** expression in primary trophoblast cultures blocked syncytial fusion (Malassiné et al., 2003). The effect of this gap junction molecule is possibly to allow the exchange of cellular messenger molecules that regulate the molecular machinery leading to fusion since blockage of fusion was accompanied by reduced transcription of the syncytin gene, another fusogenic protein (see below).

In addition, the adhesion molecules **cadherin-11** and **E-cadherin** appear to play (opposing) roles in mediating trophoblast fusion (Getsios and MacCalman, 2003).

### The ADAM Family of Fusogenic Proteins

A family of proteins called ADAM (**a** disintegrin and **a** metalloproteinase domain) is involved in many cell-cell fusion processes (for review, see Wolfsberg & White,

1996). ADAM 1 and 2 (fertilins  $\alpha$  and  $\beta$ ) were shown to be crucial for sperm–egg fusion in the mouse (Cho et al., 1997, 1998; Evans et al., 1998). The human fertilin gene, however, is dysfunctional so that fertilins are no candidate molecules for any type of cell–cell fusion in the human (Jury et al., 1997, 1998). ADAM 12 (meltrin  $\alpha$ ) triggers fusion of myoblasts into skeletal muscle fibers (Yagami-Hiromasa et al., 1995; Gilpin et al., 1998; Galliano et al., 2000) and also the formation of osteoclasts (Abe et al., 1999). Meltrin- $\alpha$  mRNA was also detected in the human placenta (Gilpin et al., 1998), but as yet it is not clear whether trophoblast or another cell type (e.g., blood mononuclear cells) was responsible for this expression.

### Endogenous Retroviral Envelope Proteins of the HERV Family (Syncytins) and Their Receptors

Retroviruses use fusogenic envelope proteins to attach to and to fuse with host cells. In the course of phylogenesis, certain retroviral proteins have been incorporated into the human genome. Special attention has been attributed to envelope elements of three human endogenous retroviruses (HERV), namely ERV-3 Env, HERV-W Env, and HERV-FRD Env (for review, see Rote et al., 2004).

- Among those, the functional role of the **ERV-3 Env (HERV-R Env) protein** in the placenta is still a mystery. In isolated trophoblast its expression is upregulated during differentiation and in parallel to the expression of the  $\beta$ -subunit of hCG (for review see Rote et al., 2004). The same authors speculate that expression of this retroviral protein commits the trophoblast cells to cell cycle arrest.
- More is known about the fusogenic retroviral envelope protein **HERV-W, named syncytin-1** (Blond et al., 1999; Mi et al., 2000; Lee et al., 2001). Syncytin seems to play a key role in syncytial trophoblast fusion. It was shown to be expressed in human trophoblast and, upon transfection into other cells, induced the formation of syncytia (Blond et al., 2000; Mi et al., 2000). Frendo et al. (2003) showed that syncytin expression was upregulated after stimulating syncytial fusion of primary cytotrophoblast by a cyclic adenosine monophosphate (cAMP) analogue. Furthermore, they showed that antisense inhibition of syncytin in these primary cell cultures actually inhibited fusion.
- A second fusogenic protein of the closely related **HERV-FRD** family was identified in placental tissues recently and named **syncytin-2** (Blaise et al., 2003). It appears to have another receptor. Functional differences as compared to syncytin 1 are not yet known.

Blond et al. (2000) identified the type D mammalian retrovirus receptor (RDR), also known as neutral amino

acid transporter system ATB0 (ASCT2 or SLC1A5) (Kekuda et al., 1996; Rasko et al., 1999; Taylor et al., 1999) as a **syncytin receptor**. A second amino acid transporter, ASCT1, was described as an alternative syncytin receptor (Lavillette et al., 1998; Marin et al., 2000, 2003).

Interestingly, also other amino acid transporters are under discussion as candidate fusogenic proteins: CD98 is a subunit of a family of amino acid transporter molecules. Apart from its transporter function, it has been proposed to play a role in cellular differentiation, activation, adhesion, as well as fusion. It has been shown to play a modulating role in cell fusion of monocytes/macrophages into osteoclasts, as well as in virus-mediated cell fusion (reviewed in Devés & Boyd, 2000). Kudo et al. (2003b) have recently shown that reduction of CD98 expression through an antisense oligonucleotide inhibited fusion of BeWo cells. The mechanisms by which CD98 influences cell–cell fusion as well as the question of whether, comparable with ASCT 2, it acts as a receptor for another fusogenic protein, is not yet clear (Devés & Boyd, 2000).

The distribution of syncytin-1 in the human placenta was studied by various means. Syncytin-1 mRNA was detected by Northern blot in the placenta (Mi et al., 2000). By in situ hybridization, mRNA encoding syncytin-1 so far was described only in syncytiotrophoblast of term and preterm placentas (Mi et al., 2000). Immunohistochemical data concerning syncytin-1 localization were quite confusing. Mi et al. (2000) found staining at the basal syncytiotrophoblast membrane, but in some cases also at the apical syncytiotrophoblast membrane. In placentas from pregnancies complicated by preeclampsia syncytin was nearly almost detected in the apical syncytiotrophoblast membrane (Lee et al., 2001). Using the same antibody on first trimester placenta specimens, syncytin-1 immunoreactivities were not only found in villous but also in extravillous trophoblast (Muir et al., 2003). Blond et al. (2000) raised a new recombinant antibody and showed most staining in the syncytiotrophoblast, but there were also areas of positive staining in villous cytotrophoblast. Smallwood et al. (2003) supported these data and additionally found in Western blots that syncytin expression was higher in first trimester compared to term placenta. By contrast, using the same antibody, Frendo et al. (2003) demonstrated anti-syncytin-1 reactivity at the apical syncytiotrophoblast membrane in both first trimester and term placental sections. Using a polyclonal antibody raised by Yu et al. (2002), we found uniform staining in the syncytiotrophoblast of first trimester placental paraffin sections. In the villous cytotrophoblast layer, only a few cells were stained (Pötgens et al., 2004).

Little is known about local distribution of the syncytin receptors ASCT1 and ASCT2. To date, no antibodies against these amino acid transporters/receptors are available, and in situ hybridization on placental sections has not been performed, yet. Functional studies with isolated membrane vesicles suggest that little ASCT1 but high concentrations of ASCT2 are present in the basal

syncytiotrophoblast plasmalemma (for review see Jansson, 2001; Cariappa et al., 2003). Unfortunately, preparations of trophoblastic membrane vesicles do not allow any conclusion regarding villous cytotrophoblast.

### Molecular Control of Syncytial Fusion

Interaction between syncytins and their receptors is not yet understood. The few, partly contradictory data on localization of syncytin and ASCT cannot exclude the possibility that both syncytins and receptors are constitutively expressed in both the syncytiotrophoblast and the cytotrophoblast. Assuming that both are the only actors realizing syncytial fusion, this would allow uncontrolled fusion of cytotrophoblast with neighboring syncytiotrophoblast, resulting in complete loss of villous cytotrophoblast within a short period of time. Accordingly, in a recent report we showed that both BeWo and JAR cells expressed the mRNA for ASCT2 and syncytin at nearly equal levels; however, unlike BeWo cells, the JAR cells

did not fuse (Borges et al., 2003). Consequently, the simple presence of syncytin and its receptor, or at least the presence of the mRNA of both, is not enough to guarantee fusion.

Rather, whether syncytins and their receptors are part of a complex cascade of events leading to fusion should be investigated (Pötgens et al., 2004). The need for such a complex cascade is underlined by morphologic data reported already above:

- Undifferentiated Langhans' cells are regularly associated with syncytiotrophoblast that is equipped with ample rough endoplasmic reticulum, polyribosomes, and numerous mitochondria (Kaufmann & Stegner, 1972; Jones & Fox, 1991; Martinez et al., 1997) (Figs. 6.7A and 6.14)—thus syncytiotrophoblast without any signs of degeneration or progressing apoptosis.
- With increasing degree of differentiation of the Langhans' cells, in the overlying syncytiotrophoblast the numbers of free and membrane-bound ribosomes as well as mitochondria decrease, to the benefit of smooth endoplasmic reticulum or degenerative/apoptotic features (Figs. 6.15B and 6.18).
- Similar relations are seen in enzyme histochemical preparations (Fig. 6.22). Decreasing syncytial activities of enzymes related to the

FIGURE 6.22. A: Semithin section of enzyme histochemical demonstration of lactate dehydrogenase. Cytotrophoblast shows increasing enzyme activities from the undifferentiated (u), via the highly differentiated (h), to the syncytial fusing (s) form.  $\times 840$ . (Source: Kaufmann & Stark, 1972, with permission.) B: Semithin section of enzyme histochemical demonstration of lactate dehydrogenase. Note the complete absence of this

enzyme in an undifferentiated cytotrophoblastic cell (u) compared to the high activity in a cell that is in syncytial fusion (s). The large, bright nucleus of the latter can easily be distinguished from the smaller nuclei of the surrounding older syncytiotrophoblast.  $\times 840$ . (Source: Kaufmann & Stark, 1972, with permission.)

energy metabolism are associated with increasing activities in the cytotrophoblast (Fig. 6.22) (Kaufmann & Stark, 1972).

- Stages of syncytial fusion always involve cytotrophoblast showing the highest degrees of differentiation, and syncytiotrophoblast showing advanced stages of apoptosis, (e.g., complete loss of ribosomes) (Figs. 6.15 to 6.18) (Kaufmann 1972; Kaufmann & Stegner, 1972).

We have concluded that degenerative (progressing apoptotic) changes within the syncytiotrophoblast induce (1) differentiation of the underlying cytotrophoblast (Kaufmann, 1972; Kaufmann & Stark, 1972) and (2) in parallel the initiation stages of cytotrophoblast apoptosis including PS flip, which are thought to be prerequisites of syncytial fusion (Huppertz et al., 1998; Black et al., 2004).

Taken together, according to Pötgens and coworkers (2004) any model of molecular control of syncytial fusion should take into account molecular players which

1. not only represent the ligand-receptor mechanisms that enable firm attachment and finally fusion of the adjacent membranes,
2. but also sense the readiness for fusion of cytotrophoblast, and
3. sense the syncytiotrophoblastic need to incorporate new cytotrophoblast with new organelles and new mRNA.

Re (1): In the ligand-receptor interactions very likely syncytins and receptors, ASCT1 and ASCT2 are involved. Whether also ADAMs and or adhesion molecules are involved, remains open.

Re (2): The readiness to fuse of cytotrophoblast possibly is sensed by the PS flip. Syncytiotrophoblast as a latent apoptotic tissue as visualized by annexin-binding always shows a certain degree of PS flip. In villous cytotrophoblast PS accumulates in the outer plasma-membral leaflet only after the cell has left the cell cycle, has started the initiation stages of apoptosis and thus has reached a certain degree of differentiation. Additionally, the expression of sufficient levels of ASCT 1 and 2 (or syncytin) may well depend on a sufficient degree of differentiation.

Re (3): The most logical way to report the syncytial need for fusion to the cell surface, would be by lack of respective mRNA and thus by decreasing expression of a protein that is functionally important and at the same time involved in the fusion process (Pötgens et al., 2004). A nice example is the syncytin receptor ASCT2, which acts as amino acid transporter for maternofetal amino acid transfer. This hypothesis depends on the following provisions: First, ASCT2 is expressed by differentiated cytotrophoblast (not yet proven!). Second, syncytin is expressed mainly or exclusively by syncytiotrophoblast. Third, high levels of ASCT2 expression in “young” syncytiotrophoblast would block the coexpressed syncytin for interaction

with ASCT2 in the opposing cell<sup>1</sup>; but decreasing ASCT2 expression in aging/apoptotic syncytiotrophoblast would liberate syncytin for interacting with ASCT2 in the opposing cytotrophoblast and would induce fusion.

## The Role of Oxygen and Cytokines in Trophoblast Proliferation and Fusion

**Trophoblast proliferation** resulting in increased numbers of villous cytotrophoblast cells and in increased syncytiotrophoblast thickness is a striking feature in several pathologic conditions related to hypoxia. Among those are maternal anemia (Piotrowicz et al., 1969; Kosanke et al., 1998), maternal hypertensive disorders (Wigglesworth, 1962), preeclampsia (Jeffcoate & Scott, 1959; Wigglesworth, 1962; Fox, 1964, 1997), and pregnancies at high altitude (Jackson et al., 1985; Mayhew et al., 1990; Mayhew, 1991; Ali, 1997); for review, see Kingdom and Kaufmann (1997). Tissue culture experiments (Fox, 1964; Amaladoss & Burton, 1985; Burton et al., 1989; Castellucci et al., 1990a; Ong & Burton, 1991) have proven the importance of hypoxia for trophoblast proliferation.

A common finding in villous histology illustrates the regulatory influence of local oxygen partial pressure on the turnover of cytotrophoblast. With reduction of the cytotrophoblast layer in the course of pregnancy, the remaining trophoblast cells accumulate in the neighborhood of fetal capillaries, situated near the trophoblastic surface (Fig. 6.23A) (Kaufmann, 1972). Finally, in the term placenta most trophoblast cells are located at the vasculosyncytial membranes, separating the thin syncytial lamella from the fetal capillary (Figs. 6.1D, 6.4, 6.7A, and 6.14; also see Chapter 7, Fig. 7.8). On the first glance, this association appears illogical, as this localization increases the maternofetal diffusion distances at the main sites of diffusional exchange. Reconstructing the oxygen isobars in a respective villous cross section suggests that this finding is a consequence of local oxygen partial pressures (Kaufmann, 1972). As can be seen in Figure 6.23B, the PO<sub>2</sub> gradient is much steeper in places where the fetal capillaries directly face the trophoblast. In this location, the cytotrophoblast is exposed to much lower PO<sub>2</sub> levels than those that are far from the capillaries, indicating that decreased PO<sub>2</sub> stimulates proliferation. Consequently, far from the capillaries, in zones of higher PO<sub>2</sub>, the poorly proliferating cytotrophoblast fuses and finally disappears. In contrast, increased proliferation in zones of low PO<sub>2</sub> near the capillaries helps some of the trophoblast cells to persist. This kind of regulation makes sense if we assume that hypoxic conditions damage the syncytiotrophoblast functionally and structurally.

<sup>1</sup> Syncytin, as a retroviral envelope protein has the ability to block its own receptors if coexpressed with its receptors in the same cell (Ponferada et al., 2003; for review see Colman & Lawrence, 2003). Consequently, the mere presence of syncytin in a certain cell or syncytial membrane does not necessarily mean that syncytin is available to interact with a receptor molecule in an opposing cell membrane. If coexpressed on the same side, syncytins and receptors may neutralize each other and may not be available for the respective ligands or receptors in the neighboring membrane. Hence, not the mere presence of both but rather the balance between local syncytin and receptor expression levels may determine whether fusion is initiated or not.

FIGURE 6.23. A: Semithin section of the 22nd gestational week p.m. In contrast to earlier stages of pregnancy, from this stage onward the fetal capillaries (C) come into a more peripheral position and establish close contacts to the trophoblastic surface of the villus because of the reduced villous diameter. Cytotrophoblast is concentrated in the neighborhood of the capillaries.  $\times 820$ . (Source: Kaufmann, 1972, with permission.) B: Why is cytotrophoblast concentrated near the fetal capillaries? This idealized cross section of a placental villus demonstrates the distribution of the villous cytotrophoblast related to the oxygen tension. The PO<sub>2</sub> is symbolized by the density of dots. The basic assumption is that the PO<sub>2</sub> of the intervillous space (IVS, densely dotted) is highest, whereas the PO<sub>2</sub> in the arterial capillary limb (aC, not dotted) is lowest; despite unlimited oxygen diffusion, this gradient is kept constant so long as the maternal and fetal

circulations are intact. If this assumption is true, one expects a steeper PO<sub>2</sub> gradient near the arterial capillary limb (aC) than far from it, as symbolized by the dotting patterns. As becomes evident in this diagram, cytotrophoblast near a capillary is located in zones of lower PO<sub>2</sub>, because of its steep gradient, as compared to cytotrophoblast being far away from fetal capillaries and lying in zones of a moderate PO<sub>2</sub>-gradient. The stimulating influence of low oxygen tension on cytotrophoblastic mitoses explains the persistence of cytotrophoblast near the capillaries. On the other hand, in zones of elevated PO<sub>2</sub> far from capillaries, retarded mitotic activity and continuous loss of cytotrophoblast by syncytial fusion lead to the disappearance of the cytotrophoblast, as depicted in part A. ST, syncytiotrophoblast; CT, cytotrophoblast; vC, venous capillary limb. (Source: Modified from Kaufmann, 1972, with permission.)

Villous oxygenation better than normal, so-called hyperoxia (Kingdom & Kaufmann, 1997), negatively influences trophoblast proliferation. In most placentas, one observes villi with obstructed fetal vessels. This leads to increasing intravillous oxygen partial pressure since the missing fetal circulation no longer extracts oxygen. Loss of villous cytotrophoblast normally accompanies this finding, provided that the maternal circulation is not impaired in these areas. Panigel and Myers (1972) have generated this condition experimentally. These authors ligated the umbilical vessels of one placental disk of the bidiscoidal rhesus monkey placenta. The fetus survived. After disintegration of the fetal villous capillaries in the ligated disk, the authors observed an involution of the villous cytotrophoblast and, finally, degenerative/apoptotic changes of the syncytiotrophoblast. Because the maternal circulation was still intact, the syncytiotrophoblast changes could not be explained as being a consequence of deficient nutrition or hypoxia. Rather, it must be the result of deficient proliferation of cytotrophoblast and deficient syncytial fusion caused by abnormally high intravillous PO<sub>2</sub>.

Growth factors and their receptors involved in the regulation of trophoblast proliferation among others

comprise the insulin-like growth factors IGF-I and IGF-II and their receptors (Boehm et al., 1989a; Ohlsson, 1989; Ohlsson et al., 1989). In particular, IGF-II is expressed primarily in highly proliferative cytotrophoblast, as for example in cell islands and cell columns, while other cellular components such as villous cytotrophoblast or mesenchymal stromal cells harbor less active IGF-II genes (Ohlsson et al., 1989). Because numerous IGF receptors are expressed in villous cytotrophoblast, it has been suggested that IGF mediates autocrine or short-range paracrine growth control of placental development (Ohlsson et al., 1989). There are only a few data on the interactions between oxygen and IGF action. Owens and coworkers (1994) reported that in sheep the secretion of both IGF-I and IGF-II under hypoxia is decreased, whereas hypoxia increases the secretion of the IGF-inhibiting, IGF-binding proteins (Morrish et al., 1998; Popovici et al., 2001;

Verhaeghe et al., 2001). Epidermal growth factor (EGF) seems to have no effect on trophoblast proliferation (Maruo et al., 1996). The data on transforming growth factor- $\beta$  (TGF- $\beta$ ) are again confusing: TGF- $\beta$ , the expression of which is increased by hypoxia (Patel et al., 1994), was found to inhibit (Lysiak et al., 1993; Tse et al., 2002), whereas TGF- $\alpha$  (Lysiak et al., 1993; Filla & Kaul, 1997) stimulates trophoblast proliferation.

Hypoxia-induced trophoblast proliferation would make particular sense as a compensatory mechanism, if hypoxia would also stimulate **trophoblast apoptosis**. This in fact has been reported by Morrish et al. (1998) and by Levy et al. (2000). In addition, in vitro data by Benyo et al. (1997) have shown that villous TNF- $\alpha$  secretion is significantly increased under hypoxic conditions; TNF- $\alpha$  is one of the cytokines capable of inducing trophoblastic apoptosis (see earlier). Its p55 receptor, responsible for the start of the initiation stages of apoptosis, is expressed by villous cytotrophoblast (Yui et al., 1994, 1996). Moreover, the data available show increased trophoblastic apoptosis in pregnancies complicated by preeclampsia and intrauterine growth restriction (IUGR) (Hayakawa et al., 1995; S.C. Smith et al., 1997b), pregnancy complications in the pathogenesis of which abnormal oxygen supply is involved (Kingdom & Kaufmann, 1997).

Data regarding the effects of oxygen on **syncytial fusion** are rare and difficult to interpret. Using cell line BeWo, Kudo et al. (2003a) and Knerr et al. (2003) have demonstrated that under hypoxia syncytin mRNA levels decreased, and were less inducible by forskolin, compared to "normoxia" (20% oxygen). Hypoxia also decreased fusion of BeWo cells (Kudo et al., 2003a). Downregulation of syncytin expression by hypoxia may explain the findings of Lee et al. (2001) that syncytin expression was very low in placentas of preeclamptic pregnancies. It is also our experience from cell culture as well as from evaluation of villous histology that severe degrees of hypoxia completely block syncytial fusion. By contrast, in moderate hypoxia the negative effect of hypoxia may be overridden by the increased availability of cytotrophoblast that is ready to fuse. Cytokines, which were reported to control syncytial fusion, include EGF, which stimulates fusion, and TGF- $\beta$ , which inhibits fusion (for review, see Morrish et al., 1998). On the other hand, in various tissues, hypoxia increases the expression of TGF- $\beta$  (Patel et al., 1994), an effect that should again result in inhibitory effects of low oxygen on syncytial fusion.

Recently, Bukovsky and coworkers (2003a,b) have presented new data, which may add to our understanding of the regulation of trophoblast turnover. When studying the expression of estrogen receptors in the human placenta, these authors found that villous cytotrophoblast expresses estrogen receptor  $\alpha$ . Upon syncytial fusion in vivo and in vitro, the expression switched to estrogen

receptor  $\beta$  (Bukovsky et al., 2003a). These data suggest that also estrogens may be involved in proliferation and differentiation of villous trophoblast.

## The Impact of Trophoblast Turnover on Syncytiotrophoblast Specialization

The structurally and functionally specialized areas of syncytiotrophoblast described above very unlikely are stable structures. Rather, the comparison of these subtypes of syncytiotrophoblast with the events that take place during trophoblast apoptosis and turnover leads us to suspect that they are an expression of a highly dynamic process of differentiation and degeneration.

Taken together, the data lead us to suggest the following cycle of structural and functional changes within in the villous trophoblastic cover (Fig. 6.21):

- Upon syncytial fusion, syncytiotrophoblast with well-developed rough endoplasmic reticulum, focused on protein metabolism, is generated.
- Within days to a very few weeks, due to missing transcription activity of the syncytial nuclei, the ribosomes are lost and the respective area is transformed into syncytiotrophoblast with smooth endoplasmic reticulum and tubular mitochondria, focused on steroid metabolism.
- As a consequence of progressive apoptotic degradation of the syncytiotrophoblastic cytoskeleton, the aging nuclei are focally aggregated, forming apoptotic knots, which shortly are pinched off from the syncytial surface and are deported into the maternal circulation. The sorting process, which on the one side accumulates the syncytial nuclei and on the other side generates enucleated, thin layers of syncytiotrophoblast, is probably driven by pressure of the underlying fetal capillaries and sinusoids.
- After aggregation and extrusion of the nuclei result enucleated areas of syncytiotrophoblast, which mostly span over (1) fetal sinusoids (vasculosyncytial membranes, specialized in diffusional exchange) or (2) undifferentiated cytotrophoblast in G<sub>0</sub>-stage (syncytial lamellae covering cytotrophoblast, possibly specialized in steroid metabolism).
- Formation of the latter structures should be investigated as a signal for the cytotrophoblast to enter the cell cycle, later to differentiate and to fuse.
- By syncytial fusion, the vasculosyncytial membranes and the lamellae covering cytotrophoblast are again equipped with new syncytial nuclei, cell organelles, and RNA so that the turnover cycle can start anew.

As discussed before, the length of such a cycle is estimated to last 3 to 4 weeks.

Also throughout the first 4 months of pregnancy, when the respective syncytiotrophoblast specialization is not

demonstrable, similar turnover processes take place within the villous trophoblast (for review, see Huppertz et al., 2002). They are possibly less impressive due to (1) much higher relative numbers of villous cytotrophoblast, (2) higher turnover rates, and (3) reduced villous capillarization as the speculated driving force for nuclear sorting of the differentiation processes within the syncytiotrophoblast, and thus escape electron microscopical and histochemical detection.

## Trophoblastic Basement Membrane

The trophoblastic basement membrane separates the trophoblastic epithelium from the villous stroma. It forms a supportive matrix for the cytotrophoblast and, where the latter is lacking, for the syncytiotrophoblast (see Figs. 6.1 and 6.4A). Under normal conditions, the average thickness of the trophoblast basement membrane ranges from 20 to 50 nm. Polarization optical methods as well as fluorescence microscopy by Scheuner (1972, 1975), Scheuner and Hutschenreiter (1972, 1977), and Pfister et al. (1989) have provided basic information about the structural organization and fiber orientation.

The main components of basement membranes of other origin, namely collagen IV, laminin, and heparan sulfate, are also expressed in the basement membrane of the trophoblast (Ohno et al., 1986; Autio-Harminen et al., 1991; Castellucci et al., 1993a,b). In addition, fibronectin was shown to be present (Virtanen et al., 1988). This molecule has binding sites for various collagens and proteoglycans (Bray, 1978; Duance & Bailey, 1983) and is thought to attach the basal lamina to the connective tissue fibers beneath. Recent analyses of laminin and fibronectin isoforms suggest that the molecular composition changes during maturation of villous trophoblastic and endothelial basement membranes; these changes are particularly obvious in areas of trophoblast proliferation and villous sprouting (Korhonen & Virtanen, 2001). Using lectin histochemistry, Sgambati and coworkers (2002) have added data on oligosaccharide distribution of glycoconjugates with the basal lamina.

Functionally, the basement membrane acts as a support for the trophoblastic epithelium and allows a certain amount of movement. Matrix proteins, such as tenascin, which counteracts the action of fibronectin (Aufderheide & Ekblom, 1988), can possibly unlock the attachment of cytotrophoblast cells. This effect could enable postmitotic Langhans' cells to migrate along the basal lamina to those places where they are needed for syncytial fusion. Accordingly, tenascin is regularly expressed in sites of Langhans' cell mitosis and degenerative syncytiotrophoblastic foci (Castellucci et al., 1991).

Another important function of the basal lamina is to act as a filtration barrier between maternal and fetal

circulations. Calcification of the villous trophoblastic basal lamina, a regular finding in intrauterine fetal death, but a rare one with living fetuses (Roberts et al., 2000; Kasznica & Petcu, 2003), may be a hint in this direction. Whether the trophoblastic basal lamina plays a role as a molecular sieve limiting transepithelial (transplacental) transport, as reported for the glomerular basal lamina, remains to be studied.

## Connective Tissue

The basic architecture of the villous stroma is constructed of fixed connective tissue cells that form a network; they enmesh connective tissue fibers, and free connective tissue cells (Hofbauer cells) and fetal vessels. Depending on the age of the placenta, on the type of villus, and on the position within the villus, at least five different types of fixed stromal cells have been described (see Fig. 6.26) (Boyd & Hamilton, 1967; Kaufmann et al., 1977b; Castellucci et al., 1980; Castellucci & Kaufmann, 1982a; Martinoli et al., 1984; King, 1987). According to more recent immunohistochemical analyses they represent different stages of a differentiation gradient, ranging from indifferent, proliferating mesenchymal cells (pluripotent stem cells) up to highly differentiated myofibroblasts and possibly even myocytes (Kohnen et al., 1995, 1996; Demir et al., 1997).

### Mesenchymal Cells (V Cells)

Mesenchymal cells, or undifferentiated stromal cells, are the prevailing cell type until the end of the second month (Kaufmann et al., 1977b; Martinoli et al., 1984). At all later stages of pregnancy, they are found only in newly formed villi, the mesenchymal villi, and beneath the trophoblastic surface of immature intermediate and stem villi (Kohnen et al., 1996; Demir et al., 1997).

**Structure:** They are usually small (10–20  $\mu\text{m}$  long and 3–4  $\mu\text{m}$  wide), spindle-shaped cells with little cytoplasm, which are connected to each other by a few thin, long processes. Polyribosomes are the prevailing organelles. Mitotic mesenchymal cells may have much more cytoplasm and form nearly epithelioid cells (see Chapter 7, Fig. 7.14). As cytoskeletal filaments, they usually express only vimentin, but not desmin, sm-actins, or sm-myosin, and are therefore also called **V cells** (Kohnen et al., 1996).

**Distribution:** In the early stages of pregnancy, these cells make up most of the mesenchymal stroma, which is the primitive forerunner of all other stromal types. Throughout all the later stages of pregnancy, these cells persist in two different locations: first, within mesenchymal villi, the first stages of newly sprouting villi; second, as a small proliferating subset of connective tissue cells

beneath the trophoblastic surface of large caliber villi (see Fig. 6.26) (Kohnen et al., 1996; Demir et al., 1997).

### Fibroblasts (VD Cells and VDA Cells)

The differentiation of this cell type is closely linked to the development of a new villous type, the immature intermediate villi (see Chapter 7) at the beginning of the third month p.m. At this time, dramatic changes in stromal architecture and cellular composition of villi take place (Kaufmann et al., 1977b; Martinoli et al., 1984). King (1987) reported similar changes for the rhesus monkey placenta.

**Structure:** Within a few days, starting in the centers of the villi and then slowly spreading toward the villous surface, most of the mesenchymal cells (V cells) acquire desmin as the second cytoskeletal filament and henceforth are characterized as **VD cells** (Kohnen et al., 1995, 1996). Structurally, these cells are very heterogeneous and occasionally have been called reticulum cells (Kaufmann et al., 1977b) or fibroblasts (King, 1987) (Figs. 6.24 and 6.25). The newly formed fibroblasts (VD cells) have elongated, bizarre-shaped cell bodies that measure about 20 to 30  $\mu\text{m}$  in length. From the cell bodies, several long, thin, branching cytoplasmic processes take off.

Serial sections studied by transmission electron microscopy and scanning electron microscopy of immature intermediate villi revealed that the processes are flat sails of cytoplasm (Kaufmann et al., 1977b; Castellucci & Kaufmann, 1982a; Martinoli et al., 1984). They branch in a cone-like pattern, the apex of the cone pointing to the cell body. In sections, these extensions form nets by establishing contacts to the extensions of neighboring cells (see Fig. 7.4C).

In later stages of pregnancy and close to the centrally located fetal stem vessels, these cells additionally may acquire  $\alpha$ -sm actin as a third cytoskeletal filament (**VDA cells**), without change in their body shape (Fig. 6.26). This is interpreted as a first step toward differentiation of myofibroblasts (Kohnen et al., 1996) (see following discussion).

**Distribution:** In three-dimensional preparations of immature intermediate villi, the sail-like processes of several VD cells in series make up longitudinally oriented stromal channels. In cross sections, the latter appear as rounded compartments or chambers 20 to 50  $\mu\text{m}$  in diameter (see Figs. 7.2 and 7.7). Fetal vessels and the connective tissue fibers are fitted into the spaces between the channels, as well as between channels and trophoblastic basement membrane. This reticular structure has been

FIGURE 6.24. Transmission electron micrograph shows the typical variety of connective tissue cells in a mature intermediate villus at the 36th week p.m. Small reticulum cells (S) with long, slender, richly branched cytoplasmic extensions, a large

reticulum cell (below), and a macrophage (Hofbauer cell, H) are seemingly scattered irregularly among loosely arranged connective tissue fibers.  $\times 2500$ . (Source: Kaufmann et al., 1977a, with permission.)

FIGURE 6.25. Electron micrograph of fibroblast with sparse cytoplasm and short but richly branched cytoplasmic extensions, surrounded by bundles of collagen fibers.  $\times 9300$ .

described in detail by Castellucci and Kaufmann (1982a,b), Castellucci et al. (1984), and Martinoli et al. (1984). It is highly characteristic only for the immature intermediate villi.

In mature intermediate and terminal villi (see Chapter 7) a structurally different subgroup of fibroblasts (VD cells) is found. Fewer and filiform processes but abundant perinuclear cytoplasm characterizes these cells (Fig. 6.24). They do not delimit stromal channels; rather, they are enmeshed in a loose mixture of connective tissue fibers.

### Myofibroblasts (VDAG Cells and VDAGM Cells)

A third group of connective tissue cells that are structurally and immunohistochemically different from mesenchymal cells and fibroblasts characterizes the central parts of immature intermediate villi as well as stem villi (Fig. 6.26). They gradually differentiate out of VDA cells so that clear-cut borders among both populations are not always visible.

**Structure:** The cells have much cytoplasm and are 30 to 100  $\mu\text{m}$  long but only 5 to 8  $\mu\text{m}$  wide. In contrast to the fibroblasts, they have only a few short, filiform, or thick processes. The cytoplasm is rich in rough endoplasmic

reticulum, stress fibers, cytoplasmic dense plaques, and caveolae. Locally, the cell body is surrounded by a basal lamina (Demir et al., 1992; Kohnen et al., 1996). These cells obviously correspond to the extravascular contractile cells described in large stem villi by Spanner (1935) as well as Krantz and Parker (1963) and in anchoring villi by Farley et al. (2004). Feller et al. (1985) provided histochemical evidence that these were positive for dipeptidyl-peptidase IV; the isoenzyme pattern of this enzyme is identical with that of myofibroblasts of other origin.

Immunohistochemical analysis of the cytoskeleton of the villous stromal cells (Kohnen et al., 1995, 1996; Demir et al., 1997) revealed a differentiation gradient even within these cells. Those neighboring the VDA cells expressed  $\gamma$ -sm actin in addition to vimentin, desmin, and  $\alpha$ -sm actin (**VDAG cells**) (Fig. 6.26). Those directly facing the media of the central stem vessels additionally partly showed expression of sm-myosin (**VDAGM cells**).

**Distribution:** These same authors demonstrated advancing differentiation of mesenchymal cells via fibroblasts to myofibroblasts (1) from early to later stages of pregnancy, (2) from mesenchymal to stem villi, and (3) from the subtrophoblastic stromal layer to the perivascular stroma (Fig. 6.26). In immature intermediate and stem villi, all stages of differentiation arranged from the

FIGURE 6.26. Representation of stromal differentiation in a stem villus, illustrating the usual differentiation route of villous stromal cells from proliferating mesenchymal precursors to myofibroblasts. A thin subtrophoblastic layer of proliferating mesenchymal cells (V cells) represent the stem cells for the entire extravascular stroma. By proliferation, these cells generate new peripheral layers of stroma and thus contribute to the

growing thickness of the villus. More centrally, older and higher differentiated layers of connective tissue cells can be found. V, vimentin; D, desmin; A,  $\alpha$ -smooth muscle actin; G,  $\gamma$ -smooth muscle actin; M, smooth muscle myosin. At the bottom, the occurrence of the same stromal cells in other villous types is summarized. (Source: Modified from Kohnen et al., 1996, with permission.)

periphery to the center can be observed. The most peripheral, proliferating cells express only vimentin. Slightly more centrally, a layer of cells with the typical shape of fibroblasts, expressing vimentin,  $\alpha$ -smooth muscle actin, and desmin, follows. Near the larger vessels, typical myofibroblasts can be seen that express the full range of cytoskeletal antigens and closely resemble smooth muscle cells. The existence of this centripetal differentiation gradient was supported by Kacemi et al. (1999) using a similar panel of immunohistochemical markers.

**Function:** In contrast to the vascular smooth muscle cells of the central villous stem vessels, the surrounding myofibroblasts are arranged parallel to the longitudinal axis of the villi (Demir et al., 1997). In large stem villi they form a clearly defined perivascular contractile sheath that has been discussed in detail by Graf et al. (1994, 1995). It has been suggested that the contraction of extravascular contractile cells is important for the turgor of the villi (Krantz & Parker, 1963; Graf et al., 1995). Moreover, contraction of longitudinally arranged myofibroblasts within anchoring villi may influence the length of anchoring villi and the width of the intervillous space, thus regulating maternal intravillous blood pressure (Kohnen et al., 1996; Demir et al., 1997). Recently, Farley et al. (2004) have supported this hypothesis. They showed that treatment of isolated anchoring villi with KCl and l-NAME resulted in longitudinal contraction up to 62% and 74%, respectively, over resting tone. Some of the myofibroblasts are positive for nitric oxide synthase (NOS) (Schönfelder et al., 1993), an enzyme that is involved in production of nitric oxide, a potent vasodilator; NOS inhibition in guinea pigs and rats has been shown to result in preeclamptic symptoms, including intrauterine growth retardation (Yallampalli & Garfield, 1993; Chwalisz et al., 1994; Garfield et al., 1994).

Several authors have described immunoreactivities for cytokeratins 6, 8, 17, 18, and 19 in contractile cells (myocytes and myofibroblasts) of placental and embryonic origin (Kasper et al., 1988; Bozhok et al., 1990; Nanaev et al., 1997; Haigh et al., 1999). According to our experience, such cells are particularly frequent in and around vessel walls of large-caliber villi. It is still an open question whether or not all contractile stromal cells coexpress these cytokeratin isoforms, or whether an additional subpopulation of cytokeratin-expressing stromal cells hides among the contractile cells in and around the stem vessels (Haigh et al., 1999). In any case, special care is advisable when using cytokeratin antibodies as a marker for the trophoblastic origin of cells isolated from placental villi.

## Matrix Components of the Villous Stroma

Database mining revealed 102 extracellular matrix genes among about 10,000 mRNA species expressed in the human placenta (Chen & Aplin, 2003). Out of these, 23 coded for collagens, 59 for noncollagenous glycoproteins, and 23 for proteoglycans.

**Extracellular matrix proteins** represent the prevailing matrix molecules. Different types of collagens have been identified in the core of the placental villi by immunohistochemistry, for example, collagen I, III, IV, and VI (Amenta et al., 1986; Autio-Harmainen et al., 1991; Nanaev et al., 1991; Rukosuev, 1992; Castellucci et al., 1993a,b; Frank et al., 1994). In addition, some fibronectin isoforms, tenascin C, fibrillin I, and thrombospondin I, have been detected in the villous stroma (Pfister et al., 1988; Virtanen et al., 1988; Earl et al., 1990; Autio-Harmainen et al., 1991; Castellucci et al., 1991, 1993a,b; Rukosuev, 1992; Frank et al., 1994; Mühlhauser et al., 1996; Chen & Aplin, 2003).

In human placental villi, different from most other organs, molecules such as laminin, collagen IV, and heparan sulfate are not restricted to the basement membranes but are also present throughout the villous stroma or at least in specialized areas of the latter (Yamada et al., 1987; Nanaev et al., 1991; Rukosuev, 1992; Mühlhauser et al., 1996; Chen & Aplin, 2003). The universal presence of these molecules in the extracellular matrix may facilitate remodeling of basement membranes and thus increase morphogenetic and functional flexibility of the various villous cell populations.

**Ultrastructural data** concerning reticular (precollagen) and collagen fibers have been reported (Enders & King, 1970; Vacek, 1970; Kaufmann et al., 1977b). Precollagen or reticular fibers have a diameter of 5 nm or less. They form seemingly unoriented meshworks without predominant fiber direction. In mesenchymal connective tissue, they are the prevailing fiber type.

The thicker collagen fibers have diameters of 20 to 60 nm. They show the typical 64.9-nm cross-striation. Usually, grouped in twisted bundles of about 100 parallel fibers, they are arranged as a coarse meshwork, running in spiral courses around the fetal vessels (Kaufmann et al., 1977b). The amount of collagenous fibers increases from mesenchymal stroma, via reticular sinusoidal to fibrous stroma (see Figs. 7.3C and 7.7D). Histologically, collagen fibers stain with the usual connective tissue stains and reticular fibers do not.

**Proteoglycans** are less well studied. Decorin, a small leucine-rich proteoglycan that seems to have a primary function in the organization of the extracellular matrix (Hardingham & Fosang, 1992), has also been detected in the villous stroma (Bianco et al., 1990). Interestingly, the core protein of decorin (whose synthesis is induced by TGF- $\beta$ ) binds and neutralizes TGF- $\beta$  (Yamaguchi et al., 1990).

Hyaluronan is a high molecular mass polysaccharide that plays a particular role in developmental processes involving cell motility (for review, see Marziani et al., 2001). In accordance with this view, hyaluronan expression is particularly impressive in newly developing villi

(so-called mesenchymal villi, cf. Chapter 7). By contrast, fully developed villi in early stages of pregnancy and all villi in later pregnancy are characterized by moderate hyaluronan content (Marzioni et al., 2001). Interestingly, CD44, the hyaluronan receptor of cells exposed to the extracellular matrix of the villous stroma, shows increasing activity throughout pregnancy (Marzioni et al., 2001).

**Matrix-degrading proteolytic enzymes** (matrix metalloproteinases) are likely to be involved in remodeling of the villous stroma during placental development. It has been shown that the trophoblast expresses interstitial and type IV collagenolytic activities (Emonard et al., 1990; Moll & Lane, 1990; Librach et al., 1991), and the former has been detected in villous fibroblasts (Moll & Lane, 1990). Autio-Harmainen et al. (1992) detected 70-kd type IV collagenase in endothelial cells and fibroblasts of the villi. Moreover, the exclusive expression of tissue inhibitors of matrix metalloproteinases in the stroma of mesenchymal villi, just those villous types that are most active in villous sprouting and branching, points to the importance of matrix turnover for villous development.

Stromal fibrosis and thickening of basal laminas are considered typical features in many pregnancy pathologies and are often referred to as consequence of hypoxic or ischemic conditions. For review, see Fox (1997). Based on his own experience, Fox, however, has refuted this hypothesis and arrived at the conclusion that oxygen supply that is better than normal increases villous fibrosis (e.g., following intrauterine fetal death). Recent in vitro culture data by Chen and Aplin (2003) suggest a more differentiated reaction pattern that well may explain the above-mentioned discrepancies in the literature. Expression of fibronectins and collagen IV is more strongly upregulated by hypoxia than is expression of collagen I, fibrillin I, and thrombospondin I, whereas expression of laminins and elastin under hypoxia was extremely low.

There is increasing use of extracellular matrix molecules for in vitro studies of the trophoblast. Such molecules influence trophoblast differentiation (Kao et al., 1988; Nelson et al., 1990); they can play a pivotal role in repair mechanisms (Nelson et al., 1990), may participate in modulating hormone and protein production (Castellucci et al., 1990a), and can influence the morphology and proteolytic activity of the trophoblast (Kliman & Feinberg, 1990; Bischof et al., 1991).

## Hofbauer Cells (Villous Macrophages)

It is generally agreed that Hofbauer cells are fetal tissue macrophages of the human placenta. Statements concerning their macrophage character are based on morphologic, cytochemical, histochemical, immunologic, and

immunohistochemical studies (for reviews, see Bourne, 1962; Boyd & Hamilton, 1970; Castellucci & Zaccheo, 1989; Castellucci et al., 1990b; Vince & Johnson, 1996). Here, we review the main aspects of these cells.

## First Descriptions

From the middle of the 19th century, several authors have reported the presence of large cells in the stroma of chorionic villi of the human placenta (Müller, 1847; Schroeder van der Kolk, 1851; Virchow, 1863, 1871; Langhans, 1877; Merttens, 1894; Ulesko-Stroganova, 1896; Marchand, 1898). Kastschenko (1885) first described their precise location in the villous stroma. Virchow (1871), and later Chaletzky (1891) and Neumann (1897), first commented on the particular association of hydatidiform mole with large isolated cells, having clear cytoplasm. This observation led to the term **Chaletzky-Neumann cells**, used in the past by several pathologists. Hofbauer, whose name has come to be associated with these cells, gave a comprehensive description of the cells in normal villi at the beginning of the 20th century (1903, 1905). It is because of these detailed morphologic studies and because of the long-lasting uncertainties about the macrophage nature of these cells that the term **Hofbauer cell** has been widely accepted in the literature.

## Morphology

Hofbauer cells were described as frequent, pleomorphic cells of the villous stroma (Fig. 6.28) with round, fusiform, or stellate appearance (Langhans, 1877; Hofbauer, 1903, 1905; Schmidt, 1956; for a review, see Bourne, 1962). Their size depends on the length of their processes. The cells vary from 10 to 30 µm in diameter. Early investigations had already pointed out that the most striking aspects of the Hofbauer cells are their highly vacuolated appearance and their granulated cytoplasm (Virchow, 1863, 1871; Langhans, 1877; Minot, 1889; Merttens, 1894; Hofbauer, 1903, 1905; Graf Spee, 1915; Meyer, 1919; Lewis, 1924). Later studies have pointed out that these cells are characterized by numerous membrane-bound, electron-lucent vacuoles of different sizes, possessing amorphous material of varying density, dense granules (presumably lysosomes), and short profiles of endoplasmic reticulum (Fig. 6.28A,B; see Fig. 7.7B,D) (Hörmann, 1947; Boyd & Hughes, 1955; Rodway & Marsh, 1956; Geller, 1957; Bargmann & Knoop, 1959; Rhodin & Terzakis, 1962; Panigel & Anh, 1964; Boyd & Hamilton, 1967; Fox, 1967a, 1997; Wynn, 1967a,b, 1973, 1975; Enders & King, 1970; Tedde, 1970; Vacek, 1970; Demir & Erben, 1984; King, 1987; Katabuchi et al., 1989; for reviews, see Snoeck, 1958; Bourne, 1962; Boyd & Hamilton, 1970; Castellucci & Zaccheo, 1989).

Different phenotypes of Hofbauer cells have been described (Fig. 6.27):

- Enders and King (1970) pointed out that **vacuolated Hofbauer cells** showing large intracytoplasmic vacuoles, containing varying amounts of flocculent precipitate, are numerous, and large during the first half of pregnancy (Fig. 6.28A,B; see Fig. 7.7B).
- As pregnancy progresses, the vacuoles decrease in number and size, and the Hofbauer cells show an increase of intracytoplasmic granules (Figs. 7.7D and 7.11) that are presumably lysosomes (Enders & King, 1970; Castellucci et al., 1980). This **granulated type of Hofbauer cell** can easily be differentiated from the rare mast cells (Fig. 6.28C) because of the metachromasia of the latter.
- **Hofbauer cells largely lacking vacuoles and granules** are present during early pregnancy and have been considered immature Hofbauer cells (Castellucci et al., 1987; Katabuchi et al., 1989). Immunohistochemical studies using macrophage markers, however, have revealed many such undifferentiated Hofbauer cells also in all mature placental villi. This finding is in agree-

ment with immunologic investigations, which consider the vacuolated Hofbauer cells to be the morphologically obvious and fully differentiated member of a much larger mononuclear phagocyte population (Wood, 1980; Frauli & Ludwig, 1987a).

The first three-dimensional visualization of Hofbauer cells, their intracytoplasmic vacuoles, surface aspects, and relationship with other components of the villous core (see Fig. 7.7C) was made possible by combining the cryofracture method with scanning electron microscopy (SEM) (Castellucci et al., 1980; Martinoli et al., 1984). The surface morphology of Hofbauer cells was found to be characterized by spherical or elongated blebs or microplicae (see Fig. 7.7C). These features were irregularly distributed. Other Hofbauer cells showed a ruffled surface, characterized by lamellipodia, which were large, smooth surfaced, and well developed. They sometimes overlapped one another, creating cups or funnel-like structures. Sometimes, Hofbauer cells bearing both lamellipodia and blebs were observed (Castellucci et al., 1980, 1984; Martinoli et al., 1984).

In addition, SEM of chorionic villous stroma during the first half of pregnancy revealed that most of the Hofbauer cells were inside collagen-free intercommunicating stromal channels (see Fig. 7.7C) composed of large sail-like processes of fixed stromal cells (Castellucci et al., 1980, 1984; Castellucci & Kaufmann, 1982a). These channels were particularly well developed in the central region of the core of the chorionic villi and were oriented mostly parallel to the major axis of the villus. Some Hofbauer cells inside the channels had an elongated shape and extended their cellular bodies between intercommunicating channels or between channels and intercellular substance outside the channels (Castellucci et al., 1980, 1984). These morphologic features strongly suggest motility of Hofbauer cells in the villous core.

The channels characterized most of the chorionic villi of the first half of pregnancy (Fig. 6.28A,B; see Fig. 7.7B,C). Toward term, their number was decreased. In the mature placenta, they were found only in villi at the center of the placentones (Fig. 7.7D) (Schuhmann, 1981; Castellucci & Kaufmann, 1982a,b; Castellucci et al., 1990c). During the last trimester of gestation, Hofbauer cells present in villi outside the placentone centers, that is, villi characterized by a core with large amounts of collagen fibers and narrow or absent channels, showed mostly blebs or microplicae at their surface, but rarely lamellipodia (Fig. 6.24; see Fig. 7.11) (Castellucci & Kaufmann, 1982a; Martinoli et al., 1984).

The morphologic features provided the basis for the first functional interpretations:

- The intracytoplasmic vacuoles and large lamellipodia of the Hofbauer cells have been considered **phagocytic**

FIGURE 6.27. Cross section of a transitional stage from mesenchymal to immature intermediate villus at the end of the first trimester immunostained with the antibody leu-M3 (anti-CD14), a marker of macrophages. Both the distribution pattern of immunoreactivities and the gradually increasing staining intensities from fibroblast-like phenotypes to macrophage-like phenotypes suggest that fibroblast-like stromal cells may achieve macrophage character.  $\times 170$ .

FIGURE 6.28. A: Transmission electron micrograph: sail-like cytoplasmic processes (arrows) of the small reticulum cells line channel-like stromal cavities within immature intermediate villi. They are filled with some fluid, but are devoid of connective tissue fibers. The latter can only be found in the vicinity of the channels. Suspended in the fluid of the channels, one finds the macrophages (Hofbauer cells, H).  $\times 5300$ . B: Light microscopic, semithin section of reticular stroma of an immature intermediate villus from the 12th week p.m., showing two Hofbauer cells. Both are located in longitudinally sectioned stromal channels, delimited by long, thin cytoplasmic extensions of fixed stromal cells. The left Hofbauer cell belongs to the highly vacuolated type that prevails in early pregnancy. The right cell shows fewer vacuoles and is characterized by its rounded appearance and by numerous bleb-like protrusions on its surface. This cell is in mitosis.  $\times 1000$ . C: Transmission electron micrograph. As a second type of free connective tissue cells, mast cells are observed in villous tissues. Their prevailing location is in the vicinity of larger fetal vessels of stem villi. This cell type is easily identified by its typical secretory granules.  $\times 16,000$ .

**cells** involved in the reduction of fetal serum proteins contained in the villous stroma and in the water balance of the early placenta. This function is also likely because the placenta lacks a lymphatic system to return proteins from the interstitial space to the blood vascular system (Enders & King, 1970). Closely related to these concepts is the presence of stromal channels that could allow relatively easy movement of Hofbauer cells along the villous cores of chorionic villi and thus function as a substitute for the lymphatic system (Enders & King, 1970; Castellucci & Kaufmann, 1982a). It must be considered, however, that the motility of Hofbauer cells is hindered, at least in part, in the villi during the last trimester. Here, the stromal channels are mostly narrow or absent (see Figs. 6.24 and 7.11). It is therefore conceivable that the Hofbauer cells assume additional tasks in these villi (Martinoli et al., 1984).

- Moreover, the motility of Hofbauer cells inside the stromal channels might allow these macrophages to exert their role in maintaining **host defense** (Castellucci et al., 1980; Wood, 1980).
- Last but not least, Hofbauer cells are thought to control villous development by (1) remodeling of the villous core by stimulating or inhibiting the proliferation of other mesenchymal cells (Castellucci et al., 1980; Martinoli et al., 1984; King, 1987), (2) controlling villous angiogenesis by secreting angiogenetic cytokines (see Chapter 7), and (3) controlling trophoblast turnover by inducing trophoblast apoptosis and syncytial fusion (see earlier in this chapter).
- Several authors have speculated on questionable endocrine activities of Hofbauer cells (Acconci, 1925; Pescetto, 1952; Rodway & Marsh, 1956). Prosdocimi (1953) suggested hCG synthesis by these cells, and

we detected hCG immunohistochemically within Hofbauer cells (Kaufmann & Stark, 1973); however, it was unlikely that this glycoprotein was synthesized in the cells but, rather, that it was phagocytosed from the surrounding environment. Still, the regular presence of hCG proves to be a useful marker for villous macrophages (Frauli & Ludwig, 1987b); on the other hand, phagocytic activity must be considered when interpreting immunohistochemical findings concerning the presence of proteins in these macrophages, such as hormones and placental proteins.

## Occurrence and Distribution

Some initial reports of Hofbauer cells described them to be present in villi that had undergone hydatid degeneration (Virchow, 1871; Chaletzky, 1891; Neumann, 1897); however, for 100 years it has been established that these cells are present in both normal and pathologic conditions (Hofbauer, 1903, 1905, 1925; Graf Spee, 1915; Lewis, 1924; for reviews, see Bourne, 1962; Boyd & Hamilton, 1970; Becker & Röckelein, 1989; Fox, 1997).

Hofbauer cells are first seen in placental villi on day 18 p.c. (Boyd & Hamilton, 1970). In normal pregnancies, they are always present in the villi of immature placentas (Fig. 7.7B,C). It has been claimed that, in placentas from uncomplicated pregnancies, Hofbauer cells either disappear or become scanty after the 4th to 5th month of gestation (see Fox, 1967a, 1997). Geller (1957), Bleyl (1962), Fox (1967a), and several electron microscopy studies have demonstrated, however, that Hofbauer cells are present until term, and not only in immature villi of the center of the placenta (compare Figs. 7.7D and 7.11). The apparent reduction in number as pregnancy progresses occurs because they are compressed and masked by the condensation of the villous stroma (see Fig. 7.11) during placental maturation (Fox, 1967a). This view is supported by Bleyl (1962), who found many Hofbauer cells in villi in which edema is produced by postpartum saline perfusion through the umbilical artery. In normal term placentas, Hofbauer cells can easily be recognized by structural means only in immature intermediate villi. Immunohistochemistry using macrophage markers, however, reveals that a high percentage if not the majority of stromal cells in term placental villi has macrophage character (Fig. 6.28) and thus belongs to the Hofbauer cells.

They are more easily identifiable in many cases of pregnancy pathologies, for example, in placentas from delayed villous maturation, in prematurely delivered placentas, and in cases of maternal diabetes (Horky, 1964; Fox, 1967a, 1997), as well as in rhesus incompatibility (Hörmann, 1947; Thomsen & Berle, 1960; De Cecco et al., 1963; for review, see Fox, 1997). Fox (1967a, 1997) emphasized that villous edema, occurring in the two latter

pathologic conditions by the distention of the villous stroma, can unmask numerous Hofbauer cells.

Hofbauer cells have also been described in placental membranes, in both amnion and chorion laeve (Meyer, 1919; Bautzmann & Schröder, 1955; Schmidt, 1956; Bourne, 1962; for review, see Boyd & Hamilton, 1970).

## Origin

The origin of Hofbauer cells has received much attention, starting with the first descriptions (for historical details and reviews, see Geller, 1957; Snoeck, 1958; Bourne, 1962; Wynn, 1967a; Boyd & Hamilton, 1970; Vacek, 1970; Schiebler & Kaufmann, 1981). Numerous theories have been abandoned. These include those proposed by Chaletzky (1891), who derived them from cells of maternal decidua; those by Neumann (1897), who considered them to be derivatives of the syncytium and an expression of malignancy; and those by ten Berge (1922), who supposed them to be derivatives of endothelial cells.

An important finding concerning the origin of Hofbauer cells was Wynn's (1967b) observation, based on sex chromatin staining, that these are fetal cells. This allows different interpretations:

- Most authors now consider Hofbauer cells to be of chorionic mesenchymal origin. That means that these cells gradually differentiate from the fixed stromal cells of the villous core (Fox, 1967a; Wynn, 1967a; Vacek, 1970; Kaufmann et al., 1977b). Morphologic investigations originally have questioned this concept (Martinoli et al., 1984; King, 1987) because no transitional forms between the two cell types have been clearly recognized. There are, however, some observations in the placenta (Demir et al., 1989) and on macrophages in other organs (Sorokin and Hoyt, 1987, 1992; Naito et al., 1989; Mebius et al., 1991; Sorokin et al., 1992a,b), that require one to consider this concept honestly. Hofbauer cells very likely originate from mesenchymal cells during the early stages of pregnancy, before the fetal circulation is established (see Chapter 7, Fig. 7.22).
- Later, once fetal circulation is established, the Hofbauer cells may additionally originate from fetal bone marrow-derived monocytes, as macrophages in other organs do (van Furth, 1982; Castellucci et al., 1987). Indeed, Moskalewski et al. (1975) observed transitional forms between Hofbauer cells and monocytes. Concerning this hypothesis, it must be emphasized that human cord blood contains almost three times as many monocytes at the end of pregnancy as does adult blood (Khansari & Fudenberg, 1984; Santiago-Schwarz & Fleit, 1988). These monocytes show subpopulations with considerable functional heterogeneity (Khansari & Fudenberg, 1984).

- Finally, it has been proposed that Hofbauer cells may have different origins throughout gestation and that they may represent a heterogeneous group of cells (Castellucci et al., 1987). These data related to *in vivo* (Fig. 6.28B) and *in vitro* observations, stating that Hofbauer cells can undergo mitotic division (Hofbauer, 1903; Hörmann, 1947; Geller, 1957; Boyd & Hamilton, 1970; Castellucci et al., 1985, 1987; Frauli & Ludwig, 1987b). Mitosis of Hofbauer cells (Fig. 6.28B) may be important for the permanent presence of cell subpopulations with different origins and functions. In addition, the mitotic activity suggests that they may be, in part, an independent self-replicating population, allowing rapid increase in number when required by the local microenvironment (Castellucci et al., 1987).

## Immunologic Aspects

Immunologic data indicate that Hofbauer cells are numerous in the chorionic plate and in the villous stroma throughout pregnancy (Wood, 1980; Goldstein et al., 1988; Vince & Johnson, 1996). Studies on isolated Hofbauer cells, as well as immunohistochemical investigations, have provided data that have furthered our knowledge concerning the immunologic role of this cell population. Isolation of Hofbauer cells has usually employed proteolytic enzymes (Moskalewski et al., 1975; Wood et al., 1978a,b; Flynn et al., 1982; Loke et al., 1982; Frauli & Ludwig, 1987a), a combination of enzymatic digestion and density gradient centrifugation (Wilson et al., 1983; Uren & Boyle, 1985; Sutton et al., 1989). Additionally, cell separation methods, based on mechanical action with (Zaccheo et al., 1989) or without (Oliveira et al., 1986) density gradient centrifugation have been used. It has been demonstrated that Hofbauer cells possess Fc receptors for immunoglobulin G (Moskalewski et al., 1975; Wood et al., 1978a,b; Wood, 1980; Johnson & Brown, 1981; Loke et al., 1982; Zaccheo et al., 1982; Uren & Boyle, 1985; Oliveira et al., 1986; Goldstein et al., 1988).

Three different subtypes of leukocyte Fc receptors (FcR) have been identified on the basis of molecular and chemical analysis as well as cloning of cDNA; FcRI (CD64), FcRII (CD32), and FcRIII (CD16) (Stengelin et al., 1988). The three subtypes are expressed on the Hofbauer cells (Goldstein et al., 1988; Kristoffersen et al., 1990; Kameda et al., 1991; Sedmak et al., 1991; Wainwright & Holmes, 1993; Bright et al., 1994), and these receptors have been postulated to serve a protective function by binding maternal antifetal antigen-antibody complexes (Wood, 1980; Johnson & Brown, 1981; Goldstein et al., 1988).

C3b receptor (CR1[CD35]) activity has been shown on isolated Hofbauer cells by only some authors (Wood, 1980; Loke et al., 1982; Oliveira et al., 1986). Others have

failed to detect C3b receptors in human placental sections using either tissue hemabsorption techniques with C3b-coated erythrocytes (Faulk et al., 1980), or monoclonal antibodies against C3b receptor (Bulmer & Johnson, 1984; Goldstein et al., 1988). By application of monoclonal antibodies on tissue sections, Goldstein et al. (1988) demonstrated that receptors for the C3bi complement component (CR3 [CD11b/CD18] and CR4 [CD11c/CD18]) are expressed by Hofbauer cells. Moreover, Hofbauer cells are capable of immune and nonimmune phagocytosis (Moskalewski et al., 1975; Wood, 1980; Loke et al., 1982; Wilson et al., 1983; Uren & Boyle, 1985; Oliveira et al., 1986; Zaccheo et al., 1989) and elimination of exogenous antigen-antibody complexes (Wood & King, 1982).

Hofbauer cells also show strong immunostaining for the protease inhibitors  $\alpha_1$ -antitrypsin and  $\alpha_1$ -antichymotrypsin (Braunhut et al., 1984; Castellucci et al., 1994) suggesting that placental macrophages are involved in villous remodeling and differentiation (Castellucci et al., 1994). Braunhut et al. (1984) failed to demonstrate lysozyme in the cells derived from term placentas when using immunohistochemical methods. Zaccheo et al. (1989) showed that Hofbauer cells from first trimester placentas are capable of secreting lysozyme *in vitro*. It is at present not clear whether these discrepant results are due to the different techniques used or whether they reflect a functional heterogeneity in lysozyme production between Hofbauer cells from the first trimester and those at term.

Hofbauer cells have been shown to bear Toll-like receptors (TLRs) as TLR4 (Kumazaki et al., 2004). The TLRs are essential for innate immune responses. Indeed, the immune system can be broadly categorized into innate immunity and adaptive immunity. The innate immunity system provides a rapid nonspecific response that acts as the first line of defense against pathogens. Recent reports suggest that innate immune responses are activated by TLRs that recognize certain molecular patterns derived from pathogens and stimulate proinflammatory cytokine gene transcription (Aderem & Ulevitch, 2000; Akira et al., 2001). A protein family that is homologous to Toll has been identified in humans and termed TLR (Rock et al., 1998; Aderem & Ulevitch, 2000). TLR4 has been genetically identified as a mediator of lipopolysaccharide (LPS)-induced signal transduction (Poltorak et al., 1998). Effective TLR4 activation by LPS requires the interaction of LPS with CD14 (see below) and the accessory protein MD-2, which associates with surface TLR4 molecules (Akira et al., 2001). TLR can also be activated by other kinds of molecules such as heat shock proteins (Ohashi et al., 2000) and cellular fibronectin fragments (Okamura et al., 2001). Interestingly, Kumazaki et al. (2004) showed an increased expression of TLR4 in the villous Hofbauer cells of preterm chorioamnionitis,

suggesting an important role of the villous Hofbauer cells in the activation of innate immune responses.

It has been established that Hofbauer cells can express class I and II major histocompatibility complex (MHC) determinants (Bulmer & Johnson, 1984; Uren & Boyle, 1985; Sutton et al., 1986; Bulmer et al., 1988; Blaschitz et al., 2001). Concerning the class II MHC determinants, it is well known that they include at least three well-defined subregions: DR, DP, and DQ. First trimester Hofbauer cells are rarely DR- and DP-positive, and DQ antigens are not expressed (Bulmer & Johnson, 1984; Sutton et al., 1986; Bulmer et al., 1988; Goldstein et al., 1988; Lessin et al., 1988; Zaccheo et al., 1989). It may be important that DQ antigens, missing on first trimester cells, are restriction elements for T-cell clones (Thorsby, 1984) and have been implicated in the generation of cytotoxic cells (Corte et al., 1982). Class II MHC antigens are acquired by increasing numbers of placental macrophages from the second trimester on (Edwards et al., 1985; Sutton et al., 1986; Bulmer et al., 1988; Goldstein et al., 1988; Lessin et al., 1988; for a review, see Vince and Johnson, 1996). In term placental tissues, DR-positive villous stromal macrophages are often observed within groups of closely associated chorionic villi (Bulmer & Johnson, 1984; Bulmer et al., 1988). On the other hand, DP and DQ antigens are detected on a small number of Hofbauer cells, mostly located in villi immediately adjacent to the basal plate (Bulmer et al., 1988). In addition, such DP or DQ antigens are not detected in the absence of DR antigens on any placental macrophage (Bulmer et al., 1988). The patchy expression of class II MHC antigens in chorionic villi and the accumulation of DR-, DP-, and DQ-positive cells at the villous decidual junction may indicate areas of enhanced immune stimulation. Although clear evidence is still lacking, these data, and particularly the increasing expression of DR antigens as gestation proceeds, may represent acquisition of antigen-presenting capacity by the Hofbauer cells to fetal lymphocytes. This point may be relevant for fetal responses to transplacental infection.

Goldstein et al. (1988), Nakamura & Ohta (1990), and Lairmore et al. (1993) have shown that Hofbauer cells react strongly with antibodies to the CD4 antigen throughout gestation. This cell-surface glycoprotein is thought to interact with nonpolymorphic determinants of class II MHC molecules (Lamarre et al., 1989). The antigen is present on the T-helper subset of lymphocytes and has been shown to be expressed weakly by blood monocytes, some tissue macrophages, and dendritic cells (Wood et al., 1983, 1985; Buckley et al., 1987). It also functions as the membrane "receptor" for infection of cells by the human immunodeficiency virus (HIV). Lewis et al. (1990) have identified HIV-1 antigen and nucleic acid by immunohistochemical and in situ hybridization techniques in Hofbauer cells of placentas from seropositive patients.

This result has been confirmed in studies of HIV infection of cultured human placental cells where double labeling has demonstrated that the HIV-positive cells are macrophages and not trophoblast (McGann et al., 1994). Thus, the Hofbauer cells could serve as the portal of entry or reservoir for HIV in fetuses of HIV-positive women (Lairmore et al., 1993). The CD4 antigen seems not to be expressed on the surfaces of syncytiotrophoblast (Cuthbert et al., 1992).

One of the most consistent immunohistologic markers of Hofbauer cells throughout gestation is the monoclonal antibody leu-M3 (Fig. 6.27) (Bulmer & Johnson, 1984; Zaccheo et al., 1989). This antibody detects the CD14 monocyte differentiation antigen (Goyert et al., 1986), which is a 55-kd glycoprotein, expressed primarily by monocytes and macrophages (Goyert et al., 1988); it is anchored to the cell membrane by a phosphatidylinositol linkage (Haziot et al., 1988). Its restricted expression on mature cells suggests an important effector function (Goyert et al., 1988). In addition, it has been shown that the gene encoding CD14 is located in a region of chromosome 5 (Goyert et al., 1988) known to encode several growth factors or receptors, including interleukin-3 (IL-3), granulocyte-macrophage colony-stimulating factor (GM-CSF), CSF-1, CSF-1 receptor, and the platelet-derived growth factor receptor. Thus, it has been suggested that the CD14 antigen may also serve as some type of growth factor receptor (Goyert et al., 1988; Ziegler-Heitbrock, 1989), which could be involved in the regulation of the activity of the Hofbauer cells related to the process of villous morphogenesis (Castellucci et al., 1980; Martinoli et al., 1984; King, 1987). CD14 has been found to bind complexes of LPS and LPS-binding protein (Wright et al., 1990). These data suggest that CD14 could play an important role in infections. Some but not all studies have shown that Hofbauer cells express the leukocyte marker CD1 (as recognized by the monoclonal antibody NA1/34), the expression of which is reduced as gestation progresses (Bulmer & Johnson, 1984; Sutton et al., 1986; Goldstein et al., 1988; for a review, see Vince & Johnson, 1996).

Type I interferons (IFN- $\alpha$ , IFN- $\beta$ ) are molecules with multiple biologic activities (reviewed by Russel & Pace, 1987); IFN- $\alpha$  has been found (by immunohistochemical methods) in Hofbauer cells (Howatson et al., 1988; Bulmer et al., 1990); IFN- $\beta$  has been demonstrated to be produced by isolated Hofbauer cells, particularly in large amounts after priming (Toth et al., 1991). Thus, in vivo the interferon produced by the trophoblast (Toth et al., 1990) could prime placental macrophages and induce these cells to secrete large amounts of interferon. Type I interferons may play important roles in the protection of the fetus against intrauterine infection, in several differentiation processes, and can interact with interferon- $\gamma$  and other cytokines (Wang et al., 1981;

Taylor-Papadimitriou & Rozengurt, 1985; Hunt, 1989; Toth et al., 1991).

Flynn et al. (1982, 1985), and Glover et al. (1987) showed that placental villous macrophages produce IL-1. Because the antigen presentation correlates with class II antigen expression and IL-1 secretion, the authors suggested that fetal placental macrophages function nearly as efficiently as adult cells for antigen presentation (Glover et al., 1987), which could present a hazard for maintenance of the fetal allograft. They hypothesized that competence for tissue-specific factors or other mediators (Glover et al., 1987) may regulate antigen presentation. In support of this idea is the study by Yagel et al. (1987), which showed that physiologic concentrations of progesterone induced a significant increase in fetal placental macrophage prostaglandin E<sub>2</sub>, a potent immunosuppressant. This finding suggested a functional role for fetal placental macrophages in immunosuppression at the fetomaternal surface. Isolated Hofbauer cells consistently demonstrated inhibition or suppression of both mixed lymphocyte reaction (MLR) and cell-mediated lympholysis (CML) (Uren & Boyle, 1990). Therefore, Hofbauer cells may in fact exert a sentinel function that would prevent strong, destructive maternal T-cell responses against the fetus. These data are also in agreement with the observation of Mues et al. (1989), who detected a large number of Hofbauer cells positive for the monoclonal antibody RM3/1. This antibody recognizes an antigen that is strongly induced by dexamethasone, but downregulated by interferon- $\gamma$ , LPS, and triphorbolacetate on in vitro cultured monocytes. In vivo, RM3/1 macrophage populations are the predominant cells in liver and heart allografts from patients receiving a high-dose corticosteroid medication (Mues et al., 1989). The dominance of a corticosteroid-induced antiinflammatory macrophage phenotype within the placental villous core suggests localized immunosuppression, and it is probably related to the fact that cortisone is a prominent steroid in the human placenta (Murphy, 1979). In this context the observation of Moussa et al. (2001) showing that Hofbauer cells produce a classical chemokine, the macrophage inflammatory protein 1 (MIP1) beta is intriguing.

Interleukin-1 is a well-known stimulus for T-lymphocyte IL-2 production, and therefore placental macrophage-derived IL-1 may stimulate the expression of IL-2 by placental components. Indeed, Boehm et al. (1989b) pointed out that the IL-2 gene is expressed in the syncytiotrophoblast of the human placenta. Interleukin-2 is an important regulator of immune function. If it is produced by the syncytiotrophoblast it would most certainly play a major role in any scheme of immune interaction(s) postulated to exist between the mother and the fetoplacental graft.

Other macrophage cytokines of special interest for villous cell biology are TNF- $\alpha$  and TGF- $\beta$ ; TGF- $\beta$  and

TGF- $\beta$  mRNA have been isolated from the human placenta (Frolik et al., 1983). This growth factor is a multifunctional peptide involved in immunosuppressive activities and, depending on the cell type, in stimulation or inhibition of cell growth (Miller et al., 1990; Sporn & Roberts, 1990). Concerning the human placenta, Morrish et al. (1991) have shown that it acts as a major inhibitor of trophoblast differentiation and concomitant peptide secretion. Tumor necrosis factor- $\alpha$  binding to its p55 receptor, which is expressed by villous cytotrophoblast, induces trophoblast apoptosis in vitro (Yui et al., 1996). This finding is in agreement with other data that showed that villous trophoblastic apoptosis is started already on the cellular level (Huppertz et al., 1998; for review see Huppertz 2001, 2003).

### Other Free Connective Tissue Cells

Most free connective tissue cells of the human placental villi have been identified to be macrophages. There are a few cells, however, without macrophage character, among which are mast cells and plasma cells. Pescetto (1950), Latta and Beber (1953), Mahnke and Jacob (1972), and Durst-Zivkovic (1973) have reported the structural peculiarities of mast cells (Fig. 6.28C). According to these reports, the cells are found mainly in the walls of the large fetal blood vessels of stem villi. Structurally, they correspond to mast cells of other origin. The same is true for plasma cells, the occasional appearance of which in the stroma of stem villi of immature placentas has been reported by Benirschke and Bourne (1958); it is often seen in various types of chronic villitis.

## Basic Structure of the Vessel Walls

The fetal placental vessels vary little from the vessels of other organs. Only some peculiarities, which may be considered placenta-specific, shall be listed below (for details, see Kaufmann & Miller, 1988).

### Fetal Capillaries

The endothelial cells of capillaries and sinusoids are arranged as a monolayer (Fig. 6.29). During the last trimester, they rest on a basal lamina. The cells are connected to each other by intercellular junctions. Although the rat and mouse placentas display a fenestrated endothelium (Metz et al., 1976; Heinrich et al., 1977), a continuous endothelium is found in the human, guinea pig, and rabbit placenta (Becker & Seifert, 1965; Heinrich et al., 1976, 1977; Kaufmann et al., 1982; Orgnero de Gaisan et al., 1985). Whether it is valid for all segments—from the arterial beginning to the venous end of the long capil-

lary loops—of both the perivascular capillaries and the terminal capillary bed is unresolved. In the human, two types of endothelial cells have been described that differ ultrastructurally (Nikolov & Schiebler, 1973, 1981; Heinrich et al., 1976). Normally, these cell types can be found in the same capillary cross section (Fig. 6.29C). Also, the lectin-binding patterns point to a considerable heterogeneity of the fetal villous endothelium (Lang et al., 1993a, 1994a,b).

The lateral intercellular spaces that separate the single endothelial cells are bridged by intercellular junctions (Fig. 6.29C), which serve as mechanical links between apposed cells and as gates that limit permeability for the paracellular transfer route. In the human placental capillaries and sinusoids, most of these junctions according to their structural features are tight junctions (zonulae occludentes) (Heinrich et al., 1988; Firth & Leach, 1996, 1997; Leach & Firth, 1997). They are known to limit paracellular transfer along the intercellular clefts to molecules of a molecular weight of about 40,000 daltons (molecular diameter about 6 nm) or less. Because of this, the transendothelial transport of immunoglobulin G takes place via plasmalemmal vesicles (Leach et al., 1989). As a second parameter, the molecular charge influences the permeability: This molecular size is valid for cationic probes, whereas anionic molecules of even smaller size may not pass (Firth et al., 1988).

Interestingly, the tight junction molecule occludin was not found in capillaries of peripheral villous exchange vessels but rather within the endothelium of villous stem vessels (Leach et al., 2000). By contrast, the same authors found the tight junction molecule ZO-1 throughout the endothelium of all types of villous vessels. Occludin is not necessarily involved in the permeability features of tight junctions but may be important for their mechanical features. Therefore, this differential expression pattern may simply point to increased plasticity of capillaries and sinusoids in the periphery of villous trees where full functional activity and continuous expansion of the exchange surfaces are required simultaneously.

There exist some hints that the transplacental traffic of smaller molecules is influenced by the capillary endothelium. Mühlhauser et al. (1994) found immunoreactivity of carbonic anhydrase isoenzymes I and II in fetal villous endothelium, which suggests that the capillaries are actively involved in fetomaternal bicarbonate transfer and thus in carbon dioxide removal and fetal pH regulation. During the second and third trimesters, the human villous endothelium acquires insulin receptors that were present in the first trimester only at the intervillous surface of the syncytiotrophoblast (Jones et al., 1993; Desoye et al., 1994, 1997). It is still an open question whether the endothelial receptors bind fetal insulin to regulate maternofetal glucose transfer. Another explanation would be that fetal insulin acts as a growth factor regulating endothelial proliferation and villous angiogenesis according to the fetal demands.

To provide experimental access to fetal villous endothelium and to assess potential organ-specific differences as compared to other systemic endothelium, attempts were made to isolate villous endothelial cells. Lang et al. (1993b, 2001) and Leach et al. (1993, 1994) have developed respective isolation protocols that partly allow differential isolation of villous macro- and microvascular endothelium.

## Large Fetal Vessels

The composition of arterial and venous walls of the stem villi largely corresponds to that of the vessels of the chorionic plate and of the umbilical cord (see Chapter 12). In both vessel types, elastic membranes are largely absent. The muscular coats are thinner, and the muscle cells are more dispersed than in corresponding arteries and veins of other organs (Fig. 7.3A).

Nikolov and Schiebler (1973) described numerous myoendothelial contacts. Extensions of smooth muscle cells, as well as of endothelial cells, pass through gaps in the basal lamina into the neighboring layer, where they establish intense intercellular contacts. The attached parts of either cell type are characterized by increased amounts of plasmalemmal vesicles. Nikolov and Schiebler have interpreted this as a “musculoendothelial system” that may have importance for an autonomous, local vasoregulation. Such local regulatory mechanisms of fetal intravillous blood flow must exist, as nerves are absent in the fetoplacental vessel system.

In conventional histologic sections, the arteries and arterioles are often characterized by inappropriately preserved endothelium. It mostly appears to be columnar and the hydropic endothelial cell bodies partly obstruct the lumens. Moreover, deep herniation of muscle cells through gaps in the basal lamina, between or into the endothelial cells, is a usual finding. Such features have been interpreted as results of pathologic processes such as in placentas of HIV-infected mothers (Jimenez et al., 1988). Röckelein and Hey (1985; Hey & Röckelein, 1989) opposed this interpretation. They found endothelial hydrops and myoendothelial herniation to be the results of delayed immersion fixation. It could have been avoided by perfusion fixation of the fetal vascular system. We have shown wide vascular lumina, surrounded by flat endothelium, in large vessels following fetal or maternal perfusion fixation (Fig. 7.3A,B; compare these with the occluded arteriole in the lower right of Fig. 7.7B, obtained from an immersion-fixed specimen).

These considerations do not rule out the possibility that in vivo constrictions or occlusions of the major fetal arteries and arterioles may occur and influence fetal hemodynamics of the placenta. Ample evidence exists that they occur frequently. These findings have achieved major importance in the interpretation of Doppler measurements of umbilical artery flow velocity waveforms (Trudinger et al., 1985; Jimenez et al., 1988; Nessmann et al., 1988). The influence of fixation artifacts must be carefully considered when evaluating factors such as arterial lumen width, endothelial hydrops, and myoendothelial herniation.

FIGURE 6.29. Comparison of fetal capillaries in delayed versus immediately fixed terminal villi. A: Fetal capillaries with endothelial cells protrude into the lumen and compress the erythrocytes. This phenomenon is best explained by postpartal capillary collapse caused by delayed fixation. In such cases, the tight junctions (arrows) are restricted to the basal parts of the endothelial cell bodies.  $\times 10,300$ . (Source: Demir et al., 1989, with permission.) B: Distended terminal villi are characterized by a mixture of dilated fetal sinusoids with an extremely thin endothelium and neighboring smaller capillary cross sections with the same thin endothelial lining. Such pictures can usually be obtained

only from immediately fixed specimens obtained at cesarean section. Even in this well-preserved specimen, angular shapes of the smaller capillaries point to early capillary collapse.  $\times 2000$ . (Source: Demir et al., 1989, with permission.) C: Transmission electron micrograph of fetal vessel cross section at higher magnification demonstrates that the endothelial lining may be composed of differently structured endothelial cells. The functional meaning of this is uncertain. The darker cells, containing numerous filaments, may be contractile and may be involved in peripheral blood flow regulation. It is uncertain whether this vessel is a capillary or a small collecting venule.  $\times 18,000$ .

Note that the distribution of major fetal vessels throughout the villous trees is not homogeneous. Its density (number of vessel cross sections per surface unit of histologic section) is highest in the centers of the villous trees near the chorionic plate, where the large trunci chorii and rami chorii and their branches prevail; it is lowest in the periphery of the villous trees (placentones), where we find predominantly mature, intermediate, and terminal villi. Thus, without a careful sampling regimen, meaningful results cannot be obtained (Mayhew & Burton, 1988). The principles of sampling and tissue preservation, and of the structural heterogeneity of the organ with artifacts that bias central findings, are further explored in Chapter 28, Tables 28.6, 28.8, 28.9, and 28.10.

## Vasomotor Control

Fetal vasoactivity has been described by several authors. Mayer et al. (1959), Sakata (1960), Freese (1966), and Panigel (1968) reported fetal vessel constriction by cinematographic methods. Lemtis (1970) found experimental proof for an uneven blood supply of the various villous trees and interpreted it to result from autonomous regulation and an attempt of adaptation to changing functional demands.

Several substances have been shown to participate in the vasomotor control of the fetoplacental vessels. The most potent vasodilator is the former endothelial-derived relaxing factor (EDRF) (Pinto et al., 1991), which is identical with **nitric oxide (NO)** (Myatt et al., 1991; for review, see Macara et al., 1993). Nitric oxide is formed from the conversion of L-arginine to citrulline by NO synthase (NOS). The activity of the latter enzyme has been found in human placental homogenates (King et al., 1995). The enzyme was found histochemically [reduced nicotinamide dinucleotide phosphate (NADPH) diaphorase], and endothelial NOS (eNOS) and macrophage NOS (mNOS), respectively, have been localized immunohistochemically in the fetal endothelium (Myatt et al., 1993, 1997), villous myofibroblasts (Schönfelder et al., 1993), Hofbauer cells (Myatt et al., 1997), and the syncytiotrophoblast (Myatt et al., 1993, 1997). In cultured trophoblast cells, NOS expression changed with changes in oxygen supply (Seligman et al., 1997).

Data on **carbon monoxide-mediated vasorelaxation** in the placenta are still scarce. From the two hemoxygenases (HOs) involved in CO metabolism, Yoshiki and coworkers (2000) found HO-1 to be constitutively expressed by villous trophoblast cells, whereas HO-2 expression by fetal villous endothelium and smooth muscle cells considerably increased throughout pregnancy (Yoshiki et al., 2000). Other authors described a less differential expression pattern across syncytio- and cytotrophoblast, endothelium, and smooth muscle (McLean et al., 2000; Lash et al., 2003). In preeclampsia expression of HO-2 is locally compromised, suggesting that either vasoregulation or hemoxygenase-related defense mechanisms against oxidate stress may be compromised, too (Lash et al., 2003).

Another vasodilator is **atrial natriuretic peptide**, the receptors of which have been detected in the smooth muscle cells of placental stem vessels (Salas et al., 1991).

Finally, also **calcitonin gene-related peptide (CGRP)** seems to be involved in fetoplacental vascular relaxation. The CGRP receptor was shown to be present in villous endothelium and in the underlying smooth musculature (Dong et al., 2004). In vitro, upon CGRP administration, the same authors were able to show dose-dependent relaxation of placental stem vessels.

Concerning vasoconstrictors, **endothelin-1** has been demonstrated biochemically in the human placenta (Hemsen et al., 1991) and localized to the trophoblast and endothelial cells of villous vessels (Malassine et al., 1993; Marinoni et al., 1995). Endothelin-1 receptor sites have been demonstrated on placental vascular smooth muscle cells, particularly within stem villi (Wilkes et al., 1990; Bourgeois et al., 1997).

## Fibrinoid of the Villous Trees

Fibrinoid is a summarizing term for any acellular, eosinophilic, largely homogeneous substance in the placenta (see Fibrinoid in Chapter 9). Disseminated fibrinoid deposition in the intervillous space and the villous trees is a regular finding in every normal placenta. Excess amounts of fibrinoid deposits within and around villi may be pathologic events and are often incompatible with normal fetal outcome.

It is not surprising, then, that pathologists have classified and attempted to define the fibrinoid deposits in this area (Wilkin, 1965; Benirschke & Driscoll, 1967; Fox, 1967b, 1968, 1975; Oswald & Gerl, 1972; Becker, 1981). From an anatomical point of view, the nomenclature used by Fox (1967b, 1968, 1975) seems to be the most appropriate. He differentiated between

- **perivillous fibrin(oid)**, which surrounds more or less altered but still identifiable villi, and
- **intravillous fibrinoid** (syncytial fibrinoid, villous fibrinoid necrosis), which primarily affects the villous interior.

Although the two processes may later mix, they appear to have a different pathogenesis, at least in the beginning. Moreover, the composition of both types of fibrinoid is different.

### Perivillous Fibrinoid

The perivillous fibrinoid or perivillous fibrin as defined by Fox (1967b, 1975) is probably identical with the micro-

fibrinoid of Oswald and Gerl (1972) and with the gitter-infarct designated by Becker (1981). It probably partly overlaps with the fibrinoid found in the maternal floor infarction, discussed in Chapter 9.

**Structure:** Perivillous fibrinoid can be found in every term placenta, but Fox (1967b) identified macroscopically such deposits in only 22.3% of normal placentas after 37 weeks of pregnancy. In our own experience, this figure is much too low. A mature placenta, free from macroscopically identifiable perivillous fibrinoid, is a rare exception. Problems may exist only insofar as it might be impossible to differentiate macroscopically among perivillous fibrinoid, intervillous fibrinoid, and old intervillous hematomas. The diameter of perivillous deposits lies in most cases between a few hundred micrometers and some millimeters. Larger deposits that reach a few centimeters usually represent intervillous hematomas and displace villi rather than encasing them. The “placental floor infarction” is easily differentiated because of its large size and normally basal position, being directly connected to the basal plate.

Histologically, perivillous fibrinoid is lamellar in structure (Toth et al., 1973). Immunohistochemically, its superficial layer always represents **fibrin-type fibrinoid** (Frank et al., 1994) (see Chapter 9), which is a blood clot product. This layer may directly contact the trophoblastic lamina of the villi, or it may be followed by the more homogeneous **matrix-type fibrinoid** (see Chapter 9), a secretory product of large trophoblast cells that embeds the latter (Frank et al., 1994).

Perivillous fibrinoid either fills gaps in the syncytiotrophoblastic cover of villi or encases entire villi or even groups of villi. The syncytiotrophoblast of these villi degenerates during the early stages of fibrinoid formation, and in later stages it disappears completely. A thickened trophoblastic basal lamina surrounds the fibrotic villous stroma. Their fetal vessels sometimes remain intact, but in most cases, they obliterate.

The villous cytotrophoblast beneath perivillous fibrinoid may disappear or may show increased proliferation. Like the extravillous trophoblast cells of the basal plate, the cell islands, and the septa, the cells grow to considerable size. Immunohistochemically, they cannot be distinguished from extravillous trophoblast cells of other localizations. They partly lose their connection to the basal lamina and develop in strings or as single cells deep in the fibrinoid (Villee, 1960; Wilkin, 1965; Fox, 1967b), adding by secretion and degeneration additional matrix-type fibrinoid.

This finding suggests that villous cytotrophoblast (Langhans' cells) and extravillous cytotrophoblast do not represent two completely different lines of trophoblast differentiation that separate during the early stages of placentation. Rather it implies that villous trophoblast cells even in late pregnancy can be transformed into extravillous ones, losing their

polarization and secreting matrix-type fibrinoid instead of a basal lamina, as soon as these cells are covered by fibrin-type fibrinoid rather than by villous syncytiotrophoblast.

**Origin:** Moe and Joergensen (1968) studied aggregates of platelets at the villous syncytial surfaces by electron microscopy and described these aggregates as representing the initial stages of fibrinoid deposition. Also according to Fox (1967b), syncytiotrophoblastic degeneration is only a secondary phenomenon that is introduced by platelet aggregation on the intact syncytial surfaces. The latter process is thought to be caused by a disturbed intervillous circulation.

On the other hand, it is known that collagens (Kunicki et al., 1988), fibronectins (Piotrowicz et al., 1988), and laminin (Sonnenberg et al., 1988) can initiate blood clotting. These molecules are constituents of the trophoblastic basal lamina. Thus, it is reasonable to assume that **focal degeneration of syncytiotrophoblast** with free exposure of the basal lamina to the intervillous blood results in local blood clotting and closure of the trophoblastic defect by a fibrinoid plug. As has been demonstrated by Edwards et al. (1991), it must be discussed how far such fibrinoid plugs are sufficient barriers controlling maternofetal macromolecule transfer.

Also our experimental studies in the pregnant guinea pig (Kaufmann et al., 1974b; Kaufmann, 1975b) led us to assume that, in addition to mere intervillous, circulatory factors, there are intrasyncytial causes for perivillous fibrinoid deposition. Inhibition of intrasyncytial energy metabolism, using monoiodine acetate or sodium fluoride, within minutes after application induced focal ultrastructural degenerative changes in the syncytiotrophoblast, followed by fibrin/fibrinoid deposition in the neighboring maternal blood. This finding is in agreement with older findings by Hörmann (1965), who considered that factors such as hypoxia and acidosis might lead to syncytial degeneration and eventually result in replacement of the syncytium by fibrinoid.

Statistical results published by Fox (1967b, 1975) suggested that perivillous fibrinoid is a more frequent phenomenon in placentas from normal pregnancies than in those involved in pathologic processes. This finding may be an indicator that just the maximal maternal perfusion of the intervillous space predisposes to perivillous fibrin deposition. In agreement with this conclusion, the same author failed to find any local or statistical correlation between perivillous fibrinoid and placental infarction. In general, there seemed to be no influence on fetal well-being.

Even though these findings and theories by Fox are supported by earlier publications (Siddall & Hartman, 1926; Huber et al., 1961), there are many reports that point in another direction. Eden (1897), who was probably also the first author to state that infarcts are the result of maternal vascular occlusion, considered derivation from blood coagulation and degeneration; Sala et al. (1982) found with stereologic techniques that significantly more fibrin was deposited in “venous” (“hypoxic”) areas of the placenta, where there is stasis of blood. Huguenin (1909), Wilkin (1965), Boyd and Hamilton (1970), and Toth

et al. (1973) considered perivillous fibrinoid to be the result of trophoblastic degeneration. Boyd and Hamilton (1970) and Wilkin (1965) described fibrinoid deposition below the syncytiotrophoblast, preceding intervillous clotting. Thomsen (1954) reported cases of villous rupture with fetal bleeding into the intervillous space as being responsible for this process.

### Intravillous Fibrinoid

**Structure:** Fox (1968) first described and defined a separate kind of fibrinoid that appears in the subtrophoblastic space and finally occupies the entire villous stroma. According to his views, as many as 3% of the villous cross sections may be replaced partially or completely by intravillous fibrinoid during normal pregnancy. The intravillous deposition is increased in pregnancies complicated by such conditions as maternal diabetes, Rh-incompatibility, and preeclampsia.

Composition and nature of the intravillous fibrinoid are still controversially discussed. Based on Liebhart's description (1971) of a primarily intracytotrophoblastic deposition, Fox (1975) concluded that this material cannot be fibrin. In contradistinction to what he has defined to be perivillous "fibrin," he proposed the term **intravillous**

**fibrinoid**. It seems obvious that an intact syncytiotrophoblastic barrier as well as an intact fetal capillary wall prevent a maternal or fetal fibrin imbibition of the villous interior. On the other hand, Moe (1969a-c) immunohistochemically demonstrated fibrinogen and fibrin in the cytotrophoblast. Moreover, several immunohistochemical studies found proof for an intra-villous existence of fibrin and fibrinogen in both the trophoblastic basal lamina (McCormick et al., 1971) and the intravillous fibrinoid (Gille et al., 1974; Faulk et al., 1975), thus supporting earlier respective data (Kline, 1951; McKay et al., 1958; Wigglesworth, 1964). Finally, our own studies concerning the immunohistochemistry of fibrinoids (Frank et al., 1994) gave clear evidence that intravillous fibrinoid may contain both fibrin (fibrin-type fibrinoid) and extracellular matrix molecules such as oncofetal fibronectin, laminin, and collagen IV (matrix-type fibrinoid) (see Origin of Fibrinoids in Chapter 9). Only the question as to a maternal or fetal derivation of the fibrin remained open.

**Genesis:** The process of intravillous fibrinoid deposition is thought to be initiated by small, subsyncytially positioned nodules that are periodic acid-Schiff (PAS) positive. They later increase in size (Fig. 6.30) and finally

FIGURE 6.30. Intravillous fibrinoid. A large, heterogeneous plaque of fibrinoid intermingled with degenerative cellular remains and white blood cells is deposited between the syncytial covering of the villus and its stromal core.  $\times 2400$ .

replace the stroma. This view has been supported by Wilkin (1965) and Boyd and Hamilton (1970). As stated by these authors, the originally intact syncytium degenerates only secondarily, if at all.

Liebhart (1971) has described degeneration of the villous cytotrophoblast as the initial process. Some immunologic studies have supported the idea of an extracellular fibrinoid deposition in the villous stroma, independent from cellular degeneration (Gille et al., 1974; Faulk et al., 1975). There has been ample discussion about whether this process is completely independent from the genesis of perivillous fibrinoid (Fox, 1967b) or whether it may be complicated by the latter (Wilkin, 1965; Boyd & Hamilton, 1970; Burstein et al., 1973).

Concerning the etiology of the formation of the intra-villous fibrinoid, Fox (1968) discussed an immunologic attack against the villous cytotrophoblast. Wislocki and Bennett (1943) proposed villous degeneration as a result of placental aging to be the primary agent. The histologic and histochemical studies by Burstein and coworkers (1973) have provided some evidence that intravillous fibrinoid and amyloid might be identical, whereas perivillous fibrinoid showed staining patterns that were different from those of amyloid. In agreement with the extraplacental genesis of amyloid, these authors suggested that intravillous fibrinoid is a result of placental degeneration induced by aging and by immunologic processes.

Intravillous fibrinoid, involved in immunologic processes, has been discussed on many occasions. McCormick et al. (1971) described this type of fibrinoid as a result of antigen-antibody reactions in the villous stroma and as resulting in an immunologic barrier between maternal and fetal circulations. Burstein et al. (1963) have even named the villous stroma as an immunologic battlefield, as they found a specific stromal binding of insulin in cases of maternal diabetes mellitus and of anti-D antibodies in cases of Rh incompatibility. Differing slightly from the foregoing and based on experimental studies in healthy pregnant women, Gille et al. (1974) came to the conclusion that immunologic diseases may affect the syncytiotrophoblastic barrier. Consequently, the latter was thought to become permeable for antigen-antibody complexes, which then may become enriched and finally deposited as fibrinoid in the villous stroma.

# Architecture of Normal Villous Trees

## Classification of Villous Types

The ramifications of the villous trees can be subdivided into segments that differ mainly as to caliber, stromal structure, vessel structure, and position within the villous tree (Fig. 7.1). Five villous types have been described (Kaufmann et al., 1979; Sen et al., 1979; Castellucci & Kaufmann, 1982a,b; Kaufmann, 1982; Castellucci et al., 1984, 1990, 2000; Burton, 1987), some of which can be further subdivided. As will be discussed below, all villous types derive from single precursors, the mesenchymal villi, which correspond to the tertiary villi of the early stages of placentation.

The following villous types have been described (Fig. 7.2):

1. Stem villi are characterized by a condensed fibrous stroma, arteries and veins, or arterioles and venules with a media or adventitia identifiable by light microscopy (Fig. 7.2). They comprise the following structures (see Fig. 7.17A):

- The main stems (truncus chorii) of a villous tree, which connect the latter with the chorionic plate;
- Up to four generations of branchings (rami chorii of the first to fourth orders), which are short, thick branches derived from the truncus already in the vicinity of the chorionic plate;
- Two to 30 (mean, 10) more generations of unequal dichotomous branchings (ramuli chorii of the first to tenth orders), which are more slender branches that extend into the periphery of the villous trees;
- A special group of stem villi represented by the anchoring villi; these villi are ramuli chorii, which connect to the basal plate by a cell column. The proliferating trophoblast cells of the latter act as a growth zone for both, the anchoring villus as well as for the basal plate.

2. Immature intermediate villi (Fig. 7.2) are bulbous, peripheral, immature continuations of stem villi. They are in a position comparable to that of the mature intermediate villi, that is, interposed between stem villi and peripheral branches, and they prevail in immature placentas. Normally, this type persists in small groups within the centers of the villous trees (placentones) and represents the immature forerunners of stem villi.

3. Mature intermediate villi (Fig. 7.2) are long, slender, peripheral ramifications characterized by the absence of vessels with a light-microscopically identifiable media and/or adventitia.

4. Terminal villi (Fig. 7.2) are the final, grape-like ramifications of the mature intermediate villi, characterized by their high degree of capillarization and the presence of highly dilated sinusoids. They represent the main sites of fetomaternal exchange.

5. Mesenchymal villi (Fig. 7.2) are the most primitive. They prevail during the first stages of pregnancy, where they are the forerunners of immature intermediate villi. During later stages of pregnancy, these villi are inconspicuous, mostly small, slender structures that can be found along the surfaces of immature intermediate villi or at the tips of mature intermediate villi. At this stage they also act as zones of villous proliferation and further branching.

The principal morphometric data of the various villous types are shown in Chapter 28, Table 28.7, and in Fig. 7.15.

## Stem Villi

Trunci chorii, rami chorii, ramuli chorii, and the anchoring villi are summarized as stem villi because they exhibit similar histologic features and differ from each other only in caliber and position within the hierarchy of villous branching (Demir et al., 1997). The calibers vary from

FIGURE 7.1. Semithin section from the 40th week postmenstruation (p.m.) to demonstrate the structural and staining variability of villous cross sections. Such pictures suggest that the villous tree is composed of several villous types that differ from each

other regarding size, stromal fibrosis, and density of fetal vascularization. s, stem villi; mi, mature intermediate villi; t, terminal villi.  $\times 140$ .

about  $80\mu\text{m}$  (smallest ramuli chorii) to about  $3000\mu\text{m}$  (some trunci, near the chorionic plate). In the normal mature placenta, they make up 20% to 25% of the total villous volume (see Table 28.7). Because of the typical branching patterns of the villous trees, the volumetric share of the stem villi is the highest in the central subchorionic portion of the villous tree.

The trophoblast cover of stem villi is uniformly thick and lacks epithelial plates. Cytotrophoblastic cells, located below the superficial syncytiotrophoblast, can be found on about 20% of the villous surfaces. In the mature placenta, the trophoblast is often degenerated and largely replaced by perivillous fibrinoid (Figs. 7.3A,B and 7.4). The trophoblastic degeneration is more impressive in stem villi of large caliber than in the small peripheral villi. Moreover, there seems to be a certain positive correlation with intrauterine growth retardation (Ara et al., 1984; Macara et al., 1996).

The stroma is characterized by huge, condensed bundles of collagen fibers that encase occasional fibroblasts and rare macrophages (Fig. 7.3C). Within trunci, rami, and large ramuli, the fetal vessels are composed of arteries and veins that are accompanied by smaller arterioles and venules as well as superficially located paravascular capillaries (Fig. 7.3A). The latter are comparable to vasa vasorum of large-caliber vessels of other organs. In the smaller, more peripheral ramuli, arteries and veins are lacking; rather, the fetal vessels are represented by a few arterioles and venules that typically have thin vessel walls and are accompanied by few paravascular capillaries (Fig.

7.3B). The adventitia of arteries and veins continues without sharp demarcation into the surrounding fibrous stroma of the villous core (Fig. 7.3A). The more centrally located connective tissue cells are myofibroblasts, whereas the more peripheral ones are noncontractile fibroblasts (Demir et al., 1992, 1997; Kohnen et al., 1995, 1996).

The central core of myofibroblasts is arranged around the stem vessels (Fig. 7.5) and has been called the perivascular sheath (Graf et al., 1994, 1995, 1997). In stem villi that are not yet fully mature, an additional superficial rim of reticular stroma, composed of undifferentiated, proliferating connective tissue cells but deficient in fibers, may separate the fibrous stroma from the trophoblastic cover (see Chapter 8, Figs. 8.5 to 8.8). All three layers together represent a differentiation gradient; the most peripheral cells are the proliferating stem cells and the most central cells represent the highest degrees of differentiation. As soon as the trophoblastic cover is replaced by fibrinoid, the stromal stem cells stop proliferation and start differentiation, thus leading to a homogeneously fibrosed stem villus stroma (Demir et al., 1997). These data suggest paracrine interactions between trophoblastic epithelium and the stromal stem cells beneath. Macrophages are evenly distributed throughout the stroma (Demir et al., 1992, 1997). Occasionally mast cells are present in the vascular walls of the stem villi (see Chapter 6).

**Function:** Stem villi serve to mechanically support the structures of the villous trees. Considering the low degree of fetal capillarization and degenerative changes of the trophoblast, their share in fetomaternal exchange and

FIGURE 7.2. Simplified representation of the peripheral part of a mature placental villous tree, and typical cross sections of the various villous types. For further details see text. (Source: Kaufmann & Scheffen, 1992, with permission.)

FIGURE 7.3. Structural features of stem villi. A: Semithin cross section of a large stem villus. Note that the adventitias of the artery (right) and vein (left) directly continue into the surrounding dense fibrous stroma of the villus. Superficially, numerous smaller vessels of the paravascular capillary net are seen. As is typical for stem villi of the mature placenta, the trophoblastic covering of this villus has been removed by fibrinoid in many places.  $\times 115$ . (Source: Leiser et al., 1985, with permission.) B: More peripherally positioned stem villi of small caliber can

be identified by the condensed fibrous stroma, located between the fetal arterioles and venules (large lumens). Fetal capillaries are rare.  $\times 430$ . C: Transmission electron micrograph of the fibrous stroma of a stem villus. The interstitial space between the various types of connective tissue cells is mostly occupied by dense bundles of collagen fibers. Residual macrophages (upper right) partly surrounded by sail-like extensions of fibroblasts remind us that fibrous stroma is derived from reticular stroma.  $\times 2400$ .

endocrine activity is presumably negligible. The presence of the large fetal vessels with thick muscular walls as well as the presence of extravascular myofibroblasts (Demir et al., 1992, 1997; Kohnen et al., 1996) makes their contribution to the autoregulation of the fetoplacental vascular system likely. Moreover, the myofibroblasts that are ori-

ented in parallel to the longitudinal axis of the villous stems, the so-called perivascular sheath (Graf et al., 1994, 1995, 1997), may provide a regulating system for the maternal circulation in the intervillous space (Fig. 7.6). Because many of the larger villous stems are anchoring villi that connect the chorion and basal plate, their longi-

FIGURE 7.4. Peripheral stem villi. 40 weeks p.m. A: Structural features of a not yet fully matured stem villus from the center of a fetal cotyledon. The trophoblastic surface cover is still largely complete. Below the trophoblastic surface, locally paravascular capillaries can be seen, which are embedded in highly cellular connective tissue. B: In contrast, in a fully matured stem

villus of the same size, derived from the peripheral parts of a fetal cotyledon of the identical placenta, the trophoblast is largely replaced by fibrinoid. The number of subtrophoblastic paravascular capillaries has decreased. Paraffin sections, hematoxylin and eosin (H&E) stain.  $\times 430$ .

FIGURE 7.5. Mature placental villi immunostained with an antibody against  $\gamma$ -smooth muscle actin. This antibody stains both vascular smooth muscle cells and extravascular myofibroblasts. Nuclei counterstained with hematoxylin. Terminal villi and mature intermediate villi are immunonegative. Only stem villi are immunoreactive (brown). Cross sections of small-sized peripheral stem villi (upper and lower left) can be identified by immunoreactive smooth muscle cells concentrically surrounding villous arterioles and venules. In the centrally located longitudinally sectioned large-caliber stem villus between the immunopositive vessel walls (brown) and villous surface longitudinally sectioned, filiform, immunopositive myofibroblasts can be seen.  $\times 100$ .

FIGURE 7.6. Schematic representation of the distribution of villous extravascular myofibroblasts (lilac) in large-caliber stem and anchoring villi. Upon contraction, these cells shorten the length of stem and anchoring villi, thereby reduce the width of the intervillous space, and increase the impedance of maternal intervillous blood flow (red arrows). In this way the fetus is thought to gain control over the maternal blood flow in the placenta, which the mother has lost as a consequence of trophoblast invasion of the uteroplacental arteries.

tudinal contraction decreases intervillous volume (Krantz & Parker, 1963; Kohnen et al., 1996; Demir et al., 1997; Farley et al., 2004) and very likely increases uteroplacental flow impedance. As was discussed in Chapter 6, in this way the fetus gains control over the maternal blood flow in the placenta, which the mother has lost as a consequence of trophoblast invasion of the uteroplacental arteries.

Blood flow and blood pressure control in the intervillous space are important, as has been demonstrated in vitro by Karimu and Burton (1994): pressure increases in the intervillous space reduce the width of the fetoplacental capillaries and thus increase fetoplacental impedance and reduce fetal perfusion of the placenta. Respective malregulation is thought to be a major mechanism in the pathogenesis of intrauterine growth restriction (IUGR) with absent or reversed end-diastolic (ARED) umbilical flow (Kingdom & Kaufmann, 1997; Kingdom et al., 1997a). In conclusion, myofibroblasts may act as an important link adapting maternal and fetal perfusion of the placenta to each other. Increase in fetoplacental blood flow impedance caused by high pressure in the villous surrounding can be downregulated by relaxation of the myofibroblasts (Demir et al., 1997; Kohnen et al., 1995, 1996).

### Immature Intermediate Villi

The immature intermediate villi have been known as immature villi or immature terminal villi. We have suggested that the term **immature intermediate** is more appropriate because these villi are not the only immature

villous type, nor are they immature forerunners of later terminal villi (Kaufmann et al., 1979; Kaufmann, 1982). Rather, both types of intermediate villi (immature and mature intermediate villi) are differentiated successors of mesenchymal villi:

- The immature intermediate villi result from maturation of mesenchymal villi throughout the first two trimesters. Later they are transformed into stem villi.
- The mature intermediate villi, which derive from mesenchymal precursors during the last trimester, produce the terminal villi.

Thus, both “intermediate” villi are in an intermediate developmental position between mesenchymal and fully mature villi. Moreover, both are in an intermediate topographic position between stem villi and the most peripheral branches.

Histologically, immature intermediate villi have the same uniform, thick trophoblastic cover as stem villi (Figs. 7.2 and 7.7A,B). Epithelial plates are absent. During early pregnancy, Langhans’ cells can be found below the syncytium on more than 50% of the villous surfaces. During late pregnancy, their prevalence is reduced to about 20%.

The most characteristic feature of the immature intermediate villi is their reticular stroma, typified by numerous fluid-filled channels that are delimited by large, sail-like processes of the fixed stromal cells (Kaufmann et al., 1977b) (Fig. 7.7A–C). Hofbauer cells are inside the channels (Enders & King, 1970; Castellucci & Kaufmann, 1982a), suspended in some fluid.

Fetal vessels, such as the capillaries, arterioles, and venules, together with scarce bundles of collagen fibers,

FIGURE 7.7. Typical structure of the immature intermediate villus. A: Paraffin section, 6th week p.m., H&E. staining. Note the reticular appearance of the villous stroma with enmeshed highly vacuolated macrophages.  $\times 400$ . B: Semithin section of an immature intermediate villus from the 22nd week of pregnancy p.m. with its typical reticular stroma. The rounded, vacuolated macrophages (Hofbauer cells) are located in stromal channels, which are devoid of connective tissue fibers and therefore appear as empty holes. In faintly stained histologic sections, this feature can be misinterpreted as villous edema.  $\times 520$ . (Source: Kaufmann, 1981, with permission.) C: Scanning electron micrograph of a freeze-fractured immature intermediate villus shows the three-dimensional view of the reticular stroma with its characteristic stromal channels.  $\times 1050$ . (Courtesy of M. Castellucci.) D: Transmission electron micrograph of the reticular stroma of an immature intermediate villus at term. Several stromal channels, each containing a macrophage, can be identified. They are delimited from the surrounding connective tissue fibers by slender, sail-like extensions of fixed connective tissue cells (small reticulum cells, R). A small fetal arteriole (A) is seen in the lower left corner.  $\times 2700$ . (Source: Castellucci & Kaufmann, 1982a, with permission.)

are positioned between the stromal channels. Collagen bundles and vessel walls are separated from the lumina of the channels by the sail-like extensions of the connective tissue cells (Fig. 7.7B,D).

Transformation of immature intermediate villi into stem villi takes place during the first trimester. It is a gradual process that results in numerous intermediate steps. The starting point for the stromal fibrosis is the vascular wall. In the beginning, vessels acquire a distinct media and adventitia. The latter expands in later stages over the entire villous thickness. During this process the intercanalicular bundles of connective tissue fibers increase in diameter and thus compress the neighboring stromal channels. Eventually, they disappear. Residues can be found in all stem villi when one studies the stroma carefully for Hofbauer cells (Fig. 7.3C).

The first immature intermediate villi are formed around the 8th week postmenstruation (p.m.) (compare Figs. 8.2 with 8.3; see Table 8.1). Between the 14th and 20th weeks (Figs. 8.3 to 8.5) they comprise most of the villous cross sections. At term, they may be completely absent; in most cases they can be found in small groups in the centers of the villous trees, the "placentones," where they still act as growth zones and produce new sprouts. At term, a volumetric share of 0% to 5% is normal for immature intermediate villi. This figure is applicable only when all parts of a placentone are equally represented in the histologic section. Sections restricted to the more central parts of a villous tree may show higher values and must thus be interpreted with care.

**Function:** The immature intermediate villi can be regarded as the growth centers of the villous trees. These produce the true sprouts (see chapter 15), which are transformed into mesenchymal villi as forerunners of all other villous types. Because of the long maternofetal diffusion distances, immature intermediate villi are the principal sites of exchange only during the first two trimesters, so long as other specialized villous types are not yet differentiated.

Immature intermediate villi may cause diagnostic problems, as their reticular stromal core has only a weak affinity for conventional stains because of the lack of collagen. Typical features are depicted in Figs. 7.7A,B and 8.3 through 8.5. The weaker staining, however, often results in the disappearance of the stromal channels so that the resulting histologic picture is that of a seemingly edematous villus that has accumulated much interstitial fluid. Such true edematous villi indeed exist. They are particularly impressive in hydatidiform moles but may also be found in maternal diabetes mellitus and some infections (e.g., syphilis, toxoplasmosis, cytomegalovirus infection). On the other hand, as experienced a pathologist as Harold Fox expressed some doubt when he wrote: "This has long been recognized as one of the characteristic features of placentae from diabetic women and from

cases of materno-fetal rhesus incompatibility, though in fact only a proportion of such placentae are edematous." For other cases, he simply stated villous immaturity to be the correct designation (Fox, 1978, 1997). We believe that many villi referred to as "edematous villi" in the literature are in fact normal, immature intermediate villi (e.g., in most cases of rhesus incompatibility) (Pilz et al., 1980; Kaufmann et al., 1987). Naeye et al. (1983) have discussed in much detail the clinical significance of placental villous edema. We cannot exclude, based on their publication, that these changes represent true edematous alterations; however, at least one of the two examples they depicted, their Figure 2, is a normal, immature intermediate villus. They described it as follows: "Villous edema was recognized by the finding of open spaces in the interstitium of the villi," but they pointed to normal stromal channels.

This contradiction does not negate the existence of villous edema. It is probable that true generalized villous edema has functional significance, as it may compress the intervillous space and thus limit maternal blood flow (Alvarez et al., 1972; Fox, 1978); it also increases the maternofetal diffusion distances. Fox (1978) stated that "villous oedema is usually considered to be of no clinical significance," and that "there is, as yet, no clear evidence that villous oedema has, in itself, any effect on fetal growth or nutrition." Perhaps this negative conclusion is based on the interpretation that most cases of "villous edema" are misinterpretations of normal villous structures.

For further details regarding normal structure and function of immature intermediate villi, see the publications by Castellucci and Kaufmann (1982a,b), Castellucci et al. (1984), Highison and Tibbitts (1986), Kaufmann (1982), Kaufmann et al. (1977b, 1979), and Sen et al. (1979).

## Mature Intermediate Villi

Mature intermediate villi are long slender villi with diameters of about 60 to 150  $\mu$ m. As soon as their surfaces bear terminal villi, their shape is characterized by numerous slight bends at points where the terminal villi branch off, resulting in a typical zigzag course (see Fig. 7.10A,D). This pattern is absent when terminal side branches are not present (see Chapter 15), features that may be of diagnostic importance. Mature intermediate villi have roughly the same diameters as terminal villi. Because of their zigzag courses, longitudinal histologic sections are rare. As long as mature intermediate villi do not produce terminal villi, they do not pursue the zigzag course but, rather, remain straight. This appearance, in sections of weeks 32 to 34, is one of groups of cross sections that alternate with bundles of slender longitudinal sections (see Chapter 15, Fig. 15.9).

The trophoblast cover of mature intermediate villi is much thinner than those of stem and immature interme-

diate villi. Where it covers capillaries, it often is reduced to epithelial plates of less than  $1\mu\text{m}$  thickness. Also the rare cytotrophoblastic cells are mostly found close to the capillaries.

The stroma of mature intermediate villi is composed of seemingly unoriented, loose bundles of connective tissue fibers and fixed connective tissue cells. In some places it surrounds rudimentary narrow stromal channels that are usually devoid of macrophages (Figs. 7.8 and 7.9).

The vessels comprise numerous capillaries, small terminal arterioles, and collecting venules. The media of the latter is usually too thin for light microscopic identification. Because the terminal villi originate from the surface of the mature intermediate villi, there is a gradual transition. Cross sections are defined as mature intermediate villi, the stroma of which contains fewer than 50% vascular lumens (see Table 28.6). Roughly one fourth of the villous volume in the normal term placenta is composed of this villous type (see Table 28.7).

**Function:** The mature intermediate villi produce the terminal villi. The high degree of fetal vascularization and the large share in the exchange surface make them important for fetomaternal exchange. When studying the enzyme patterns and the immunolocalization of placental hormones, one gains the impression that they are prominent sites for hormone production. In analogy with the vascular bed of other organs, one may conclude that the presence of terminal arterioles allows participation in vasoregulation and thus intravillous blood distribution (Nikolov & Schiebler, 1973).

### Terminal Villi

Terminal villi are the final ramifications of the villous tree during the last trimester. They are grape-like outgrowths of the mature intermediate villi, where they appear as single or poorly branched side branches (Fig. 7.10). The peripheral end of the mature intermediate villus normally branches into a larger aggregate of such terminal villi (Fig. 7.10B). They usually connect to the mature intermediate villi by a narrow neck region (Fig. 7.10C,D; see also Fig. 7.20A). Only an extremely small proportion of the terminal villi are directly connected to stem villi or to immature intermediate villi.

Histologically, the trophoblast cover of terminal villi is thin and forms numerous epithelial plates. Depending on

FIGURE 7.8. Semithin section of the richly vascularized peripheral end of a mature intermediate villus (upper half), with a terminal villus (lower half) arising at a narrow neck region (center). The fetal vessels show the typical composition of narrow capillaries and dilated sinusoids. The latter are closely related to the trophoblastic surface, forming thin epithelial plates.  $\times 430$ . (Source: Kaufmann et al., 1979, with permission.)

Note the peripheral position of the small fetal capillaries and the ample connective tissue, deficient in cells and fibers. The syncytiotrophoblastic covering of the villus is more uniform in structure than that of the terminal villi.  $\times 730$ . B: Transmission electron micrograph of the typical loose connective tissue of a mature intermediate villus. The seemingly unoriented mixture of small reticulum cells (R) with long processes, macrophages (M), and loosely arranged connective tissue fibers is highly characteristic for this villous type.  $\times 2150$ .

FIGURE 7.10. Scanning electron microscopic appearance of terminal villi. A: A single, long, mature intermediate villus shows the characteristic bends of its longitudinal axis and multiple grape-like terminal villi. Note that the terminal villi largely have the same diameter as the mature intermediate villus from which they branch.  $\times 180$ . (Source: Kaufmann et al., 1979, with permission.) B: Tip of a mature intermediate villus with rich final branching into terminal villi.  $\times 470$ . (Source: Kaufmann et al., 1979, with permission.) C: A group of terminal villi, the central one showing a typical constricted neck region and a dilated final portion.  $\times 500$ . (Source: Kaufmann et al., 1979, with permission.) D: Simplified drawing of a mature intermediate villus (line shaded) and its branching terminal villi (point shading). As is typical, most terminal villi arise from the convex sides of each bend, either directly or with a narrow neck region. They branch repeatedly, particularly at the end of the mature intermediate villus. (Source: Kaufmann et al., 1979, with permission.)

the quality of tissue preservation, they amount to 30% to 40% of the villous surface (see Table 28.6 and Fig. 7.20).

Fetal vessels are represented by sinusoidally dilated capillaries. The latter occupy more than 50% of the stromal volume and more than 35% of the villous volume (see Table 28.6) (Figs. 7.8 and 7.11; also see Fig. 7.20) (Kaufmann et al., 1979; Sen et al., 1979). The fetal sinusoids are in intimate contact with the trophoblastic surface and form the epithelial plates.

The remaining connective tissue has scant fibers and cells. Macrophages are rare (Fig. 7.11). The average diameter of terminal villi ranges from 30 to 80  $\mu\text{m}$ . Their histologic appearance differs, depending on where they are sectioned. The slender neck region, containing mostly undilated capillaries, is easily differentiated from the

bulbous tip containing mostly sinusoids and from flat sections across tips (see Fig. 7.20).

It must be pointed out that the light microscopic appearance is heavily influenced by the mode of tissue preservation. Delayed fixation (see Tables 28.6 and 28.9), inappropriate osmolarity of the fixative (see Table 28.10), and time and mode of cord clamping (see Table 28.9) influence the villous structure. In particular, the highly dilated sinusoids respond to postpartal changes of fetal blood pressure. They tend to collapse within minutes, thus dramatically changing the villous proportions (Voigt et al., 1978; Burton & Palmer, 1988). An increase in pressure in the peripheral fetal vessels, as during cord compression (knots, torsion, nuchal cord), leads to congestion in the terminal capillaries and results in seemingly “hyper-

FIGURE 7.11. Survey electron micrograph of a typical, well-fixed terminal villus illustrates the high degree of fetal capillarization, with some of the capillaries (C) being narrow and others dilated, forming sinusoids (SI). The sparse connective tissue is composed of macrophages (H), fibroblasts or small reticulum cells

(R), and a loose meshwork of connective tissue fibers. The stroma is surrounded by a structurally highly variable layer of syncytiotrophoblast (S) below which a few cytotrophoblastic cells (CT) can be seen.  $\times 2000$ . (Source: Schiebler & Kaufmann, 1981, with permission.)

capillarized" villi ("chorangiosis"). We found this feature frequently with preterm rupture of membranes, and the correlation is highly significant. There was also an increase in villous blood volume, sometimes of more than 50%. It may be speculated that loss of amniotic fluid predisposes to compression of the umbilical veins and thus inhibits placental venous backflow (Paprocki, 1992).

**Function:** The high degree of vascularization and minimal mean maternofetal diffusion distance of about  $3.7\mu\text{m}$  (Voigt et al., 1978; Sen et al., 1979; Feneley & Burton, 1991) (see Table 28.6) make this villous type the most appropriate place for diffusional exchange (e.g., transfer of oxygen, carbon dioxide, and water). In the normal mature placenta, the terminal villi comprise nearly 40% of the villous volume. Because of their small diameters, the sum of their surfaces amounts to 50% of the total villous surface. They comprise about 60% of villous cross sections. These figures explain why a remarkable reduction of terminal villi (as in IUGR with ARED umbilical flow) (Macara et al., 1996; Kingdom et al., 1997b) may lead to fetal hypoxia. Also, according to Fox (1978), there is a clear-cut inverse relation between the incidence of villous vasculosyncytial membranes and fetal hypoxia.

### Mesenchymal Villi

The term **mesenchymal villi** has been proposed for the first generation of tertiary villi, which are characterized

by a seemingly primitive stromal core resembling fetal mesenchyme (Castellucci & Kaufmann, 1982a). From the 5th (onset of villous vascularization) to the 7th week p.m., this is the only vascularized villous type. At later stages, their number continuously decreases. Some of these villi are still found at term, indicating that expansion of the villous trees in normal pregnancies never comes to a standstill.

These villi comprise the first generation of newly formed villi, not only during the first trimester but also at later stages. Differentiation of every new villus starts in the mesenchymal stage. It is derived from trophoblastic sprouts by mesenchymal invasion and vascularization and precedes the formation of new intermediate villi (Figs. 7.12 to 7.14). In accordance with their role as proliferating segments, the mesenchymal villi decrease in number as pregnancy advances. At term, they are primarily found in small numbers on the surfaces of immature intermediate villi. They are located in the centers of the villous trees.

Mesenchymal villi have thick trophoblast surfaces with large numbers of Langhans' cells, which are interposed between syncytium and the trophoblastic basal lamina on 50% to 100% of the villous surfaces (Castellucci et al., 1990, 2000).

The stroma is characterized by loosely arranged collagen fibers that enmesh mesenchymal and some Hofbauer cells (Fig. 7.14). Condensed collagen is sometimes observed.

FIGURE 7.12. Structural features of villous sprouts and mesenchymal villi in a methacrylate section of placental villi from the 6th week p.m. From a larger mesenchymal villus (below), several true sprouts protrude into the intervillous space. At their tips, the latter consist merely of syncytiotrophoblast. Nearer the base

they are invaded by cytotrophoblast and finally by loose connective tissue (villous sprout, V). The latter is the forerunner of a new mesenchymal villus, which becomes established as soon as the sprout is invaded by fetal vessels.  $\times 390$ .

FIGURE 7.13. This longitudinal section of a newly sprouting villus demonstrates the various stages of the sprouting process: as the first step, a group of syncytial sprouts (upper third, ss) is formed; these become invaded by cytotrophoblast (trophoblastic sprout, ts), followed by invasion by dense, avascular cellular stroma (villous sprout, vs). Development of fetal capillaries marks the transition into a mesenchymal villus (mv). The latter branches from an immature intermediate villus (iiv), which was the starting point of the sprouting process. Paraffin section, H&E. staining,  $\times 560$ .

Fetal capillaries are poorly developed and never show sinusoidal dilatation. Near the villous tips, capillary lumens may still be occluded and are made up of a string of endothelium (Figs. 7.13 and 7.14); several steps in the formation of lumens can be observed.

The still unvascularized tips of mesenchymal villi are referred to as villous sprouts. At their tips, the villous sprouts continue into trophoblastic sprouts (Figs. 7.2, 7.12, and 7.13). In summary, the typical sequence of structures representing the process of villous sprouting is as follows: syncytial sprout, trophoblastic sprout with a central core of cytotrophoblast, villous sprout with some connective tissue, and mesenchymal villus with fetal capillaries (Fig. 7.13).

**Function:** During the first weeks of pregnancy, mesenchymal villi are not only the places of villous proliferation but also the sites of maternofetal exchange and nearly all endocrine activity. With advancing pregnancy and development of more advanced villous types, their functional importance is reduced to villous growth. At term, their share in total villous volume is far below 1% (Fig. 7.15) (Castellucci et al., 1990, 2000).

### Immunohistochemistry of Villous Types

Villous classification is based on two parameters (Kaufmann et al., 1979; Kohnen et al., 1996; see also foregoing text):

- Differences in stromal structure (mesenchymal, reticular, or fibrous);
- Distribution of the various segments of the fetal vessel system: (1) capillaries without media and adventitia; (2) arterioles and venules with thin media and nonfibrous adventitia; or (3) arteries and veins with thick muscular media and fibrous adventitia.

Consequently, immunohistochemistry of cytoskeletal proteins within the villous stroma and the vessel walls provides a useful tool for the identification of various villous types. The above-mentioned differences in stromal structure as well as the differences in vascular wall structure are reflected by different degrees of cytoskeletal differentiation. According to Kohnen et al. (1995, 1996) and Demir et al. (1997), the following mesenchymal derivatives show a highly specific distribution pattern

FIGURE 7.14. Transmission electron microscopic cross section of a transitional stage between a villous sprout and a mesenchymal villus from the term placenta. This villus is characterized by large, epithelioid connective tissue cells (CO) and capillary sprouts. The latter consist of densely packed endothelial cells (E) connected to each other by tight junctions, showing no or only minimal lumens (inset), and surrounded by basal laminas. The latter form sometimes thick convolutions (arrow). It is

interesting to note that many of the villous sprouts and mesenchymal villi observed exhibit degenerative signs (compare the highly vacuolated syncytiotrophoblast), which can be explained by the fact that not all syncytial sprouts survive, depending on the local circulatory conditions in the intervillous space. By this selection, the shape of the villous tree is adapted to the intervillous hemodynamics.  $\times 5200$ ; inset  $\times 13,000$ . (Source: Demir et al., 1989, with permission.)

FIGURE 7.15. Development of total villous weight and the weight of the various villous types (in grams), from the 2nd month p.m. until term. Abscissa, villous weight in grams per placenta; ordinate, gestational age p.m. in months. The arrows demonstrate the routes of transformation or formation of villi. The lightly stippled areas around the arrows symbolize transitional stages between closely related villous types. At term, the mean villous weight per placenta amounts to 273 g. After morphometric evaluation of representative histologic sections, this weight can be assigned to the various villous types at term as follows: stem villi (SV), 31 g, 11%; transitional stages to immature intermediate villi, 24 g, 9%; immature intermediate villi (IIV), 9 g, 3%; mesenchymal villi (MV), less than 1%; transi-

tional stages to mature intermediate villi, 3 g, 1%; mature intermediate villi (MIV), 77 g, 28%; transitional stages to terminal villi, 31 g, 11%; terminal villi (TV), 95 g, 35%. Rough data for earlier stages of pregnancy can be deduced from the diagram. It must be pointed out that these data are preliminary, obtained from only a few placentas. There is a considerable local and interindividual variation. It becomes evident that the sum of stem villi (SV) plus immature intermediate villi (IIV) decreases throughout the last 3 months of pregnancy; the decrease can be explained by a massive transformation of stem villi into fibrinoid. (Source: Modified from Castellucci et al., 1990, with permission.)

within the various villous types and can be identified immunohistochemically by the expression of the cytoskeletal proteins listed (Table 7.1):

1. Undifferentiated mesenchymal cells express only vimentin (V cells). They are the only fixed connective tissue cells in undifferentiated mesenchymal villi.
2. Fibroblasts express vimentin and desmin (VD cells), and partly even  $\alpha$ -smooth muscle actin (VDA cells). Together with the former cell type they make up the stromal core in mesenchymal villi in later pregnancy as well as in mature intermediate and terminal villi.

3. Myofibroblasts in addition to vimentin and desmin are characterized by the expression of  $\alpha$ - and  $\gamma$ -smooth muscle actin (VDAG cells). These are the typical representatives of immature intermediate villi.

4. The highest stages of myofibroblast differentiation are characterized by the additional expression of smooth muscle myosin (VDAGM cells). These latter cells share most but not all structural features with smooth muscle cells (see Chapter 6). Their appearance characterizes the transformation of an immature intermediate villus into a stem villus.

TABLE 7.1. Immunohistochemical classification of villous types using monoclonal antibodies directed against various cytoskeletal filaments

Villous type	Stroma	Vimentin	Desmin	$\alpha$ -sm-Actin	$\gamma$ -sm-Actin	sm-Myosin	Ultrastructure
Undifferentiated mesenchymal villi		+	0	0	0	0	Mesenchymal cells
Differentiated mesenchymal villi		+	+	0	0	0	Mesenchymal and reticulum cells
Immature intermediate villi	Reticular stroma	+	+	0	0	0	Reticulum cells
	Fibrosed surrounding of larger vessels	+	+	+	0	0	Fibroblasts or myofibroblasts
	Inner adventitia of larger vessels	+	+	+	+	0	Myofibroblasts
Stem villi (in general)	Superficial cellular rim	+	+	0	0	0	Reticulum cells or fibroblasts
	Fibrous stroma	+	+	+	0	0	Fibroblasts or Myofibroblasts
	Adventitia of larger vessels	+	+	+	+	Partly +	Myofibroblasts
Type I stem villi (caliber >250mm)	Adventitia and media of arteries and veins	+	+	+	+ in adventitia and media of arteries and veins	Partly + in adventitia	Myofibroblasts and smooth muscle cells
Type II stem villi (caliber 120–300mm)	Adventitia and media of arterioles and venules	+	+	+	+ only in media of arterioles and venules	+ in media	Smooth muscle cells
Type III stem villi (caliber <150mmh)	Adventitia and media of arterioles and venules	+	+	+	+ only in media of arterioles	+ in media	Smooth muscle cells
Mature intermediate villi		+	+	0	0	0	Fibroblasts or reticulum cells
Terminal villi		+	+	0	0	0	Fibroblasts or reticulum cells

## Differentiation and Maturation of Villous Types

The mechanisms of villous maturation have attracted little attention, perhaps because they may seem to be unimportant for the understanding of placental pathology. This notion is supported by the experience that, with conventional paraffin histology, it is difficult to identify the various villous types and stages of villous differentiation. Direct structural evidence of villous differentiation and maturation are usually lacking. Only if one compares the villous trees of a mature placenta (see Fig. 8.12) with early villous trees (see Fig. 8.1) does one realize that important developmental steps must have occurred.

Immunohistochemistry and availability of human material from most stages of pregnancy enabled us to consider the mechanism of villous maturation and differentiation in some detail (Kaufmann, 1982; Castellucci

et al., 1990, 2000; Kohnen et al., 1996; Demir et al., 1997). Further insights into the dynamics of the growth of the villous trees can be obtained from their topologic analysis of the branching patterns and their later comparison with theoretical branching models (Kosanke et al., 1993). Our insight is still superficial, and our conclusions are accordingly preliminary. We believe, however, that we must discuss this concern because clinical methods (e.g., chorion biopsy and Doppler studies) have caused renewed interest; moreover, our understanding of the pathogenetic mechanisms of IUGR depends on an understanding of villous development.

### Development of the Mesenchymal Villi

The first tertiary villi recognizable are represented by mesenchymal villi (Castellucci & Kaufmann, 1982a). They are derived from the following sources (Castellucci et al., 1990, 2000):

- Up to the 6th week p.m., the mesenchymal villi are formed from primary villi via secondary villi (Boyd & Hamilton, 1970). The numerous trophoblastic primary villi are transformed into secondary villi by invagination of extraembryonic mesenchyme. Immediately thereafter, the first capillaries form, giving rise to tertiary villi, the mesenchymal villi considered here.
- Beginning from the 6th week p.m., the supply of primary and secondary villi is exhausted and new mesenchymal villi are henceforth formed by vascularization of trophoblastic sprouts. These structures are trophoblastic outgrowths of the surfaces of mesenchymal and immature intermediate villi and result from trophoblastic proliferation (Figs. 7.12, 7.13, and 7.16).

Not all sprouts (i.e., fungiform outgrowths from the villous surface) are signs of trophoblastic sprouting. Some represent stages of expulsion of apoptotic syncytial nuclei (see Chapters 6 and 15), and others are simply flat sections of villous surfaces (see Chapter 15) (Cantle et al., 1987). The true trophoblastic sprouts correspond to the primary villi of the early stages of placentation; the latter sprouts are invaded by mesenchyme and transformed into villous sprouts. These sprouts then correspond to secondary villi of early development. The first signs of capillary formation mark the transformation into mesenchymal villi.

The concentration of Langhans' cells is greater in mesenchymal villi than in all other villi. In addition, the mitotic index of villous cytotrophoblast, counted from autoradiographs following  $^3\text{H}$ -thymidine incorporation and from immunohistochemical preparations using the antibodies Ki-67, MIB-1, or proliferating-cell nuclear antigen (PCNA) (Kohnen et al., 1993; Kosanke et al., 1998), considerably exceeds that of all other villi. This fact was not evident in previous publications (Moe, 1971; Tedde & Tedde-Piras, 1978; Kaufmann et al., 1983; Arnholdt et al., 1991) because the authors did not differentiate among the various villous types.

### Development and Fate of Immature Intermediate Villi

Beginning between the 7th and 8th weeks p.m., mesenchymal villi transform to immature intermediate villi. This process is characterized by (1) an increase in villous diameter; (2) the formation of the stromal channels (Fig. 7.7) containing numerous macrophages (Enders & King, 1970; Kaufmann et al., 1979; Castellucci & Kaufmann, 1982a,b; Castellucci et al., 1984; King, 1987); (3) the transformation of mesenchymal cells in structurally and immunohistochemically different reticulum cells and fibroblasts (Kohnen et al., 1996); and (4) a decrease in thickness of syncytiotrophoblast and in the number of Langhans' cells.

The reticular stroma is the most characteristic feature of immature intermediate villi. It seems to play an important role during transformation of these villi into fibrosed

stem villi. According to G. Petry (personal communication, 1981), the accumulation of connective tissue fibers is preceded by a similar reticular architecture of connective tissue cells during the course of early scar formation in the skin. The significance of this stromal type appears to be defined by the role of macrophages (Hofbauer cells), which are involved in the remodeling of the connective tissue (Scott & Cohn, 1982; Werb, 1983; Castellucci et al., 1984; Takemura & Werb, 1984). There is presently no specific function for the immature intermediate villi, other than being a quickly growing developmental precursor for stem villi (Fig. 7.16).

Development of additional immature intermediate villi from mesenchymal villi gradually ceases at the end of the second trimester (Castellucci et al., 1990, 2000; Bukovsky et al., 1999). Their transformation into stem villi, however, continues to term. Therefore, the number of immature intermediate villi decreases steeply (Fig. 7.15). Sometimes they completely disappear before term. It is common, however, that small numbers persist in the centers of the villous trees and serve as growth zones.

### Development of Stem Villi

The development of stem villi is closely related to the formation of the immature intermediate villi. As early as in the 8th week p.m., the central vessels of the proximal segments of immature intermediate villi, near the chorionic plate, commence constructing a compact adventitia. They thus slowly transform into arteries and veins. Centrifugal expansion of the adventitia, paralleled by transformation of reticulum cells and fibroblasts into myofibroblasts, leads to a reduction of the adjacent reticular connective tissue (see Chapter 8, Figs. 8.4 to 8.8).

The transition of immature intermediate villi into stem villi is a gradual process. According to our definition, stem villi are established as soon as the superficial sheet of reticular connective tissue beneath the trophoblast is thinner than the fibrous center surrounding stem vessels (Figs. 8.5, 8.6) (Castellucci et al., 1990, 2000). Stem vessels have then been transformed into arteries and veins or arterioles and venules. The persistence of a small rim of reticular connective tissue beneath the trophoblast in the term placenta can be regarded as a reliable sign of placental immaturity (Kaufmann, 1981).

The formation of additional stem villi depends on the availability of immature intermediate villi. Therefore, the expansion of villous stems gradually ceases during the course of the last trimester, as soon as most of the immature intermediate villi have been transformed and new ones are no longer produced.

Increased stromal fibrosis outside stem villi is considered to be a pathologic phenomenon. Such villi are usually referred to as being fibrotic. Fox (1978) reported several conditions that are commonly associated with fibrotic villi:

FIGURE 7.16. Routes of villous development during early and late pregnancy. White arrows, transformation of one villous type into another; black arrows, new production of villi or sprouts along the surface of other villi. Upper half: First and second trimester. Trophoblastic sprouts are produced along the surfaces of mesenchymal and immature intermediate villi. Via villous sprouts, they are transformed into mesenchymal villi. The latter differentiate into immature intermediate villi, which produce new sprouts before they are transformed into stem

villi. Lower half: Throughout the third trimester, the mesenchymal villi become transformed into mature intermediate villi, which later produce terminal villi along their surfaces. There is no longer transformation of mesenchymal into immature intermediate villi. The remaining immature intermediate villi differentiate into stem villi. Thus, their number steeply decreases toward term. Thus, the base for the formation of new sprouts is also reduced, and the growth capacity of the villous trees gradually slows.

1. Stromal fibrosis is a regular finding of peripheral villi following fetal artery thrombosis.
2. It may also be found in inadequately vascularized villi adjacent to areas of infarction.
3. In placentas from macerated stillbirths, increased numbers of fibrotic villi have also been observed. Fox (1978) concluded that this must be a postmortem change because this feature is absent in placentas from fresh stillbirths. This issue, however, is still debated and probably depends on the causes of fetal demise.
4. A marked increase of fibrosed villi may be found in placentas of prolonged pregnancy.

Contrary to many other reports, Fox (1978) was unable to show an association between villous fibrosis and fetal complications, such as hypoxia or low birth weight. He thus refutes the theory that increased stromal fibrosis is a response to uteroplacental ischemia. In his opinion, it is more likely a result of reduced intravillous blood flow. This situation may result in intravillous hyperoxic conditions as oxygen transfer from the villi to the fetus is impaired (Macara et al., 1996; Kingdom & Kaufmann, 1997; see following).

## Development of the Mature Intermediate Villi

One of the most important steps for an understanding of villous development occurs at the beginning of the last trimester. At this time, the transformation of newly formed mesenchymal villi into immature intermediate villi switches to a transformation into mature intermediate villi (Figs. 7.15 and 7.16; also see Figs. 8.7 and 8.8) (Castellucci et al., 1990, 2000). Little is known about the factors causing this switch. The structurally most striking event at this developmental stage (Kaufmann & Kingdom, 2000; Kaufmann et al., 2004) is the switch

- from branching angiogenesis, which is responsible for the development of immature intermediate villi out of mesenchymal ones,
- to nonbranching angiogenesis, which is necessary for the growth of the long, poorly branched capillary loops characteristic for mature intermediate villi developing out of mesenchymal ones.

As will be dealt with later in this chapter, this switch from branching to nonbranching angiogenesis is modulated by a downregulation of vascular endothelial growth factor (VEGF) and an upregulation of placental growth factor (PlGF), as well as by respective changes of their receptors KDR and flt-1 (for review see Kingdom & Kaufmann, 1997; Charnock-Jones et al., 2004; Kaufmann et al., 2004; Mayhew et al., 2004). The factors, however, that trigger this switch in growth factor expression still remain unknown (see below).

Differing in two respects from immature intermediate villi, the mature intermediate villi provide the matrix out of which terminal villi develop, but they do not transform into stem villi.

## Development of the Terminal Villi

The first terminal villi, as defined in the past (Kaufmann et al., 1979; Sen et al., 1979), are produced soon after the first mature intermediate villi are formed (Fig. 7.15; see Table 8.1). The formation of terminal villi is closely related to the longitudinal growth of capillaries within the mature intermediate villi (see Figs. 7.19 and 7.23). As soon as longitudinal capillary growth exceeds longitudinal villous growth, the capillaries become coiled and form loops (Kaufmann et al., 1985, 1988). Because of the slender shape of these villi, the loops bulge on the trophoblastic surface and finally protrude as grape-like outgrowths into the intervillous space. This process is not accompanied by trophoblastic proliferation and, therefore, leads to considerable stretching of trophoblast. This process results in numerous vasculosyncytial membranes of terminal villi.

It follows that, in contrast to the development of other villous types, the terminal villi are not active outgrowths induced by proliferation; rather, they represent passive formations caused by capillary coiling. Accordingly, maldevelopment of terminal villi is always an immediate consequence of abnormal fetoplacental angiogenesis.

- Impaired angiogenesis results in deficiency of terminal villi (see Fig. 15.17).
- Overstimulated angiogenesis leads to the development of large conglomerates of terminal villi (see Fig. 15.16).

The slight bends of the mature intermediate villi, at points where terminal villi branch off (see Fig. 7.10A,D), illustrate the mechanical forces that have been active during capillary growth and coiling. Terminal villi, at the surfaces of stem villi and immature intermediate villi and derived from coiling of paravascular capillaries, are the exceptions because these particular capillaries show less impressive longitudinal growth (Leiser et al., 1985).

## Angioarchitecture of Villi

### Vascular Arrangement in Immature Villi

The first vascular nets formed in early placental villi show no differentiation into arteries, veins, or capillaries (Demir et al., 1989), a picture that changes around the 8th week p.m. (cf. Fig. 7.23, stage III). As a consequence of fusion of locally developed intravillous vascular nets with the fetal vessels that invade the villous trees via the connective stalk (the forerunner of the umbilical cord), the fetoplacental circulation becomes established. Because of pressure gradients between arterial and venous limbs, differently structured vessel walls appear (see Fig. 8.3). Connective tissue cells that aggregate around the endothelial tubes in a circular fashion are the first steps in the

formation of the walls of future arteries and veins. Normally, one artery and one vein are formed. The remaining capillary net that surrounds the larger vessels is referred to as the paravascular net. An example of this phenomenon has been illustrated by Boe (1969) (see Fig. 7.18). When he traced single vessels, he found numerous capillaries that formed shortcuts between arteries and veins but also between neighboring arteries (arterioarterial anastomoses). Because of the low blood pressure in the vascular system, effective arteriovenous shunting is unlikely.

The villus depicted by Boe (see Fig. 7.18) is consistent with what we described as an immature intermediate villus. It is an undifferentiated, still growing villous type that can even be found in the mature placenta, although in only small restricted groups. The small branching-off villi described by Boe as "terminal villi" are likely newly formed mesenchymal villi (see Figs. 7.12 and 7.18). As it is typical for newly formed villi, their richly branched capillary nets are connected only with the paravascular net, rather than directly with arteries and veins. Only after further development, as soon as some of their capillaries have been transformed to arterioles and venules, are direct connections to the fetal stem vessel established.

### Larger Vessels of Stem Villi

Large stem villi normally contain one artery in a nearly central position. If not constricted or collapsed, the lumen accounts for about one third of the villous caliber (see Fig. 7.3A). The endothelium is surrounded by a few layers of smooth muscle cells. The adventitia is continuous with the surrounding connective tissue without a sharp line of demarcation. The artery is normally accompanied by a corresponding vein. Its luminal width does not much exceed that of the artery in most preparations owing to the collapse occurring after delivery. In addition to the two main vessels, varying numbers of smaller arterioles and venules exist (Leiser et al., 1985; Kaufmann et al., 1988).

The most peripheral generations of stem villi branch or continue into mature intermediate villi and have diameters ranging from 80 to 150  $\mu\text{m}$  (Fig. 7.3B). The stem vessels are represented by arterioles and venules (Fig. 7.17; also see Fig. 7.19) that are surrounded by one or two layers of smooth muscle cells. The inconspicuous venules have one, usually incomplete, layer of muscle cells. Some are surrounded only by pericytes and correspond to the collecting venules of Rhodin (1968), despite their different diameter. Frequently, arterioles and venules of these segments are so similar that they cannot be identified on cross sectioning but only from reconstructions. For quantitative estimations of stem vessels, we refer to a survey by Leiser et al. (1991).

### Paravascular Capillary Net of Stem Villi

Beneath the trophoblast, numerous cross sections of capillaries with small calibers appear (Fig. 7.17; also see Figs. 7.19 and 7.24D). They belong to the paravascular net (Boe, 1953). This system is derived from the subtrophoblastic capillary net of the earlier immature villi. Because of vascular obstruction during transformation of the immature intermediate villi into stem villi, a rarefied and poorly branching system of slender capillary loops develops. It can be seen in most stem villi depicted in the literature (Arts, 1961; Thiriot & Panigel, 1978; Habashi et al., 1983; Leiser et al., 1985; Kaufmann et al., 1988). The paravascular capillaries follow a straight course, mostly parallel to the longitudinal axis of the villus. In our material of mature stem villi, net-like connections have been uncommon. We have seen such richly branched and dense paravascular capillary nets as depicted by Burton (1987) only in immature intermediate villi (Fig. 7.18) and in not yet fully matured stem villi. We concede, however, that our impression may be incomplete. The paravascular capillaries are connected to the arteries and veins by short arteriolar and venular segments, measuring up to 100  $\mu\text{m}$  in length.

Only in rare cases do the paravascular capillaries show focal sinusoidal dilatations. If this happens, the dilated and coiling segments bulge on the stem villus surface and form a terminal villus that arises from the stem villus (Kaufmann et al., 1979; Burton, 1987) (Fig. 7.17C, upper half). Such terminal villi are serially intercalated into the paravascular net. According to our experience, this occurrence is rare (less than 5% of all terminal villi), whereas Burton (1987) described it to be a regular finding.

When we traced individual paravascular capillaries from their arteriolar beginnings to their venular ends, we found an average length of 1000 to 2000  $\mu\text{m}$ . Arteriovenous and arterioarterial shortcuts, as described by Boe (1953, 1969) for the earlier stages of development, could no longer be detected in mature stem villi. There is therefore no real basis for speculations that the paravascular net participates in the regulation of fetal blood flow impedance as an arteriovenous shunting system.

The functional relevance of the paravascular capillary net is still uncertain. Thiriot and Panigel (1978) suggested that this was the site for effective fetomaternal exchange. The long diffusion distances in these places make this interpretation implausible. Moreover, the assumption by Arts (1961) that the paravascular net may be of nutritional importance for the stem villi, acting as a kind of vasa vasorum, seems unlikely to us. The concentration of oxygen and most nutrients in the surrounding intervillous space considerably exceeds that in the fetal vessels. Thus, the nutrition by direct diffusion from the maternal blood is probably more effective. This finding is in agreement with those of Zeek and Assali (1950) as well as Fox (1978),

FIGURE 7.18. Classical representation of the villous vascularization by Boe (1969) represents an immature intermediate villus with numerous mesenchymal side branches. The web-like arrangement of the fetal capillaries protruding from the paravascular net of the immature intermediate villus into its sprouting side branches is highly characteristic, not only for early placentas but also for villous sprouting patterns in the term placenta. As depicted in the foregoing pictures, it is normally absent in the mature villous types. (Source: Based on findings of Boe, 1969.)

who found not only survival of stroma but also increased fibroblast proliferation and collagen production within stem villi after fetal death.

Boyd and Hamilton (1970) described the paravascular net to be simply a residual indication of better vascularization during early stages of development. Keeping in mind that the developmental forerunners of the stem villi were immature intermediate villi with a well-developed paravascular net (Kaufmann et al., 1988), the respective

capillaries of the mature stem villi probably represent the remains of the immature state where terminal villi with their effective exchange system were absent and the paravascular net had to sustain maternofetal exchange. The development of better-vascularized terminal villi during the course of the last trimester renders the paravascular capillaries largely nonfunctional.

### Arrangement of Vessels in Mature Intermediate and Terminal Villi

The mature intermediate villi serve as junctional segments between the most peripheral stem villi and most of the terminal villi. Their vessels are direct continuations of the smallest stem villous vessels (Figs. 7.17C and 7.19). One or two small arterioles, with luminal diameters ranging from 20 to 40  $\mu\text{m}$ , appear histologically as bare endothelial tubes, accompanied by occasional muscle cells. Precapillary sphincters, or comparable narrow segments with complete muscular coats as described for other vascular beds (Rhodin, 1967), have not been identified. Rather, the terminal ends of arterioles continue directly into one or two capillaries by a gradual reduction of their diameters and loss of smooth muscle (Kaufmann et al., 1985; Leiser et al., 1991).

Although the arterioles occupy a more central position in the villous stroma, one or two venules can be found more superficially. Surprisingly, their diameter usually appears to be considerably smaller than that of the arterioles, usually 15 to 20  $\mu\text{m}$ . In agreement with the classification of Rhodin (1968), the term **postcapillary venule** seems to be most appropriate because of the absence of muscle cells and the existence of a nearly complete sheet of pericytes. The most peripheral loops of the paravascular capillaries of the stem villi surround the terminal arterioles and postcapillary venules. They extend to about the middle of the mature intermediate villi (Figs. 7.17C and 7.19).

In the distal half of the mature intermediate villi, the paravascular capillaries are absent. Histologically, the

FIGURE 7.17. Fetal vascularization of term placental villi based on the spatial reconstruction of serial sections. A: Large stem villi of the villous tree. ChP, chorionic plate; BP, basal plate; T, truncus; I, II, III, IV, rami chorii of the first to the fourth order. The more peripheral branches depicted in this drawing are ramuli chorii of the first to the tenth order. The marked peripheral ramulus with its terminal branches refers to part B. B: Higher magnification of peripheral branches of the villous tree. A peripheral stem branches into several mature intermediated villi (slender) and one immature intermediate villus (thick). The shaded rectangular area corresponds to the reconstructed branches depicted in part C. C: Fetal vascular branching patterns of a peripheral stem villus (above), continuing into a

mature intermediate villus, extending into several terminal villi, reconstructed from a series of 2300 semithin sections. Length and caliber of the villi are drawn on the same scale, whereas the diameter of the vessels is reduced to two thirds (necessary because of two-dimensional representation of a three-dimensional system). Occasional spots of fibrinoid necrosis on the villous surface are marked by hatching. Note that the capillary loops of neighboring terminal villi are serially connected. These are normally not continuous with the straight paravascular capillaries of the stem and mature intermediate villi, but form a second independent capillary bed. (Source: Modified from Kaufmann et al., 1988, with permission.)

FIGURE 7.19. Arrangement of the fetal vessels in a group of terminal villi (stroma unstained) derived from one mature intermediate villus (green dotted stroma). Based on a three-dimensional reconstruction of the peripheral branches of a mature villous tree. Note the highly complex loop formation of the terminal fetal capillaries. Branching is usually followed

shortly later by refusion of the two capillary branches. Such a branching pattern avoids basal shortcuts. Each erythrocyte must pass the terminal capillaries of several terminal villi in their full length. Local dilatations, so-called sinusoids, reduce blood flow impedance. Blue, fetal arteries and arterioles; lilac fetal villous capillaries and sinusoids; red, fetal villous venules and veins.

distal segment can easily be differentiated from the more proximal segments by the absence of larger vessel cross sections and the absence of vessels in the center of the stromal core; most capillaries are located directly beneath the trophoblast. In most cases, the abrupt end of the paravascular “net” causes a sharp line of demarcation between the more proximal segments, which are rich in capillaries, and the distal, less vascularized part (Figs. 7.17C and 7.19).

The terminal capillaries are different from the mostly straight paravascular capillaries and are characterized by the formation of loops and coilings. Focally dilated segments may bulge against the trophoblast and thus form vasculosyncytial membranes, knob-like protrusions, or even terminal villi. As one approaches the peripheral end of the mature intermediate villus, the number and extent of capillary coilings increases and so does the number of terminal outgrowths that cover the surface of the mature intermediate villus (Figs. 7.17, 7.19, and 7.20). At its end, the mature intermediate villus regularly branches into a cluster of terminal villi (Fig. 7.20).

There is no sharp demarcation between mature intermediate and terminal villi. Increased capillary coiling, accompanied by increased sinusoidal dilatation and reduced stromal connective tissue, is responsible for the structural differences. The descriptive name “terminal villus” is used for those villi

Depending on the level at which such terminal villi are sectioned, their histologic appearance is highly variable. An example is depicted in Fig. 7.20. The capillary loops of the peripheral terminal villi are direct continuations of terminal arterioles. According to our experience, they show only on occasion cross-connections to peripheral loops of the paravascular capillaries, described as a regular feature by Arts (1961). It is of particular importance to note that the capillary loops of neighboring terminal villi are serially connected to each other (Figs. 7.17C, 7.19, and 7.20A). Fetal blood leaving a terminal arteriole and entering the terminal capillaries normally passes through the capillary loops of three to five terminal villi in series before entering a postcapillary venule. This passage is responsible for the length of terminal capillaries, which we measured as ranging from 3000 to 5000  $\mu\text{m}$  (Kaufmann et al., 1985). Shortcuts at the base of terminal capillary loops are the exception, so that each erythrocyte has to pass the full length of the capillaries. As reported earlier, the paravascular capillary loops measure only 1000 to 2000  $\mu\text{m}$  in length.

When one looks at casts of vessels such as those depicted in Figure 7.20, it seems that the terminal capillary bed is made up of a highly branching network, and it has usually been described as such (Boe, 1953, 1968; Arts, 1961; Boyd & Hamilton, 1970; Thiriot & Panigel, 1978; Habashi et al., 1983; Burton, 1987). In contrast, our reconstructions of terminal vessel beds revealed only a low degree of branching. When discussing this discrepancy, Burton (1987) stated that “the superimposition of SEM [scanning electron microscopy] images can lead to mistaken estimates of the incidence of vessels joining, but it cannot be denied that branching and union

1. that contain no vessels other than capillaries and sinusoids, and
2. in which the vascular lumens comprise at least one half of the stromal volume (Kaufmann et al., 1979, 1985).

FIGURE 7.20. Fetal vascularization of terminal villi. A: Cast of vessels from a neck region (right) branching into three terminal villi. Comparable to mature intermediate villi, the capillaries of the neck region are strikingly straight and arranged in parallel; however, the diameter of the villus is much smaller.  $\times 520$ . Corresponding semithin sections of the neck region (B), the basis

of the branching terminal villi (C), a single terminal villus near its tip (D), and a flat section of the terminal villous tip (E). The fetal capillaries and the highly dilated sinusoids amount to more than 50% of the stromal volume as long as postpartal collapse can be avoided by early fixation.  $\times 630$ . (Source: From Kaufmann et al., 1988, with permission.)

between capillaries does occur within terminal villi. The problem may be only one of degree. . . .” We admit that our results were obtained from the reconstruction of only a few cases (Kaufmann et al., 1985); it is our opinion, however, that the more likely explanation for the discrepancy is one of definition. Branching, with directly subsequent union, is indeed a frequent feature (Fig. 7.19). It must not be confused with the establishment of true, complex intravillous capillary nets, which offer the possibility of basal shortcuts. The latter arrangement might considerably shorten the individual capillary length. On the other hand, a high degree of coiling with serially intercalated branching and direct fusion has no influence on the mean capillary length. This difference may have physiologic importance for fetal blood flow impedance. Jirkovska and coworkers (1998) have shown that three-dimensional reconstructions of terminal villi using confocal microscopy are a useful approach to solve these questions. This is particularly valid if sophisticated methods of tissue preparation are applied such as dual perfusion fixation (Larsen et al., 1995).

### Sinusoids of Terminal Villi

Sinusoids are focal capillary enlargements that attain diameters to about 50  $\mu\text{m}$  (Figs. 7.11 and 7.20). They are thought to be typical features of the mature placenta and are not comparable to the sinusoids of liver, spleen, and bone marrow, as the former possess a continuous endothelium and complete basal lamina. Sinusoids thus differ from conventional capillaries only by their increased diameters.

In semithin sections, the sinusoids are normally positioned near the villous tips. Vascular casts, however, reveal that they are randomly scattered over the full length of the terminal capillaries, rather than dilatations of defined segments (Kaufmann et al., 1985). They may narrow and dilate serially several times (Fig. 7.19). Statistically, they can be found more frequently near the villous tips and along the venous limbs, as well as at points of branching and fusion. The grade of dilatation and the degree of tortuosity of the capillary loops seem to depend on each other.

We have measured the diameters of capillaries and sinusoids in semithin sections and compared them to casts of vessels (Kaufmann et al., 1985). The results, obtained with both methods, were largely consistent. The mean diameters of capillaries and sinusoids of the mature placenta varied from 12.2  $\mu\text{m}$  ( $\pm 0.58 \mu\text{m}$ ) in vessel casts to 14.4  $\mu\text{m}$  ( $\pm 1.94 \mu\text{m}$ ) in semithin sections. The difference can be explained by different degrees of shrinkage of the resins used for preparation. In our experience, the higher values seem to be more appropriate. The maximum values were 39  $\mu\text{m}$  in casts of vessels and 45  $\mu\text{m}$  in semithin sections. Depending on the method applied, 60% to 80% of the vessel lumens had diameters larger than 10  $\mu\text{m}$ . Our data are largely consistent with those reported by Becker (1962a), Becker and Seifert (1965), and Boyd and Hamilton (1970).

The smaller diameters reported by Habashi et al. (1983) and O'Neill (1983), the latter author giving a range of only 4 to 7  $\mu\text{m}$ , are probably the result of incomplete filling of vessels of their casts and resin shrinkage. Even more contradictory are the physiologic results published by Penfold et al. (1981). These authors perfused capillaries with microspheres of varying diameters and concluded that as many as 25% of capillaries measure less than 4  $\mu\text{m}$  in diameter and virtually no capillary exceeds 11  $\mu\text{m}$  in diameter. Their results were based on the erroneous assumption that narrow and dilated capillary loops are arranged in parallel; their results must be refuted (Habashi et al., 1983). In fact, the capillaries become narrow and dilate serially. Thus, when using microsphere perfusion, the diameter for the narrowest segment of each capillary loop can only be estimated. Even so, the value of 4  $\mu\text{m}$  for 25% of the capillary loops cannot be accepted.

**Function:** The functional relevance of the sinusoids has caused much speculation. It is evident from the foregoing description that the sinusoidal dilatation cannot be regarded as dilated venous limbs of the capillary loops that allow retarded venous backflow, as was discussed by Nikolov and Schiebler (1973). The localization of most sinusoids near the villous tips supports the conclusion of Arts (1961) that the sinusoids locally decelerate blood flow, thus providing ample opportunity for fetomaternal exchange. This assumption is in agreement with the finding that the sinusoids are regularly situated in contiguity with the epithelial plates (Boyd & Hamilton, 1970; Nikolov & Schiebler, 1973, 1981; Schiebler & Kaufmann, 1981). These plates are thought to represent areas of maximal diffusional exchange (Amstutz, 1960; Kaufmann et al., 1974).

It is still a matter of dispute whether the reduced blood flow velocity facilitates the maternofetal exchange or whether the increased diffusion distance from the center of sinusoids to villous surface negatively influences the diffusion capacity. Another explanation for the existence of sinusoids has been that they serve as functionally specialized segments devoted to specific transport processes. Nikolov and Schiebler (1981) described two types of endothelial cells. These findings, however, cannot serve as arguments for a functional specialization of sinusoids compared to narrow capillaries, as they seem to be evenly distributed in both vessel segments.

We have discussed another explanation for the function of the sinusoids elsewhere (Kaufmann et al., 1985, 1987, 1988). It is remarkable that the sinusoids are pro-

duced at the end of pregnancy (Becker, 1981), as soon as the terminal villi achieve the highest degree of branching and twisting and as the terminal capillary loops reach their maximal length of 3000 to 5000  $\mu\text{m}$ . On the other hand, sinusoids are largely absent in the shorter terminal capillary loops of immature placentas and in the shorter paravascular capillaries. Moreover, they are not found in labyrinthine placentas such as those of the guinea pig (Kaufmann & Davidoff, 1977) and chinchilla (Dantzer et al., 1988), both of which are characterized by short fetal capillaries, ranging from 500 to 1000  $\mu\text{m}$ . We have also studied some capybara placentas (Kaufmann, 2004). This species is of the same suborder of caviomorph rodents as the guinea pig and chinchilla but it has a much larger placenta with fetal capillaries of about twice their lengths. Its placenta shows fetal sinusoids. The same is true for the goat placenta, which has long capillary loops comparable to those of the human placenta (Leiser, 1987; Dantzer et al., 1988).

According to the law of Hagen-Poiseuille, blood flow resistance is reduced by the fourth power of the vascular radius. It can be concluded that even limited and focal sinusoidal dilatation of the long terminal capillary loops may considerably decrease blood flow impedance to such a degree that it no longer exceeds that in the shorter paravascular capillaries. In this way, an even blood flow distribution is guaranteed for all capillaries, independent of their length and diameter. In addition, for this low-pressure fetal circulatory system, the perfusion of the huge extracorporeal organ becomes much easier.

## Fetoplacental Angiogenesis as the Driving Force for Villous Development

As already noted before, the structural comparison of (1) villous development with (2) vascular development within the villi suggests that both processes depend on each other. This impression is further substantiated by the analysis of normally as compared to abnormally matured terminal villous ramifications:

- More than 95% of terminal villi arise from the surfaces of mature intermediate villi by simple bulging of coiled capillaries (Kaufmann et al., 1985) (Fig. 7.19).
- "Hypermature villi" (Salvatore, 1968; Kaufmann, 1982; Kaufmann et al., 1987), villi in maternal anemia (Kingdom & Kaufmann, 1997; Kosanke et al., 1998), and villi in IUGR with abnormal but still preserved end-diastolic (PED) flow in the umbilical arteries (IUGR with PED) (Todros et al., 1999) show an increased number of highly branched terminal villi, together with highly branched capillary networks (see Fig. 7.23).

- In contrast, placentas from IUGR with ARED umbilical flow exhibit nearly naked, unbranched mature intermediate villi that continue in one single terminal villus (Krebs et al., 1996; Macara et al., 1996; Kingdom et al., 1997a,b). The terminal capillaries are much shorter, and uncoiled, with only a few sinusoidal dilations (see Fig. 7.23).

We conclude from these observations that the development of terminal villi is influenced by the balance of longitudinal growth of mature intermediate villi with that of their capillary loops. The more capillary growth exceeds the longitudinal villous growth, the more do the capillaries become coiled. The single coils bulge against the surfaces of the mature intermediate villi and thus produce the terminal villi. We interpret the terminal villi as passive outpocketings, rather than the result of trophoblastic proliferation.

Even more simplified, one can say that the placental villous trees are fetoplacental vascular trees covered by a flexible wrapping of trophoblast. The latter does not shape the villi but rather follows the vascular shapes.

### General Aspects of Placental Vasculogenesis and Angiogenesis

Because of the obvious importance of formation of vessels for the understanding of decisive steps of villus development, some general principles of vasculogenesis

and angiogenesis (Fig. 7.21) as well as the respective findings in the placenta shall be summarized here (for review see also Breier, 2000).

According to Folkman and Shing (1992), Risau and Flamme (1995), and Risau (1997), formation of vessels can be subdivided in two processes that differ regarding mechanisms and control:

- Vasculogenesis involves de novo formation of blood vessels from mesodermally derived precursor cells. Throughout placentation, it takes place during the development of the first villous vessels at the transition from secondary to the tertiary villous stage (from day 18 through about day 35), and later in pregnancy during formation of mesenchymal villi out of immature intermediate ones.
- Angiogenesis is the expansion of a preexisting vessel bed and involves creation of new vessel branches from preexisting ones as well as longitudinal growth of vessels. Throughout placentation it is the principal mechanism for the development of the vascular supply of immature intermediate villi, stem villi, mature intermediate villi, and terminal villi.

Placental angiogenesis must be further subdivided regarding its mechanisms and the geometry of the resulting vascular bed (Kingdom & Kaufmann, 1997; Kaufmann & Kingdom, 2000; Charnock-Jones et al., 2004) into of the following categories:

FIGURE 7.21. Diagrammatic survey of basic mechanisms of vasculogenesis and angiogenesis, their attribution to villous development and their presumed paracrine control (red). For details see text.

- **Branching angiogenesis:** This term describes a pattern in which multiple sprouting of microvessels produces a complex, multiply branched capillary web. This is the principal type of angiogenesis from day 32 until about week 24 during development of mesenchymal and immature intermediate villi.
- **Nonbranching angiogenesis:** In this type of angiogenesis branching by sprouting is the exception. Rather, the vascular bed expands by elongation of existing capillary loops. This mode of angiogenesis starts at about week 24 when mesenchymal villi start developing into mature intermediate villi and the latter start producing terminal villi. It lasts until term. Under pathologic conditions it may become the only mode of angiogenesis. Under normal conditions it takes place in combination with branching angiogenesis.

### Vasculogenesis 1: Origin of Hemangiogenic Progenitor Cells (Days 15 to 21)

The first generations of placental villi develop by local *de novo* formation of capillaries (vasculogenesis) rather than protrusion of embryonic vessels via the umbilical cord into the placenta. In the rhesus monkey (gestation 166 days), the onset of vasculogenesis is around day 19 postconception (King, 1987). The few existing respective data in the human (Knoth, 1968; Demir et al., 1989) suggest a slightly later date, at about 21 days postconception, in four-somite embryos. At this stage, the villous trees comprise solid trophoblastic primary villi and secondary villi containing a villous core of loose mesenchymal stroma invading from the exocoelomic cavity.

Hertig (1935) formulated the classic theory that villous mesenchymal cells and hemangioblastic cells are derived from villous cytotrophoblast by *in situ* delamination. This view has been refuted by all subsequent authors (Dempsey, 1972; Luckett, 1978; King, 1987; Demir et al., 1989), who found that the villous mesenchyme is directly derived from the fetus and invades the villi. The hemangiogenic progenitor cells differentiate locally in the villi from the fetally derived mesenchymal cells. The two cell types are structurally similar.

Using the monoclonal antibody QBend10, which detects the endothelial cell surface marker CD34, the endothelial precursor cells (hemangiogenic progenitor cells) can be demonstrated already from day 15 postconception onwards (Figs. 7.22, 7.23, and 7.24A). Within a short period of time the originally dispersed hemangiogenic progenitor cells form string-like aggregates of polygonal cells (hemangiogenic cords), which differ from their mesenchymal precursors by the absence of cellular extensions and the presence of fewer organelles. The narrow intercellular spaces between these

cells are bridged by desmosomes and primitive tight junctions (Fig. 7.22c). Extensions of surrounding mesenchymal cells are often integrated into these clusters.

A variety of angiogenic growth factors are involved in angiogenesis and vasculogenesis (Table 7.2). Basic fibroblast growth factor (FGF-2 or bFGF) and its receptor FGFR are thought to be involved in recruitment of hemangiogenic progenitor cells. Its expression in human placental villi has been described repeatedly (Ferriani et al., 1994; Shams & Ahmed, 1994; Crescimanno et al., 1995) but, due to shortage of respective material, never at this early stage of pregnancy. Vascular endothelial growth factor A (VEGF-A) and its receptor VEGFR-2 (KDR/flk-1), which were found to be responsible for recruitment, growth, and aggregation of the hemangiogenic progenitor cells in other organs, are highly expressed in early placental specimens (Sharkey et al., 1993; Ahmed et al., 1995, 1997; Wheeler et al., 1995; Shore et al., 1997; Vuorela et al., 1997; Demir et al., 2004). *In situ* hybridization and immunohistochemistry revealed that villous trophoblast and villous stromal macrophages are the main sources of this cytokine (Sharkey et al., 1993; Ahmed et al., 1995; Vuorela et al., 1997; Demir et al., 2004). VEGF-A secretion by human trophoblast was also demonstrated *in vitro* by Shore et al. (1997). The assumption that macrophages and their cytokines are involved in these first steps of capillary formation is in line with the finding that macrophages differentiate locally in villous stroma even prior to the development of hemangiogenic cords (Demir et al., 1989). Knockout experiments in mice have also highlighted the importance of VEGFR-2 for specification and early differentiation of hemangioblastic precursors of fetoplacental capillaries (Shalaby et al., 1995).

### Vasculogenesis 2: Formation of Endothelial Tubes (Days 21 to 32)

Lumen formation within the hemangiogenic cords and thus formation of short segments of endothelial tubes starts at day 21 postconception. This occurs by enlargement of the centrally located intercellular clefts that fuse to become a larger lumen (Fig. 7.22c,d). We have never observed lumen formation by fusion of intraendothelial vacuoles, as this has been described in other organs (Folkman & Haudenschild, 1980; Bär et al., 1984). Rather, the fetoplacental capillary lumen in the human, as in placentas of other mammals, always seems to form by acquisition of a junctionally defined extracellular compartment within the hemangioblastic cords (guinea pig: Davidoff & Schiebler, 1970; rhesus monkey: King, 1987; human: Demir et al., 1989). The acquisition of such still unconnected, isolated segments of capillaries (Fig. 7.23, stage I) defines the transition from secondary to tertiary villi.

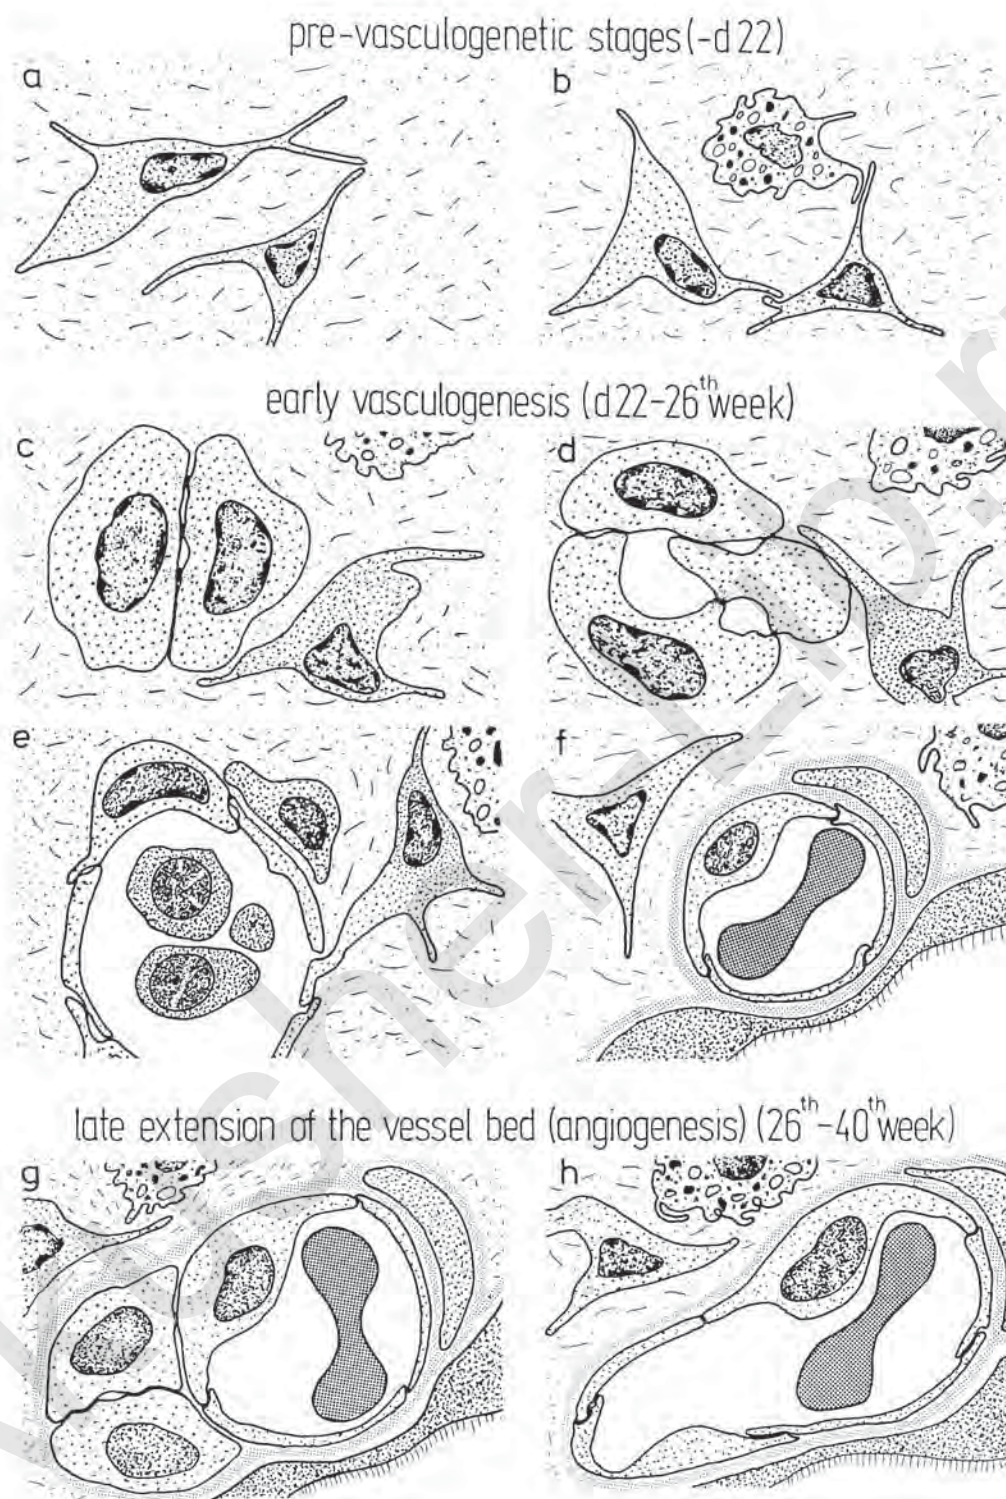

FIGURE 7.22. Vasculogenesis and angiogenesis in early and late placental villi. For further details, see text. (Source: Demir et al., 1989, with permission.)

FIGURE 7.23. Villous development in relation to fetal vascular development. Stage I: In the first stage (weeks 5 to 6 p.m.), within mesenchymal villi (mv) fetal capillary segments are formed by vasculogenesis (see Fig. 7.18). Stage II: In weeks 7 to 8 p.m. the primitive vessel segments fuse to form a simple net-like capillary bed. Stage III: During development of immature intermediate villi (iiv) from mesenchymal villi (mv) between weeks 9 and 25 p.m., the preexisting capillary bed enormously expands by branching angiogenesis. This process is likely to be driven predominantly by vascular endothelial growth factor (VEGF). Stage IV: During weeks 15 to 32 p.m., most of the older immature intermediate villi are transformed into highly fibrosed stem villi. In the course of this process, the centrally located capillaries become transformed into stem vessels (arteries and veins), whereas most of the peripheral capillaries undergo regression. In the periphery of these primitive stem villi, mesenchymal villi (mv) are transformed into mature intermediate villi (miv) by nonbranching angiogenesis, resulting in considerable elongation of preexisting capillary loops. The switch from branching angiogenesis toward capillary regression and nonbranching angiogenesis, respectively, is likely to be controlled by increasing levels of placental growth factor (PIGF) and decreasing levels of VEGF. Stage V: Throughout the last

trimester (weeks 25 to 40 p.m.), generally increasing levels of angiogenetic growth factors stimulate longitudinal capillary growth within the mature intermediate villi; as a consequence, elongation of capillary loops exceeds elongation of the villi themselves. This difference results in coiling of the capillaries, the coils bulging against the surface, thereby causing the development of terminal villi (tv). Different types of terminal villous development result from varying degrees of imbalance between villous and capillary growth in context with prevalence of branching or nonbranching angiogenesis (compare Fig. 15.5). Prevalence of PIGF is responsible for predominance of nonbranching angiogenesis, resulting in long, filiform terminal villi (stage Va), typical for postplacental hypoxia. The prevalence of VEGF stimulates terminal branching angiogenesis, resulting in highly branched convolutes of short and multiply notched terminal villi (stage Vc), typical for preplacental and uteroplacental hypoxia. Well-balanced secretory levels of VEGF and PIGF are responsible for a balance of branching and nonbranching angiogenesis; thus, evenly formed grape-like terminal villi represent the dominating features in normal term pregnancy. Green, collagen fibers; brown, vascular smooth muscle cells; blue, endothelial tubes.

FIGURE 7.24. Stages of villous vasculogenesis and angiogenesis, immunostained with the endothelial marker antibody Qbend10. A: Day 15 to day 20 postconception. The antibody stains weakly hemangiogenic cell cords (light brown). True capillaries are still missing.  $\times 650$ . (Source: From Kaufmann & Kingdom, 2000, with permission). B: Mesenchymal villi in week 7 p.m. The majority of capillary cross sections have developed lumens. The capillaries are still evenly distributed across the villous stroma.  $\times 320$ . C: Immature intermediate villi at the end of the first trimester.

Note the subtrophoblastic localization of richly developed capillary nets. The remaining central vessels are the precursors of arterioles and venules.  $\times 320$ . D: Terminal and mature intermediate villi (left) and a large-caliber stem villus (right) in week 20 p.m. Note the dense capillarization of the peripheral villous branches, as opposed to the scarce capillarization of the stem villus, largely consisting of superficially located paravascular capillaries.  $\times 320$ . (Source: Kaufmann & Kingdom, 2000, with permission).

TABLE 7.2. Expression of angiogenic growth factors and their receptors in normal and pathologic pregnancies

Growth factors and their receptors	Placental site of expression	Serum levels throughout pregnancy	Data from pathologic pregnancies
VEGF-A	Trophoblast, Hofbauer cells, vascular smooth muscle (1–5)	Moderate increase of total VEGF serum levels throughout pregnancy (including VEGF bound to its antagonist sflt-1) (6,34)	Total is increased in preeclampsia; free VEGF-A may be lower. Placental VEGF-A immunostaining lower (6–10)
VEGF-B	None detected (2)	"	%
VEGF-C	Decidual NK cells (11)	"	%
VEGF-D	None detected	"	%
PlGF	Trophoblast (2,12)	Marked increase of PlGF serum levels throughout pregnancy, peaking at weeks 28–32 (13,15)	Reduced in maternal plasma in preeclampsia (13–15)
VEGFR-1 (flt-1)	Trophoblast, endothelial cells (1,5,10,27)	%	%
VEGFR-2 (kdr)	Villous endothelial cells (1,5,10,28)	%	%

Extended and modified after Charnock-Jones et al., 2004.

Immunohistochemical studies have found that the receptor VEGFR-1 (flt-1) is expressed on human villous endothelium (Crescimanno et al., 1995; Clark et al., 1996a; Vuckovic et al., 1996; Demir et al., 2004) but also in villous macrophages and trophoblast (Ahmed et al., 1995; Clark et al., 1996a). Analysis of knockout animals by Fong et al. (1995, 1999) has suggested that VEGFR-1 mediates the action of VEGF-A on endothelial precursors. Interestingly, deletion of the tyrosine kinase encoding intracellular portion of the *VEGFR-1* gene has no effect on vascular structures (Hiratsuka et al., 1998), suggesting that it is the extracellular portion of the molecule (i.e., the soluble VEGF

antagonist, sflt-1) that is required for placental vascular development.

By day 28 postconception, most villi show clearly defined, long, polygonal capillary lumens with surrounding endothelial cells becoming considerably flattened (Fig. 7.22D,E). Additional mesenchymal cells are integrated by their extensions into both the mesenchymal network and the endothelial tubes (Fig. 7.22E). These "juxta-hemangiogenic" cells are characterized by richly developed rough endoplasmic reticulum and are considered to become pericytes (Dempsey, 1972; King, 1987). Also their inclusion into the endothelial lining has been discussed, since focal extension of these cells may even

protrude between endothelial cells (Dempsey, 1972; Challier et al., 1999).

As soon as capillary lumens have been formed, around day 28 postconception, the first hematopoietic stem cells develop by delamination from the primitive vessel walls into the early lumens and start further differentiation (Fig. 7.22E). These cells are not yet circulating since most of the endothelial tubes are still isolated. Also an anatomic connection via the cord to the embryonic circulation does not exist yet. The latter is established a few days later (between days 32 and 35 postconception) by fusion of villous capillaries with each other (Fig. 7.23, stage II) and with the larger, allantoic vessels. The latter are formed by vasculogenesis within the allantois (Downs et al., 1998) and thereafter spread in both embryonic and placental directions and finally establish the connection between intraembryonic and placental vascular beds.

### Angiogenesis 1: Branching Angiogenesis (Day 32 to Week 25)

At around day 32 postconception many villous endothelial tubes have created contact among each other (Fig. 7.23, stage II) and with the fetal allantoic vessels in the presumptive umbilical cord. A primitive fetoplacental circulation is established. From this data onward, vasculogenetic de novo formation of capillaries out of mesenchymal precursors is an exception that usually can only be found at the tips of newly sprouting mesenchymal villi. Rather, further expansion of the villous vascular system until term mainly takes place by angiogenesis.

The angiogenic processes from day 32 until term can be divided into three periods that partly overlap:

1. Formation of capillary networks from day 32 to 25 weeks post conception by prevalence of branching angiogenesis (Fig. 7.23, stage III)
2. Regression of peripheral capillary webs and formation of central stem vessels mainly through weeks 15 to 32 postconception (Fig. 7.23, stage IV)
3. Formation of terminal capillary loops by prevalence of nonbranching angiogenesis (25 weeks postconception until term) (Fig. 7.23, stage V)

From day 32 postconception until the end of the first trimester, the endothelial tube segments formed by vasculogenesis are transformed into primitive capillary networks by the interaction of two mechanisms: (1) elongation of preexisting tubes by nonbranching angiogenesis, and (2) ramification of these tubes by lateral sprouting (sprouting angiogenesis; Carmeliet, 2003) and possibly also by intussusceptive microvascular growth (branching of a preexisting vessel by formation of an endothelial pillar along the vessel lumen (Burri & Tarek, 1990).

In the first generation of small-caliber villi (mesenchymal villi), branching angiogenesis is less expressed and the resulting capillary webs are only poorly developed (Fig. 7.23, stage II; Fig. 7.24B). With increasing diameter of the immature intermediate villi differentiating out of the mesenchymal villi, branching angiogenesis is stimulated and results in a dense two-dimensional network which is located just below the villous surface (Fig. 7.23, stage III; Fig. 7.24C).

Around the capillaries differentiation processes occur. The endothelial tubes acquire an incomplete layer of pericytes. First spots of basal lamina material are deposited around the endothelial tubes and around the pericytes from about 6 weeks postconception. Complete wrapping of capillaries by basal lamina has been observed only in the last 10 weeks of pregnancy (Fig. 7.22; Demir et al., 1989).

In vitro experiments on the chorioallantoic membrane of the chicken (Wilting et al., 1995, 1996) have shown that binding of VEGF to both of its receptors (VEGFR-1 and -2) stimulates branching angiogenesis and results in highly branched capillary webs. Expression of VEGF-A and VEGFR-2 are most intense in these early stages of pregnancy. Whether they decline or moderately increase as pregnancy advances is still a matter of controversy (Jackson et al., 1994; Cooper et al., 1996; Sharkey et al., 1996; Shiraishi et al., 1996; Vuckovic et al., 1996; Evans et al., 1998; Kumazaki et al., 2002). By contrast, expression of PlGF and the soluble form of VEGFR-1 (Crescimanno et al., 1995; Clark et al., 1998b,c; He et al., 1999; Kumazaki et al., 2002) have been found steeply to increase toward term when branching angiogenesis is increasingly replaced by nonbranching angiogenic mechanisms. Placental growth factor binds selectively to VEGFR-1 and, in some systems, appears to suppress sprouting angiogenesis (chorioallantoic membrane of the chicken; Wilting, personal communication). However, in other systems (rabbit cornea and mouse skin), PlGF stimulates formation of highly branched capillary networks (Ziche et al., 1997; Odorisio, 2002).

### Angiogenesis 2: Formation of Stem Vessels and Regression of Capillaries in Stem Villi (Weeks 15 to 32)

In the third month of pregnancy differentiation of stem villi out of immature intermediate villi is started: some of the centrally located endothelial tubes of immature intermediate villi achieve larger diameters of 100  $\mu$ m and more. Within a short period of time, they establish thin sheaths of contractile cells expressing  $\alpha$ - and  $\gamma$ -smooth (sm) actins in addition to vimentin and desmin. This is followed soon afterward by the expression of sm-myosin (Kohnen et al., 1996; Demir et al., 1997). The surrounding stroma shows concentric, centrifugally spreading fibrosis.

These vessels are forerunners of villous arteries and veins. In larger immature intermediate villi, the adventitia of arteries and veins fuse, thereby forming a fibrosed stromal core within the villus. As soon as more than 50% of the reticular stroma of the former immature intermediate villi is replaced by fibrosed stroma, this type of villus is called a stem villus.

Establishment of the outer parts of vessel walls is thought to be controlled by the balance of angiopoietin-1 (Ang-1), and angiopoietin-2 (Ang-2), interacting at their receptor Tie-2 (Tek) (Hanahan, 1997). Accordingly, Ang-1 and Ang-2 protein and messenger RNA (mRNA) have been detected in perivascular cells of immature intermediate villi (Geva et al., 2002) where differentiation of stem vessels takes place.

In the course of pregnancy, fibrosis of the stroma of the stem villi advances in a centrifugal manner toward the villous trophoblast (Fig. 7.24D). In parallel, the superficial, subtrophoblastic capillary net become rarified into few largely unbranched paravascular capillaries (Fig. 7.23, stage IV) (Arts, 1961; Leiser et al., 1985). The mechanisms by which capillary regression occurs in stem villi are unstudied, nor is it known whether Ang-2 and its receptor Tie-2 (Hanahan, 1997), the lack of VEGF-A, or the increase of PlGF is involved. The latter is under discussion since Cao et al. (1996) and Khaliq et al. (1999) reported that PlGF may antagonize VEGF action and thus suppresses angiogenesis. Interestingly, regression of capillary nets in developing stem villi is contemporaneous with loss of trophoblast at the villous surface and reduction of macrophages in the fibrosing stroma (own data; Demir et al., 1997), both known to be rich sources of VEGF-A (Sharkey et al., 1993, Ahmed et al., 1995, Vuorela et al., 1997).

### Angiogenesis 3: Prevailing Nonbranching Angiogenesis (Week 25 to Term)

From about 25 weeks postconception until term, mesenchymal villi transform no longer into immature intermediate villi but rather into a new villous types, the mature intermediate villi. These are slender (80 to 120  $\mu\text{m}$  diameter), elongated villi (>1000  $\mu\text{m}$  long) containing one or two long, poorly branched capillary loops. Differentiation of this new villous type out of mesenchymal precursors becomes possible since the pattern of villous vascular growth switches from prevailing branching angiogenesis (leading to immature intermediate villi) to the prevalence of nonbranching angiogenesis (Kaufmann & Kingdom, 2000).

Analysis of proliferation markers at this stage reveals a relative reduction of trophoblast proliferation and an increase in endothelial proliferation along the entire length of the mature intermediate villi, resulting in non-sprouting angiogenesis by proliferative elongation. An

alternative mechanism of capillary elongation would be intercalation (Raffi et al., 2002), that is, by recruitment of circulating endothelial progenitor cells into existing vascular endothelium; but currently there is no evidence to support this.

The final length of these peripheral capillary loops exceeds 4000  $\mu\text{m}$  (Kaufmann et al., 1985, 1988). Most importantly, they grow at a rate that exceeds that of the mature intermediate villi themselves, resulting in coiling of the capillaries (Fig. 7.23, stage V). The looping capillaries bulge toward the trophoblastic surface and thereby contribute to formation of the terminal villi, the number of terminal villi depending on the degree of capillary elongation and the resulting degree of coiling (Fig. 7.23, stage Va–c; Fig. 7.24D). Each of the terminal villi is supplied by one or two capillary coils and is covered by an extremely thin (<2  $\mu\text{m}$ ) layer of trophoblast that contributes to the so-called vasculosyncytial membranes. Normally, the capillary loops of five to 10 such terminal villi are connected to each other in series by the slender, elongated capillaries of the central mature intermediate villus (Figs. 7.19 and 7.24D).

Immunohistochemical studies on the expression patterns of VEGF-A, PlGF, and their receptors give hints as to their importance in villous angiogenesis. Expression of VEGF-A and VEGFR-2 are intense early in pregnancy and decline as pregnancy advances (Jackson et al., 1994, Cooper et al., 1996, Shiraishi et al., 1996, Vuckovic et al., 1996; Kumazaki et al., 2002) or at least increase much less than placental weight does (Sharkey et al., 1996; Evans et al., 1998). By contrast, expression of VEGFR-1 and PlGF steeply increase toward term (Crescimanno et al., 1995; Clark et al., 1996a; Kumazaki et al., 2002). Placental growth factor is expressed in both villous syncytiotrophoblast (Shore et al., 1997, Vuorela et al., 1997) and the media of larger stem vessels (Khaliq et al., 1996, 1999). Experiments on the avian chorioallantoic membrane (Wilting et al., 1995, 1996) have shown that binding of VEGF-A to its receptors results in sprouting angiogenesis and a highly branched capillary web. In contrast, PlGF (which binds selectively to VEGFR-1) is reported to suppress angiogenesis (Cao et al., 1996).

As already indicated above, the role of PlGF may be very complex. Initially, it was reported that this factor had little potency *in vitro* to stimulate endothelial cell proliferation. Therefore, it was suggested that PlGF functioned either as a weak stimulator or, more likely, as an antagonist of the proangiogenic actions of VEGF-A (Cao et al., 1996; Khaliq et al., 1999). However, Lang et al. (2003) showed that PlGF *in vivo* stimulates proliferation of microvascular endothelial cells in human term placenta, and Ziche et al. (1997) showed that PlGF *in vivo* is a potent stimulator of angiogenesis. Overexpression of PlGF in mouse skin leads to a substantial increase in vessel growth, and ischemic tissues can revascularize

following PIGF treatment (Luttun et al., 2002; Odorisio et al., 2002).

In spite of these contradictions, correlation of growth factor data (Jackson et al., 1994, Cooper et al., 1996, Sharkey et al., 1996; Shiraishi et al., 1996, Vuckovic et al., 1996; Evans et al., 1998; Torry et al., 1998; Chappell et al., 2002; Kumazaki et al., 2002) with development of the villous angioarchitecture (Kaufmann et al., 1985, 1988, Leiser et al., 1985; Kaufmann & Kingdom, 2000) suggests that the final geometry of villous vascular bed is defined, at least to some degree, by the balance of VEGF-A and PIGF together with their receptors.

- Total circulating VEGF is high in early pregnancy (Jackson et al., 1994, Cooper et al., 1996, Sharkey et al., 1996; Shiraishi et al., 1996, Vuckovic et al., 1996; Evans et al., 1998; Kumazaki et al., 2002), whereas circulating PIGF is low (Torry et al., 1998; Chappell et al., 2002). The predominance of VEGF in this period promotes establishment of richly branched, low-resistance capillary beds within mesenchymal and immature intermediate villi, both of which prevail during the first two trimesters of pregnancy.
- By contrast, in the second half of pregnancy VEGF either decreases (Jackson et al., 1994, Cooper et al., 1996; Shiraishi et al., 1996; Vuckovic et al., 1996; Kumazaki et al., 2002) or shows only a moderate further increase (Sharkey et al., 1996; Evans et al., 1998), whereas PIGF levels steeply increase and peak between weeks 28 and 32, the period of the most dramatic non-branching angiogenesis. The balanced secretion of both cytokines in this period or even the predominance of PIGF and its receptor VEGFR-1 seems to block the development of complex capillary beds to the benefit of poorly branched terminal capillary loops in the last trimester.

## Oxygen and Oxygen-Controlled Growth Factors as Regulators of Villous and Vascular Development

Only a little is known concerning the control of villous development. On the other hand, a broad variety of pathologic conditions, such as genetic abnormalities but also such as diabetes mellitus, maternal hypertension, maternal anemia or pregnancy in high altitude, rhesus incompatibility, and smoking during pregnancy, severely affect villous and fetoplacental vascular development. This list suggests that the villous and vascular maturational processes are influenced not only by genes but also by endocrine, metabolic, and environmental parameters. From these, only the role of oxygen has been studied in some more detail.

## The Special Role of Oxygen in the Placenta

When discussing effects of oxygen in the placenta, one should be aware of the special role of this gas in the placenta.

First, transplacental oxygen transfer is only one of many villous functions; however, its particular importance becomes evident from the fact that it is nearly the only villous function that, upon disturbance, within a short period of time may cause fetal death. Because of this, it is not surprising that the maternal oxygen supply to the placenta has a stronger impact on villous growth and differentiation than any other known parameter.

Second and even more importantly, in **most organs** the interactions among density of vascularization, tissue oxygenation, and capillary growth follow the same pattern: a low degree of local vascularization results in insufficient oxygen delivery to this tissue. The resulting tissue hypoxia stimulates capillary growth and thus improves capillary density and local tissue oxygenation. On the other hand, optimum capillarization of a tissue under otherwise normal conditions guarantees a high tissue oxygenation and this, in turn, will block further angiogenesis.

By contrast, in **placental villi** tissue oxygenation appears to be inversely related to the numerical density of fetal capillaries since, rather than delivering oxygen to the surrounding tissue, the latter extract it from the villi (Kingdom & Kaufmann, 1997).

- Consequently, a low numerical density of fetal capillaries because of reduced oxygen extraction by the fetal circulation, results in increasing intraplacental oxygen levels (Todros et al., 1999; Sibley et al., 2002), which, in turn, may negatively impact on the already poor vascularization (Charnock-Jones et al., 2004).
- And under otherwise constant conditions, high numerical densities of capillaries, resulting in high oxygen extraction by the fetal circulation, would lower intraplacental oxygen tensions (Todros et al., 1999; Sibley et al., 2002) and thus further stimulate growth of the already well-developed capillary bed (Charnock-Jones et al., 2004).

It is evident that, when exceeding certain limits, both situations are predetermined to develop vicious circles.

## Types of Hypoxia and Its Effects on Villous Development

Because of the above-mentioned inverse relationship between the degree of capillarization and the level of tissue oxygenation, the term **hypoxia** in pregnancy often causes confusion. This is particularly true when the hypoxic compartment is not exactly defined. Does the hypoxia relate

FIGURE 7.25. Depending on the origins of fetal hypoxia, placental oxygenation and placental structural reaction patterns to oxygenation are different. In preplacental hypoxia the hypoxic mother (anemia, cyanotic heart disease, high altitude, etc.) causes hypoxia of placenta and fetus. In uteroplacental hypoxia the mother is normoxic, whereas placenta and fetus are hypoxic as the result of uteroplacental malperfusion. In both these conditions, placental hypoxia stimulates angiogenesis and villous proliferation, which may partly compensate for the hypoxic effects. By contrast, in postplacental hypoxia mother and placenta are normoxic and only the fetus is hypoxic from fetoplacental malperfusion; reduced oxygen extraction from the placenta typically results in an intraplacental  $pO_2$  exceeding normal values. This high  $pO_2$  inhibits villous growth and accordingly causes the most severe degrees of intrauterine growth restriction. Red point shading: oxygenation of maternal blood. Blue point shading, oxygenation of fetal blood. Dense point shading, oxygen partial pressure shows normal values for that particular tissue; light point shading, oxygen partial pressure is below normal. (Source: Kingdom & Kaufmann, 1997, with permission.)

- to mother, uterus, placenta, and the fetus, or
- to uterus, placenta, and fetus, or
- only to the fetus?

Based on a respective international symposium 1996 in Banff, the following types of hypoxia in the fetoplacental unit have been defined (Kingdom & Kaufmann, 1997):

1. In **preplacental hypoxia**, the mother, the placenta, and the fetus are hypoxic (Fig. 7.25). Underlying pathologies include pregnancy at high altitude (Jackson et al., 1987; Reshetnikova et al., 1993), maternal anemia (Piotrowicz et al., 1969; Beischer et al., 1970; Kadyrov et al., 1998), and cyanotic maternal cardiac diseases. In this condition, the peripheral placental villi show increased branching angiogenesis with formation of richly branched but shorter terminal capillary loops (Fig. 7.23, stage Vc). These human data are consistent with animal experiments in chronically hypoxic guinea pigs (Scheffen et al., 1990) and chronically hypoxic sheep (Krebs et al., 1997), in which both demonstrated increased branching angiogenesis. Interestingly, in the guinea pig, capillary diameters were reduced under these conditions (Bacon et al., 1984; Scheffen et al., 1990), whereas they were increased in the sheep (Krebs et al., 1997). At the present time, however, we do not understand which factors are responsible for controlling capillary diameter in the human placenta.

2. In **uteroplacental hypoxia** (e.g., preeclampsia with preserved umbilical end-diastolic flow), maternal oxygenation is normal, but because of impaired uteroplacental circulation (Alvarez et al., 1970; for review, see Brosens, 1988), the placenta and fetus are both hypoxic (Fig. 7.25). In this situation, peripheral placental villi similarly show the formation of richly branching capillary networks

(Fig. 7.23, stage Vc), and fetal blood flow impedance is normal or even reduced (Kiserud et al., 1994; Hitschold et al., 1996). Preliminary Western blot data show increased expression of VEGF and reduced PIGF values in placentas of comparable cases (Ahmed et al., 1997), suggesting that placental VEGF expression was upregulated in vivo and caused the changes in angiogenesis.

3. In **postplacental hypoxia** (e.g., IUGR with absent umbilical end-diastolic flow), the fetus is hypoxic whereas the mother is normoxic and the placenta may show even higher  $pO_2$  levels than normal, a situation described as placental hyperoxia (Fig. 7.25) (Macara et al., 1996; Kingdom & Kaufmann, 1997; for commentary, see Ahmed & Kilby, 1997). In this situation, the terminal villus

capillaries are poorly developed, capillary branching is virtually absent (Fig. 7.23, stage Va), and the resulting fetoplacental flow impedance is considerably increased. Perinatal mortality is more than 40% in these circumstances, and survivors of neonatal intensive care are at risk of neurodevelopmental handicap. Similar situations occur in locally restricted parts of the placenta as a consequence of fetoplacental vessel obstruction (Panigel & Myers, 1972; Fox, 1997). Preliminary Western blot data in postplacental hypoxia suggest a pattern of angiogenic growth factor expression in the placenta very different from that of preeclampsia with preserved umbilical end-diastolic flow, namely, a reduction of VEGF expression and relative dominance of PlGF (Ahmed et al., 1997).

Several data support the view that the three variables described above, (1) intraplacental oxygen partial pressure, (2) the balance between VEGF and PlGF expression, and (3) the balance between branching and nonbranching angiogenesis, depend on each other:

- In normal first trimester pregnancy, physiologic intraplacental hypoxia favors VEGF expression and branching angiogenesis.
- In normal third trimester pregnancy, increased intraplacental  $pO_2$  results in a slight prevalence of PlGF expression and dominating but not exclusive nonbranching angiogenesis.
- In several pathologic conditions of third trimester pregnancies, severe intraplacental hypoxia results in prevalence of VEGF expression and marked branching angiogenesis.
- Elevated placental oxygen pressures in severe early-onset IUGR pregnancies (postplacental hypoxia) are combined with the dominance of PlGF expression and complete absence of branching angiogenesis in terminal villi.

### Evidence for Oxygen-Controlled Fetoplacental Angiogenesis

Histopathologic and experimental studies have been employed to study the response of fetal villous endothelium to hypoxia (for review, see Kingdom & Kaufmann, 1977).

**Histopathology:** Complicated pregnancies suffering from intrauterine hypoxia show villous “hypercapillarization” (Hözl et al., 1974); the same is true for placentas obtained in pregnancies from high altitude (Jackson et al., 1987; Reshetnikova et al., 1993) and those from cases of maternal anemia (Kosanke et al., 1998).

**Animal experiments:** Experimental chronic hypoxia in pregnant guinea pigs resulted in increased fetal capillarization and in elevated  $CO_2$  diffusion capacity (Bacon et al., 1984). More detailed studies have revealed that this was caused by stimulated sprouting and branching of capillaries; the mean capillary length and the mean capil-

lary diameter were reduced, and the number of parallel capillary loops was considerably increased (Scheffen et al., 1990). As the trophoblastic thickness also decreased, the mean maternofetal diffusion distance was much shorter when compared to normoxic placentas (Bacon et al., 1984). Despite considerable species differences, later repetition of these experiments in sheep revealed a similar reaction pattern (Krebs et al., 1997).

**In vitro culture:** Using culture of villous explants, the reaction of villous trophoblast to hypoxia was studied in some detail (Tominaga & Page, 1966; Fox, 1970; Amaladoss & Burton, 1985; Ong & Burton, 1991); however, it is difficult to find experimental evidence for an endothelial reactivity in explant culture, because the isolated and unperfused fragments of fetal endothelial tubes tend to disintegrate in culture.

### Oxygen-Controlled Angiogenic Growth Factors

The first evidence for the existence of oxygen-controlled endothelial growth factors was obtained from experiments with endothelial cell cultures (Werb, 1983; Ogawa et al., 1991; Shreenivas et al., 1991). Surprisingly, endothelial cells showed reduced mitotic rates and reduced motility when cultured under hypoxic conditions (Ogawa et al., 1991; Shreenivas et al., 1991). The addition of conditioned medium obtained from hypoxic macrophages, however, stimulated endothelial proliferation (Ogawa et al., 1991). Moreover, the same authors showed that an increased production of bFGF (FGF-2) by hypoxic macrophages and enhanced expression of bFGF receptor by the hypoxic endothelium were responsible for the enhanced endothelial proliferation.

Since these pilot studies, the list of angiogenic growth factors under discussion to mediate hypoxic signals in the placenta has grown to include

- the platelet-derived growth factor B (PDGF-B) produced by villous cytotrophoblast or by endothelium (Holmgren et al., 1991),
- acidic and basic fibroblast growth factor (FGF-1 and FGF-2) (Ferriani et al., 1994; Shams & Ahmed, 1994; Crescimanno et al., 1995),
- vascular endothelial growth factor (VEGF) (Sharkey et al., 1993; Ahmed et al., 1995, 1997; Wheeler et al., 1995; Shore et al., 1997; Vuorela et al., 1997; for review, see Ahmed et al., 2000), and
- placental growth factor (PlGF) (Khaliq et al., 1996; Ahmed et al., 1997; Shore et al., 1997; Vuorela et al., 1997).

From this list, more recently only VEGF and PlGF and their receptors have been studied in more detail regarding their oxygen dependence

The balance between VEGF-A and PlGF secretion may be regulated by oxygen partial pressures. It has been

shown that the expression of VEGF and its receptors in placental and related chorioallantoic tissues is upregulated under conditions of reduced oxygen (Wheeler et al., 1995; Wilting et al., 1995, 1996; Shore et al., 1997; Khaliq et al., 1999), whereas PlGF expression appears to be downregulated under hypoxic conditions (Shore et al., 1997; Khaliq et al., 1999). These findings raise the question of whether or not the switch (from VEGF-A dominance in early pregnancy to PlGF dominance in the second and third trimesters), together with the concomitant changes in vascular geometry, result from increasing intraplacental oxygenation reported by Rodesch et al. (1992).

Throughout the last decade it was shown that oxygen-control of growth factors is mediated by hypoxia-inducible factor (HIF), which transcriptionally regulates the genes of growth factors that are involved in developmental, physiologic, and pathologic responses to hypoxia (Epstein et al., 2001; Semenza, 2001; Pugh & Ratcliffe, 2003). The HIF-1 complex is a heterodimer composed of a constitutively expressed HIF-1 $\beta$  subunit (also known as ARNT, aryl-hydrocarbon receptor nuclear translocator) and the hypoxia-dependent HIF-1 $\alpha$  subunit. The level and transcriptional activity of this complex is precisely regulated by the cellular oxygen concentration. In most tissues, the level of the HIF-1 $\alpha$  protein is acutely sensitive to cellular oxygen concentration. Under normal oxygen concentrations, the protein is rapidly destroyed, whereas at low oxygen concentrations HIF-1 $\alpha$  is stabilized and accumulates within the cell. It then dimerizes with HIF-1 $\beta$  to form an effective transcriptional activator. The HIF-1 dimer binds to specific DNA sequences of the hypoxia-responsive growth factors and activates transcription of the latter.

So far only HIF action in extravillous trophoblast has raised some interest. Relevant data on HIF action in placental villi, however, are scarce. Among the few available data, those by Caniggia et al. (2000) suggest that HIF-1 $\alpha$  expression is high in the first trimester, as long as intervillous pO<sub>2</sub> is low and that it decreases thereafter. Unfortunately, the HIF data available at present are not helpful in explaining the oxygen-controlled balance of VEGF and PlGF secretion or the timing mismatch among the increase in placental oxygenation, changes in growth factor expression, and the switch in fetoplacental angiogenesis.

### The Timing Mismatch Between Changes in Oxygenation and Morphologic Changes

Throughout pregnancy it is necessary to protect the fetus from the potentially harmful effects of high oxygen tensions (Burton, 1997; Burton & Caniggia, 2001; Hung et al., 2001). Development and remodeling of the fetoplacental vasculature may be part of this protection. As men-

tioned above, it is tempting to speculate about causal interactions among changes in placental oxygenation, the switch from VEGF-A dominance to PlGF dominance, and the switch from branching to nonbranching angiogenesis. Interestingly, there is a time lag of about 2 months between the rises in intervillous pO<sub>2</sub> levels and perfusion rates (after week 12, Rodesch et al., 1992) and the evidence of morphologic changes (transition from mainly branching to predominantly nonbranching angiogenesis around week 25; Kaufmann & Kingdom, 2000; Mayhew, 2002). The explanation for this time lag may be that the anatomic changes are considerably more protracted than the rapid *in vitro* effects of altered oxygen tensions on cultured cells. This situation possibly reflects the difference between the acute (short-term and rapid-onset) and chronic (long-term and delayed-onset) responses to oxygen (Semenza, 2001). Sculpting the fetoplacental vascular network takes time and, if the placenta as a whole is to function in a coordinated manner, vascular changes must be integrated with changes in other villous compartments, especially the trophoblast (Mayhew, 2002).

Downregulation of VEGF-A and upregulation of PlGF may occur almost contemporaneously with the oxygen switch, although there is no direct evidence for this at present. The time course of respective vascular adaptation in the placenta is not known, but in the eye and in tumors these events occur within just a few days (Alon et al., 1995; Benjamin & Keshet, 1997). In the placenta stimulated vascularization may take much more time since the interactions between fetoplacental vascularization and villous development are much more complex. Regression of capillaries in immature intermediate villi, together with establishment of a tunica media around maturing vessels in developing stem villi, may begin at about the time of the oxygen switch. The transition from branching angiogenesis (in mesenchymal and immature intermediate villi) to nonbranching angiogenesis (in mature intermediate and terminal villi), however, involves different generations of villi. Only when the key types of villi for nonbranching angiogenesis (mature intermediate villi) are generated, persistently-high pO<sub>2</sub> levels may combine with low VEGF-A and high PlGF levels (and changes in other, as yet unidentified, factors) to facilitate nonbranching angiogenesis.

Intervillous pO<sub>2</sub> values seem to peak during the second trimester (about 60 mm Hg at 16 weeks, Soothill et al., 1986; Rodesch et al., 1992; Jauniaux et al., 2001). This is in seeming contradiction to the assumption that, as pregnancy advances, also the fetal demand for oxygen will rise further. Possibly the final drop to about 45 mm Hg at term (Soothill et al., 1986; Rodesch et al., 1992; Jauniaux et al., 2001) is a consequence of fetoplacental vascular remodeling resulting in increased oxygen extraction from the intervillous space.

## Oxygen and Villous Trophoblast

Histopathologic reports unanimously describe that the amount of villous cytotrophoblast is increased in all those pathologic conditions that are thought to be related to intrauterine hypoxia (Fox, 1964, 1970; Piotrowicz et al., 1969; Beischer et al., 1970; Kaufmann et al., 1977a; Kosanke et al., 1998). Arnholdt and coworkers (1991) found evidence that this is the result not only of an increased mitotic index but also of a reduction of the length of the cell cycle. In contrast, unusually good oxygenation of villi reduces the rate of proliferation as well as the quantity of villous cytotrophoblast (Panigel & Myers, 1971, 1972; Myers & Panigel, 1973; Kaufmann et al., 1977a; Macara et al., 1996; for review, see Kingdom & Kaufmann, 1997).

In addition, the villous syncytiotrophoblast is affected by hypoxia as was shown experimentally by Tominaga and Page (1966) and Ong and Burton (1991), and in pathologic specimens (Alvarez et al., 1969, 1970). It is reduced in thickness and simultaneously increased numbers of syncytial knots are produced, the nuclei of which show signs of chromatin clumping and partly of apoptosis. Tominaga and Page interpreted this as a sign of adaptation by reducing diffusion distances. More stringent stereologic studies have suggested, however, that the changes are more likely caused by degenerative processes (Ong & Burton, 1991). Recent experiments by Burton pose the question of whether or not all insults seen after ischemic/hypoxic periods are in fact due to lack of oxygen; the authors found that damage by oxygen radicals in the reoxygenation period may be even more important (Hung et al., 2002a).

Most in vitro studies on the effects of hypoxia have been performed on villous explants rather than on villous cytotrophoblast cultures. For that reason it is still an open question whether cytotrophoblast responds directly to variations of the oxygen partial pressure, or whether this response is mediated by factors released by other hypoxic tissue components such as syncytiotrophoblast or villous macrophages. There are several candidate mediators of hypoxic signals: epidermal growth factor (EGF) may be derived from maternal sources and is additionally produced by syncytiotrophoblast (for review, see Prager et al., 1992); its mitogenic action on trophoblast has been shown by Lysiak and coworkers (1992), and its receptors have been detected on the syncytiotrophoblastic surfaces (Rao et al., 1985) as well as on cytotrophoblastic membranes (Mühlhauser et al., 1993). Transforming growth factor- $\alpha$  (TGF- $\alpha$ ) (Lysiak et al., 1992) and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) (Hung et al., 2002b), the latter produced by macrophages (for review, see Hunt, 1989), and colony-stimulating factor 1 (CSF-1) produced by mesenchymal cells (Jokhi et al., 1992; Shorter et al., 1992) are other candidates. Finally, TGF- $\beta_1$  and TGF- $\beta_2$ , both

produced by macrophages (for review, see Hunt, 1989) and by trophoblast (Graham & Lala, 1991), seem to be involved in the regulation of syncytial fusion of the post-proliferative cytotrophoblast to regenerate the hypoxically damaged syncytiotrophoblast. As already mentioned above, oxygen-dependent regulation of most of these cytokines involves HIF as hypoxia-responsive transcriptional factor.

## Oxygen and Villous Stroma

It is a common experience in pathologic studies of the placenta that the villous connective tissue responds to variations in the intrauterine oxygen supply. This is nicely illustrated by the low degree of villous fibrosis throughout the first trimester when intervillous  $pO_2$  is low, and the increasing fibrosis, for example, in stem villi at the transition to the second trimester when placental oxygen levels steeply increase. Chronic hypoxia results in minimal fibrosis of the villi (Fox, 1978); in contrast, higher levels of intravillous  $pO_2$  increase villous fibrosis (for example following intrauterine death when intraplacental oxygen partial pressure, because of lacking fetal oxygen extraction, approaches maternal arterial values) (Panigel & Myers, 1971, 1972; Fox, 1978). Related in vitro experiments with placental tissues are still to be done. Possible mediators are macrophage products such as TGF- $\beta$ , which stimulates collagen-I transcription (Rossi et al., 1988), or interleukin-1, which, among other functions, regulates fibroblast proliferation (Schmidt et al., 1982).

## Oxygen and Intervillous Circulation

There are few data concerning hypoxic influences on the maternal vascularization of the placenta. In the guinea pig, volume and surface of maternal blood lacunae are reduced under hypoxic conditions (Bacon et al., 1984). In contrast, in human placentas from patients at high altitude, the intervillous space was described to be increased (Jackson et al., 1987). For the cow placenta, Reynolds and coworkers (1992) have demonstrated maternal endothelial mitogens of endometrial origin.

Numerous experimental data have been provided concerning the influence of oxygen on trophoblast invasion (Genbacev et al., 1996, 1997; Graham & McCrae, 1997; Fitzpatrick & Graham, 1998; Zhou et al., 1998; Caniggia et al., 2000). Trophoblast invasion triggers adaptation of uteroplacental arteries to pregnancy conditions and thus has an important effect on intervillous blood flow. Unfortunately, these data are controversial. Therefore, no actual conclusions can be drawn as to whether hypoxia affects maternal blood flow to the intervillous space, and if so, in which direction.

## Hormones as Regulators of Villous Development

Even though it should be expected that villous development is controlled by maternal and fetal hormones, there are only very few relevant clinical indications. Reliable experimental proof is completely missing. Here, we briefly discuss data that look promising for future research.

**Ovarian steroids** are the most likely group of hormones to be involved in placental development and probably represent the only group of hormones that, in few cases, have been used for the treatment of villous maldevelopment. The following examples may give an idea of how ovarian steroids can influence villous development:

- Placentas from pregnancies complicated by IUGR and combined with decreased or absent end-diastolic blood flow are characterized by very homogeneous features of villous maldevelopment (Macara et al., 1996). These are reduced trophoblastic proliferation rate, reduced numbers of terminal villi, reduced total villous volume, poor branching of terminal villous capillaries, increased terminal villous fibrosis, and increased differentiation of villous myofibroblasts. The functional consequences of these alterations are likely to be responsible for the impaired fetal nutrition, as well as for the increased fetoplacental blood flow impedance. Several groups of investigators have found evidence that third trimester treatment with gestagens (allylestrenol) decreased blood flow impedance and increased fetal birth weight as well as placental weight (Kaneoka et al., 1983; Kurjak & Pal, 1986; Marzolf et al., 1986). The only histologic study of these placentas provided by Papierowski (1981) described a "stimulated development" of villi. As far as we were able to see from Papierowski's data, a numerical increase in immature, proliferating villous types was responsible for the overall increased villous growth rate.
- In contrast, P. Prahallada (personal communication, 1982) found that treatment of rhesus monkeys with higher doses of estrogens during midpregnancy caused reduced placental and fetal growth rates. To our knowledge, these placentas have not been studied histologically.
- The latter findings were supported by experimental data by Yallampalli and Garfield (1993), Chwalisz et al. (1994), and Garfield et al. (1994). These authors induced symptoms of preeclampsia including IUGR in rats and guinea pigs by blocking nitric oxide synthase by L-NAME, and reversed these effects by treatment with gestagens.

The above data suggest that gestagens and estrogens may have antagonistic effects on villous development and differentiation. Possibly not only the oxygen-controlled balance of VEGF and PlGF (see above) but also both steroid hormones control the switch of mesenchymal villous transformation either into continuously growing immature intermediate villi or into differentiating mature intermediate villi.

Also **insulin** is under discussion regarding its influence on villous development. The prevailing finding in placentas of diabetic mothers is that of an overall increased proliferation rate of villous trophoblast, villous stromal cells, and villous capillaries, resulting in large placentas that are characterized by large-caliber villi with high cellular density (Widmaier, 1970; Werner & Schneiderhan, 1972; Fox, 1978).

So far, all attempts have failed to demonstrate classic insulin effects on the maternal side of the placental barrier, such as stimulation of glucose uptake (Challier et al., 1986), of amino acid transport (Montgomery & Young, 1982), and increase in glycogen levels in trophoblast cells (Schmon et al., 1991). These negative results can be explained by the low levels of insulin receptors on the syncytiotrophoblastic surface during the second half of pregnancy (Jones et al., 1993; Desoye et al., 1994, 1997).

On the other hand, direct growth-promoting effects of insulin (for review, see Strauss, 1984) on the various placental tissues must be considered.

- In the first trimester, insulin receptors available at the maternal/intervillous surface of villous trophoblast are expressed mainly along the surfaces of sprouting segments of the villous trees (true trophoblastic sprouts, mesenchymal villi) (Desoye et al., 1994, 1997). This finding indicates that maternal insulin might be involved in first-trimester villous growth, which is mainly a result of trophoblastic proliferation (Castellucci et al., 1990, 2000).
- In the last trimester, the highest immunoreactivities for insulin receptors are found in fetal villous endothelium (Jones et al., 1993), in particular in segments with capillary sprouting, such as mature intermediate villi and terminal villus necks (Desoye et al., 1994, 1997). In this period, expansion and differentiation of the villous trees are mainly a result of capillary sprouting (Kaufmann et al., 1988; Castellucci et al., 1990, 2000).

A switch in villous growth control from maternal insulin (with insulin receptors along the maternal trophoblastic surface) in early pregnancy to fetal insulin (with endothelial insulin receptors) in late pregnancy would make sense because it would enable the fetus to control villous differentiation in accordance with its own nutritional needs.

Also **thyroid hormones** are candidate regulators of villous development. It is now recognized that in pregnancy, maternal thyroid function is mediated by the placenta (Fisher, 1983). The placenta plays a major role in the synthesis and metabolism of the thyroid hormones: the putative trophoblastic thyrotropin (Hershman, 1972) as well as human chorionic gonadotropin (hCG) (Kennedy & Darne, 1991) stimulate the maternal thyroid hormone production; thyroid-stimulating hormone (TSH), triiodothyronine ( $T_3$ ), thyroxine ( $T_4$ ), and thyroglobulin cannot pass the placental barrier, while thyroid-releasing hormone (TRH), iodine, and thyroid-stimulating immunoglobulins can (Cappoen, 1989). Placental tissue as well as the decidua has a high nuclear-binding capacity for  $T_3$ . Therefore, Banovac et al. (1986) have suggested the placenta to be a thyroid hormone-dependent tissue. Maruo et al. (1991) have described stimulatory effects of maternal  $T_3$  and  $T_4$  on trophoblastic endocrine functions; moreover, they found that  $T_3$  enhances trophoblastic production of epidermal growth factor (EGF), a potent trophoblastic mitogen, and concluded that thyroid hormone, in synergy with EGF, regulates villous growth (Matsuo et al., 1993).

There are fewer data concerning the correlation of thyroid malfunction with placental function or development. According to experiments in rats (Kumar & Chaudhuri, 1989), the levels of maternal thyroid hormone secretion are positively correlated with fetal growth. Thorpe Beeston et al. (1991) found significantly reduced maternal  $T_4$  levels in small-for-gestational-age fetuses combined with fetal hypoxemia and acidemia.

All these data suggest that maternal thyroid hormones are involved in villous development and thus influence placental transfer functions for nutrients and gases. Relevant clinical data, however, are difficult to interpret. We have seen some placentas of hypothyroid mothers medicated with thyroid hormones. The placentas of all of these cases were characterized by stimulated nonbranching angiogenesis and correspondingly reduced branching of terminal villi; partly, the respective cases comprised persisting villous immaturity with predominance of mature intermediate villi (see Chapter 15, Fig. 15.9) as well as IUGR with ARED flow in the umbilical arteries (Fig. 15.17). We found similar features in two cases of untreated hyperthyroid mothers.

## Intervillous Space as Related to the Villous Trees

The human placenta is a hemochorial, villous placental type. After leaving the spiral arteries, the maternal blood circulates through the diffuse intervillous space and flows directly around the villi. The maternal blood is outside

the confines of the endothelium of the maternal vascular system.

### Width of the Intervillous Space

The anatomical investigations concerning the width of the intervillous space suffer the disadvantage of having been made on delivered placentas, which have lost considerable amount of maternal blood during delivery. They are also usually fixed without the *in vivo* maternal blood pressure distending the intervillous space. Therefore, the usual appearance of the intervillous space of the delivered placenta is that of a system of **narrow intervillous clefts**. Hörmann (1951, 1953, 1958a,b) and Lemtis (1955) called it the intervillous cleft system. This view was supported by Becker (1962b), who attempted to reestablish *in vivo* pressure conditions before fixation and found the same narrow clefts. Becker described neighboring villi as clinging closely to one another, the tips of some fitting into notches of others, as in a jigsaw puzzle. Becker interpreted the occasional appearance of a wider intervillous space (in conventional histologic material) as the result of shrinkage. Freese (1966) also failed to demonstrate an intervillous space of larger than capillary dimensions, except for the subchorial lake. Boyd and Hamilton (1970) contradicted these interpretations. According to their experience from *in vivo* radioangiographs, the rapid filling of the intervillous space is not compatible with a cleft system of capillary dimensions.

Using the data for postpartal intervillous blood volume (23.3% to 37.9% of the placental volume) and for the villous surface (11.0 to 13.3 m<sup>2</sup>) (see Tables 28.5 and 28.8), we calculate the mean width of the intervillous space (blood volume divided by one half of the villous surface) as ranging from 16.4 to 32  $\mu$ m. The villous surface must be divided by 2 because it covers the clefts on both sides. Bouw et al. (1976) demonstrated that late cord clamping is responsible for a loss of intervillous volume, probably owing to the decreasing turgor of the villi that border the intervillous space (see Table 28.8). If we calculate the mean width of the intervillous space with their data from term placentas obtained after early cord clamping, it amounts to 31.6  $\mu$ m. One must bear in mind that there is a considerable subchorial lake, and that wide spaces also exist in the arterial inflow area. Thus, the real “intervillous” volume is likely to be lower and the intervillous clefts narrower. On the other hand, when one adds the considerable loss of maternal blood during labor, we consider that these calculations may be near the truth.

Also recent *in vivo* studies in various stages of pregnancy using color power Doppler ultrasonography with three-dimensional (3D) option did not answer the question as to the *in vivo* width of the intervillous space at term (Konje et al., 2003). They suggest, however, that the width of the intervillous space becomes considerably reduced in the course of pregnancy: the 3D reconstruc-

tions (Fig. 7.26B) revealed high maternal blood flow velocities in the maternal inflow and outflow areas on the intervillous space throughout the second and third trimesters of pregnancy. In the second trimester even between peripheral ramifications of the villous trees minor maternal flows could be visualized, suggesting wide intervillous clefts ( $\gg 100 \mu$ m) with high flow velocities. In the third trimester velocities and width of the intervillous clefts between the peripheral villi were too small for detection.

### Organization of Villous Trees

Wigglesworth (1967) studied corrosion casts of fetal vessels and suggested that most villous trees are arranged “as hollow-centered bud-like structures” around a central cavity. When he injected the spiral arteries, Wigglesworth found the injection mass to collect in the loose centers of the villous trees. This finding is in agreement with most descriptions of the maternal arterial inlets as being located near the centers of the villous trees (Schuhmann & Wehler, 1971; Schuhmann, 1981), which direct the bloodstreams into these centers (Panigel & Pascaud, 1968). The 50 to 200 maternal venous outlets of each placenta are thought to be arranged around the periphery of the villous trees. Thus, each fetomaternal circulatory unit is composed of one villous tree with a corresponding, centrifugally perfused portion of the intervillous space (Figs. 4.7, 7.26A, and 7.27A). This unit was called a “placentone” by Schuhmann and Wehler (1971) (for review, see Schuhmann, 1982).

Most placentologists agree that, under *in vivo* conditions, most of the 40 to 60 placentones are in contact with each other and that they overlap more or less broadly. This supposition is highly probable, as structural borderlines, such as placental septa, are absent (Becker & Jipp, 1963). It is our experience that the peripheral placentones are more clearly separated from each other and thus exhibit typical structural differences between their central and peripheral zones. In the thicker, more central regions of the placenta, most villous trees overlap (Figs. 7.26A and 7.27A), causing less distinct differences between maternal inflow and outflow areas of the placentone.

According to studies of Schuhmann and Wehler (1971), the centers of typical placentones exhibit loosely arranged villi, mostly of the immature intermediate type, and provide a large intervillous space for the maternal arterial inflow, the central arterial inflow area (Figs. 7.26A and 7.27). It is still uncertain if these large, loosely arranged villi regularly delineate a central cavity as described by Wilkin (1965). Schuhmann (1981) suggested that these cavities are pressure-dependent *in vivo* structures that rapidly collapse after delivery, and his suggestion is borne out by ultrasonographic findings. If one accepts the considerations of Moll (1981), the existence of such a central cavity makes sense because it guarantees the rapid and

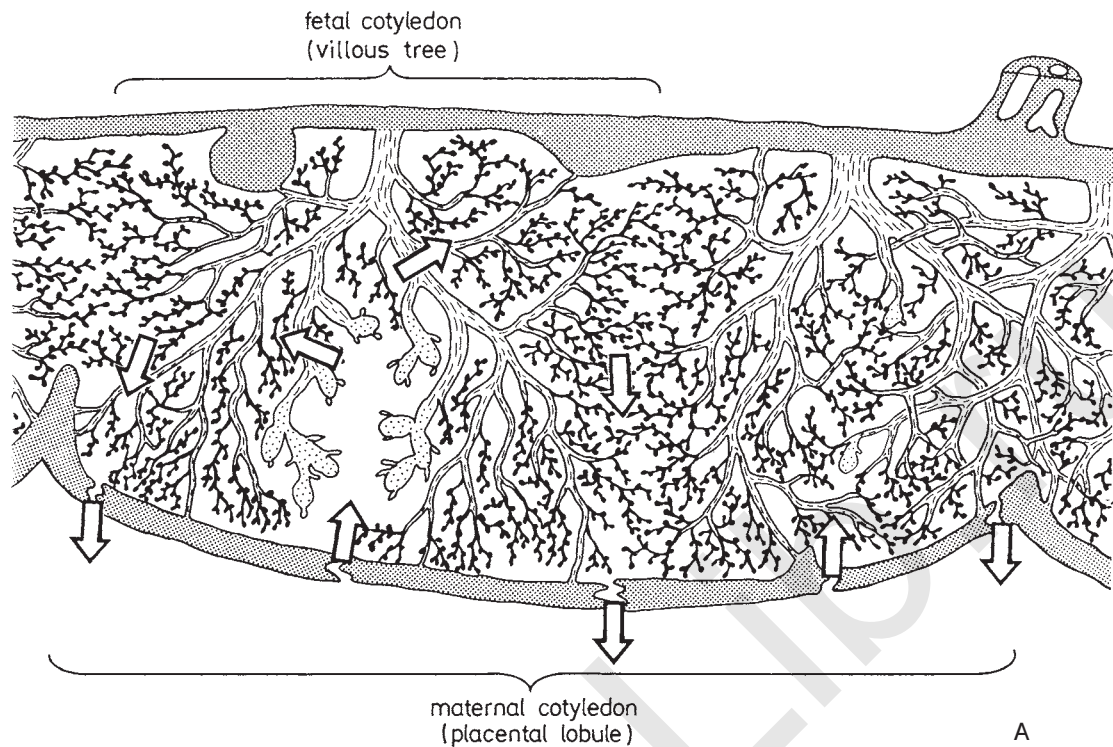

FIGURE 7.26. A: Typical spatial relations between villous trees, single villous types, and the maternal bloodstream. According to the placentone theory of Schuhmann (1981), a placentone is one villous tree together with the related part of the intervillous space. In the case of typical placentones (left half of the diagram), which prevail in the periphery of the placenta, the maternal blood (arrows) enters the intervillous space near the center of the villous tree and leaves the intervillous space near the clefts between neighboring villous trees. In the term placenta, the larger stem villi (line shaded), the immature intermediate villi (point shaded), and their tiny branches (unshaded) are concentrated in the centers of the villous trees, surrounding a central cavity as maternal blood inflow area. The mature intermediate villi (black) together with their terminal branches (black, grape-like) make up the periphery of the villous trees, near the venous outflow area. One or few villous trees occupy one placental lobule (see Chapter 2, Fig. 2.2), which is delimited by grooves in the basal surface of the placenta (see Fig. 2.1B). In the central

parts of the placenta, the villous trees, because of size and nearby location, may partly overlap (right half of the diagram) so that the zonal arrangement of the placentone disappears. (Source: Modified from Kaufmann, 1985, with permission.) B: Corresponding in vivo photograph, generated by power-Doppler ultrasonography with 3D option, shows two villous trees, corresponding to those depicted in part A. The villous trees are derived from villous trunci (t), which are connected to the chorionic plate (cp). As is typical for the power Doppler technique, the picture shows not only the larger vessels in chorionic and basal plates but also the larger stem villi in which the Doppler signals of arteries and veins add to each other. The maternal arterial bloodstreams ("jets") entering the intervillous space (arrowheads), as well as the maternal venous blood (arrow) leaving the intervillous space, are also seen. Since blood flow velocities across the fetal cotyledons are too slow, the remaining parts of the intervillous space are black. Near-term placenta,  $\times 2$ . (Courtesy of Dr. Justin Konje, Leicester, UK.)

FIGURE 7.27. Placentone arrangement of villous trees. A: Horizontal paraffin section across the marginal zone of a mature placenta. H&E stain. Note the existence of three ring-shaped placentones (fetal cotyledons), each single one composed of a loose center (arterial inflow area), surrounded by a dense ring of small peripheral villi (exchange area), and finally surrounded by the loosely structured venous outflow area.  $\times 3.6$ . B: Higher

magnification of the placentone center of a fetal cotyledon. Note the large empty appearing arterial inflow area, which is bordered by some immature intermediate villi, easily recognizable by their light staining. This immature center of the cotyledon is surrounded by a densely packed mantle of smaller villi which provide the maternofetal exchange area.  $\times 20$ .

homogeneous distribution of blood into the surrounding mantle of small, densely packed villi with little loss of pressure.

The surrounding mantle is composed mostly of small villi of the mature intermediate and terminal types and provides the peripheral exchange area. The villi are densely packed. Schmid-Schönbein (1988) described the intervillous space in this zone as a system of randomly shaped and oriented, interconnected clefts, or "connected voids." With respect to their topology, these clefts lack the regular connectivity seen in dichotomously branching vascular beds. The fixed relations of the latter vessels, which orient pressure gradients, are not found in randomly connected voids as in the intervillous space. This feature may be advantageous under normal conditions, but it may also cause hazards to the intervillous circulation.

The most peripheral zone of a placentone, the venous outflow area, is the loosely arranged area that separates neighboring villous trees (Fig. 7.27A) and that, subchorially, is connected to the subchorial lake. It collects the maternal venous blood that has left the high impedance area of the fetomaternal exchange zone of the densely packed terminal villi. Moll (1981) called this the perilobular zone, which is functionally comparable to wide venules of other vascular beds. It allows venous backflow under conditions of low blood flow resistance.

The radioangiographic studies of Ramsey et al. (1963) in rhesus monkey placentas, and those of Borell et al. (1958) in human placentas, are consistent with the placentone concept. They demonstrated rapid filling of the centers of the villous trees and called them "jets," or "spurts." More recent physiologic concepts of intervillous circulation (Moll, 1981; Schmid-Schönbein, 1988) do not agree with these terms,

as the actual filling velocities amount to only a few centimeters per second, which might not be enough to describe the driving force of a fountain as implied by the terms **jet** or **spurt**. After passage of the central cavity, a subsequent rather slow centrifugal spreading of the blood toward the subchorial and peripheral zone was observed. Wallenburg et al. (1973) ligated single spiral arteries in rhesus monkeys, which resulted in obliteration of the intervillous space and degeneration of the corresponding villous tree. This experiment demonstrated that each villous tree depends on its own spiral artery. Even though the intervillous space is a widely open, freely communicating system, villous arrangement and pressure gradients are coordinated in such a way that blood perfusion depends strictly on the original flow arrangement. Reversal of the direction is impossible.

If one accepts these considerations, the immature intermediate villi, together with their sprouting mesenchymal side branches (Figs. 7.26A and 7.27B), are concentrated in the placentone center and are thus in the zones of highest  $pO_2$  in the intervillous space. Schuhmann's group found that  $^3H$ -thymidine incorporation, as an index for the mitotic rate, is twice as high in the center of the placentone as at the periphery (Geier et al., 1975). This finding is in seeming contrast to several experimental and histologic findings. The latter authors also suggested that low oxygen concentration serves as a stimulus for trophoblastic proliferation and villous sprouting (Alvarez, 1967; Alvarez et al., 1970; Fox, 1970). The most likely explanation for this discrepancy is that oxygen delivery to the centrally located large villi, those in the central cavity and its close vicinity, is reduced owing to high blood flow velocity and long diffusion distances. The adjacent densely packed zones, although already located nearer the venous pole, probably have a much higher oxygen delivery, as blood flow velocity is reduced in the slender intervillous clefts and diffusion distances are short. This situation results in high mean  $pO_2$  values at the villous surfaces, which is a prerequisite for effective maternofetal oxygen transfer. At the same time, it inhibits villous proliferation and stimulates villous differentiation in the placentone periphery.

These relations may be the basis for regulatory mechanisms. Wide intervillous clefts in the periphery of the villous trees of immature placentas, which lack fine and richly branched terminal villi, result in long diffusion distances and high blood flow velocities—and thus in reduced oxygen delivery. The resulting intravillous  $pO_2$  in this area is low, which stimulates villous sprouting and especially capillary sprouting (Bacon et al., 1984; Scheffen et al., 1990). Increased capillary sprouting is followed by the production of new terminal villi. The latter narrow the intervillous space, reduce blood flow velocity and diffusion distances, and thus increase oxygen delivery. Finally, the elevated  $pO_2$  inhibits further villous branching.

According to this hypothesis, the maternal bloodstream, oxygenation, and villous branching act as limbs of a simple feedback mechanism that regulates growth of the villous trees. As a further consequence, a functional diversity of the placentone is obtained. Whereas the centers act as proliferative zones that guarantee placental growth until term, the periphery is the functionally fully active exchange and secretory area. This situation has also been highlighted by the histochemically and biochemically higher activity of enzymes such as alkaline phosphatase (Schuhmann et al., 1976) and by the higher conversion rate of steroid hormones (Lehmann et al., 1973) in the placentone periphery.

The zonal differences become evident only after the development of mature intermediate villi, at the end of the second trimester. Up to that time, the villous trees are largely homogeneous. In most placentas, the immature placentone centers are present until term, at least in the more peripheral areas of the placenta. Only in cases of preterm maturation of the placenta (hypermaturation,

maturitas praecox) do we regularly find mature placentone centers, resulting in a virtually homogeneous structure of the placentones. Thus, such a placenta has lost its capacity to grow, as only the immature intermediate villi and their immediate mesenchymal branches are able to sprout and act as growth zones.

## Histopathologic Importance of Inhomogeneity of Villous Trees

For the histopathologist, the inhomogeneity of the villous trees causes considerable problems of interpretation. Because the average diameter of placentone is 1 to 4 cm, histologic sections often do not cover a representative part of the placentone, which would comprise immature growth zones as well as highly differentiated, mature tissue. The prevalence of one or the other tissue may influence the diagnosis. This danger is even greater when one considers that placentones from various locations may show varying degrees of maturation. Thus, even the careful study of several sections from a given placenta may lead to wrong interpretations. This point is of particular importance when performing morphometric evaluations of the placenta. Burton (1987) remarked that "strict attention must be paid to the sampling regimen if meaningful results are to be obtained. Sadly this has not always been taken into consideration in the past, and so many of the published claims must be qualified accordingly."

This problem is greater still when one uses small tissue samples, such as semithin sections for light microscopy or ultrathin sections for electron microscopy. Neither section type allows a diagnosis concerning the degree of maturation upon which one can rely. The same holds true for samples obtained by aspiration from the intact uterus (Alvarez et al., 1964; Aladjem, 1968), the placenta at cesarean section (Schweikhart & Kaufmann, 1977), and chorion villus sampling (CVS). While the latter samples are of greatest value for genetic purposes (Hugentobler et al., 1987), one must be careful with a histologic evaluation of such material (Gerl et al., 1973; Ehrhardt et al., 1974), even during early stages of pregnancy. In these situations one does not have the problem of heterogeneity of the placentones but rather the problem of general heterogeneity.

## Fetomaternal Flow Interrelations

The efficiency of diffusional exchange (e.g., oxygen, carbon dioxide, water), among other factors, depends on the arrangement of fetal and maternal blood flows to each other. As early as 1926 Mossman described counter-current flow conditions in the rabbit placenta; neighboring maternal and fetal bloodstreams were thought to be arranged in parallel but with opposite flow directions.

Later, Mossman (1965) found the same condition to be valid for the human placenta. This finding, however, is not supported by anatomic or physiologic results. Rather, it has been recognized for many years that the anatomic arrangement of placental vascular pathways differs from one species to another. For the human, we have described three major morphologic objections to the existence of countercurrent flow conditions (Kaufmann, 1985):

1. All villi would have to be oriented in the same direction, parallel to the maternal bloodstream. They are, in fact, arranged at varying angles to each other because of the structure of the villous tree.

2. Only one limb of the hairpin-like fetal capillary loops is allowed to have interchange contact with the maternal blood; in fact, both limbs normally exhibit the same structure and the same diffusion distance to the maternal blood.

3. According to the results of Lemtis (1969), one must consider the possibility that considerable amounts of venous maternal blood are recirculated by the arterial "jet" before leaving the intervillous space. Thus, intraplacental circulatory "orbits" are formed.

The anatomic situation and the physiologic effectiveness of the human placenta are much more in agreement with the concept of a multivillous flow arrangement (Bartels & Moll, 1964; Moll, 1981). In this condition, the maternal bloodstream crosses subsequent villi with hairpin-like arranged fetal capillaries. It seems to be of minor importance with which angle the maternal bloodstream crosses the individual villi or whether the vessels of the villi are serially connected to each other or arranged in parallel. The multivillous blood flow is less effective for diffusional transfer (Moll, 1981).

This difference may be the reason why 1 g of human placenta supplies only 6 g of fetus at term, compared to a relation of 1:20 in the guinea pig with a countercurrent flow placenta (see Chapter 4, Table 4.1) (Dantzer et al., 1988). On the other hand, the multivillous arrangement is structurally more flexible. It allows rearrangement and adaptation to changing developmental conditions and the continuous growth to a much greater extent. In this respect, it is worthy of note that the highly effective guinea pig placenta is small (about 5 g) and functions for only 68 days. The capybara (Kaufmann, 2004), which belongs to the same suborder of rodents, has a structurally closely related placenta but a much longer pregnancy (150 days) and a much higher placental weight (150 g), but is less effective than the guinea pig placenta (1 g of placenta at term supplies 10 g of fetus).

# 8

## Characterization of the Developmental Stages

This chapter is a synopsis and presents brief descriptions of the average data of placenta and membranes throughout the single stages of placental development. Embryologic data concerning embryo and fetus are given only insofar as they are of importance for the definition of the stage. It is not the intention of this chapter to compare data of various sources on a scientific level but rather to present data that are directly applicable to the pathologic and histologic examination of human material. For this purpose, all data have been extrapolated and were standardized where necessary.

The data are based on the following publications: embryonic staging according to O’Rahilly (1973) and Boyd and Hamilton (1970): crown–rump length (CRL), embryonic and fetal weight, mean diameter of the chorionic sac, placental diameter and thickness, placental weight according to Boyd and Hamilton (1970), O’Rahilly (1973), and Kaufmann (1981); placental and uterine thickness in vivo following Johannigmann et al. (1972); length of umbilical cord according to Winckel (1893); villous surfaces, villous volumes, and villous diameters following Hörmann (1951), Knopp (1960), Clavero-Núñez and Botella-Llusia (1961, 1963), Aherne and Dunnill (1966), Kaufmann (1981), Schiemer (1981), and Gloede (1984); and mean trophoblastic thickness, distribution of villous cytotrophoblast, mean maternofetal diffusion distance according to Kaufmann (1972), Kaufmann and Stegner (1972), Gloede (1984), and Kaufmann (1981). For further details see the summarizing tables in Chapter 28.

### Stages of Development

**Day 1 p.c.** (p.c. = postcoitus) Carnegie stage 1: one fertilized cell; diameter 0.1 mm.

**Day 2 p.c.** Carnegie stage 2a: from 2 to 4 cells; diameter 0.1 to 0.2 mm.

**Day 3 p.c.** Carnegie stage 2b: from 4 to about 16 cells; diameter 0.1 to 0.2 mm.

**Day 4 p.c.** Carnegie stage 3: free blastocyst, from 16 to about 64 cells; diameter about 0.2 mm.

**Day 5 to early day 6 p.c.** Carnegie stage 4: blastocyst attached to the endometrium, from about 128 to about 256 cells; diameter 0.2 to 0.3 mm.

**Late day 6 to early day 8 p.c.** Carnegie stage 5a: implantation, prelacunar stage of the trophoblast; the flattened blastocyst measures about  $0.3 \times 0.3 \times 0.15$  mm. The blastocyst is partially implanted. The implanted part of the blastocyst wall is considerably thickened, largely consisting of solid syncytiotrophoblast. The still not implanted, thin part of the blastocyst wall consists of a single layer of cytotrophoblast. The embryonic disk measures about 0.1 mm in diameter.

**Late day 8 to day 12 p.c.** Lacunar or trabecular stage.

**Late day 8 to day 9 p.c.** Carnegie stage 5b: diameter of chorionic sac  $0.5 \times 0.5 \times 0.3$  mm; embryonic disk about 0.1 mm. The syncytiotrophoblast at the implantation pole exhibits vacuoles as forerunners of the lacunar system.

**Day 10 to day 12 p.c.** Carnegie stage 5c: diameter of chorionic sac  $0.9 \times 0.9 \times 0.6$  mm. The vacuoles in the syncytiotrophoblast fuse to form the lacunar system; first lacunae at the antiimplantation pole. First contact of lacunar system with eroded endometrial capillaries. Some maternal erythrocytes may be observed in the lacunae. Around day 11, implantation is complete; the defect in the endometrial epithelium is closed by a blood coagulum and is covered by epithelium on day 12. At the implantation site, the endometrium measures 5 mm in thickness; first signs of decidualization.

**Day 13 to day 14 p.c.** Carnegie stage 6, villous stage (first free primary villi).

**Day 13 p.c.** The nearly round chorionic sac has a diameter of 1.2 to 1.5 mm; length of embryonic disk is 0.2 mm.

**Day 14 p.c.** Diameter of chorionic sac 1.6 to 2.1 mm; length of embryonic disk 0.2 to 0.4 mm. First appearance of primitive streak and of yolk sac.

With the expansion of the lacunar system, the syncytiotrophoblast becomes reduced to radially oriented trophoblastic trabeculae, the forerunners of the stem villi. After invasion of cytotrophoblast into the trabeculae, free trophoblastic outgrowths into the lacunae, the “free primary villi”, are formed. The trabeculae are now called villous stems. By definition, from this date onward, the lacunae are transformed into the intervillous space. Cytotrophoblast from the former trabeculae penetrates the trophoblastic shell and invades the endometrium.

**Days 15 to 18 p.c.** Villous stage (secondary villi).

**Days 15 to 16 p.c.** Carnegie stage 7: diameter of chorionic sac about 5 mm; length of embryonic disk less than 0.9 mm; appearance of notochordal process and primitive node (Hensen).

**Day 17 to 18 p.c.** Carnegie stage 8: diameter of embryonic sac less than 8 mm; length of chorionic disk less than 1.3 mm. On the germinal disk, the notochordal and neur-enteric canals, and primitive pit can be discerned.

Starting at the implantation pole and continuing all around the circumference to the antiimplantation pole, mesenchyme (derived from the extraembryonic mesoderm in the chorionic cavity) invades the villi, transforming them into secondary villi. The basal feet of the villous stems, connecting the latter with the trophoblastic shell, as well as some villous tips remain free of mesenchyme and thus persist in the primary villous stage (forerunners of the cell columns and cell islands).

**Day 19 to 23 p.c.** This is the beginning of the 2nd month postmenstruation (p.m.), villous stage (early tertiary villi).

**Day 19 to 21 p.c.** Carnegie stage 9: diameter of chorionic sac less than 12 mm; length of embryonic disk equals the crown-rump length of the embryo, 1.5 to 2.5 mm, 1 to 3 somites. Neural folds appear; first cardiac contractions.

**Day 22 to 23 p.c.** Carnegie stage 10: diameter of chorionic sac less than 15 mm; crown-rump length 2.0 to 3.5 mm; 4 to 12 somites. Neural folds start to fuse; two visceral arches.

The villous mesenchyme is characterized by the appearance of the first fetal capillaries (formation of first tertiary villi). The villous diameters are largely homogeneous, presenting two different-sized groups of villi. The larger villous stems and their branches exhibit diameter of 120 to 250  $\mu$ m. Histologically, the stroma of both is mesenchymal in nature. Along their surfaces, one finds numerous small (diameters 30–60  $\mu$ m) trophoblastic and villous sprouts.

**Days 23 to 29 p.c.** Early tertiary villus stage.

**Days 23 to 26 p.c.** Carnegie stage 11: diameter of the chorionic sac less than 18 mm; crown-rump length 2.5 to 4.5 mm; 13 to 20 somites; closure of the rostral neuropore; optic vesicles identifiable.

**Days 26 to 29 p.c.** Carnegie stage 12: diameter of chorionic sac less than 21 mm; crown-rump length 3 to 5 mm; 21 to 29 somites; closure of the caudal neuropore; three visceral arches; upper limb buds appear.

The length of villous stems between chorionic plate and trophoblastic shell varies from 1 mm (antiimplantation pole) to 2 mm (implantation pole). The central two thirds are supplied with mesenchyme and capillaries (Fig. 8.1); the peripheral one third remains in the primary villous stage (cell columns). The villous calibers are similar to those described for the previous stage. The amount of trophoblastic and villous sprouts is reduced. Most villi contain loose mesenchyme together with centrally positioned fetal capillaries (mesenchymal villi). Peripherally, they continue via villous sprouts (with unvascularized mesenchymal core) into massive trophoblastic sprouts. In the villous stems, vessels of larger caliber acquire the first signs of a surrounding adventitia (beginning of formation of typical stem villi characterized by fibrous stroma). The villous trophoblastic surface is composed of an outer syncytiotrophoblast and complete inner layer of cytotrophoblast. Together they measure 20 to 30  $\mu$ m in thickness.

The chorionic plate, consisting of fetal mesenchyme, cytotrophoblast, and syncytiotrophoblast, still lacks fibrinoid. The trophoblastic shell is transformed into the basal plate by intense mixing of decidual and trophoblastic cells. Secretory activities or tissue necrosis of both cell types causes the appearance of the first foci of Nitabuch fibrinoid. The superficial syncytiotrophoblastic layer of the basal plate, bordering the intervillous space, becomes locally replaced by Rohr fibrinoid.

**Days 29 to 42 p.c.** Late 2nd month p.m.

**Days 29 to 32 p.c.** Carnegie stage 13: diameter of chorionic sac less than 25 mm; crown-rump length 4 to 6 mm; 30 + somites; four limb buds and optic vesicle.

**Days 32 to 35 p.c.** Carnegie stage 14: diameter of chorionic sac less than 28 mm; crown-rump length 5 to 8 mm; first appearance of lens pit and optic cup.

**Days 35 to 37 p.c.** Carnegie stage 15: diameter of chorionic sac less than 31 mm; crown-rump length 7 to 10 mm; closure of lens vesicle; clear evidence of cerebral vesicles; hand plates.

**Days 37 to 42 p.c.** Carnegie stage 16: diameter of chorionic sac less than 34 mm; crown-rump length 8 to 12 mm; embryonic weight about 1.1 g; retinal pigment visible; foot plates.

The net weight of the chorionic sac in stage 16 is about 6 to 10 g; thickness of the chorion at the implantation pole

FIGURE 8.1. Placental villi of the 6th week postmenstruation (p.m.). Note the thick trophoblastic covering, consisting of complete layers of cytotrophoblast and syncytiotrophoblast. Fetal capillaries are poorly developed or, in some places, are still

lacking. In the lower right corner, an early step of the formation of a cell island can be seen attached to the villous surface. Paraffin section.  $\times 125$ .

FIGURE 8.2. Placental villi of the 8th week p.m. All villi are vascularized. As can be seen from the diffuse stromal structure, the villi still belong to the mesenchymal type. Paraffin section.  $\times 125$ . (From Kaufmann, 1981, with permission.)

is about 6mm and at the antiimplantation pole about 3mm. The uterine lumen is still open, and parietal and capsular decidua are not yet in contact.

The range of villous calibers changes slightly from the previous stage (Fig. 8.2). The largest stems reach diameters of less than 400 $\mu$ m. A variety of medium-sized mesenchymal villi is found between the stem villi that measure about 200 $\mu$ m in diameter and the small sprouts. The mean villous caliber is about 200 $\mu$ m. The total placental villous surface is about 0.08m<sup>2</sup>. The connective tissue layer of the chorionic plate is completely fibrosed, the fibrous tissue partly extending in the initial parts of the villous stems. The overwhelming share of the villous stroma is still mesenchymal in nature. The villous cytotrophoblastic layer is incomplete; 85% of the villous surface is double layered (cytotrophoblast plus syncytium). The thickness of the villous trophoblast varies between 10 and 30 $\mu$ m (mean, 15.4 $\mu$ m). Near the end of this period, most of the mesenchymal villi show increased numbers of macrophages, as well as the first signs of reticular transformation of their stroma toward immature intermediate villi. Only 2.7% of the villous volume is occupied by fetal vascular lumens. The mean maternofetal diffusion distance is more than 50 $\mu$ m.

The villous stems are nearly completely occupied by connective tissue; basal segments, persisting in the primary villous stage, are the exception. Those segments now show the typical appearance of cell columns. Short portions of villous side branches, persisting in the primary villus stage and that are positioned somewhere between chorionic and basal plate, may increase in size by continuous cell proliferation with subsequent fibrinoid degeneration; they thus establish the first cell islands.

**Third month p.m.** 9th to 12th weeks p.m.; days 43 to 70 p.c.

**Days 43 to 44 p.c.** Carnegie stage 17: maximum diameter of chorionic sac 38mm; crown-rump length 10 to 14mm; finger rays.

**Days 44 to 48 p.c.** Carnegie stage 18: maximum diameter of chorionic sac 42mm; crown-rump length 12 to 16mm. Elbow region, toe rays, nipples, and eyelids appear.

**Days 48 to 51 p.c.** Carnegie stage 19: maximum diameter of chorionic sac 44mm; crown-rump length 14 to 18mm.

**Days 51 to 53 p.c.** Carnegie stage 20: maximum diameter of chorionic sac 47mm; crown-rump length 17 to 22mm. Upper limbs at the elbow region; first signs of finger separation.

**Days 53 to 54 p.c.** Carnegie stage 21: maximum diameter of the oval chorionic sac 51 mm; crown-rump length 20 to 24mm.

**Day 54 to 56 p.c.** Carnegie stage 22: maximum diameter of the oval chorionic sac 58mm; crown-rump length 23 to 28mm.

**Days 56 to 60 p.c.** Carnegie stage 23: maximum diameter of the oval chorionic sac 63mm; crown-rump length 26 to 31mm.

**Days 61 to 70 p.c.** Maximum diameter of the oval to irregular chorionic sac 68mm; crown-rump length 26 to 31mm.

**Days 61 to 70 p.c.** Maximum diameter of the oval to irregular chorionic sac 68mm; crown-rump length 30 to 40mm.

The embryonic weight increases throughout the 3rd month from 2g to 17g and the net weight of the chorionic sac from 10g to 30g. The chorionic sac is covered by villi over its surface; it is not yet subdivided into smooth chorion and placenta.

All villi are vascularized. Around the antiimplantation pole, the increased degenerative changes of villi and fibrinoid deposition in the intervillous space indicate that the formation of the smooth chorion will commence soon. Parietal and capsular decidua may come into contact locally, but they remain unfused.

The heterogeneity of villous diameters and villous structures increases. Fibrosis of the villous stems slowly extends into the more peripheral parts of the largest villi (diameters less than 500 $\mu$ m). During the course of the 3rd month, most of the villi measuring between 100 and 400 $\mu$ m establish the typical reticular appearance of immature intermediate villi (Fig. 8.3), characterized by numerous macrophages (Hofbauer cells). Small villi with diameters less than 100 $\mu$ m show mesenchymal stroma. Trophoblastic and villous sprouts are numerous. Total villous surface is about 0.3m<sup>2</sup>. The trophoblastic thickness varies from 10 to 20 $\mu$ m. Eighty percent of the villous surfaces are covered by cytotrophoblast. Fetal vessel lumens occupy about 4% of the villous volume. Some of the larger fetal vessels achieve a thick adventitia, consisting of fibrous stroma, which occupies larger parts of the villous stroma. The reticular stroma, as a sign of immaturity of the stem villi, is restricted to the superficial parts of the stroma positioned under the trophoblast.

In the previous stages fibrinoid was restricted to the cell islands and the basal plate, but now spot-like fibrinoid deposition at some of the villous surfaces can be observed. Fibrinoid deposition at the intervillous surface of the chorionic plate is still an exception. The amniotic cavity has extended to such a degree that the amniotic mesoderm comes into contact with the connective tissue layer of the chorionic plate in many places.

**Fourth month p.m.** 13th to 16th week p.m.; 11th to 14th weeks p.c.

The shape of the chorionic sac becomes more and more irregular because of compression between uterine wall

FIGURE 8.3. Placental villi of the 12th week p.m. The larger villi have achieved the reticular stroma of typical immature, intermediate villi. The smaller villi are mesenchymal in structure. The

first small fetal arteries and veins can be seen. Paraffin section.  $\times 125$ .

and fetus. Its maximum diameter increases throughout this period from 68 mm to 80 to 90 mm. The crown-rump length grows from 45 mm to 80 mm, and the fetal weight from 20 g to 70 g. The length of the umbilical cord is between 160 and 200 mm.

The continuous degeneration of placental villi at the antiimplantation pole, which is free of villi from the middle of the 4th month onward, as well as the villous proliferation at the implantation pole, initiates the differentiation of the chorionic sac into smooth chorion and placenta. The placental diameter increases from 50 mm to 75 mm at the end of this month and the placental weight from 30 g to 70 g. The maximal placental thickness in the delivered specimens is 10 to 12 mm. Numerous placental septa become visible. The cell columns become more deeply incorporated into the basal plate by fibrinoid deposition in their surrounding. The chorionic plate is in close contact with the amnion over its entire surface, giving it definite shape and layering. It consists of amnionic epithelium, amnionic mesoderm, chorionic mesoderm, a cytotrophoblast layer, and superficial syncytiotrophoblast.

The distribution of the villous calibers (Fig. 8.4) is similar to that described for the preceding month. The inhomogeneous mixture of villi is composed of stem villi

with diameters of 300 to 500  $\mu\text{m}$ , the vascular adventitia of which occupies at least 75% of the villous stroma, and of immature intermediate villi with diameters of 100 to about 300  $\mu\text{m}$ . Mesenchymal villi and sprouts, 40 to 80  $\mu\text{m}$  in diameter, are numerous, but because of their size they occupy only a small proportion of the total villous volume. Because the immature intermediate villi have the most characteristic reticular stroma at this stage and comprise the highest proportion of villi, one observes more villous macrophages (Hofbauer cells) than at all other stages of placental development. The total villous surface was measured to be 0.5 to 0.6  $\text{m}^2$ . The share of fetal vessel lumens is increased to about 6%. Some of the capillaries establish contact with the villous trophoblast. In such places the syncytial nuclei are moved aside, resulting in the first epithelial plates; therefore, the trophoblastic thickness varies between 2 and 12  $\mu\text{m}$  (mean, 9.6  $\mu\text{m}$ ). As during the previous month, one observes cytotrophoblast on about 80% of the villous surface. Fibrinoid deposition becomes a usual finding on the villous surfaces.

**Fifth month p.m.** 17th to 20th week p.m.; 15 to 18th week p.c.

Because of the geometrically irregular outer shape of the fetus, the diameter of the chorionic sac cannot be

FIGURE 8.4. Placental villi of the 15th week p.m. The larger immature intermediate villi exhibit the first signs of central stromal fibrosis, originating from the larger fetal vessels, thus establishing the first stem villi (SV). Several typical immature intermediate

villi (IV) and mesenchymal villi (MV) can be seen. As is typical for mesenchymal villi of the second and third trimester, they are associated with degenerating villi being more or less transformed into intravillous fibrinoid. Paraffin section.  $\times 125$ .

estimated from this period onward. Over the course of the 5th month the crown-rump length increases from 80 mm to 130 mm and the fetal weight from 70 g to 290 g. The placenta is clearly separated from the smooth chorion. The placental diameter is between 75 mm and 100 mm, and the placental weight increases from 70 g to 120 g. The maximum placental thickness after delivery is about 12 to 15 mm; measured by ultrasonography and in situ, including the uterine wall, it is approximately 28 mm. The length of the umbilical cord varies between 200 and 315 mm.

The structure of the stem villi is nearly the same as in the previous month; however, their number is considerably increased throughout this month (Fig. 8.5). During the 20th week p.m., most of the large caliber villi (those exceeding 300  $\mu$ m) have achieved the fibrous stroma of stem villi. The number of slender, long mesenchymal villi with diameters around 80 to 100  $\mu$ m increases. The mean diameter of the remaining immature intermediate villi is slightly reduced to values around 150  $\mu$ m. The mean villous diameter is 108  $\mu$ m. The total villous surface is about 1.5 m<sup>2</sup>. Because the amount of villous cytotrophoblast is reduced to about 60% of the villous surface, the

extent of thin trophoblastic areas from 1 to 2  $\mu$ m in thickness increases. Continuous development of fetal capillaries causes the reduction of mean maternofetal diffusion distance to about 22  $\mu$ m.

Septa and cell islands that originally consisted mainly of accumulations of cells now grow considerably by apposition of fibrinoid. In their centers, cysts are often found.

**Sixth month p.m.** 21st to 24th week p.m.; 19th to 22nd week p.c.

The fetus grows from 130 mm to 180 mm in crown-rump length. Its weight increases from 290 g to 600 g. The placental diameter is between 100 and 125 mm, and the placental weight increases from 120 g to 190 g. Placental thickness after delivery is 15 to 18 mm, and ultrasonographic measurements in situ, including the uterine wall, indicate a thickness of about 34 mm. The mean length of the cord is between 315 and 360 mm.

The histologic features change considerably. Most of the immature intermediate villi become transformed into stem villi of large caliber. More of the stem villi measure about 200  $\mu$ m in thickness, some achieving diameters of

FIGURE 8.5. Placental villi of the 18th week p.m. This picture is comparable to that of the preceding stage. Formation of stem villi with stromal fibrosis is somewhat more expressed. Paraffin section.  $\times 125$ .

more than  $1000\mu\text{m}$ . Their fibrous stroma still exhibits a small superficial rim of reticular connective tissue, indicating their immaturity (Fig. 8.6). Different from all earlier stages, increasing numbers of newly formed intermediate villi exhibit small calibers (only  $100\text{--}150\mu\text{m}$ ). Some of these villi are reticular in stromal structure, as are their parent villi, whereas others are slender, mature intermediate villi with poorly vascularized and poorly fibrosed, nonreticular stroma ( $80\text{--}120\mu\text{m}$ ) (Fig. 8.7). At their surfaces, the first richly capillarized terminal villi are formed. They are difficult to identify in the large group of smallest villi, measuring  $50$  to  $80\mu\text{m}$ , because the other members of this group, the small mesenchymal villi and villous sprouts, exhibit structural features similar to those of the terminal villi in paraffin sections. The total villous surface amounts to  $2.8\text{m}^2$ . The mean trophoblastic thickness is reduced to  $7.4\mu\text{m}$ , and the mean maternofetal diffusion distance is about  $22\mu\text{m}$ .

**Seventh month p.m.** 25th to 28th week p.m.; 23rd to 26th week p.c.

When compared to the 6th month, there are only quantitative changes. The crown–rump length increases from  $180\text{mm}$  to  $230\text{mm}$  and the fetal weight from  $600\text{g}$  to  $1050\text{g}$ . The placental diameter is  $125$  to  $150\text{mm}$ , and the placental weight is increased to  $190$  to  $260\text{g}$ . The thickness of the

delivered placenta is  $18$  to  $20\text{mm}$ ; by ultrasonography, including the uterine wall, it is  $38\text{mm}$ . The mean length of the umbilical cord increases from  $360$  to  $410\text{mm}$ .

The total villous surface of the placenta exceeds  $4\text{m}^2$ . The distribution of structure and caliber of the villi are similar to what was seen during the 6th month. Only  $45\%$  of the villous surface is covered by cytotrophoblast. The trophoblastic thickness varies between  $0.5$  and  $8\mu\text{m}$  (mean,  $6.9\mu\text{m}$ ). The number of immature intermediate villi decreases in favor of stem villi and mature intermediate and terminal villi. The lumens of fetal vessel amount to  $9.1\%$  of the villous volume.

Cell columns are surrounded by increasing amounts of fibrinoid and become deeply invaginated in the basal plate. The syncytiotrophoblastic covering of the chorionic plate begins to degenerate. It becomes replaced by an initially thin layer of fibrinoid that grows in thickness throughout the following weeks and forms the Langhans' stria.

**Eighth month p.m.** 29th to 32nd week p.m.; 27th to 30th week p.c.

The crown–rump length is  $230$  to  $280\text{mm}$ , fetal weight is  $1050$  to  $1600\text{g}$ . The placental diameter normally varies between  $150$  and  $170\text{mm}$ ; the placental weight increases from  $260\text{g}$  to  $320\text{g}$ . The placental thickness after delivery

FIGURE 8.6. Placental villi of the 21st week p.m. The stroma of the stem villi (SV) is largely fibrous. Only a discontinuous thin superficial rim of reticular connective tissue is reminiscent

of their derivation from immature intermediate villi. Paraffin section.  $\times 125$ .

FIGURE 8.7. Placental villi of the 24th week p.m. Compared to the preceding stages, the variability in villous shapes and diameters is sharply increasing. The population of small slender villi

(X's at lower left, lower right, and at center), originally referred to as mesenchymal villi, has achieved structural characteristics of mature intermediate villi. Paraffin section.  $\times 125$ .

is about 20 to 22 mm; measured by ultrasonography in situ and including the uterine wall, it is 43 mm. The umbilical cord has a mean length between 410 and 455 mm.

Steeply increasing numbers of mature intermediate villi and terminal villi, both of which exhibit calibers of 40 to 100  $\mu\text{m}$ , are the reason for considerably increased numbers of villous cross sections per square millimeter of histologic sections (Fig. 8.8). The total villous surface is increased to a mean of about 7  $\text{m}^2$ . In addition to the villi of small caliber that compose most of the villi, there are mainly stem villi of large caliber. Intermediate calibers of 100 to 200  $\mu\text{m}$  are rare, causing a typical gap in the range of calibers. This gap may be evident as early as the second half of the 7th month. The few existing villi of this particular caliber, mostly immature intermediate villi, are grouped together in the centers of the villous trees. Villous cytotrophoblast is reduced to about 35% of the villous surface. As a result of the beginning sinusoidal dilatation of the fetal capillaries in the newly formed terminal villi, the amount of vasculosyncytial membranes (epithelial plates) is increased, and the mean trophoblastic thickness reduced to about 6  $\mu\text{m}$ .

**Ninth month p.m.** 33rd to 36th week p.m.; 31st to 34th week p.c.

The crown-rump length is 280 to 330 mm, fetal weight is 1600 to 2400 g, placental diameter is 170 to 200 mm, and the placental weight is 320 to 400 g. The placental thickness postpartum is 22 to 24 mm; by ultrasonography in situ, including the uterine wall, it is 45 mm. The mean cord length increases from 455 to 495 mm.

Histologically, the developmental processes described for the preceding month become even more prominent: The total villous surface of the placenta is increased to about 10  $\text{m}^2$ . Capillary growth and continuous sinusoidal dilatation cause the mean maternofetal diffusion distance to decrease to less than 12  $\mu\text{m}$  and the mean trophoblastic thickness to about 5  $\mu\text{m}$ . Cytotrophoblast is found on only 25% of the villous surfaces. The largest stem villi reach 500 to 1500  $\mu\text{m}$  in diameter. The small stromal rim, consisting of reticular connective tissue and indicating their immaturity, has normally disappeared to the credit of fibrous stroma that completely occupies the villous core (Fig. 8.9). The originally reticular superficial zone of the stroma shows an increased number of connective tissue cells for a few weeks, compared to

FIGURE 8.8. Placental villi of the 29th week p.m. During this period, the mature intermediate villi and the stem villi (lower left) are the prevailing villous types. Immature intermediate villi

with typical reticular stroma (lower right) are less common. Paraffin section.  $\times 125$ .

FIGURE 8.9. Placental villi of the 33rd week p.m. The number of immature intermediate villi is further decreasing. Most villi are stem villi and mature intermediate villi; the latter are intermingled with the first few terminal villi, which in paraffin sections

(because of their similar diameters) are difficult to differentiate from mature intermediate villi. The stem villi are still not fully fibrosed; rather, they show a thin superficial layer that has few fibers and is rich in connective tissue cells. Paraffin section.  $\times 125$ .

the more central parts of the stem villi. This difference usually is no longer observed at term. Larger parts of the syncytiotrophoblast of the stem villi are replaced by fibrinoid. Most villi are mature intermediate and terminal villi (Fig. 8.10). Small groups of immature intermediate villi, with calibers of 100 to 200  $\mu\text{m}$ , can regularly be found in the centers of the villous trees, indicating placental growth is still active.

**Tenth month p.m.** 37th to 40th week p.m.; 35th to 38th week p.c.

The mean crown–rump length is increased from 330 mm to its final value of 380 mm and the mean fetal weight from 2400 to 3400 g. The placental diameter during the last month of pregnancy varies between 200 and 220 mm, and the mean placental weight increases from 400 g to 470 g. There are considerable individual variations. Early clamping of the cord after delivery of the baby may even increase placental weight by as much as 100 g. The final maximal placental thickness postpartum is about 25 mm; measured by ultrasonography in situ, the uterine wall and placenta amount to 45 mm. The mean cord length at term is 495 to 520 mm.

The kind and amount of villous types differ from the foregoing stage in several aspects. There are considerably

increased numbers of terminal villi (about 40% of the total villous volume of the placenta) (Fig. 8.11) and a higher degree of capillarization of the latter, mainly because many of the capillary cross sections are dilated sinusoidally to maximally 40  $\mu\text{m}$ . In well-preserved, early-fixed placentas that are not suffering from fetal vessel collapse, the terminal fetal villous capillary lumens amount to 40% or more of the villous volume. About 20% of the villi are stem villi. In the fully matured placenta, the fibrous stroma reaches the trophoblastic or fibrinoid surface of the stem villi everywhere; a superficial reticular rim, or a superficial accumulation of fibroblasts, as during the 9th month, is usually absent at term. If not, it has to be interpreted as a sign of persisting immaturity. The syncytiotrophoblastic cover of the stem villi is degenerated in most places and often it is replaced by fibrinoid (Fig. 8.12). About 30% to 40% of the villous volume is made up of mature intermediate villi, which can be differentiated histologically from the terminal villi by their reduced degree of fetal capillarization, and from the stem villi by the absence of large fetal vessels with media and adventitia identifiable by light microscopy. Maximally, only 10% of the total villous volume is of the immature, intermediate variety; they normally appear as small, loosely arranged groups

FIGURE 8.10. Placental villi of the 35th week p.m. The distribution of villous types is largely comparable to that demonstrated for the preceding stage. Paraffin section.  $\times 125$ .

FIGURE 8.11. Placental villi of the 38th week p.m. Dominating villous types are mature intermediate villi and terminal villi, both of small caliber. Several stem villi of varying caliber can be seen in between. As is typical for near-term placentas, the trophoblastic cover of the stem villi is partly replaced by

fibrinoid. The stromal core is completely fibrosed. Reticular stroma or cellular connective tissue (which as a typical sign of immaturity was visible below the trophoblast in earlier stages) is absent throughout the last few weeks. Paraffin section.  $\times 125$ .

FIGURE 8.12. Placental villi of the 40th week p.m. Caliber distribution is little different from that of the 38th week. Despite this fact, some remarkable changes exist: The fibrinoid deposits (homogeneously gray) around the larger stem villi and the number of terminal villi are considerably increased; also, because

of the irregular shapes of terminal villi at term, numerous flat sections of villous surfaces can be seen. Here these structures appear as dark spots of seemingly accumulated nuclei (“trophoblastic knotting”). Paraffin section.  $\times 125$ .

in the centers of the villous trees, sometimes surrounding a central cavity.

The total villous volume of the placenta is about  $12.5\text{ m}^2$ . The mean trophoblastic thickness is reduced to about  $4\mu\text{m}$  and the mean maternofetal diffusion distance to less than  $5\mu\text{m}$ . About 20% of the villous surfaces are double layered, consisting of cytotrophoblast and syncytiotrophoblast; the remaining 80% are only covered by syncytium of highly varying thickness ( $0.5\text{--}10\mu\text{m}$ ). The cell bodies of the existing villous cytotrophoblast, however, are so thin at times that they may be difficult to identify; thus, many investigators tend to underestimate their quantity or even deny their existence. The amount of fibrinoid in and around the villi is variable. We have never observed a complete absence of fibrinoid. Amounts exceeding 10% of the total placental villous volume are an exception and likely to be a sign of disease processes. The amount of fibrinoid, inside and at the surfaces of the chorionic and the basal plate, is even more variable.

**Table 8.1** summarizes the development of villous types throughout pregnancy.

#### NUCLEATED RED BLOOD CELLS

There is considerable confusion about the normal numbers of nucleated red blood cells (NRBCs) in neonatal blood and it is for this reason that this information is included here. In the truly normal term pregnancy very few, if any, red blood cells with nuclei are visible in the fetal blood during the microscopic placental examination. When NRBCs are seen in the fetal blood at term (and it is important that they be correctly diagnosed as such), this is a distinctly abnormal finding. The pathologist should endeavor to ascertain the reason for the presence of the NRBCs when they are seen in placental sections (Fig. 8.13). This is most conveniently done by making a blood smear of neonatal blood.

An extensive literature exists on this topic and the findings in these contributions are not always in agreement. They have indeed led to considerable controversy as to how many NRBCs may be found in truly normal neonates. Most studies are based on neonatal blood smears, rather than placental sections. It is difficult to estimate the number accurately by studying placental slides. One reason for the results to be discrepant, especially in the older citations, is that the authors have not always stated the exact age of the neonates they studied. They have also not excluded infants who suffered from any of the many causes of hypoxia. Most reports made no reference to the possible existence of growth retardation and many other factors that are only now becoming known as causing fetal erythropoietin (EPO) release, presumably the main reason for secretion of NRBCs.

One of the earliest contributions to this topic is that by Geissler and Japha (1901), who stated emphatically that “contrary to the dogma,”

TABLE 8.1. Structural characteristics of the five villous types from the 4th to the 40th week p.m.

Week	Stem villi	Immature intermediate villi	Mesenchymal villi	Mature intermediate villi	Terminal villi
4			Only mesenchymal villi (120–250µm) and trophoblastic sprouts (30–60µm) are present.		
5			Large mesenchymal villi (>200µm) may show diffuse, moderate stromal fibrosis.		
6		<i>Not existing in this stage</i>			
7					
8			The first stromal channels appear within the mesenchymal villi.		
9			Numerous short mesenchymal villi		
10			(60–100µm), partly continuous with slim trophoblastic sprouts, branch from the surfaces of

18					
19					

*Not existing in this stage*

*Not existing in this stage*

The numbers of mesenchymal villi and trophoblastic sprouts are slowly decreasing.

20	First true stem villi appear.	Immature intermediate villi are still the dominating villous type.	The number of mesenchymal villi with poorly fibrosed and poorly vascularized stroma, rich in cells, increases considerably. They grow in length and in width (calibers 80–150µm) and show a continuous transition into mature intermediate villi.	Local spot-like groups of first typical terminal villi appear; they show calibers of about 60µm, about half of their stromal volume being occupied by capillary lumens.
21	Smaller ones (150–300µm) show centrally fibrosed core with arterial and venous adventitia being fused. Those >300µm show a largely fibrosed core.	Those with calibers of 100–150µm show no stromal fibrosis. The larger ones show fibrosis of the walls of larger vessels.		
22				
23				
24	Caliber >300µm: completely fibrosed stroma; caliber <300µm: superficial layer of reticular stroma below the trophoblast.	Number and size of immature intermediate villi are decreasing.	Typical mesenchymal villi are rare and mostly located in the surrounding of immature intermediate villi.	Mature intermediate villi with dense stroma, rich in stromal cells and poor in fibers, with calibers of 100–150µm, comprise the dominating villous type.
25				
26				
27				
28			Mesenchymal villi are histologically inconspicuous; the few identifiable ones are usually located around the central cavities.	Increasing amount of evenly distributed terminal villi with sinusoidally dilated capillaries and few epithelial plates.
29	Caliber >200µm: completely fibrosed stroma;	Only a few evenly distributed immature intermediate villi can be found; the stroma is only partly reticular in nature.		
30	caliber <200µm: incomplete superficial rim of reticular stroma.			
31				
32	Usually, all stem villi are void of reticular stroma; however, below the trophoblast still is a less densely fibrosed rim, rich in fibroblasts.	The few remaining immature intermediate villi are no longer evenly dispersed but, rather, concentrated as small groups in the centers of the villous trees lining the central cavities. The extremely loose reticular stroma shows only a few typical stromal channels.	The relative number of mature intermediate villi is decreasing to about 25% of total villous volume. The caliber is reduced to 80–120µm.	Terminal villi are the dominating villous type; they amount to about 40% of the total villous volume.
33				
34				
35				
36	All stem villi (except a few around the central cavity) are completely fibrosed. The trophoblast of the larger ones often is replaced by fibrinoid.

FIGURE 8.13. Immature intermediate villus of the 6th week p.m. The villus is covered by a uniform layer of syncytiotrophoblast lining the intervillous space (above), followed by a nearly complete layer of villous cytotrophoblast directly below. The villous

stroma is largely occupied by a fetal vessel containing numerous nucleated red blood cells, as is typical for this stage of pregnancy. Hematoxylin and eosin (H&E) stain.  $\times 800$ .

NRBCs are not found in young children; it is possible, however, that they occur rarely in prematures. These authors were adamant in their opinion that the presence of NRBCs is to be viewed as "showing disease." As many others, they did not specify the children's ages or clinical conditions of their births. Lippman (1924) enumerated the NRBCs of neonatal blood, followed the children up to 5 days of life, and reviewed all prior literature. Lippman concluded that term neonates have an average of 3.2 NRBCs/100 white blood cells (WBCs). (To express the number of NRBCs per total WBC is a convenient and widely practiced way of enumerating these cells, but an alternate method is referred to below.) The number of NRBCs was found to fall rapidly after birth, and at the age of 5 days there were none left. The condition of the newborns is again not clearly stated in this paper, except that children with congenital syphilis were excluded; however, mothers with preeclampsia were not.

Ryerson and Sanes (1934) undertook one of the more incisive studies of placentally contained NRBCs. They were anxious to ascertain parameters that allowed specifying the age of a gestation by histologic examination of the placenta. They concluded that virtually all NRBCs had disappeared at the end of the third month of pregnancy. They suggested also that, if more than 1% NRBCs are found, this indicated prematurity (Fig. 8.13). Anderson (1941) made the next significant contribution and more or less confirmed the previous findings. He indicated that in approximately 16.5% of term placentas one or two NRBCs could be found among 1000 red blood cells (RBCs); in the remaining 83.5% there were none at term. Stillborns were observed to have greater numbers, and he stated that a "decided increase . . . points to pathologic states." Fox (1967) next published on this phenomenon; he related it to hypoxia or asphyxia. We concur with this interpretation of a relationship to fetal tissue hypoxia, and it is our practice to always take special note of the presence of NRBCs when examining placentas microscopically.

Green and Mimouni (1990) have addressed the question of NRBCs in newborns of diabetic mothers; their observation was that normative data are lacking in the literature. These authors stated the desirability to express NRBCs in absolute numbers, rather than as NRBCs/WBCs, as has been the common practice. One reason for so doing is that elevated WBC counts would lead to artificially low numbers of NRBCs when the usual method of enumeration (NRBC/100 WBCs) is employed. Green and Mimouni also provided rigid criteria for the selection and suggested that "a value greater than  $1 \times 10^9/L$  should be considered as a potential index of intrauterine hypoxia." Normally, there were no NRBCs in term neonates, and the 95th percentile was 1.7 in absolute counts. Diabetic mothers' babies had increased numbers, as did infants with hypoxia and growth-retarded neonates. Shurin (1987) concluded

that there are about 200 to 600 NRBCs/ $mm^3$  and 10,000 to 30,000 WBCs; she also stated that the normal infant has 4 to 5 NRBCs/100 WBCs in cord blood samples, which is higher than is our experience. Shurin reflected that this number indicates the erythroid hyperplasia caused by high levels of EPO production.

Erythropoietin, initially made in liver and later in kidneys (Eckardt et al., 1992), is the principal agent in the secretion of NRBCs from the sites of hematopoiesis. It is now being measured with greater frequency in cord blood, and correlations are beginning to be made to perinatal circumstances. Maier et al. (1993) found that elevated levels of EPO in cord blood indicate prolonged fetal hypoxia and advocated that the determination of EPO levels might give the exact time course of events. The EPO levels did not correlate with gestational age, meconium staining, or Apgar scores, but they related to umbilical arterial pH level and were elevated in fetal growth retardation; they also quoted authors who found a relation to fetal death and cerebral palsy. These findings are of great significance to the perinatologist and pathologist with an interest in ascertaining more precisely than now possible the time of possible fetal hypoxia, especially its relation to possible problems during labor. It is hoped that the rapidity (or sluggishness) of the EPO response and the appearance of NRBCs will be further defined in the future so as to allow a better analysis of perinatal hypoxia. Because these phenomena require some significant metabolic steps in fetal performance, one would expect that very many hours must pass from an hypoxic event to significantly elevate the levels of EPO and NRBCs of the fetus; but we do not presently know the exact number of hours. We also do not know whether the fetal response with EPO and numbers of NRBCs secreted to different amounts of acute blood loss is the same or if it is a graded response. There are, however, occasionally specific cases that allow some insight into these questions. They need to be recorded for a better understanding of the response. It is then essential that the precise status of the gestation and the well-being of the fetus be known for accurate assessment. Thus, it would be impossible to compare accurately the levels of NRBCs found after a hemorrhage in a neonate with intrauterine growth restriction (IUGR) and those of a normal neonate; the former may have started at a higher baseline. Experimental observations (presently known only from sheep) are insufficient for the clinical setting. Quantitative and temporal sequences by Shields et al. (1993) have reviewed what is known of this aspect of RBC restoration after experimental hemorrhage in sheep. Despite an initial rise in erythropoietin level, a significant hemorrhage (40%) is not followed by a significant increase in reticulocyte count, nor are the former blood volume and hematocrits restored before birth. Thus, the ovine model may not be adequate to settle these important questions.

Phelan et al. (1993) studied NRBCs in asphyxiated and normal neonates. They found that normal infants do not have NRBCs but that asphyxiated newborns have elevated counts. The most elevated NRBC counts were explicable only by assuming hypoxia to have occurred long before birth. Nicolini et al. (1990) made the observation that IUGR fetuses have elevated NRBC counts in cordocentesis samples.

The following observations may have relevance in this context.

1. A patient at term whom we have known had a major "gush of bright red blood" (later identified as fetal blood from disrupted velamentous vessels) upon insertion of an intrauterine pressure catheter. She was delivered by cesarean section 48 minutes later; the infant was pale but the placenta otherwise entirely normal. The cord arterial pH was 7.05, the fetal hemoglobin 14.6g, hematocrit 44.8%, WBC 28,000, and platelets 120,000 and falling to 71,000. Three transfusions of packed RBCs were given to the newborn and the hemoglobin level was then only 10.3g, hematocrit 29.9%. The first enumeration of NRBCs occurred at 1.5 hours as 19 NRBCs/100 WBCs; 6 hours later it was 32 NRBCs/100 WBCs. Thus, there was a continued hematologic response after the delivery of the anemic child, and the initial NRBC response was detectable already within 1 hour. This finding is contrary to the rapid decline of NRBCs postnatally when the hypoxic event has been more remote; under those circumstances most NRBCs are gone on the second day.

2. Another relevant case was a woman who had a car accident while wearing a lap belt and was at 28 weeks' gestation. Approximately 12 ( $\pm$  1) hours later, the fetus was born with a hematocrit of 25% and an estimated 40 to 50mL of fetal blood in the maternal circulation; 45 NRBCs/100 WBCs were then found. Moreover, villous edema indicated some degree of early fetal heart failure. This finding may be surprising with a hematocrit of 25% and suggests that final adjustment of blood volume had not yet been made.

3. A 24-year-old gravida 1 was involved in a car accident at 33 weeks. The baby was delivered 12 hours later by cesarean section. There was a large retroplacental hematoma, consistent with age 12 hours. At 0.5 hour later, a complete blood count (CBC) showed 45 NRBCs/100 WBCs and a WBC count of 20,000; hematocrit of 39.7%. Eleven hours later the number of NRBCs was 5/100 WBCs, but packed cells had been given; WBC was then 11,000. The child suffered cerebral palsy.

4. A gravida 1 without toxemia, at 39 weeks and 4 days, with normal pregnancy awoke at 6:45 a.m. with a brief abdominal pain, finding many blood clots in the bed; she ruptured the membranes but stopped bleeding; there was no pain. At 8:12 a.m. she came to the hospital. Findings were fetal heart tone (FHT) 140 to 150; good fetal movements; speculum examination showed blood-tinged fluid in the vagina; no blood from the 1-cm cervix; nontender uterus. At 10:12 a.m. massive bradycardia occurred, followed by emergency cesarean section delivery at 10:37 a.m. Hematocrit was 19%, pH 6.77, PCO<sub>2</sub> 125, PO<sub>2</sub> 32, base deficit -20; NRBCs 18/100 WBCs; Apgar scores 0/0/0. Despite resuscitation and transfusion with packed cells, the child died the next day having a flat EEG. At autopsy, several myocardial infarcts, brain necroses, and infarcted adrenals, kidneys, spleen, and areas of liver were found. One velamentous vessel had ruptured, of a velamentous cord with bilobed placenta. This happened in bed, and bleeding was presumably stopped because the engaging head compressed the ruptured vessel. The brick-red myocardial necroses and the finding of 18 NRBCs at birth suggest that on admission the damage had already been done.

Through the courtesy of Dr. G. Altshuler, we provide here a more accurate means of assessing the precise number of NRBCs, as it is heavily influenced by WBC counts:

To calculate the absolute NRBC count from NRBCs/WBCs (number/mm<sup>3</sup>), one first needs to correct the machine-counted WBCs to a CWBC (corrected WBC) by the following formula:

$$CWBC = \frac{WBC_{(\text{machine-counted total WBC count})} \times 100}{100 + (NRBC/100 \text{ WBC})}$$

Then: NRBC = WBC - CWBC, or the total NRBC count = total CWBC  $\times$  NRBC/100 WBC.

# Nonvillous Parts and Trophoblast Invasion

H.G. Frank and P. Kaufmann

The nonvillous parts of the placenta include the chorionic plate, cell islands, cell columns, placental septa, basal plate, marginal zone, and fibrinoid deposits in all parts of the organ (Fig. 9.1). In contrast to the villous parts of the placenta, they do not participate in maternofetal exchange since they are never vascularized by both the maternal and fetal circulations, but rather by fetal stem vessels alone (chorionic plate), or maternal stem vessels alone (basal plate), or neither of both (marginal zone, cell islands, cell columns, fibrinoid deposits).

Irrespective of their heterogeneous location and structure, the nonvillous parts of the placenta have the same basic components (Fig. 9.2):

- extravillous trophoblast,
- fibrinoid, and
- in some locations, decidualized endometrial stroma.

These basic tissue components structurally and functionally do not vary from one nonvillous part to another and therefore are considered first.

## Extravillous Trophoblast

### HISTORICAL ASPECTS AND NOMENCLATURE

Placentologists have known for about 100 years that different cell types exist in the nonvillous parts of the placenta and that they differ markedly in shape and staining patterns. Among those, in particular, the large, intensely basophilic staining cells of all nonvillous parts have raised an enormous interest. Scipiadès and Burg (1930) first employed the term **X cells**, the name implying that their origin was in dispute. The search for Barr bodies (sex chromatin, the heterochromatic second X chromosome of females) in X cells gave conflicting results (maternal origin: Klinger & Ludwig, 1957; fetal origin: Zhemkova, 1960). Systematic radioautographic studies on <sup>3</sup>H-thymidine incorporation (Kim & Benirschke, 1971), as well as detailed structural (Kaufmann & Stark, 1971) and enzyme histochemical analyses (Stark & Kaufmann, 1971) gave first evidence that X cells are trophoblastic in nature. Final proof for the trophoblastic, fetal origin of the X cells was obtained by Y-specific fluorescence in X cells of placentas from male infants (Faller & Ferenci, 1973; Khudr et al., 1973; Maidman et al., 1973; Steininger, 1978).

Today, normally antibodies against cytokeratin, an epithelial intermediate filament, are used as an easily applicable immunohistochemical marker of these cells (Khong et al., 1986b; Yeh et al., 1988, 1990; Daya & Sabet, 1991; Mühlhauser et al., 1995). This antigen is not trophoblast specific but rather is expressed by all cells of epithelial origin. Because of this, in the nonvillous parts of the placenta, also the amnionic epithelium and residual maternal glandular epithelium are cytokeratin positive; moreover, some smooth muscle cells may express certain isoforms of this cytoskeletal antigen (except cytokeratin 7). In spite of these limitations, cytokeratin antibodies represent the most suitable markers for the distinction of extravillous trophoblast cells from decidual cells (see Fig. 9.4A), since all cells of decidual origin (decidual cells, endometrial stromal cells, macrophages, lymphocytes, natural killer cells) are clearly cytokeratin negative.

Antibodies against different cytokeratin isoforms have been employed to identify special subtypes of trophoblast (Mühlhauser et al., 1995; Pröll et al., 1997a). An antibody against placental protein 19 (PP19) is another immunohistochemical marker that is said to react specifically with extravillous trophoblast (Takayama et al., 1989). The antibody BC-1 (Loke et al., 1992) was shown to differentiate between villous and extravillous trophoblast, binding specifically to the latter.

As soon as the trophoblastic origin of the X cells was proven, new and more appropriate designations were proposed. Among those are extravillous trophoblast, nonvillous trophoblast, intermediate trophoblast. Regrettably, each of these terms has a slightly different definition. In addition, names for trophoblast of special nonvillous localizations have been introduced (e.g., interstitial trophoblast, endovascular trophoblast, intraarterial trophoblast, clear trophoblastic cells, trophoblastic giant cells, trophocytes, and spongiotrophoblast-like cells).

Recently, among placentologists the term **extravillous trophoblast** (EVT) has been generally accepted as general heading for the entire population of trophoblast cells residing outside the villi. This term ideally describes the topographic situation of these trophoblast cells. According to its localization and degree of differentiation, the extravillous trophoblast may be further subdivided. The respective nomenclature is summarized and defined in Figure 9.3.

Among clinicians and pathologists the term **intermediate trophoblast** (Kurman et al., 1984a,b) is still widely applied. Regrettably, this term has never been well defined and it remains open how far, for instance, proliferative extravillous trophoblast and endovascular trophoblast are included. The term intermediate trophoblast was first used for villous trophoblast cells showing a phenotype intermediate between villous cytotrophoblast and syncytiotrophoblast (Tighe et al., 1967). Later it was applied to extravillous trophoblast cells, which were thought to show a similar "intermediate" phenotype (Kurman et al., 1984a,b). Descriptions such as "intermediate trophoblast of the villous sprouts"

FIGURE 9.1. Schematic drawing of the distribution of the various trophoblast populations (blue) of the human placenta. All those trophoblast cells that rest on the trophoblastic basal lamina of membranes, chorionic plate, villi, cell columns and cell islands, represent the proliferating trophoblastic stem cells (Langhans' cells). Where these are close to the intervillous space (ivs) they differentiate and fuse to form the syncytiotrophoblast. Usually this event takes place in the placental villi (v). Without contact with the intervillous space, the daughter cells of the proliferat-

ing stem cells (marked by asterisks) do not fuse syncytially but rather differentiate and become invasive, forming the extravillous trophoblast cells. Their routes of invasion/migration are symbolized by arrows. Extravillous trophoblast cells can be found in cell columns (c), cell islands (ci), chorionic plate (cp), chorion laeve (cl), septa (s), basal plate (bp), and uteroplacental arteries (ua). Matrix-type fibrinoid: point-shaded; fibrin-type fibrinoid is line-shaded. (Source: Modified from Kaufmann and Castellucci, 1997, with permission.)

FIGURE 9.2. Semithin sections of the basal plate at term. A: Enzyme histochemical proof of  $\beta$ -glucuronidase to demonstrate the typical mixture of cell types in the basal plate. D, decidua cell with its clearly visible surrounding basal lamina; X, highly differentiated extravillous cytotrophoblast; UT, less differentiated, proliferative extravillous cytotrophoblast.  $\times 810$ . (Source:

Stark & Kaufmann, 1973, with permission.) B: Enzyme histochemical proof of glucose-6-phosphate dehydrogenase. As is typical for this enzyme, extravillous trophoblast cells (X) exhibit intense reaction patterns, whereas decidua cells (D) stain largely negative, except slight granular staining along their surfaces.  $\times 360$ .

**EXTRAVILLOUS TROPHOBLAST**

(all cellular and syncytial trophoblast outside the villi)

**extravillous syncytiotrophoblast**  
(syncytiotrophoblast remainders, mostly at the intervillous surfaces of all nonvillous parts of the placenta)

**extravillous cytotrophoblast**  
(all mononuclear trophoblast outside the villi)

**proliferative phenotype of extravillous trophoblast**  
(proliferating stem cells resting on, or near to the basal lamina facing the villous or chorionic stroma, = proximal extravillous trophoblast cells)

**invasive phenotype of extravillous trophoblast**  
(non-proliferative, disseminated daughter cells with invasive phenotype, = distal extravillous trophoblast cells)

**interstitial trophoblast ("intermediate trophoblast")**  
(all invasive trophoblast cells which do not invade uteroplacental vessels)

**small spindle-shaped trophoblast cells**  
(highly invasive, diploid to tetraploid trophoblast cells, which prevail in early stages of pregnancy, from the superficial basal plate until the myometrium)

**large polygonal trophoblast cells ("X-cells")<sup>1</sup>**  
(polyploid, mononuclear, basophilic cells of low invasiveness, accumulating preferably in the basal plate; prevalent extravillous cell type throughout the last trimester)

**multinucleated trophoblastic giant cells<sup>1</sup>**  
(polyploid multinucleated elements of low invasiveness, located deep in the invasive zone; probably derived from syncytial fusion of highly invasive spindle-shaped trophoblast cells)

**endovascular trophoblast**  
(trophoblast cells invading walls and lumina of uteroplacental vessels)

**intramural trophoblast**  
(invasive trophoblast cells infiltrating the walls of uteroplacental vessels)

**intraarterial trophoblast**  
(invasive trophoblast cells replacing endothelium and forming intraluminal plugs in uteroplacental arteries)

<sup>1</sup>The additional widely applied term **placental site giant cells** is a pathologic term for highly differentiated mono- and multinucleated trophoblastic elements in the maternofetal junctional zone, comprising a degenerative subset of interstitial trophoblast and multinucleated trophoblastic giant cells.

FIGURE 9.3. Nomenclature of the various subtypes of trophoblast cells residing outside the villous trees (so-called extravillous trophoblast). For developmental relations of these cell types cf. Figure 9.8.

(Pampfer et al., 1992) or "intermediate trophoblast cells at both villous and extravillous sites" (Riley et al., 1992) illustrate how confusing this term can be.

## Extravillous Trophoblast Is a Tissue of Its Own

Extravillous trophoblast is derived from the trophoblastic wall of the blastocyst and therefore without doubt is an epithelially derived tissue:

- Extravillous trophoblast reveals its epithelial phenotype by expressing cytokeratins as intermediate filaments. Depending on the stage of differentiation, however, the isoforms pattern may vary (see Immunohistochemical Markers in Chapter 3).
- As in other stratified epithelia, the **proliferation** of extravillous trophoblast is strictly restricted to a population of stem cells resting as a true epithelial layer on a basal lamina. The latter represents the interface between fetoplacental (chorionic) stroma and extravillous trophoblast. Right after leaving the basal lamina, the cells also leave the cell cycle (see next section).
- When leaving the basal lamina, the extravillous trophoblast cells achieve an **interstitial, apolar phenotype** (Fig. 9.1). This process has been analyzed ultrastructurally and immunohistochemically in much detail in the rhesus monkey (Enders, 1995, 1997a,b). Among others, this interstitial phenotype is expressed by the kind and arrangement of extracellular matrix molecules secreted and by the pattern of integrins exposed, binding to

this self-produced interstitial extracellular matrix (for review see Kaufmann & Castellucci, 1997) (see below).

- In most cases, this apolar extracellular matrix (ECM) is secreted in the direct vicinity of maternal tissues, namely facing the maternal blood (e.g., cell islands, intervillous surface of the chorionic plate, placental septa) or maternal decidua (basal plate with cell columns, chorion laeve). As a consequence, the maternal tissues add to the formation of the ECM. The maternal ECM additions may be derived from maternal blood (e.g., fibrin) or are secretory products of decidual and endometrial stromal cells. The resulting peritrophoblastic accumulations of extracellular matrix are partly difficult to assign to maternal or fetal origin and are summarized under the summarizing term **fibrioid** (see below).
- After exiting the cell cycle, the postproliferative daughter cells like typical epithelial cells leave the basal lamina. In a first stage of movement, they are pushed forward by proliferation pressure by the subsequent generations of cells. Only later they start migrating actively in theirself-secreted matrix. In a last step of differentiation, they achieve a **truly invasive phenotype** and pass the maternal host tissue by destroying it (see below).

All of the above features are characteristic for extravillous trophoblast in general. They do not differ in different extravillous locations.

### Proliferation Patterns of Extravillous Trophoblast and the Invasive Pathway

When extravillous trophoblast is stained with proliferation markers such as  $^3\text{H}$ -thymidine, BrdU, Ki-67, MIB-1, or antibodies against proliferating-cell nuclear antigen (PCNA), only those cells are marked that are close to the basal lamina of the neighboring fetal stroma. Extravillous trophoblast cells far from this basal lamina remain unstained (Figs. 9.4 and 9.5) (Bulmer et al., 1988a,c; Mühlhauser et al., 1993; Blankenship & King, 1994a; Kosanke, 1994; Kaufmann & Castellucci, 1997).

The proliferation markers listed above show characteristic differences in their staining patterns, which in the past repeatedly resulted in misinterpretations.

- Nuclei marked by  $^3\text{H}$ -thymidine or by BrdU are found only in the basal layer of cells resting directly on the basal lamina; since  $^3\text{H}$ -thymidine and BrdU are incorporated exclusively during the S-phase of the cell cycle, this pattern indicates that mitosis is restricted to this basal layer of cells.
- **Ki-67** and **MIB-1** are antibodies both directed against the same nuclear antigen (Ki-67 antigen), which is

expressed not only in the S-phase but in all stages of the cell cycle except  $G_0$  and  $G_1$ . As a result, this marker shows higher staining indices as compared to  $^3\text{H}$ -thymidine. Normally, with this marker, immunoreactivity is found in two to six proximal layers of columns. Only the deeply invasive and intravascular trophoblast cells are always negative for Ki-67 and MIB-1.

- **Proliferating cell nuclear antigen** is expressed throughout all stages of the cell cycle. It has a half-life of about 20 hours and therefore may even be found in cells that have left the cell cycle already 1 day or more before. For example, PCNA expression was found in intravascular trophoblast (King & Blankenship, 1993), suggesting that these cells were still in the cell cycle. A later study by the same group using Ki-67 made clear that most of the immunoreactivity seen with PCNA did not point to actual mitotic activity but rather was due to the long half-life of the antigen (Blankenship & King, 1994a).

In conclusion, application of the above-mentioned proliferation markers reveals that extravillous trophoblast throughout differentiation passes two subsequent phenotypes (Bulmer et al., 1988a,c; Mühlhauser et al., 1993; Blankenship & King, 1994a; Kosanke, 1994; Kaufmann & Castellucci, 1997):

1. A so-called **proliferative phenotype** of extravillous trophoblast, which according to the  $^3\text{H}$ -thymidine data is restricted to the basal layer of extravillous trophoblast within the cell columns;
2. A so-called postproliferative, migratory, and invasive phenotype, which starts as early as in the second layer of trophoblast cells of the cell columns (**postproliferative cells**), occupies the distal parts of the cell columns (**migratory trophoblast**), and finally spreads deeply into the maternal tissues (**invasive phenotype**) (for review see Kaufmann & Castellucci, 1997)

Both phenotypes of extravillous trophoblast are generally present in all nonvillous parts of the placenta (Fig. 9.1). This is clearly valid for the first two trimesters of pregnancy. In term pregnancies, extravillous trophoblast shows considerably reduced proliferative activities and locally it may be impossible to find any of the proximal cells still being in the cell cycle. In this case postproliferative cells may be attached to the basal lamina.

We conclude from these findings that the basal layer of trophoblast cells of the cell columns (cells attached to the basal lamina of anchoring villi) represent the **stem cells of the extravillous invasive pathway** (proliferative phenotype), whereas the more distal, nonproliferative extravillous trophoblast cells are the **differentiated, more or less invasive cells**, derived from the nearest proliferative center by migration or invasion (Fig. 9.4A,B). Roughly,

FIGURE 9.4. Serial paraffin sections of two anchoring villi (upper half) attached to the basal plate (below) by cell columns (center), 16th week postmenstruation (p.m.). A: Stained with anticytokeratin, which binds to all villous and extravillous trophoblast cells. B: Stained with the monoclonal antibody MIB-1, which only stains proliferating cells. Note that the invasive trophoblast cells (lower half) are nonproliferative, whereas those cells facing the basal lamina of the anchoring villus (arrowheads) and

villous cytotrophoblast are MIB-1-positive. These cells make up the proliferating stem cells (Langhans' cells).  $\times 100$ . (Courtesy of Dr. Gaby Kohnen, Aachen, Germany.) C: A 22nd week p.m. semithin section of the transition between the anchoring villus (above) and the cell column (below). The continuity of villous cytotrophoblast (VC) with the proliferating cluster of cytotrophoblast in the cell column (C) is clearly visible.  $\times 800$ .

FIGURE 9.5. Schematic drawing of a first trimester anchoring villus (above) attached to the basal plate (center) by a cell column. Extravillous trophoblast cells (blue) derived from the cell column, mix with decidual cells (white) in the depth of the basal plate. The extravillous trophoblast cells are composed of highly invasive spindle-shaped cells and noninvasive large polygonal cells. Depending on the invasion route (interstitial: straight pink arrow; endovascular: curved pink arrow), trophoblast invasion results in the formation of multinucleated giant cells (bottom) or in a cluster of endovascular trophoblast lining uteroplacental arteries (right margin). The red asterisks indicate those trophoblast cells that are marked by the proliferation markers  $^3\text{H}$ -thymidine, MIB-1/Ki-67, and anti-proliferating-cell nuclear antigen (PCNA). Note that depending on the biologic half-life of the respective antigen and depending on the stage of cell cycle that is identified by the marker, stained cells may even be found deeply invading the basal plate. Truly proliferative cells, marked by  $^3\text{H}$ -thymidine, can only be found close to the anchoring villus. (Source: Modified from Kaufmann & Castellucci, 1997, with permission.)

increasing distance from the underlying basal lamina parallels increasing differentiation.

### Stages of Extravillous Trophoblast Differentiation Within the Invasive Pathway

Upon leaving the cell cycle, extravillous trophoblast cells enter a complex differentiation pathway, resulting in various routes of differentiation. Based on the data available, this results in at least seven phenotypes of extravillous trophoblast (Fig. 9.6; also see Fig. 9.12):

Some of these phenotypes are passed subsequently during differentiation of extravillous trophoblast, for example:

- Proliferative stem cells
- Early postproliferative cells (distal compact layer of the cell columns)
- Small spindle-shaped extravillous trophoblast cells.

Others represent alternatives of final differentiation, for example:

- Large polygonal extravillous trophoblast (X-cells)
- Multinucleated trophoblastic giant cells
- Placental site giant cells

- Endovascular trophoblast (including intramural and intraarterial trophoblast).

The various phenotypes shall be defined in some more detail:

### *Proliferative Stem Cells*

These comprise all polar trophoblast cells resting on the basal lamina of cell columns. They are weakly to moderately reactive for cytokeratin 7 (Fig. 9.6A,B). Comparison of data on  $^3\text{H}$ -thymidine incorporation, as well as Ki-67/MIB-1 and PCNA positivity demonstrate that these are proliferating stem cells but that not all of the cells are actually in the cell cycle (Kosanke et al., 1998). Rather, with advancing gestation the number of cells within the cycle seems to decrease, whereas the number of  $G_0$ -cells seems to increase.

The cells of the proliferative layer as well as the postproliferative cells of the next few layers express zona occludens proteins (ZO-1 and occludin) (Marziani et al., 2001). This suggests the presence of tight junctions in this area. Their function may be to guarantee a tight mater-nofetal barrier in an area where the syncytiotrophoblast

FIGURE 9.6. Trophoblast cell types in the invasive pathway. av: anchoring villus; cc: cell column; bp: basal plate; pb: placental bed. A: Staining with an antibody against cytokeratin 7 reveals the localization of five different phenotypes of extravillous trophoblast along the invasive pathway, including proliferative and early postproliferative cells (both enlarged in part B), large polygonal cells (enlarged in part C), small spindle-shaped cells (enlarged in part D) and multinucleated giant cells (enlarged in part E). Note the long, filiform profiles of small spindle-shaped EVT, which hardly can be identified as trophoblast cells, in the upper third of part A. They easily can escape the observers' attention. B: The proliferative cells comprise the upper row of cells in direct contact with the basement membrane of anchoring villus. They are followed by a compact cluster of early postproliferative daughter cells. C: A large polygonal trophoblast cell, embedded in ample unstained extracellular matrix (ECM). Note the huge, polyploid nucleus. D: Small spindle-shaped trophoblast cells are surrounded by only little ECM and are in close contact with cytokeratin-negative endometrial cells. The various spot-like cytokeratin reactivities in this picture correspond to cross and oblique sections of the same cell type. E: Multinucleated giant cells are characterized by clusters of nuclei surrounded by ample cytoplasm that only focally shows cytokeratin 7-immunoreactivity. A:  $\times 160$ ; B–D:  $\times 770$ . (Source: From Kemp et al., 2002, with permission.)

as barrier is interrupted by a cellular epithelium with intercellular clefts.

### *Early Postproliferative Cells*

From the second layer of trophoblast cells distally, the cells very likely have left the cell cycle. There are no indications such as mitotic figures,  $^3\text{H}$ -thymidine positiv-

ity, or BrdU positivity, that after leaving the basal lamina they still stay in the cycle. As described above, positivity for other immunohistochemical proliferation markers (Mib-1 or PCNA, Fig. 9.5) is due to the fact that the respective antigens persist also beyond the cell cycle. It is a question of definition how far peripherally into the invasive pathway cells are subsumed under the heading “early postproliferative cells.” According to our defini-

tion (Kemp et al., 2002) trophoblast cells belong to this type when they (1) have left the basal lamina; (2) still form a compact cluster of cells, so-called cell columns; and (3) are not separated by light-microscopically visible amounts of extracellular matrix. This differentiation stage, too, is weakly to moderately immunoreactive for cytokeratin 7 (Fig. 9.6A,B).

### *Small Spindle-Shaped Extravillous Trophoblast Cells*

According to distribution, structure, and expression of integrins, ECM, and proteases, these are the truly invasive extravillous trophoblast cells (Kemp et al., 2002). In spite of their moderate to strong immunoreactivity for cytokeratin 7 (Fig. 9.6A,D) these cells are inconspicuous and easily escape the observer's attention. Due to their spindle-shaped to filiform structure they may easily be misinterpreted as tangential sections of larger types of extravillous cells. The cells prevail in the first and second trimester of pregnancy and are only rarely found at term (see Fig. 9.17). Different from all other phenotypes, they do not accumulate in a certain layer of the invasive pathway but rather are homogeneously distributed from the distal parts of cell columns until the first third of the myometrium. Similar to invasive tumor cells (Friedl & Brocker, 2000), their shape reflects invasiveness; movement across their host tissues forces these cells to adapt their morphology and to achieve bipolar, spindle-shaped bodies. Interestingly, those invasive trophoblast cells emerging from villous explants in vitro under the influence of insulin-like growth factor-I (IGF-I) (see Cytokines and Hormones Controlling Differentiation of Extravillous Trophoblast, below) showed the same spindle-shaped phenotype (Aplin et al., 2000). Immunocytochemistry suggests, that they secrete only a little ECM and expose mostly integrins not matching the surrounding ECM (integrin-ECM mismatch) (Kemp et al., 2002). DNA measurements suggest that these cells are diploid to tetraploid (Zybina et al., 2002, 2004).

### *Large Polygonal Extravillous Trophoblast Cells*

This is the structurally most impressive cell type within the population of extravillous trophoblast: large, polygonal, mostly basophilic cell bodies, with large irregular, hyperchromatic nuclei (Fig. 9.6 A,C). Their size and intense staining were the reason that these were the first published extravillous trophoblast cells (X-cells, Scipiadès & Burg, 1930). According to Kemp et al. (2002) and Zybina et al. (2002, 2004), they are derived from diploid (spindle-shaped?) extravillous trophoblast cells by polyploidization (Fig. 9.7). Several findings suggest that they are less invasive or noninvasive (Kemp et al., 2002):

- Their number increases with advancing gestation.
- They accumulate usually in the superficial layers of the basal plate and are much less frequent in deeper layers.
- In basal plates of term pregnancies they are by far the dominating trophoblast cell type.
- They embed themselves in large amounts of ECM (laminins, collagen IV, vitronectin, heparan sulfate, fibronectins, vitronectin) and expose the exactly matching integrins along their cell surfaces.
- They can be found deeply in the uterine wall, embedded in large amounts of ECM, even years after the last pregnancy.

Taken together, these findings suggest, that polyploidization and transformation of spindle-shaped trophoblast into large polygonal trophoblast is a mechanism to reduce invasiveness.

### *Multinucleated Trophoblastic Giant Cells*

These are multinucleated trophoblastic elements found in the depth of the basal plate (Fig. 9.6A,E). Often they accumulate in a thin layer close to the endometrial-myometrial border. Their number decreases when pregnancy advances. Attention was first directed to these elements by Kölliker (1861), who called them "Riesenzellen" and "vielkernige Riesenzellen." Similar multinucleated trophoblastic masses have been described in the junctional zone of several mammals. Terms such as **multinuclear giant cells**, **wandering cells**, **migratory cells**, **megalokaryocytes**, and **diplokaryocytes** were employed (for reviews see Mossman, 1937, 1987; Boyd & Hamilton, 1970). Despite the fact that some earlier authors have questioned the fetal origin of these structures (Keiffer, 1928; Park, 1959), there is now agreement concerning their trophoblastic nature based on their immunoreactivity for various cytokeratin isoforms. Unfortunately, they are often negative for cytokeratin 7, the most suitable marker for all uninuclear trophoblast (Fig. 9.6A,E).

There are still some doubts about whether or not multinucleated giant cells can be formed by syncytial fusion of extravillous cytotrophoblast throughout pregnancy. Data by Winterhager et al. (2000) have shown connexin 40 expression by deeply invasive extravillous trophoblast cells as soon as the latter aggregated in clusters (Hellmann et al., 1995). Connexin 40 is a gap junction molecule and formation of gap junctions is a well-studied prerequisite for syncytial fusion (Winterhager et al., 1984). These data in context with the large numbers of multinucleated trophoblastic giant cells in the superficial myometrial parts of the uterine wall (Pijnenborg et al., 1980; 1981) led us to suggest that syncytial fusion takes place preferably at the end of the invasive pathway. The view that multinucleation is a result of syncytial fusion rather than of endomitosis is further supported by the fact that signs of DNA-replication ( $^3\text{H}$ -thymidine incorporation, expres-

FIGURE 9.7. Summarizing overview of changes in the invasive pathway throughout pregnancy. The early postproliferative daughter cells of the cell columns differentiate into highly invasive small spindle-shaped cells. Their invasiveness is limited either by differentiation into ECM-secreting large polygonal EVT, or by syncytial fusion, forming multinucleated giant cells, or by apoptosis. In the first trimester, invasiveness is high since only a few cells undergo polyploidization forming large polygonal cells. In later stages of pregnancy, invasiveness gradually ceases since increasing numbers of spindle-shaped invasive trophoblast leaves the invasive pathway by polyploidization. Syncytial fusion resulting in multinucleated giant cells is a dominant mechanism for the limitation of invasiveness only in early pregnancy. Throughout pregnancy, apoptosis seems to be of marginal importance only. (Source: Modified from Kemp et al., 2002, with permission.)

sion of PCNA or Ki-67 antigen) have never been observed in this deep invasion zone.

**Residual extravillous syncytiotrophoblast** should not be confused with the multinucleated trophoblastic giant cells. In early pregnancy the nonvillous parts of the placenta (future chorion laeve, primary chorionic plate, and trophoblastic shell) are mostly composed of syncytiotrophoblast; its relative amount in all nonvillous locations is steeply decreasing toward term. In third-trimester pregnancies it is found in only a few locations, all of which face the intervillous space. These comprise largely degenerative syncytial plaques covering small spots of the intervillous surfaces of the chorionic plate, the basal plate, and sometimes even parts of cell columns, cell islands, and septa. In the course of pregnancy, most of this extravillous syncytiotrophoblast degenerates and is replaced by fibrinoid or sometimes even by maternal endothelium evading uteroplacental veins (see below).

### Placental Site Giant Cells

This term plays an important role in placental pathology, where these cells are of great diagnostic value for the

histopathologist when studying curettings; however, it has never been clearly defined in placental cell biology. The fetal/trophoblastic origin was proven by Khudr et al. (1973), but it remains an open question whether these cells are mononuclear (as extravillous cytotrophoblast) or in part multinucleated cells (Pijnenborg, 1980).

Sauramo (1961) had already characterized these cells from histologic and histochemical studies as cell populations that undergo frequent degeneration and that form, within the extraplacental membranes and placental floor, a separate compartment of cytotrophoblast. Typical placental site giant cells are often vacuolated and sometimes they appear degenerative. They may also be identical with what Yeh et al. (1989) described as a separate extravillous trophoblastic entity, the vacuolated cytotrophoblast. Other historical terms are chorionic giant cells, wandering cells, migratory cells, and megalokaryocytes (for review see Boyd & Hamilton, 1970). Thliveris and Speroff (1977) found an increased amount of fibrinoid deposition around these cells in membranes from preeclamptic women. Wynn (1967a) also noted their frequent or regular association with eosinophilic fibrin-like deposits.

Pathologists are generally reluctant to make the diagnosis of intra-uterine pregnancy merely from the presence of extravillous trophoblast cells (X cells) and in the absence of villi. To satisfy this demand for characterization of the placental site, O'Connor and Kurman (1988a,b) used the presence of human placental lactogen (hPL) contained within

placental site cells and thus demonstrated in relevant cases that an intrauterine gestation existed in curettings when an ectopic gestation needed to be ruled out.

In our opinion, placental site giant cells are highly differentiated, probably already degenerative extravillous trophoblast cells. This view is further supported by several publications dealing with the placental site trophoblastic tumor (PSTT) (Berger et al., 1984; Young et al., 1988; Duncan & Mazur, 1989; Larsen et al., 1991). This rare variant of trophoblastic disease derives from placental site giant cells and was unequivocally described to be composed of intermediate trophoblast, equivalent to extravillous cytotrophoblast.

### Endovascular Trophoblast

This is the summarizing term for all extravillous trophoblast cells found

- within the walls of uteroplacental arteries and veins (**intramural trophoblast**) where it replaces media smooth muscle cells and other vascular wall structures, and
- within the lumens of uteroplacental arteries (**intraarterial trophoblast**) where it either forms a new surface lining replacing maternal endothelium or forms big, multicellular plugs, partly or completely occluding the arterial lumens.

As will be discussed later (see Uteroplacental Vessels), endovascular trophoblast is derived from interstitial extravillous trophoblast and represents a side-route of trophoblast invasion (Fig. 9.5).

### One Stem Cell Origin for Villous Syncytiotrophoblast and the Extravillous Trophoblast?

Up to now, no obvious differences have been described between the proliferating stem cells of

- the extravillous trophoblast cells that rest on the basal lamina separating anchoring villi and cell columns, and
- villous cytotrophoblast resting on the basal lamina of all other villi.

This refers to all of the following data for expression of receptors and integrins, matrix secretion and endocrine secretion, as well as for major histocompatibility complex I (MHC-I) expression (for review see Kaufmann & Castellucci, 1997). Because of this, it seems justified to speculate that all trophoblast cells resting on the basal lamina separating placental trophoblast and fetoplacental mesenchyme (Fig. 9.1), independent of their location, represent a uniform population of trophoblastic stem cells. This

would apply for the villous cytotrophoblast, the basal layers of proliferating stem cells in cell columns, cell islands, chorionic plate, and chorion laeve.

The future fate of these stem cells, whether they fuse to form syncytiotrophoblast or whether they acquire a migratory or invasive extravillous phenotype very likely depends on surrounding microenvironmental factors (Fig. 9.8), such as

- the presence or absence of contact to maternal blood;
- polar or apolar exposition to extracellular matrix molecules;
- the presence or absence of an intact syncytiotrophoblast covering.

In mouse placental development respective transcription factors directing the cells in the one or other differentiation pathway have been identified (Anson-Cartwright et al., 2000; Cross et al., 2003; Hughes et al., 2004). For human placental development, experimental proof for the one-stem-cell hypothesis is still missing; however, the hypothesis is in agreement with many histologic and experimental findings.

- Peripheral villi, which become embedded in maternal blood clot, transform into cell islands or cell columns, showing degeneration of the covering syncytiotrophoblast and extravillous transformation of the residual cytotrophoblast (see Fibrinoid, below). The same extravillous transformation of trophoblast cells was observed when villous explants were cultivated on or in fibrin, collagens, or matrigel (Castellucci et al., 1990; Genbacev et al., 1991, 1992; Vicovac et al., 1993, 1995a). Interestingly, only first-trimester villi rather than second- or third-trimester villi showed this in vitro behavior.
- In contrast, when cultivating villous explants in tissue culture medium (Castellucci, personal communication) or on agarose (Vicovac et al., 1995b) the trophoblast maintained its villous phenotype.

### Routes of Trophoblast Differentiation

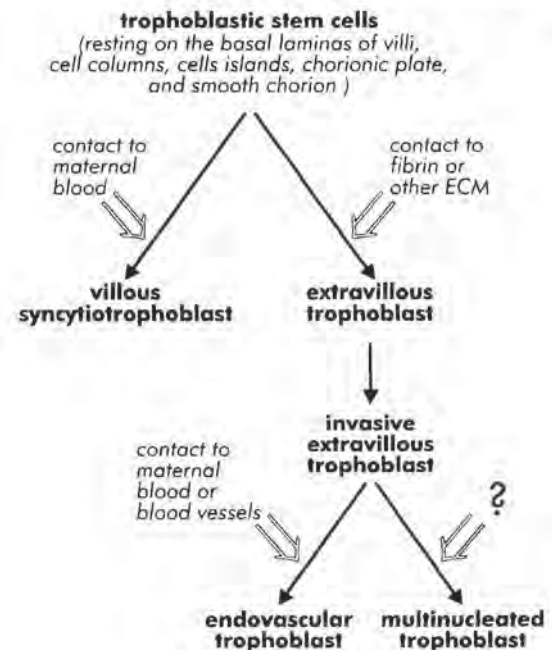

FIGURE 9.8. Factors controlling the various routes of differentiation of trophoblast. (Source: Modified from Kaufmann & Castellucci, 1997, with permission.)

Proliferation studies in anchoring villi (Kosanke, 1994) make it very likely that not all daughter cells derived from the proliferative zones of cell columns enter the invasive pathway. Rather, a subset of these cells seems to migrate laterally along the anchoring villi, thus coming into a villous position. These cells finally may be transformed into a syncytiotrophoblast. Accordingly, the stem cells of the cell columns would have a double function, contributing to trophoblast invasion and acting as a growth zone for villous trophoblast of anchoring villi.

### Cytokines and Hormones Controlling Differentiation of Extravillous Trophoblast

We focus here on oncogene products, growth factor receptors, and growth factors as well as hormones, which show obvious relations to the various stages of the invasive pathway. Several of those seem to be involved in autocrine loops as well as paracrine loops between

extravillous trophoblast and its neighboring tissues. For the discussion of potential interactions between hormones and trophoblast differentiation along the invasive pathway we also refer to the review by Malassine and Cronier (2002). The paper by Islami et al. (2001) specifically addresses the potential influence of human chorionic gonadotropin (hCG) on trophoblast invasion.

**EGFR:** Epidermal growth factor receptor encoded by the proto-oncogene *c-erbB-1*, is only expressed in those few proximal layers of trophoblastic cell columns that also express proliferation markers (Mühlhauser et al., 1993; Duello et al., 1994; Johki et al., 1994) (Fig. 9.9A). Its best known ligand, epidermal growth factor (EGF), is a potent epithelial mitogen. Moreover, its stimulatory influence on trophoblast invasion has been stressed (Bass et al., 1994). Epidermal growth factor is produced by numerous tissues.

FIGURE 9.9. A: The expression of some growth factor receptors is symbolized by red or yellow dots. Secretion of the respective ligands is indicated by red arrows. These arrows suggest that the invasive pathway of extravillous trophoblast is controlled by autocrine and paracrine regulatory loops. B: Integrin (red and yellow dots) and ECM expression (green) along the invasive pathway.  $\alpha 3\beta 1$  and  $\alpha 6\beta 4$  integrins are expressed by the proliferative phenotype of extravillous trophoblast. When switching to the invasive phenotype, the above “epithelial” integrins are

gradually replaced by “interstitial” integrins such as  $\alpha 5\beta 1$ ,  $\alpha v\beta 1$ , and  $\alpha v\beta 3$  and finally by  $\alpha 1\beta 1$ , the latter marking only the deepest cells in the pathway. In the center, the secretion patterns of ECM are depicted. The proliferative phenotype shows polar (basal lamina) or absent secretion of ECM. The invasive trophoblast cells, expressing interstitial integrins, embed themselves in apolarly secreted ECM of different types. (Source: Modified from Kaufmann & Castellucci, 1997, with permission.)

Its secretion by extravillous trophoblast has been discussed, suggesting autocrine/paracrine regulatory loops (Hofmann et al., 1992). In contrast, Loke and King (1995) suggested that local secretion at the implantation site is less likely; rather, these authors favor **transforming growth factor- $\alpha$**  (TGF- $\alpha$ ) to be the more likely ligand for EGFR. Transforming growth factor is known to have the same mitogenic effects on trophoblast as EGF. It is likely to be secreted by decidual stromal cells as well as by all trophoblast populations (Lysiak et al., 1993).

**C-*erbB-2*:** The receptor encoded by the proto-oncogene *c-erbB-2* is thought to cooperate with other receptors of the *erbB* family in neuregulin/hereregulin-mediated signaling (Holmes et al., 1992; Peles et al., 1992; Carraway & Cantley, 1994). This receptor shows a reciprocal expression pattern when compared to EGFR (Fig. 9.9A). It is expressed at the surfaces of all those extravillous trophoblast cells that are negative for EGFR (Mühlhauser et al., 1993; Jokhi et al., 1994). It thus characterizes all differentiated and invasive stages.

**HB-EGF:** Recent data by Romero's group have shed a new light on the importance of the EGF receptor family in trophoblast differentiation (Leach et al., 2004). The authors have studied the effects of the multifunctional heparin-binding EGF-like growth factor (HB-EGF), which binds to *erbB1* and *erbB4* of the EGF-receptor family. HB-EGF is downregulated in placentas of women with preeclampsia. The addition of HB-EGF during explant culture of first-trimester chorionic villi and during culture of a trophoblast cell line did not alter trophoblast proliferation, but rather enhanced extravillous trophoblast differentiation and invasive activity; expression of  $\alpha 6$  integrins decreased to the benefit of  $\alpha 1$  integrins. The authors concluded that *erbB*-mediated autocrine and paracrine signaling by HB-EGF or other EGF family members induces cytotrophoblast differentiation to an invasive phenotype.

**C-*fms*:** Also, the expression of the gene product of the oncogene *c-fms*, the receptor for **colony stimulating factor-1** (CSF-1), supports the concept of a differentiation gradient. According to Johki et al. (1993), it is strongly expressed in early invasive stages but weaker during deeper invasion including the endovascular trophoblast (Fig. 9.9A). The corresponding growth factor, CSF-1 can be derived from three different sources (Fig. 9.9A), from villous trophoblast, from endometrial cells (Shorter et al., 1992), and from invasive extravillous trophoblast cells themselves (Hamilton et al., 1995). It is a potent mitogen. Moreover, it is thought to upregulate gelatinase B and tissue inhibitor of metalloproteinase-1 (TIMP-1), both of which are important parameters of invasiveness (Hamilton et al., 1995).

**C-kit: Stem cell factor** also known as c-kit ligand, another blood cell mitogen, is expressed by invasive extravillous trophoblast cells (Sharkey et al., 1994) (Fig.

9.9A); the receptor for this growth factor, c-kit is expressed by villous macrophages and by the large granular lymphocytes [endometrial natural killer (NK) cells] of the junctional zone (Fig. 9.9A).

**TGF- $\beta$ R:** Receptors for transforming growth factor- $\beta$  have been detected in a variety of cell types at the human implantation site, and the cytokine **TGF- $\beta$**  itself is abundantly present in decidua, mostly derived from decidual NK cells (Saito et al., 1993a; Loke & King, 1995). Transforming growth factor- $\beta$  has been implicated as an immunosuppressive factor in decidua by modulating the response of maternal leukocytes to trophoblast (for review see Loke & King, 1995). In contrast to interferon- $\gamma$  (IFN- $\gamma$ ), TGF- $\beta$  has been observed to downregulate surface expression of MHC class I antigen (Geiser et al., 1993). The cytokine also restricts trophoblast invasion by downregulation of collagenase secretion and induction of TIMPs (for review, see Loke & King, 1995). The inhibitory effect of TGF- $\beta$  on trophoblast invasion is mediated by **endoglin**, a member of the TGF- $\beta$  receptor complex. Transient upregulation of endoglin expression takes place during transition from the proliferative to the invasive phenotype; the addition of endoglin antibodies or of antisense endoglin oligonucleotides to extravillous trophoblast in vitro stimulated the migratory/invasive behavior (Caniggia et al., 1997). Transforming growth factor- $\beta$  has been reported to enhance the secretion of fibronectins by trophoblast cells in vitro (Feinberg et al., 1994); to upregulate expression of integrins, which make the cells more "adhesive"; to upregulate protease inhibitors such as TIMP-1 and plasminogen activator inhibitor-1 (PAI-1) (for review see Chakraborty et al., 2002); and to upregulate E cadherin expression, which facilitates cell-cell adhesion and impairs cell motility (Karmakar & Das, 2004). Interestingly, TGF- $\beta$  can be stored extracellularly by binding to **decorin**, an ECM proteoglycan (Xu et al., 2002); the latter has been abundantly found in the decidua (Lysiak et al., 1995). All these observations suggest that TGF- $\beta$  is a modulator of trophoblast invasion. The secretion of TGF- $\beta$  seems to be controlled by oxygen via hypoxia-inducible factor-1 $\alpha$  (HIF-1 $\alpha$ ) (Caniggia et al., 2000; Caniggia & Winter, 2002). The same authors suggest that hypoxia via elevated HIF-1 $\alpha$  expression leads to TGF- $\beta$  overexpression, the latter resulting in inhibition of trophoblast differentiation and trophoblast invasion (Caniggia et al., 1999; Caniggia & Winter, 2002). As will be discussed below (see Oxygen-Mediated Regulation of the Invasive Pathway), the interactions between hypoxia and trophoblast invasion are still a matter of controversy.

**Transforming growth factor- $\alpha$ ,** in contrast to TGF- $\beta$ , appears to be a stimulator of trophoblastic growth in vitro, possibly acting via EGFR (Filla et al., 1993; Lysiak et al., 1993) (see above).

**Tumor necrosis factor- $\alpha$**  (TNF- $\alpha$ ) is a cytotoxic cytokine that according to in vitro data may act to limit

trophoblast invasion (Hunt, 1989). The **TNF-receptor I**, which upon ligand binding is able to initiate apoptosis, is expressed by invasive extravillous trophoblast cells (own unpublished observations). Correspondingly, early stages of apoptosis can be found in the same cells (Huppertz et al., 1998a). Even though TNF- $\alpha$ -messenger RNA (mRNA) has been found in a variety of cells at the implantation site, the most likely source for TNF- $\alpha$  protein are decidual macrophages and endometrial NK cells (Vince et al., 1992; Loke & King, 1995; Pijnenborg et al., 1998). Respective cytotoxic effects of macrophages on invasive trophoblast cells are further underlined by the fact that, in preeclampsia, large parts of the spiral arteries are infiltrated by macrophages and do not show trophoblast invasion (Reister et al., 1999). In contrast, in normal pregnancy the utero-placental arteries invaded by trophoblast, and rarely show intramural macrophages. Subsequent in vitro experiments by the same author (Reister et al., 2001) further underlined the notion that activated macrophages induce apoptosis of invasive extravillous trophoblast. Different from earlier assumptions, this is not only a TNF- $\alpha$  effect. Rather, induction of trophoblast apoptosis is a deleterious combination of

- TNF- $\alpha$ /TNF-receptor 1 interaction, with
- local tryptophan depletion by macrophage-secreted indolamine 2,3-dioxygenase (IDO) (see Fig. 9.35).

Interestingly, the preeclampsia-specific increase of macrophages described by Reister et al. (1999) seems to be restricted to the maternal arterial walls, whereas the number of maternal macrophages in the interstitium even seems to be reduced (Burk et al., 2001). (For further details see the sections Macrophages and Uteroplacental Vessels, below.) Tumor necrosis factor- $\alpha$  was shown to be expressed also by invasive extravillous trophoblast cells, the level of expression decreasing with advancing pregnancy and thus correlating with invasiveness of the cells (Pijnenborg et al., 1998). These data suggest that invasive trophoblast cells may exert direct cytotoxic effects during invasion of their host tissue.

**HGF:** Hepatocyte growth factor is secreted by placental villous stroma (Kauma et al., 1999) and by human decidua (Choy et al., 2004) and acts in a paracrine manner on trophoblast cells that express the HGF receptor **c-met**. In vitro studies by Kauma et al. (1999), Nasu et al. (2000), and Dokras et al. (2001) revealed that HGF significantly increased in vitro invasiveness of trophoblast cell lines. Moreover, in preeclampsia, reduced or absent villous stromal HGF expression was found, whereas expression of the receptor in extravillous trophoblast was unchanged (Nasu et al., 2000). According to Cartwright et al. (1999) the HGF effect on trophoblast invasion is closely linked to invasion, furthering nitric oxide (NO) secretion of extravillous trophoblast.

**IGF-I:** Insulin-like growth factor-I is secreted among others by villous mesenchyme. In vitro studies by Aplin and coworkers (2000) revealed that serum-free conditioned medium from placental first-trimester fibroblasts stimulated cytotrophoblast to detach from cell columns and to invade the neighboring extracellular matrix. Removal of IGF-I from the conditioned medium decreased the invasive potential, whereas the addition of IGF-I to culture medium increased invasiveness. In contrast, the addition of TGF- $\beta$  blocked invasiveness completely (see above). These data suggest paracrine interactions between the mesenchyme of anchoring villi and cytotrophoblast in cell columns. A respective paracrine control of trophoblast invasion by stromal cytokines such as IGF-I would be self-limiting because the signal diminishes with increasing invasive depth.

**VEGF, PlGF, Ang-2:** Finally, angiogenic factors, such as vascular endothelial growth factor (VEGF), placenta growth factor (PlGF), and angiopoietin-2 (Ang-2) are thought to be involved in the regulation of the extravillous pathway. All three factors are expressed by invasive trophoblast (Zhou et al., 2002, 2003a,b). PlGF was found to promote proliferation of extravillous trophoblast but not invasive behavior in vitro (Athanassiades & Lala, 1998). The closely related VEGF is secreted not only by trophoblast but also by decidual cells and decidual macrophages, whereas the VEGF-receptor **flt-1** is expressed by extravillous trophoblast cells (Ahmed et al., 1995). Vascular endothelial growth factor was supposed to be a chemoattractant for the invading trophoblast cells (Lash et al., 1999, 2003). Recent data by Anteby et al. (2004) suggest that VEGF is involved in the control of trophoblastic protease secretion. Moreover, Zhou et al. (2003b) provided in vitro evidence that VEGF, PlGF, and Ang-2 together may be involved in maintenance and turnover of uteroplacental vessels.

**Kisspeptin-10**, a newly described decapeptide derived from the translation product of the gene *KISS-1* was recently described to be a potent regulator of trophoblast invasion (Bilban et al., 2004). The *KISS-1* gene is only expressed in villous trophoblast. *KISS-1* receptor was also found in the extravillous trophoblast, suggesting paracrine loops. Kisspeptin-10 inhibited trophoblast migration in vitro in an explant as well as in a transwell assay, but did not affect proliferation. Suppressed motility was paralleled with suppressed gelatinolytic activity suggesting a Kisspeptin-10 effect on matrix metalloproteinase (MMP) secretion.

**Interleukins (ILs)** are involved at different levels of the control of the invasion process. Their role as proinflammatory (IL-2) or antiinflammatory cytokines (IL-4, -6, -10, and -13), triggering the communication among the various maternal immune cells at the implantation site, is well studied. Less is known about the direct effects on trophoblast cells (for review see Loke & King, 1995;

Bischof et al., 2000a,b). Among others **IL-1** and **IL-6** are secreted by the trophoblast cells themselves and act in an autocrine manner as stimulators of various aspects of extravillous trophoblast differentiation (for review, see Das et al., 2002). Interleukin-1 $\beta$  was found to counteract the effects of TGF- $\beta$  (see above) by downregulating E-cadherin expression and cell-cell adhesion and thus stimulating cellular invasiveness (Karmakar & Das, 2004a). By contrast, **IL-12** seems to inhibit trophoblast invasion by upregulating MMPs and downregulating TIMPs (see below; Karmakar et al., 2004b).

**T<sub>3</sub>**: Triiodothyronine has been known for a long time to play a crucial role in the maintenance of early pregnancy. Moreover, thyroid hormones seem to be involved in maldevelopment of placental villous trees (cf. Hormones as Regulators of Villous Development in Chapter 7). The mechanisms by which thyroid hormones interact with placental development still remain to be elucidated. Recent publications give some hints that an effect of T<sub>3</sub> on trophoblast invasion may be the missing link: extravillous trophoblast expresses thyroid hormone receptors (TR) (Barber et al., 2005). T<sub>3</sub> in vitro increased the expression of MMPs, fibronectins, and integrin  $\alpha 5 \beta 1$  (Oki et al., 2004), and it suppressed apoptosis of extravillous trophoblast by a variety of mechanisms (Laoag-Fernandez et al., 2004). All of these findings are consistent with the hypothesis that T<sub>3</sub> promotes trophoblast invasion, but they do not clearly prove it yet.

### Extracellular Matrix Secretion Along the Invasive Pathway

Extravillous trophoblast cells secrete large amounts of a highly heterogeneous ECM along their invasive pathway. The latter comprises fibronectin isoforms, collagen IV, laminins, vitronectin, and heparan sulfate in a patchy pattern summarized as matrix-type fibrinoid (see Fibrinoid, below). Secretion of ECM by extravillous trophoblast is different from ECM secretion in other epithelia (Frank et al., 1994, 1995; Huppertz et al., 1996, 1998d; Kemp et al., 2002):

- The first layer of still proliferative trophoblast cells behave like epithelial cells and secrete ECM in polar fashion as a basal lamina along their basal plasmalemma with collagen IV (Fig. 9.10A) and laminins (Fig. 9.10B) as dominant ECM molecules. Similar to other stratified epithelia, the following layers of early postproliferative cells completely downregulate ECM secretion (Figs. 9.9B and 9.10).
- Different from other stratified epithelia, with advancing differentiation the cells again upregulate ECM secretion, now secreting in an apolar, patchy pattern. The resulting patches of ECM. Deeper in the invasive pathway they increase in number and size, are attached

in an apolar pattern to the plasmalemma all around the cell.

- Preliminary data (Kemp et al., 2002) suggest that the highly invasive spindle-shaped trophoblast cells secrete only a little ECM, mostly composed of oncofetal fibronectin fibers embedded in a homogeneous matrix of vitronectin and heparan sulfate.
- By contrast, the large, polygonal noninvasive trophoblast cells embed themselves in large amounts of ECM composed of at least three different types of patches: (1) laminins and collagen IV; (2) vitronectin and heparan sulfate; (3) fibronectins, mostly of the non-oncofetal isoforms, embedded in vitronectin and heparan sulfate.

### Extracellular Matrix Receptors (Integrins)

The extravillous trophoblast cells embedded in the self-secreted extracellular matrix described above, express the respective ECM receptors (integrins). Depending on the type of cell, the expression and distribution patterns of integrins do not always match with the ECM molecules accumulated around.

Integrins are heterodimeric integral membrane proteins. They act as receptors for ECM molecules (for review, see Humphries, 1990). The functional importance of integrin-binding to ECM molecules has been shown in vitro by blocking them specifically by antibodies which resulted in loss of trophoblast cell adhesion to the ECM (Librach et al., 1991a; Burrows et al., 1995; Irving and Lala, 1995; for review see Burrows et al., 1997).

The following integrins have been described in extravillous trophoblast (for review see Aplin, 1993; Damsky et al., 1993; Kaufmann & Castellucci, 1997):

**$\alpha 3 \beta 1$**  integrin is a receptor for laminin that also localizes to focal contacts in cells cultured on other substrates; it seems to play a role in matrix deposition (DiPersio et al., 1995; Wu et al., 1995).  $\alpha 3 \beta 1$  is only weakly expressed in villous trophoblast and in few of the most proximal, proliferative trophoblast cells of the cell columns, resting on the basal lamina of anchoring villi (Damsky et al., 1992; Kemp et al., 2002) (Fig. 9.9B).

**$\alpha 6 \beta 4$**  is the dominating integrin of the proliferative and early postproliferative subset of trophoblast (Aplin, 1991a, 1993; Damsky et al., 1992; Burrows et al., 1993a; Kemp et al., 2002).  $\alpha 6 \beta 4$  integrin is the usual basal lamina receptor. It binds to laminin, which is then linked to collagen IV (Ruoslahti, 1991; Flug & Köpf-Maier, 1995). Its expression in trophoblast, interestingly, is not restricted to the basal trophoblastic surface of the most proximal cells, but rather can be found all around the trophoblast cells of the proximal half of the cell columns of first and second trimester pregnancies (Fig. 9.9B). Most of those are postproliferative cells that

FIGURE 9.10. Immunohistochemistry of extracellular matrix molecules in trophoblastic cell columns. The anchoring villus (above) and the cell column (center and bottom) are separated by a clearly visible basal lamina (BL). A: The collagen IV antibody shows strong immunoreactivity (green) in the basal lamina and a spotwise reaction pattern among the early postproliferative

cells and deeper in the invasive pathway. B: The staining pattern of a laminin antibody (red, counterstained with the blue nuclear stain bisbenzimidazole) is comparable to that of collagen IV. Note the accumulation of spots of laminin in the deeper parts of the invasive pathway (bottom).  $\times 300$ .

do not express ECM at all. In term pregnancies with reduced proliferative activities of extravillous trophoblast, also the  $\alpha 6 \beta 4$  expression is more restrained. In certain mature cell columns (compare Fig. 9.49B) it may completely be lost since only differentiated cells expressing interstitial integrins exist peripherally from the basal lamina.

$\alpha 5 \beta 1$ , a fibronectin receptor, is upregulated in the same zone where  $\alpha 6 \beta 4$  expression is downregulated (transition from the compact cluster of early postproliferative cells to loosely arranged, ECM-secreting cells of the invasive phenotype). Its expression is kept constant until the deepest stages of invasion (Fig. 9.9B).

$\alpha 1 \beta 1$ , a receptor for laminin and collagens I and IV, is turned on slightly later (Fig. 9.9B) (Aplin, 1991a; Fisher et al., 1991; Damsky et al., 1992, 1994; Kemp et al., 2002).

$\alpha v \beta 3$  and  $\alpha v \beta 5$ , according to in vitro findings by Irving et al. (1995), are also expressed by the invasive phenotype (Fig. 9.9B).

### Integrin Switch

The gradual switch from the basal lamina receptor  $\alpha 6 \beta 4$  to interstitial receptors such as  $\alpha 5 \beta 1$ ,  $\alpha 1 \beta 1$ , and  $\alpha v$  integrins, in normal intrauterine pregnancies is characteristic of the transition from the proliferative to the invasive phenotype of extravillous trophoblast and has been called the integrin switch. It is still an open question whether in this transitional zone all cells stepwise downregulate  $\alpha 6 \beta 4$  and upregulate interstitial integrins. The data by Kemp et al. (2002) suggest another possibility. They show that the small spindle-shaped trophoblast cells only express interstitial integrins, independent of the ECM they are attached to. By contrast, the large, polygonal trophoblast cells seem to coexpress all integrins, depending on the matrix they are attached to. If this holds true, the integrin switch would reflect the numerical balance of cells found in the respective area.

The integrin switch has raised considerable interest since it seems to be involved in the regulation of tropho-

blast invasion in the placental junctional zone (Zhou et al., 1993; Damsky et al., 1993; Lim et al., 1995). Bischof et al. (1995) found  $\alpha 6$  expression by extravillous trophoblast to be positively correlated with gelatinase secretion, whereas the secretion ceased as soon as  $\alpha 5$  expression was turned on. Cause and effect, however, are not clear. Irving and Lala (1995) stated that blocking of  $\alpha 5\beta 1$  by specific antibodies inhibited trophoblast migration in vitro. It is likely, however, that the results of such in vitro studies strongly depend on unknown experimental parameters; thus, Librach et al. (1991a) came to opposite experimental findings. In their in vitro experiments, antibody blocking of the  $\alpha 1\beta 1$  integrin impaired trophoblast invasion, whereas antibody blocking of  $\alpha 5\beta 1$  even stimulated invasion. Data by Ilic et al. (2001) on the focal adhesion kinase (FAK) underline the importance of integrins for the invasion process; FAK transduces signals from the ECM into the cell. Inhibition of FAK expression reduced invasiveness of cytotrophoblast in to ECM in vitro.

### $\alpha 5\beta 1/\alpha 1\beta 1$ Balance

These and other findings suggest that the balance of  $\alpha 5\beta 1$  and  $\alpha 1\beta 1$  expression may be critical for the regulation of trophoblast invasion:

- The importance of this  $\alpha 5/\alpha 1$  integrin balance is further underlined by recent data concerning the interactions between **antiphospholipid antibodies** and trophoblast invasion. Aminophospholipid antibodies, anticardiolipin antibodies, and antiphospholipid antibodies in lupus anticoagulant were shown to inhibit trophoblast invasion in vitro and in vivo (McIntyre, 2003; Bose et al., 2004). The antibodies primarily seem to affect endovascular trophoblast invasion rather than interstitial invasion (Sebire et al., 2002). Interestingly, antibodies obtained from the same patients decreased  $\alpha 1$  integrin expression by cytotrophoblast in vitro, but increased  $\alpha 5$  expression (di Simone et al., 2002).
- Also, insulin-like growth factor binding protein-1, **IGFBP-1**, may be involved in the control of integrin expression. Irving and Lala (1994, 1995) have shown that decidua-derived IGFBP-1 binding to  $\alpha 5\beta 1$  by means of its arginine-glycin-aspartic acid (RGD)-sequence (and thus blocking the integrin for other ligands?) promoted invasion, an effect that was inhibited by the presence of  $\alpha 5\beta 1$  blocking antibodies.
- Tumor necrosis factor- $\alpha$ , **TNF $\alpha$** , a secretory product of decidual macrophages, upregulates the expression of integrin  $\alpha 1\beta 1$  (Defilippi et al., 1992). According to Irving and Lala (1995), **TGF- $\beta$**  upregulates expression of integrin  $\alpha 5\beta 1$  and reduces the migratory effects of invasive trophoblast. Finally, according to the latter group, IGF-II has no obvious effect on integrin expression, but stimulates migration.

Even though partly contradictory, these data suggest that the balance between  $\alpha 5\beta 1$  integrin including its ligands and  $\alpha 1\beta 1$  including its ligands may be important for regulation of trophoblast invasion. Imbalance may result in insufficient invasion and is discussed as a basic pathogenetic event in preeclampsia (Damsky et al., 1993).

### Other Cell Adhesion Molecules and Gap Junction Molecules

**E-cadherin** is an adhesion molecule that establishes cell-to-cell contacts. Proliferative cells of the proximal cell columns express this adhesion molecule (Fig. 9.11A), whereas it is turned off with increasing invasiveness (MacCalman et al., 1995; Winterhager et al., 1996). In endovascular cytotrophoblast expression it is again upregulated. In tumor pathology, reduction of E-cadherin expression is regarded as an indicator of premalignant changes of epithelial tumors (Pizarro et al., 1995). This notion is further supported by the fact that antiphospholipid antibodies, which decrease trophoblast invasiveness in vitro, at the same time upregulate E-cadherin expression of these cells (di Simone et al., 2002).

**N-CAM**, the neural cell adhesion molecule, is not only responsible for cell-to-cell contacts but also for matrix adhesion. In early pregnancy, N-CAM-positive extravillous trophoblast cells are abundant in all parts of the basal plate including intraarterial trophoblast cells (Fig. 9.11A); only the intramural trophoblast cells of the arteries stained weaker if at all (King & Blankenship, 1995, findings in the rhesus monkey). With advancing pregnancy, N-CAM expression is restricted to the more proximal, proliferative phenotype. Burrows et al. (1994) confirmed these findings for the human extravillous trophoblast.

**Connexin 40** is similarly distributed to E-cadherin. Connexins are gap junction molecules that support cell-to-cell communication and seem to be important for cell proliferation and differentiation. Among the connexins studied so far, only connexin 40 (cx40) has been found in extravillous trophoblast (Winterhager et al., 2000). Its expression is most prominent in the proximal, proliferative parts of the cell columns (Fig. 9.11A) and cell islands where the cells are still in contact with each other (Hellmann et al., 1995; von Ostau et al., 1995; Winterhager et al., 1996). With transition to the invasive phenotype, cx40 is downregulated. Deeply invasive groups of aggregated trophoblast cells again express cx40, whereas endovascular trophoblast cells probably do not (Winterhager et al., 1996). (For further details concerning the role of cell adhesion molecules for the vascular invasion see Trophoblast-Endothelial Adhesion Mechanisms).

**CEACAM1** (CD66a, C-CAM, BGP) has raised interest as an adhesion molecule belonging to the carcinoembryonic antigen family. Bamberger et al. (2000)

FIGURE 9.11. A: Adhesion molecules. Expression patterns of connexin 40, E-cadherin, and neural cell adhesion molecule (N-CAM) along the invasive pathway. Question marks indicate unclear findings. For details see text. B: Matrix metalloproteinases 1, 2, 3, and 9 and their inhibitors TIMP-1 and TIMP-2 are immunoreactive in extravillous trophoblast cells (red and

yellow dots), in decidual cells (not marked) and in the surrounding extracellular matrix (not marked). The distribution patterns depend on the type of trophoblast cell and stage of pregnancy. (Source: Modified from Kaufmann & Castellucci, 1997, with permission.)

have shown that CEACAM1 was strongly expressed by the invasive phenotype of extravillous trophoblast as well as by extravillous trophoblast cells with invasive phenotype in vitro. The authors conclude from their data that the molecule is not only a useful marker for invasive trophoblast but also that it might be functionally implicated in mediating trophoblast/endometrial or trophoblast/endothelial interactions during the invasion process.

### Proteinases, Activators and Inhibitors Involved in Trophoblast Invasion

Extravillous trophoblast has to fulfill two largely different functions:

- **Invasion of maternal tissues** including infiltration of maternal vessels, supported by lytic activities of proteinases destroying a.o. maternal ECM;
- **Anchorage of the placenta** to the maternal tissues by secretion and continuous turnover of trophoblastic

ECM acting as a kind of glue between cells of maternal and fetal origin (Feinberg et al., 1991b).

Both processes require the secretion of a broad panel of proteases destroying the ECM of the host tissue (for review, see Fisher et al., 1985; Graham & Lala, 1991; Bischof & Martelli, 1992) and providing the turnover of the self-produced trophoblastic ECM. Recent data suggest that these two aspects of extravillous trophoblast function can be attributed to two different subtypes of cells:

- The highly invasive small spindle-shaped trophoblast
- The noninvasive large polygonal trophoblast cells (Kemp et al., 2002)

In accordance with these functions, both cellular subtypes would be expected to express different patterns of proteases. Respective data are, however, still meager.

Among the best studied proteinases are the **matrix metalloproteinases** (MMPs). It has been proven in vitro that they are secreted by trophoblast cells (Bischof et al., 1991). Respective immunoreactivities can be found not

only intracellularly but also with increasing invasive depth in the surrounding extracellular matrix.

**MMP-1** (interstitial collagenase) degrades various interstitial collagens, among others collagens I and III, which are most abundant in the endometrium. Because of this, it is not surprising that invasive extravillous trophoblast expresses interstitial collagenase (Fig. 9.11B) (Moll & Lane, 1990; Vettraino et al., 1996; Huppertz et al., 1998d). Its expression has also been proven in trophoblast cell culture (Emonard et al., 1990).

**MMP-2** (72-kD-type IV collagenase, gelatinase A) degrades mainly collagen IV. Its expression in extravillous trophoblast has been demonstrated by immunohistochemistry and in situ hybridization (Fig. 9.11B) (Autio-Harmainen et al., 1992; Fernandez et al., 1992; Blankenship & King, 1994b; Polette et al., 1994; Huppertz et al., 1998d) as well as by in vitro approaches (Emonard et al., 1990). The mRNA of this proteinase was found only in the invasive phenotype (Polette et al., 1994).

**MMP-3** (stromelysin-1) degrades fibronectins, laminin, various collagens, and core proteins of proteoglycans. According to Huppertz et al. (1998d), it is weakly expressed within the proximal proliferating layers, downregulated in early invasive stages, and again upregulated in later invasion (Fig. 9.11B). Most of the extracellular immunoreactivities are linked to the fibronectin fibrils in the ECM.

**MMP-7** (matrilysin) is a characteristic product of epithelial cells, cleaving among others proteoglycans, elastin and fibronectins. It was found to be predominantly expressed in the invasive phenotype of trophoblast and decidua; overexpression by the invasive trophoblast was shown in preeclampsia (Vettraino et al., 1996).

**MMP-9** (92-kD-type IV collagenase, gelatinase B) mainly degrades collagen IV and in this respect is similar to MMP-2. It is present at both mRNA and protein levels in the proximal, proliferating layers of extravillous trophoblast (Polette et al., 1994). Expression is downregulated in the early invasive stages and then upregulated again in the deeper stages of invasion (Huppertz et al., 1998d) (Fig. 9.11B). An antibody against MMP-9 completely inhibited trophoblast invasion in vitro (Librach et al., 1991b). Expression decreases toward term (Fisher et al., 1989; Librach et al., 1991b; Polette et al., 1994). In vitro findings by Graham et al. (1996) showed reduced active MMP-9 in culture supernatants of trophoblast cells derived from preeclamptic pregnancies.

**MMP-11** (stromelysin-3) is a laminin-, collagen IV-, and proteoglycan-degrading proteinase. According to immunohistochemical and in situ hybridization findings by Maquoi et al. (1995, 1997) and Polette et al. (1994), it is expressed only by the invasive phenotype of extravillous trophoblast.

**MMPs-14 and 15** (MT-MMPs, membrane-type matrix metalloproteinases) activate MMP-2 and are expressed by proliferating and invasive trophoblast cells in first and

third trimesters (Nawrocki et al., 1995, 1996; Hurskainen et al., 1998).

**TIMPs**, the tissue inhibitors of matrix metalloproteinases, regulate MMPs. In the human placenta **TIMP-1**, an inhibitor of all known MMPs, and **TIMP-2**, which preferentially interacts with MMP-2, have been described as being expressed by both decidual cells and by extravillous trophoblast cells (Fig. 9.11B) (Damsky et al., 1993; Polette et al., 1994; Ruck et al., 1995, 1996, 1997; Marzusch et al., 1996). These data suggest paracrine and autocrine control of MMP action. Moreover, **TIMP-3** an inhibitor of MMP-9 and MT-MMP1, is expressed by invasive trophoblast cells (Bass et al., 1997). The regulatory potential of TIMPs was shown in vitro: TIMP-1 and TIMP-2 completely inhibited human cytotrophoblast invasion in vitro (Librach et al., 1991b).

**MMPs and EVT phenotype:** There are only a few preliminary data on the expression of MMPs and their inhibitors by the various subtypes of extravillous trophoblast. These suggest that MMP-3 (stromelysin) is preferably expressed by the highly invasive small spindle-shaped trophoblast cells. The fibronectin-degrading activity of this protease would be in agreement with the fact that spindle-shaped trophoblast is mostly embedded in fibronectins rather than in collagens and laminins (Kemp et al., 2002). In contrast, the poorly invasive, large polygonal trophoblast cells throughout pregnancy express all MMP isoforms described so far in extravillous trophoblast (see above). This finding supports the view that MMP expression per se is not an indicator of invasiveness. Rather MMPs such as interstitial collagenase and type IV collagenases may also be required for the turnover of self-secreted ECM by a more or less noninvasive cell. This view is further underlined by recent findings by Huisman et al. (2004), who did not find differences in MMP-2 and MMP-9 activities when comparing placentas with normal trophoblast invasion and those with reduced trophoblast invasion. Also the data by Bauer et al. (2004) suggest that MMP-9 expression does not correlate with invasiveness. Several publications (Bischof et al., 2000a, 2003; Wang et al., 2001; Campbell et al., 2003; Staun-Ram et al., 2004) add further details to this puzzle but do not answer the question as to the role of the various MMPs in invasion and/or anchorage of the placenta by ECM turnover.

Provided that MMPs are involved in the turnover of ECM, acting as "glue" among maternal and fetal tissues, these proteinases may also be related to the initiation of labor and to the separation of the placenta from the uterine wall (for review see Bryant-Greenwood & Yamamoto, 1995; Bryant-Greenwood, 1998). During spontaneous labor, but before delivery, MMP-3 and MMP-9 mRNA levels are significantly increased, whereas after spontaneous delivery tissue-type plasminogen activator (tPA) (see below) and TIMP-1 mRNA levels were increased (Bryant-Greenwood & Yamamoto, 1995).

**Leptin** seems to regulate MMP expression in extravillous trophoblast. Castellucci and coworkers (2000) found the leptin receptor strongly expressed in the distal, invasive trophoblast of cell columns. In vitro invasiveness of trophoblast cells was stimulated by leptin (Castellucci et al., 2000; Schulz & Widmaier, 2004) and could be blocked by simultaneous administration of MMP inhibitors. Immunohistochemically, the expression of MMP-2 and MMP-9 as well as of oncofetal fibronectin was upregulated by leptin administration in vitro (Castellucci et al., 2000).

**Plasminogen activators** convert plasminogen to plasmin, which activates other proteinases. Two plasminogen activators are known: urokinase-type plasminogen activator (uPA) and tPA. The expression of uPA by extravillous trophoblast has been shown by Hofmann et al. (1994), and uPA mRNA has been found in isolated human cytotrophoblast (Eldar Geva et al., 1993). Moreover, uPA receptor is expressed in extravillous trophoblast (Mulhaupt et al., 1994; Pierleoni et al., 1998). There are no hints as to the expression of tPA by extravillous trophoblast. Also the inhibitors of uPA and tPA (i.e., **PAI-1** and **PAI-2**) have been found in human trophoblast (Astedt et al., 1986; Feinberg et al., 1989). In agreement with the presence of uPA, only PAI-1 is expressed by invasive cytotrophoblast of cell islands and cell columns (Feinberg et al., 1989) and was suggested to control trophoblast invasion (Floridon et al., 2000). Recent data by Chou et al. (2002) suggest that gonadotropin-releasing hormone (GnRH) I and II may facilitate trophoblast invasion by increasing the ratio of uPA/PAI-1 expression via interactions with two distinct GnRH receptors. In contrast, tPA and PAI-2 were found only in villous syncytiotrophoblast where they are thought to regulate fibrinolysis (Feinberg et al., 1989).

**Other serine protease inhibitors**, such as  $\alpha_1$ -antichymotrypsin,  $\alpha_1$ -antitrypsin, and inter- $\alpha$ -trypsin inhibitor, have only rarely been studied. None of them was immunoreactive within the extravillous trophoblast; however, the surrounding matrix-type fibrinoid in cell columns and basal plate showed ample reaction product (Castellucci et al., 1994). The authors suggested that the protein is so rapidly exported into the ECM that no intracellular immunoreactivity is detectable.

## Nitric Oxide and Trophoblast Invasion

- In lower concentrations, as produced by the endothelial isoform of the enzyme nitric oxide synthase (**eNOS**), NO causes vasodilatation.
- Higher NO levels as produced by the macrophage isoform [macrophage nitric oxide synthase (**mNOS**)/inducible nitric oxide synthase (**iNOS**)] are said to be cytotoxic.

Nitric oxide synthase immunoreactivities in extravillous trophoblast were described for the first time by Morris et al. (1993). This finding raised little attention.

The potential importance of these results, however, is stressed by experimental findings in rats and guinea pigs; Yallampalli and Garfield (1993), Chwalisz and Garfield (1994), and Garfield et al. (1994) have shown that preeclampsia-like symptoms, including hypertension, proteinuria, and fetal growth restriction, can be induced in rats and guinea pigs by blocking nitric oxide synthase with l-NAME. The experiments were successfully repeated by Osawa et al. (1995) in rats.

These findings led us to study trophoblast invasion in relation to NOS expression by means of immune- and enzyme-histochemistry in guinea pigs (Nanaev et al., 1995). The results indicated that uteroplacental vessel dilatation in this species is related to eNOS expression in periarterial trophoblast cells, the latter corresponding to the interstitial subpopulation of extravillous trophoblast in the human. Invasion and destruction of the vessel walls as well as formation of intraarterial trophoblastic plugs in the guinea pig appeared to be secondary to the NO-mediated arterial dilatation. The question remained open as to whether or not extravillous trophoblast cells in the guinea pig also express mNOS.

These findings obtained in the guinea pig were challenged by Lyall et al. (1999), who did not detect expression of eNOS or iNOS in extravillous trophoblast in human placental bed biopsies from weeks 8 to 19. In contrast, Martin and Conrad (2000), by means of immunohistochemistry and in situ hybridization, found eNOS to be expressed in human interstitial trophoblast. These latter data were further supported by in vitro findings by Cartwright and coworkers (1999): Using a human trophoblast cell line that expressed both the constitutive (eNOS) and the inducible isoforms (iNOS), these authors could demonstrate that also human trophoblast cell motility and invasion strongly depended on trophoblast-derived NO. The effect, however, depended on the contemporaneous availability of hepatocyte growth factor (HGF) (cf. Cytokines and Hormones Controlling Differentiation of Extravillous Trophoblast, above).

Data by Graham's group (Postovit et al., 2001) shed a different light on the role of NO in trophoblast invasion. Their in vitro findings reveal that low concentrations of NO-mimetic drugs (glyceryl trinitrate and sodium nitroprusside) inhibit the ability of trophoblast cells to penetrate through reconstituted ECM (Matrigel). This inhibition was accompanied by a reduced expression of the cell surface urokinase receptor, a molecule important for invasion. The authors conclude that maternal macrophages infiltrating the uteroplacental artery walls in preeclampsia (Reister et al., 1999) might secrete levels of NO high enough to inhibit endovascular trophoblast invasion.

## Major Basic Protein

Studies have shown that extravillous trophoblast cells also produce substantial quantities of major basic protein

(MBP) (Wasmoen et al., 1989, 1991). This protein is similar to that contained in the granules of eosinophilic granulocytes. Eosinophil MBP is highly toxic to parasites, as well as to cells (Maddox et al., 1984; Kephart et al., 1988). It was found to circulate in the blood of pregnant women at levels 10 to 20 times higher than in nonpregnant women, in the absence of eosinophilia (Maddox et al., 1983). The concentration of this nonglycosylated protein increases significantly before the onset of labor (Wasmoen et al., 1987). It decreases rapidly after delivery.

Immunohistochemical studies and extraction of placentas, particularly of cyst fluid, showed MBP to be derived from the extravillous trophoblast cells in the placenta (Maddox et al., 1984). Immunoreactivity for the protein was found as early as the sixth week of pregnancy

and was confined to trophoblast cells in anchoring villi, septa, basal plate, and placental site giant cells (Fig. 9.12). No immunostaining was observed in villous Langhans' cells, syncytium, fibrinoid, or decidual cells. The trophoblast of ectopic pregnancies and hydatidiform moles stained positively, whereas only one of two choriocarcinomas stained weakly. Immunohistochemistry showed the protein to be present in small granules (Fig. 9.12D) and to be packaged in membranes.

It may be premature to engage in much speculation until more is known about the physiology of this protein. For a complete consideration of all functions of eosinophils, their granules, and related phenomena, the reader is referred to the review by Gleich and Adolphson (1986).

FIGURE 9.12. A,B: Intercotyledonary septum with extravillous trophoblast cells above. There is immunofluorescent localization of major basic protein (MBP) between septal extravillous trophoblast cells but not in chorionic villi (below). Left: H&E  $\times 100$ . Right: Anti-eosinophil granule MBP stain.  $\times 100$ . C,D: Placental septum composed of extravillous trophoblast cells. (Same technique as in A,B.) Gleich, Mayo Clinic, Rochester, Minnesota.)

## Cell Surface Carbohydrates

Carbohydrate epitopes on cell surfaces and on ECM molecules represent an important subgroup of oncofetal antigens. They often have close molecular relations to normal adult blood group antigens, the differences being based either on blockage of the normal synthetic pathways or on unusual synthetic pathways resulting in chain extension or atypical sialylation and fucosylation. Such carbohydrate chains may act as immunologically relevant cell surface markers (blood group antigen “i”, Frank et al., 1995). Moreover, they may represent ligands for cell adhesion molecules (sialyl-Lewis<sup>x</sup>, King & Loke, 1988; Burrows et al., 1994).

**Blood group antigen “i”** is the most primitive precursor of the ABO system of blood groups. It is expressed not only by immature red blood cells but also by all stages of invasive extravillous trophoblast (Fig. 9.13) (Frank et al., 1995). Its expression by fetal cells invading the maternal organism raises the question of whether the cell surface expression of an immature blood group antigen that every human organism has expressed throughout embryonic

and fetal life prevents immune recognition of extravillous trophoblast cells by the maternal immune system (see Endometrial Large Granular Lymphocytes Endometrial NK Cells, uNK Cells, below). Interestingly, the identical carbohydrate chain “I” was also found extracellularly in the invasive zone bound to trophoblast-secreted fibronectin molecules (Frank et al., 1995; Huppertz et al., 1996). As was shown by Zhu and coworkers, respective glycosylation of ECM molecules decreased their collagen binding and increased their resistance to proteolytic cleavage (Zhu et al., 1984; Zhu & Laine, 1985).

The slightly more mature **blood group antigen “I”** could be detected in human trophoblast only after sialidase pretreatment, thus indicating that not “I” but rather sialyl-“I” is expressed (Frank et al., 1995). Sialyl-“I” immunoreactivity was found on villous syncytiotrophoblast and only in few cases on the surfaces of invasive extravillous trophoblast cells, where it was coexpressed with “i.”

**Sialyl-Lewis<sup>x</sup>**, another cell surface carbohydrate, is expressed by intraarterial trophoblast cells (Fig. 9.13) (King & Loke, 1988). It acts as a ligand for the lectins

FIGURE 9.13. Human leukocyte antigen G (HLA-G) as well as the glycosyl epitopes “I” and sialyl-Le<sup>x</sup> are expressed only by the invasive phenotype of extravillous trophoblast. The sialyl-Le<sup>x</sup> positive intraarterial trophoblast cells can adhere to the maternal endothelium that expresses the respective receptors, E- and P-selectin only at the implantation site.

**E-** and **P-selectin** both of which are expressed by maternal endothelium at the implantation site (Fig. 9.13) (Burrows et al., 1994). Usually, both selectins are expressed by endothelium during inflammatory reactions. They enable leukocytes expressing sialyl-Le<sup>x</sup> to attach and to leave the vessel wall. These data suggest that at the implantation site, trophoblastic invasion of the arterial walls initiates the respective inflammatory reaction, resulting in selectin expression and intraluminal trophoblast adhesion. Interestingly, the sialyl-Le<sup>x</sup>/E-selectin adhesive interaction is also involved in the adhesion of human cancer cells to human umbilical vein endothelial cells in vitro (Takada et al., 1993).

### MHC Class I Molecules

Villous cyto- and syncytiotrophoblast separating maternal blood and villous stroma express neither MHC class I nor class II antigens (for review see Loke, 1989). The proliferating stem cells of the cell columns share the MHC negativity with the villous trophoblast. By contrast, the invasive extravillous trophoblast cells express nonclassical MHC-I molecules (Schmidt & Orr, 1993; Chumbley et al., 1994a,b; Colbern et al., 1994; McMaster et al., 1995; for review, see Hutter et al., 1996 and Loke et al., 1997).

From the morphologic point of view, the situation becomes even more interesting when one compares the immunohistochemical distribution of MHC-I antigen with the distribution of the class I MHC mRNA (Hunt et al., 1990, 1991). Hunt and coworkers described three different patterns:

- Villous cytotrophoblast (Langhans' cells) contains class I mRNA but does not express the MHC I antigen.
- Villous syncytiotrophoblast neither expresses MHC I antigen nor contains class I mRNA.
- Invasive extravillous cytotrophoblast contains the mRNA message and expresses nonclassical MHC I antigen.

These results are in agreement with findings by Lata et al. (1992), who concluded that MHC-I expression is regulated by posttranscriptional events. Moreover, these findings support the view that the trophoblast cells resting on villous and extravillous basal laminae represent a uniform population of proliferating stem cells for both villous syncytiotrophoblast and extravillous cytotrophoblast (Kaufmann & Castellucci, 1997).

In 1990, these nonclassical, nonpolymorphic MHC-I molecules were identified as **human leukocyte antigen-G (HLA-G)** (Kovats et al., 1990). So far, substantial evidence for the presence of both HLA-G mRNA and protein was found only in extravillous trophoblast (Chumbley et al., 1994a,b; Hutter et al., 1996); in contrast,

HLA-G mRNA was described in various nonplacental tissues (from Loke, 1997; Shukla et al., 1990; Houlihan et al., 1992; Kirszenbaum et al., 1994; Ulbrecht et al., 1994). Detection of the HLA-G protein is difficult, since there seem to be substantial problems in raising antibodies that specifically recognize HLA-G or one of its isoforms. So far HLA-G antibodies have been generated only by using HLA-G transgenic mice (Chumbley et al., 1994a,b). The situation is complicated even more by the fact, that various soluble or membrane-bound HLA-G isoforms exist, probably generated by alternative splicing (from Loke, 1997; Ishitani & Geraghty, 1992; Fuji et al., 1994). Immunohistochemically, HLA-G protein has been detected in the invasive phenotype of extravillous trophoblast (Fig. 9.13), the expression level decreasing toward term in parallel to decreasing invasiveness of the cells (Shorter et al., 1993; McMaster et al., 1995). Also in preeclampsia the HLA-G expression levels in the maternofetal junctional zone were found to be decreased (Colbern et al., 1994); it is still a matter of debate whether this reduction is due to generally reduced numbers of invasive trophoblast cells in this condition.

The functional role of HLA-G is still a matter of investigation. The low degree of polymorphism of its gene locus does not support the hypothesis that HLA-G may have evolved for classical T-cell interaction (Loke et al., 1997). The HLA-G-reactive T cells have never been observed (King et al., 1997). It was proposed that HLA-G acts as a target for decidual NK cells rather than for T cells (King & Loke, 1991; Loke & King, 1991). In this way, extravillous trophoblast may be protected against NK cell attacks, which are to be expected against MHC-I-negative cells. Nevertheless, HLA-G is able to present intracellular nonapeptides like the classical class I molecules (for review, see Hutter et al., 1996), and thus does not necessarily prevent T-cell-mediated immune response. For further discussion of HLA-G functions see Le Bouteiller et al. (2003).

Substantial evidence has accumulated that also **HLA-C**, which is less polymorphic than HLA-A or HLA-B, is expressed in extravillous trophoblast cells (Grabowska et al., 1990; King et al., 1996; for review see Hutter et al., 1996). Similar to HLA-G, HLA-C can present nonapeptides. At the moment, the functional role of HLA-C at the maternofetal interface is discussed along the same lines as for HLA-G, including the interactions with decidual NK cells (Loke & King, 1995).

In addition, **HLA-E**, another nonpolymorphic MHC molecule, is expressed by extravillous trophoblast. Different from the other non- or minimally polymorphic HLA molecules, HLA-E is ubiquitously expressed by a wide variety of cell types. Only HLA-E molecules that present nonamer peptides derived from the signal sequences of other HLA class I molecules, are expressed at the cell surfaces and are recognized by the dimeric receptor

CD94/NKG2A (Borrego et al., 1998; Lee et al., 1998). Binding of HLA-E to this receptor prevents NK cell-mediated lysis of the target cells.

The data on HLA-E raise the question of whether expression of HLA-G or HLA-C alone is sufficient to prevent NK cell attacks or whether coexpression with HLA-E is required, the latter presenting nonapeptides of the former nonclassical MHC molecules (Llano et al., 1998).

Meanwhile there is sufficient evidence, that uterine natural killer cells (uNK cells) in fact sense extravillous trophoblastic HLA-C, HLA-G, and HLA-E molecules and react with an altered NK cell cytokine profile, which modulates the invasive properties of extravillous trophoblast (King et al., 2000).

### Normal Extravillous Trophoblast Cells Are Never Proliferative and Invasive at One Time

Taken together, different from tumor cells, normal extravillous trophoblast leaves the cell cycle before becoming invasive. Accordingly, the various stages of differentiation within the invasive pathway have been subdivided in two phenotypes: a proliferative and an invasive one (for review, see Fisher & Damsky, 1993; Kaufmann & Castellucci, 1997). In the light of recent findings, this classification probably is too simple and the following might be closer to the truth:

The **proliferative and early postproliferative phenotype** is characterized by

- the location of the cells on or close to the fetal stromal basal lamina, forming a compact cluster of cells attached to each other by intercellular junctions;
- immunopositivity for the proliferation markers MIB-1/Ki-67 and expression of EGFR (*c-erbB-1*);
- expression of epithelial integrins  $\alpha 6 \beta 4$ , and partly  $\alpha 3 \beta 1$ ;
- polar secretion of ECM as a basal lamina (only proximal layer of cells) or absence of visible matrix secretion (all following layers of cells);
- cells either resting on a basal lamina or moving away from the basal lamina by proliferation and proliferation pressure of parent cells, but the absence of the cell's own active migratory or even invasive behavior.

After switching to the **invasive phenotype** (spindle-shaped trophoblast) the trophoblast cells

- have left the basal lamina and have invaded deeper layers of the maternofetal junctional zone;
- have irreversibly left the cell cycle and express the proto-oncogene *c-erbB-2* rather than *c-erbB-1*;
- express interstitial integrins such as  $\alpha 5 \beta 1$ ,  $\alpha 1 \beta 1$ ,  $\alpha v \beta 3$ , and  $\alpha v \beta 5$  either alone or in addition to the epithelial integrin  $\alpha 6 \beta 4$ ;
- show different degrees of apolar secretion of extracellular matrix,

- upregulate certain matrix metalloproteinases (MMP-2, MMP-11);
- show active migratory behavior (across their self-secreted ECM) or true invasive behavior (across the maternal host tissue, partially destroying the latter).

The final stage of differentiation is downregulation of invasion

- by polyploidization (large polygonal trophoblast)
- or syncytial fusion (multinucleated giant cells).

These data have prompted placentologists to assume that during normal placentation proliferation and invasion do not coexist in one and the same cell. The switch from the proliferative to the invasive phenotype was thought to comprise synchronous switching of all other parameters belonging to the same phenotype, as defined above. From these conclusions it was deduced that

- **temporal and spatial separation of proliferation and invasiveness** along the normal invasive pathway of extravillous trophoblast limits the depth of trophoblast invasion to the lifespan of the individual trophoblast cell;
- **temporal and spatial coincidence of proliferation and invasion** in "malignant" invasion in tumors increase invasiveness and enable unlimited invasive depth.

These features were thought to embody the major difference between "normal" trophoblast invasion in pregnancy as compared to tumor invasion; however, this view may still be too simple. The clearly defined switch of phenotypes was questioned by earlier in vitro data from the Lala group (for review, see Irving et al., 1995) who immunoselected  $\alpha 5$ -integrin-positive cells and found them to be still proliferative. Also observations in tubal pregnancies (Kertschanska et al., 1998; Kemp et al., 1999, 2002) revealed proliferation in deeply invasive extravillous trophoblast cells that had undergone the integrin switch from  $\alpha 6 \beta 4$  to  $\alpha 5 \beta 1$  and showed apolar matrix secretion. Biologically, the extravillous trophoblast in extrauterine pregnancies is expected to be normal trophoblast, the only difference being the abnormal implantation site.

These data suggest that also in the case of normal extravillous trophoblast, proliferation and invasion do not necessarily exclude each other. More likely, proliferation is downregulated by local factors, an event that in the intrauterine milieu, but not in the fallopian tube, coincides with the integrin switch and the onset of invasion. Partial overlap of proliferation with invasiveness may explain the enhanced invasiveness in tubal pregnancies. Additional factors include missing limitation of invasiveness, for example, by missing polyploidization of spindle-shaped trophoblast (Kemp et al., 2002), by missing syncytial fusion into multinucleated trophoblastic giant cells (Kemp et al., 2002), and by reduced trophoblast apoptosis (von Rango et al., 2003).

Similarly aberrant switching of phenotypes may take place during trophoblast invasion in accreta and percreta intrauterine placentation. Both tubal pregnancy and placenta accreta/percreta have in common locally deficient decidualization. Therefore, decidual factors should be investigated to determine if they are involved in the temporal and spatial coordination of trophoblast proliferation and invasion.

## Oxygen-Mediated Regulation of the Invasive Pathway

The **oxygen partial pressure** at the fetomaternal interface varies with gestational age. Studies with oxygen electrodes (Rodesch et al., 1992) have shown that the oxygen pressure in the intervillous space rises at around week 12 of gestation as a result of increased intervillous perfusion (see Uteroplacental Vessels), but is very low throughout the early stages of pregnancy. In the first trimester the following oxygen values were reported (for review, see Lyall & Kaufmann, 2000):

- Intervillous oxygen pressure was measured to be only about 18 mm Hg.
- Maternal intraarterial  $pO_2$  is about 95 to 100 mm Hg.
- Endometrial and myometrial  $pO_2$  are expected to be between both the above values.

Thus, there is a steeply rising  $pO_2$  gradient from the proximal layers of the cell columns (close to the intervillous space) toward the myometrium and even steeper toward the uteroplacental arteries, both representing the two end points of the invasive pathway. The question was raised whether this gradient may be a driving force for trophoblast proliferation, differentiation, and invasion (for review, see Lash et al., 2002), the effects being mediated by oxygen-controlled cytokines (Kourembanas et al., 1991; Shweiki et al., 1992; for review, see Lyall & Kaufmann, 2000).

**Hypoxia stimulates trophoblast proliferation:** The effects of oxygen concentration on proliferation of trophoblast in vitro were tested by Genbacev et al. (1996, 1997). These authors have shown that hypoxic conditions increase the overall proliferative capacity of isolated trophoblast cells. By contrast, in normoxic conditions, in vitro proliferation was reduced. This in vitro behavior of human trophoblast is in agreement with in vivo data obtained from severely anemic mothers (Kosanke et al., 1997; Kadyrov et al., 2003).

**Does hypoxia reduce trophoblast invasiveness?** In the same series of in vitro experiments Genbacev et al. (1996, 1997) found evidence that hypoxia did not only stimulate proliferation of isolated trophoblast cells but also inhibited their invasiveness, whereas normoxic conditions enhanced in vitro invasiveness. These data were supported by Kilburn et al. (2000), who found  $\alpha 6$ -integrin

expression increased and  $\alpha 1$ -integrin expression down-regulated under hypoxic conditions.

Genbacev's group explained the reciprocal dependence of proliferation and invasiveness on local oxygen levels by studying the expression of the von Hippel-Lindau tumor-suppressor protein, which regulates the stability of HIF1 $\alpha$  and HIF2 $\alpha$  (Genbacev et al., 2001). Hypoxia inducible factor transcriptionally regulates the genes of growth factors that are involved in developmental, physiologic, and pathologic responses to hypoxia. The level and transcriptional activity of this complex is precisely regulated by the cellular oxygen concentration (for review see Caniggia & Winter, 2002; for further details see Oxygen-Controlled Angiogenic Growth Factors in Chapter 7). The authors found the von Hippel-Lindau tumor-suppressor protein highly expressed in proliferative trophoblast, but downregulated in the invasive phenotype.

### Or does hypoxia stimulate trophoblast invasiveness?

The finding of hypoxia-dependent reduction of trophoblast invasiveness was used to explain reduced interstitial trophoblast invasion (e.g., in preeclampsia). As became evident from the data by Kadyrov et al. (2003), trophoblast invasion in preeclampsia is in fact numerically reduced. However, in severe anemia, which provides a clearly hypoxic environment in the uterine wall, the same authors found increased invasiveness of trophoblast (Kadyrov et al., 2003). Therefore the question must be posed whether preeclampsia is really a good in vivo model for hypoxia in the uterine wall. One may argue that intrauterine hypoxia in this entity is not inducing malinvasion of trophoblast but rather that malinvasion of trophoblast induced by other factors is causal for the maladaptation of uteroplacental arteries and thus for intrauterine hypoxia.

Several data underline the notion that hypoxia does not simply impair invasiveness of trophoblast but possibly even stimulates it, as suggested by the in vivo data obtained in anemia:

- The expression of oxygen-controlled genes in trophoblast cells in vitro was studied by various approaches (Pak et al., 1998).
- Fitzpatrick and Graham (1998) could demonstrate increased expression of PAI-1 in immortalized trophoblast cells cultured under low oxygen levels. Plasminogen activator inhibitor-1 is the inhibitor of uPA and is expressed by extravillous trophoblast cells (Feinberg et al., 1989).
- Graham's group (1998) provided evidence that reduced oxygen levels increased in vitro invasiveness of cytotrophoblast, an effect linked to elevated expression of the cell surface receptor for uPA.
- The same conditions resulted in reduced expression of  $\alpha 5$  integrin and reduced adhesion to vitronectin and fibronectin (Lash et al., 2001).
- Also, the secretion of MMPs, important tools for cellular invasion, seems to be regulated by oxygen. Whereas hypoxia in vitro upregulates MMP secretion by trophoblast cells, it downregulates at the same

time the secretion of its inhibitors (TIMPs) (Canning et al., 2001).

Data by Campbell et al. (2004) suggest that *in vitro* experiments with trophoblast generally must be interpreted with care since the experimental design may influence the outcome. These authors found that hypoxia increased trophoblast migration on semipermeable membranes when cultured alone, but not in coculture with decidual endothelial cells due to increased adhesion between the two cell types.

In conclusion, all these data suggest an important role for oxygen in the regulation of cellular invasion (Graham et al., 2000; Lash et al., 2002), a role that more likely points to stimulating effects of hypoxia on invasiveness than to impairing effects.

### Extracellular pH as Trigger of Trophoblast Invasion

As discussed above, non-oncofetal cellular fibronectin can universally be found in all extracellular compartments of the placenta. In contrast, oncofetal fibronectins containing the ED-B and III-CS domains are almost exclusively secreted by extravillous trophoblast; the amount of oncofetal fibronectins accumulating around the extravillous trophoblast cells increases along the invasive pathway from early postproliferative to deeply invasive cells (Frank et al., 1994, 1995; Huppertz et al., 1996, 1998b,d; Kaufmann & Castellucci, 1997). Factors affecting the secretion patterns of oncofetal fibronectins, therefore, may be discussed as regulators of differentiation of extravillous trophoblast and of trophoblast invasion.

In a recent study (Gaus et al., 2001) we have shown interesting interactions between pH and trophoblast invasion:

- The peripheral ends of anchoring villi and the attached proliferative zone of cell columns show the strongest tissue acidity (pK about 3.9) measurable within the placenta *in vivo*; this area is the starting point of trophoblast invasion.
- Acidic extracellular pH stimulates secretion of fibronectins by extravillous trophoblast cell lines *in vitro* and shifts their isoform pattern toward oncofetal splice variants; this secretory pattern is preserved even following pH normalization.
- This behavior seems to be characteristic for extravillous trophoblast, since choriocarcinoma cells and mesenchymal cells under identical experimental conditions did not show a shift toward the secretion of oncofetal fibronectins, though at least the latter are generally responsive to changes in tissue acidity (Borsi et al., 1996).

Similar data have been reported for pH-dependent alternative splicing of tenascin (Borsi et al., 1996). Taken

together, these data suggest that local tissue acidity besides oxygen and various cytokines must be considered as another factor triggering the secretion of ECM proteins along the invasive pathway, and possibly even triggering the transition into the invasive phenotype.

### Trophoblastic Mechanisms Limiting Trophoblast Invasion

A variety of mechanisms is under discussion to limit trophoblast invasion. These include

- apoptosis (DiFederico et al., 1999; Genbacev et al., 1999; Reister et al., 1999, 2001),
- polyploidization (Kemp et al., 2002; Zybina et al., 2002, 2004), and
- syncytial fusion (Kemp et al., 2002) of the invasive trophoblast cells (Fig. 9.7).

**Apoptosis:** It has been shown that both villous and extravillous trophoblast express the molecular machinery of apoptosis (Huppertz et al., 1998a–c). Trophoblast apoptosis was shown to prevent interstitial extravillous trophoblast from invading uteroplacental arterial walls in preeclampsia (Reister et al., 1999, 2001). Moreover, DiFederico et al. (1999) and Genbacev et al. (1999) in two articles derived from the same project, have reported that in preeclampsia 15% to 50% of the extravillous trophoblast cells in “the uterine wall to which the placenta attaches” were TUNEL positive and thus destined to undergo apoptosis. Based on these data the authors suggested that increased trophoblast apoptosis is responsible for reduced interstitial trophoblast invasion in preeclampsia.

In a later study, Kadyrov and coworkers (2003) found much lower apoptosis indices of extravillous trophoblast in the placental bed, ranging from 4.4% (preeclampsia) to 7.2% (normal term placenta). Percentages of up to 50% TUNEL positivity of extravillous trophoblast, as reported by DiFederico, would lead to complete loss of this cell population within few days. Based on the photographs published in DiFederico's paper, it seems likely that the authors did not study placental bed biopsies as claimed but rather basal plate specimens from the delivered placenta.<sup>1</sup> Therefore, it has been suggested

<sup>1</sup> At this point, the importance of true placental bed studies must be emphasized: Important pregnancy problems, such as preeclampsia, fetal growth restriction, and spontaneous miscarriage have all been linked to abnormalities in trophoblast invasion into the placental bed. Unfortunately, most of the respective basic research to understand the pathogenetic mechanisms is done either on the more easily available basal plate or on *in vitro* models. In a recent review by Lyall (2002) the various studies that have attempted to sample the placental bed together with the difficulties in obtaining “true” placental bed biopsies have been impressively reviewed.

that DiFederico's unusually high apoptosis indices reflect local tissue degeneration along the demarcation zone between placental basal plate and placental bed, rather than the *in vivo* situation in the invasive pathway and a true effect of preeclampsia (Kadyrov et al., 2003).

According to von Rango et al. (2003) trophoblast apoptosis is confined to the decidua basalis, the incidence declining with advancing gestation. Interstitial apoptotic trophoblast cells were always closely colocalized with CD56<sup>+</sup> NK cells and the overall number of uNK cells declined parallel to the reduction of trophoblast apoptosis when pregnancy advances. Interestingly, in tubal pregnancies, in which uNK cells were completely missing, the incidence of trophoblast apoptosis was lowest. The authors, therefore, suggest an interaction between uNK cells and trophoblast apoptosis.

The data presented by Kadyrov et al. (2003) and von Rango et al. (2003) support the view that some of the extravillous trophoblast cells may be eliminated by apoptotic death along the invasive pathway, but the same data make it unlikely that apoptosis is the limiting factor for trophoblast invasion. The data obtained from analysis of complete placental bed/uterine wall samples revealed that trophoblast invasion in normal pregnancies clearly exceeded trophoblast invasion in preeclampsia regarding both numerical density of invading trophoblast and invasive depth. But interestingly the incidence of apoptotic death (percentage of total extravillous trophoblast in the invasive pathway) was also higher in normal pregnancy as compared to preeclampsia, suggesting that increased apoptosis cannot be made responsible for the poor and shallow invasion in preeclampsia.

**Syncytial fusion:** It is generally thought that the multinucleated trophoblastic giant cells of the placental bed are formed by syncytial fusion (Kemp et al., 2002), though respective fusion stages have not been observed yet. Endomitosis as alternative mechanism is very unlikely since MIB-1 reactivity has never been shown in these cells or in neighboring trophoblast cells that may be considered precursors.

Interestingly, the multinucleated trophoblastic giant cells accumulate usually in one layer close to the endometrial-myometrial border. The concentration of giant cells within one layer renders it quite unlikely, that they are mobile or even invasive. Rather, the presence of this layer together with the fact that the uninucleated interstitial trophoblast cells may be found above (toward the placenta) and partly also below this layer, suggest that the multinucleated giant cell layer acts as a kind of net, trapping many of those uninucleated invasive trophoblast cells by fusion that try to pass into deeper layers (Kemp et al., 2002).

**Polyploidization:** As discussed above, the uninucleated population of interstitial extravillous trophoblast cells is

composed of two different phenotypes (Kemp et al., 2002):

- **Small spindle-shaped trophoblast cells**, which express "interstitial integrins" ( $\alpha 5\beta 1$ ,  $\alpha 1\beta 1$ , and  $\alpha v$ -integrins) and secrete minor amounts of oncofetal fibronectins. This pattern has for a long time been discussed as an essential mechanism of invasiveness (Fisher & Damsky, 1993; Akiyama et al., 1995; Huppertz et al., 1996; Menzin et al., 1998). Aplin et al., (1999) have provided experimental evidence that the interaction between  $\alpha 5\beta 1$  integrins and fibronectins is crucial for trophoblast invasion. These spindle-shaped trophoblast cells are diploid to tetraploid (Zybina et al., 2002).
- **Large polygonal extravillous trophoblast cells** (the former X cells), which express epithelial ( $\alpha 6\beta 4$ ) and interstitial integrins and embed themselves in large amounts of self-secreted extracellular matrix (laminins, collagen IV, vitronectin, heparan sulfate, fibronectins). These cells are rare in the depth of the invasive pathway but rather accumulate in the basal plate. Moreover, they are the dominating cell type in the late, less invasive stages of pregnancy. The ample ECM accumulated by these cells possibly acts as a kind of trophoblast-endometrial glue (Feinberg et al., 1991) anchoring not only the cells but also the placenta to its implantation site. These cells are generally polyploid (Zybina et al., 2002). Also in rodents, insectivores, and certain carnivores trophoblastic giant cells accumulate as a compact layer of noninvasive trophoblast and show high degrees of polyploidization (Zybina & Zybina, 1996; Klisch et al., 1999a,b; Zybina et al., 2001).

According to the data by Kemp et al. (2002) and Zybina et al. (2002, 2004), the large polygonal trophoblast cells represent not a separate line of differentiation but rather a final step of differentiation of small spindle-shaped trophoblast cells that polyploidize and thereby differentiate into an ECM-secreting, noninvasive phenotype.

The degree is still open to which all three mechanisms (apoptotic death, syncytial fusion, and polyploidization) contribute to the limitation of trophoblast invasion in normal and various pathologic settings. A high incidence of multinucleated trophoblastic giant cells in the first and second trimester and of mononucleated large polygonal trophoblast cells (X cells) in term pregnancies suggests that the mechanisms vary in the course of pregnancy.

## Endocrine Activities of Extravillous Trophoblast

There are few data available on endocrine activities of extravillous trophoblast. Generally, all endocrine activities detectable within the extravillous trophoblast have been found also (mostly with higher activities) in villous trophoblast. Therefore, the question arises of whether endocrine activities of extravillous trophoblast play specific functional roles or whether they are simply due to the fact that all trophoblast, whether villous or extravillous, is derived from the same source and therefore shows similar profiles of gene expression.

TABLE 9.1. Approximate localization of placental proteins in various trophoblastic cells as identified by immunocytochemistry

Trophoblast type	First Trimester			Second Trimester			Third Trimester		
	hCG	hPL	SP <sub>1</sub>	hCG	hPL	SP <sub>1</sub>	hCG	hPL	SP <sub>1</sub>
Cytotrophoblast	—	—	—	—	—	—	—	—	—
X cells ("intermediate")	+	+	+/-	+/-	+	+	—	+	+/-
Syncytiotrophoblast	+	+	+	+	+	+	+	+	+
Syncytial giant cells	+	+	+/-	—	+	+/-	—	+	+/-
Syncytial knots	+	+	+	+	+	+	+	+	+
Placental site trophoblast	+/-	+	+/-	—	+	+/-	—	+	+/-

Endovascular trophoblast	—	+	+/-	—	+	+/-	—	+	+/-

Source: Modified from Kurman et al. 1984a.

Kurman et al. (1984a,b) has provided information on immunoreactivities of **hCG**, **hPL**, and **SP<sub>1</sub>** (pregnancy-specific  $\beta_1$ -glycoprotein) in the various forms of trophoblast. The findings are summarized in Table 9.1. Gosseye and Fox (1984) found that the villous syncytiotrophoblast was the principal source of hCG, hPL, PAPP-A, PP5, and SP<sub>1</sub>; in the invasive extravillous trophoblast, only hPL was present. The intensity of cellular hPL staining increased progressively with deeper penetration of the extravillous trophoblast. SP<sub>1</sub> and hPL were also detected in some cell populations of trophoblastic tumors (Kurman et al., 1984b; Manivel et al., 1987). The results concerning hPL and hCG immunoreactivities were largely corroborated by other investigators (Sasagawa et al., 1987; Zeng & Fu, 1991); however, Sakbun and coworkers (1990b) who measured mRNA concentrations of hPL, pointed out that villous trophoblast is the major source and that the extravillous trophoblast adds only minor amounts to total placental hPL production.

**Prostaglandin metabolism** in extravillous trophoblast cells has been discussed as being involved in control of labor: 15-hydroxy prostaglandin dehydrogenase (type I PGDH) was found not only in villous syncytiotrophoblast but also in invasive extravillous trophoblast (Cheung et al., 1990, 1992), where it is ideally located to metabolize and to maintain low concentrations of prostaglandins, in particular in close vicinity of the myometrium.

Pregnancy-associated prostaglandin synthetase inhibitor (PAPSI) was detected in amniotic epithelium, in villous macrophages, and in trophoblast throughout pregnancy (Mortimer et al., 1989). Its importance for the maintenance of pregnancy and for the control of the onset of parturition was discussed by the authors.

**Corticotropin-releasing hormone** has been described as being present not only in villous cytotrophoblast (Petraglia et al., 1987; Saijonmaa et al., 1988) but also in extravillous trophoblast of the basal plate (Riley et al., 1991) and membranes (Warren & Silverman, 1995). The authors suggested that this releasing hormone locally affects paracrine/autocrine interactions and that it may be involved in the maturation of the fetal hypothalamic-pituitary-adrenal axis.

## Does Extravillous Trophoblast Differ from One Nonvillous Part to the Other?

Most of the above data on extravillous trophoblast were obtained from studying cell columns; only a few data are available on extravillous trophoblast of cell islands, the chorionic plate, and chorion laeve (for details, we refer to the respective chapters; see below). This

raises the question as to the homogeneity of extravillous trophoblast population throughout placenta and fetal membranes.

When we compared differentiation patterns of extravillous trophoblast derived from cell columns with those from other sites, largely consistent data were found (Castellucci et al., 1991; Mühlhauser et al., 1993; Nanaev et al., 1993a,b; Frank et al., 1994). In all cases, the basal cells resting on the basal lamina or located close to it represent the proliferative subset (Fig. 9.1) and express epithelial integrins (e.g.,  $\alpha_6\beta_4$ ). Those cells that have left the basal lamina stop proliferating, achieve a migratory/invasive phenotype, express interstitial integrins (e.g.,  $\alpha_5\beta_1$  and  $\alpha_1\beta_1$ ), and start apolar ECM secretion. This is in agreement with the findings of Aplin and Campbell (1985) and Malak et al. (1993), who described the distribution patterns of various ECM molecules around the extravillous trophoblast cells of the chorion laeve. Finally, Genbacev et al. (1993c) cultured explants of cell islands and found no differences when comparing them to cell columns. They concluded that cell islands represent free-floating cell columns. All these findings make it very likely that extravillous trophoblast of all intraplacental sites represents one homogeneous population of cells that differ only regarding their stage of differentiation and their degree of invasiveness.

It has been objected that in term chorion laeve the extravillous trophoblast cells resting on the basal lamina are no longer proliferative and do express interstitial integrins (Aplin, 1993). This behavior, however, is confusing only when comparing term chorion laeve with first trimester cell columns. In third trimester cell columns, as is typical for all third trimester locations of extravillous trophoblast, the proliferative activity is downregulated (Kaufmann & Castellucci, 1997), leading to a "burned out" aspect with the invasive phenotype prevailing.

In conclusion, at the moment there is no convincing evidence for the existence of different populations of extravillous trophoblast residing in different nonvillous parts of the placenta.

## Decidua

### Composition of Decidua

The changes that occur in the human or animal endometrium in response to physiologic stimuli like blastocyst

implantation are called decidualization. If the morphogenetic stimulus was a physiologic one, the resulting tissue is the decidua; the tissue resulting from an experimental or artificial stimulus is called a pseudodecidua or, occasionally, a deciduoma.

There is a long history of confusion regarding the nomenclature. This is due to the fact that the tissue **decidua** is composed of cells of different type and origin:

- Decidualized endometrial stromal cells, the so-called **decidual cells**; and
- Considerable numbers and various types of **maternal leukocytes** invading from the bone marrow via the maternal blood; the latter belong to the decidua and inaccurately are sometimes subsumed under the heading “decidual cells.”

From all these cells involved in decidualization, only the transformed endometrial stromal cell should properly be called a decidual cell.

Padykula and Driscoll (1978) described the leukocyte infiltration to occur specifically from the 6th to 11th weeks of pregnancy. Bone marrow–derived cells comprise macrophages, T lymphocytes, few granulocytes, and considerable numbers of large granular lymphocytes (uNK cells, the former “endometrial granular cells” or “K cells”) (Enders, 1991; Khan et al., 1991; Dietl et al., 1992; Haller et al., 1993).

According to Marzusch and Dietl (1994), Loke and King (1995), and Loke et al. (1995), the decidual cell population is composed as follows:

Cell designation	First trimester	Term pregnancy
Decidual cells and endometrial stromal cells	30%	30–55%
Large granular lymphocytes (uNK cells)	40%	4–9%
T cells	8–10%	8–17%
B cells and plasma cells	<1%	<1%
Macrophages	20%	20–40%
Granulocytes	2%	3–4%

At term, considerably increased numbers of granulocytes can be found at the separation zone of the placenta and at the maternal surface of the delivered placenta. They are thought to represent an inflammatory response to the mechanisms preceding separation of the placenta.

## Endometrial Stromal Cells and Decidual Cells

Under the influence of progesterone, the endometrium is changed into decidua, a structurally different tissue. Faint signs of decidualization first become visible on day 23 of the endometrial cycle. They commence around the spiral arteries from where they spread throughout the tissue.

The youngest human implantation stage [Carnegie stage 5a, late day 6 to early day 8 postcoitus (p.c.); see Chapter 8] does not show decidualization (Enders, 1991); within the following 2 or 3 days it is barely beginning (Carnegie stage 5b). Electron microscopic studies have not been performed on these early human cases from the first 2 weeks of pregnancy, so that the exact starting point of decidualization in the human is difficult to describe.

## Structure of Decidual Cells

Decidualization is characterized by the enlargement of endometrial stromal cells that eventually assume an epithelioid appearance. This process has been described in detail by Kaiser (1960), Schmidt-Matthiesen (1963), Stegner et al. (1971), Dallenbach-Hellweg and Sievers (1975), Iwanaga (1983), as well as Welsh and Enders (1985). The final result includes cellular hypertrophy and an increase in number and complexity of cytoplasmic organelles, including the rough endoplasmic reticulum and Golgi complexes; it indicates an increase in synthetic and secretory activities. The cells accumulate glycogen as well as sometimes lipids and large areas with perinuclear bundles of intermediate filaments that are immunohistochemically positive for vimentin. Both together, typical morphology and immunoreactivity for vimentin can be used to identify decidual cells (Fig. 9.14A,C; also see Chapter 3, Figs. 3.2L and 3.4B). One to three euchromatic nuclei with prominent nucleoli can occur. The localization of a variety of enzymes in the decidua was summarized by Kearns and Lala (1983) and Lapan and Friedman (1965). Detailed ultrastructural descriptions have been provided by Wynn (1967b, 1974), Enders (1968), Lawn et al. (1971), and Spornitz and Ludwig (1984). Gap junctions were found by several groups (Lawn et al., 1971; Wadsworth et al., 1980; Ono et al., 1989) and it was then discussed whether these synchronize decidual development or decidual function.

One of the most characteristic features of the mature decidual cells is the presence of club-shaped processes that extend into the surrounding external fibrillar lamina. The tips of these processes contain dense granular bodies of about 0.5  $\mu$ m diameter (Wynn, 1965; Lawn et al., 1971; Stark & Kaufmann, 1973; Kusalus & Herr, 1988). The granules were identified to contain heparan sulfate proteoglycan, which was also released into the surrounding fibrinoid (Kusalus & Herr, 1988). There, it contributes to the acquisition of a pericellular lamina composed of argyrophilic, fibrillar material (Lawn et al., 1971; Wewer et al., 1985) that also stains with cresyl echt, aldehyde fuchsin, and other dyes (Waidl, 1963) and that resembles the basal lamina of epithelia.

The epithelial appearance of decidual cells is evident from histologic sections (Fig. 9.14C; also see Figs. 3.1K and 3.2L). The cells have often been described as rounded

B

C

FIGURE 9.14. Comparison of decidua cells with trophoblast cells. A: A 40- $\mu$ m plastic section of the basal plate. Enzyme histochemical proof of isocitrate dehydrogenase. The positively stained cells are decidua cells. In such thick sections the real structure of the elongated cells with extremely long, poorly branched cytoplasmic extensions is revealed.  $\times 520$ . (Source: From Stark & Kaufmann, 1973, with permission.) B: Paraffin section of a cluster of extravillous trophoblast cells at the

peripheral end of a cell column. Note the uniformity of cellular shapes and the fact that most cellular profiles contain nuclei. C: Comparable paraffin section of a cluster of decidua cells. Note that the cellular profiles vary very much in diameter and that the numerous small profiles do not contain nuclei. This is due to the fact that most cross sections across the long cellular bodies of decidua cells (cf. part A) do not hit the nucleus. B,C: H&E  $\times 300$ .

to polygonal (Kisalus & Herr, 1988; Enders, 1991), but according to our experience this impression is incorrect. When we studied decidual cells in thick plastic sections (20 to 50  $\mu$ m), we found large, branched cells (Fig. 9.14A) that resembled hypertrophied connective tissue cells. The length was 100 to 200  $\mu$ m. Thus, the epithelioid appearance is the result of cross-sectioning. The low number of nuclear profiles, as compared to the number of cellular cross sections, is one of the easiest available parameters to distinguish decidual from trophoblastic cells (Fig. 9.14B,C; also see Fig. 3.1K).

### *Control of Decidualization*

Few factors have been described that regulate decidualization. Progesterone is the most potent stimulator of this differentiation process. Insulin-like growth factor (IGF) is also under discussion in the promotion of decidualization; its binding protein (IGF-BP) is expressed by decidual cells (Bell, 1989; Fazleabas et al., 1989; Rutanen et al., 1991) and appears to be involved in mitosis of endometrial stromal cells and their later differentiation into decidual cells.

### *Bone Marrow Derivation of Decidual Cells*

Kearns and Lala (1983) and Lala et al. (1984) deduced from experimenting with chimeric mice that the bone marrow was the “ultimate origin” of the decidual cells. According to these authors, the bone marrow derivation is not only valid for decidual macrophages, endometrial NK cells, accidental granulocytes, and T cells, but also for the precursors of the decidualized stromal cells. This special origin could explain why only the intrauterine stromal cells, but not, for example, tubal stromal cells, decidualize under the endocrine and paracrine stimuli of pregnancy. Moreover, it would explain why endometrial stroma once locally removed by uterine connective tissue, for example, in C-section scars and following enforced curettages, does not decidualize in subsequent pregnancies.

### *Endocrine and Paracrine Aspects of Decidua*

Numerous studies have been performed concerning the functional importance of the decidua, and much speculation has been entertained. Even the more commonly suggested functions, such as limiting trophoblastic invasion and providing nourishment for the conceptus, still lack adequate supportive evidence (Enders, 1991). Despite this disillusioning statement, we will try to summarize some interesting findings that may stimulate further discussion.

**Relaxin:** Several publications ascribe relaxin secretion to decidual tissue (Bigazzi et al., 1982; Bryant-Greenwood et al., 1987; Hansell et al., 1991). Based on old immunohistochemical findings of Dallenbach and Dallenbach-Hellweg (1964), the endometrial granular cells had originally been favored as the origin. But as their identity as large granular lymphocytes has now been settled (see below), relaxin secretory activities are less likely and it is somewhat probable that decidual cells themselves represent the source at the maternofetal interface (Sakbun et al., 1990a; Bogic et al., 1995). On the other hand, relaxin is expressed in villous trophoblast of the human placenta as well as in trophoblast of several other species (Klonisch, personal communication). This suggests the need for reevaluation of the identity of relaxin-expressing cells at the maternofetal interface. In vitro studies of Qin et al. (1997a,b) have shown that trophoblast cells respond to exogenous relaxin with increased expression and activation of various proteinases such as stromelysin-1 (MMP-3), interstitial collagenase (MMP-1), and tPA. The authors suggested a role of decidual relaxin on regulation of ECM degradation in preparation of labor.

**hPL:** Older publications have favored a decidual production of hPL; however, the decidua was taken from the membranes and placental floor for most of these studies.

It was thus likely to be contaminated by extravillous trophoblast. Kurman et al. (1984a) immunostained specifically for hPL and other hormones in the basal plate, villous tissue, and membranes. They found that hPL was the principal product of what they chose to call the “intermediate trophoblast,” the extravillous trophoblast cells. Another possible explanation for the immunoreactivity of decidual cells for hPL is the fact that hPL and prolactin show considerable homology in their amino acid sequence. Correspondingly, in the early period of immunohistochemistry many antibodies were unsuitable to distinguish among both hormones, and, as will be discussed next, there is now convincing evidence that prolactin is a decidual product whereas hPL in the human is exclusively secreted by trophoblast cells.

**Prolactin:** Proof of the decidual origin of prolactin was obtained by immunohistochemistry (Golander et al., 1979; Rosenberg et al., 1980; Riddick & Daly, 1982; Andersen et al., 1987; Bryant-Greenwood et al., 1987). In vitro studies with isolated cells or tissues (Fukamatsu et al., 1984; Hamaguchi et al., 1990; Daly et al., 1983) and in situ hybridization studies (Wu et al., 1991) confirmed these results. It was noted that prolactin production in various stages of pregnancy was closely related to prolactin concentrations in the amniotic fluid and concluded that prolactin is elaborated by decidual cells contained within the membranes and transported internally, a suggestion made by many investigators. Peak prolactin release into the amniotic fluid is in the 24th week of pregnancy (Neuberg, 1992). The most important functions of decidual prolactin comprised regulatory effects on water and electrolyte transfer across the membranes, thus controlling the fetal water balance. This effect has been observed in vitro when using amniotic fluid prolactin; however, it was absent with human pituitary prolactin (de Bakker-Theunissen et al., 1988). Moreover, it was said to affect the synthesis of fetal surfactant and to influence calcium absorption in the fetal gut (for references, see Neuberg, 1992).

**Prostaglandins:** The decidual production of prostaglandin  $E_2$  ( $PGE_2$ ) has been discussed in context with the immunology of gestation;  $PGE_2$  secretion is said to block activation of decidual leukocytes with potential antitrophoblastic killer function, by inhibiting IL-2 receptor generation and IL-2 production (Parhar et al., 1989). Prostaglandins  $E_2$  and  $F_{2\alpha}$  have also been discussed in another context: During labor, the production and release of these substances seems to be considerably increased in decidual cells (Khan et al., 1992); the authors discussed the functional relations to labor. The role of  $PGE_2$  is still open, but it may play a role in prepartal ripening of the cervix, whereas  $PGF_{2\alpha}$  is essential for the stimulation of uterine muscle during labor (Fuchs & Fuchs, 1984). Casey et al. (1989) proposed that prostaglandin dehydrogenase,

resident in the decidua capsularis, regulates levels of prostaglandin therein as well as in amniotic fluid, uterus, and blood. Finally, endothelin-1, a potent vasoconstrictor and its receptors are expressed in human decidual cells (Kubota et al., 1992). Their function during pregnancy and labor is still an open question.

**Paracrine regulatory loops:** Several such loops between decidual cells and invasive extravillous trophoblast cells are under discussion. Among others, mutual effects of hCG and EGF have been described. Human chorionic gonadotropin is a secretory product not only of villous but also of extravillous trophoblast (Kurman et al., 1984a), whereas EGF is secreted by villous trophoblast (Hofmann et al., 1992; Ladines Llave et al., 1993; Matsuo et al., 1993) but also may be of maternal origin (Fisher et al., 1992). Epidermal growth factor stimulates decidual cell proliferation but inhibits prolactin secretion of decidual cells in culture (Saji et al., 1990). Decidua produces a protein that inhibits hCG release from human trophoblast (Ren & Braunstein, 1991); according to other studies it is likely that prolactin inhibits hCG production (Yuen et al., 1986). On the other hand, decidual cells not only express hCG receptors (Reshef et al., 1990), but hCG (Rosenberg & Bhatnagar, 1984), and in particular  $\alpha$ hCG (Blithe et al., 1991) stimulates decidual prolactin production in vitro. Moreover, TNF- $\alpha$ , a secretory product preferentially of decidual macrophages, inhibits trophoblast cell growth (for review, see Briese & Müller, 1992) and promotes trophoblastic apoptosis (Reister et al., 1999, 2001). According to McWey et al. (1982) decidual cells express hPL receptors and may thus be a target for trophoblastic hPL. Finally, decidual large granular lymphocytes (NK cells) are a rich source of TGF- $\beta$  (Loke & King, 1995), which inhibits trophoblast invasion (Graham et al., 1992; Irving et al., 1995; Lysiak et al., 1995). Respective mechanisms comprise modulation of integrin expression, down-regulation of MMP secretion and induction of TIMPs (Irving et al., 1995; for review see Loke & King, 1995).

## Functional Considerations of Decidualization

All of the above studies provide only a little evidence concerning the specific functional activities of the decidua. One must bear in mind that decidualization is not a general phenomenon related to placentation. Rather, it is found in hemochorial placentation, which, unavoidably, is related to invasive processes. In spite of this coincidence, however, it is not the invasive trophoblast itself that stimulates decidualization of endometrial stromal cells; rather, this is very likely to be principally a progesterone effect (see Endometrial Stroma Cells and Decidua Cells, above). In spite of this knowledge, most theories regarding decidual function discuss the decidua in the light of trophoblastic invasion, and the classical descrip-

tions see the decidual cells as being stuffed with glycogen and lipids, to serve as nutrients for the invading trophoblast.

Consequently, a series of studies focused on the interactions between decidualization and trophoblastic invasion (for review, see Bell, 1989). During the menstrual cycle, insulin-like growth factor binding protein (**IGF-BP**) appears to be associated with the stromal fibroblasts (Bell, 1989; Fazleabas et al., 1989; Rutanen et al., 1991; Giudice et al., 1998). It was proposed that IGF-BP is involved in proliferation, inhibition of apoptosis, and decidualization of these cells. Possibly trophoblast cells stimulate the decidual stroma to produce IGF-BP-1 (Lee et al., 1997). Moreover, the RGD tripeptide (Arg-Gly-Asp), which is known to be the recognition site in several adhesive matrix proteins for a range of cell receptors and which is part of the sequence of IGF-BP, has been shown to inhibit tumor cell invasion (Ruoslahti & Pierschbacher, 1987). Therefore, IGF-BP can be interpreted to be part of a paracrine loop by which the decidual cell and decidualization may regulate local proliferation and invasion of trophoblast cells (Bell et al., 1988).

Ruck et al. (1994) have studied the distribution of cell **adhesion molecules** in the decidua throughout pregnancy. The wide variety of cell adhesion molecules found in the various decidual cell populations are likely to allow interactions among all these cells as well interactions between invading trophoblast cells and cells of the decidua.

An interesting publication deals with the secretion of  **$\alpha_2$ -macroglobulin** by the rat decidua (Gu et al., 1992). This potent protease inhibitor is specifically expressed by the mesometrial decidua, the site of trophoblastic invasion in the rat. Its expression is regulated in an autocrine loop by prolactin (Gu et al., 1992). On the other hand, the  $\alpha_2$ -macroglobulin receptor is expressed by extravillous trophoblast cells (Coukos et al., 1994). Both groups of investigators have speculated that this protease inhibitor may limit tissue damage to decidual cells during extravillous trophoblastic protease secretion and invasion.

In accordance with all these findings, decidualization may be the answer of the endometrium to trophoblastic invasion, regulating the latter and solving problems posed by hemochorial placentation (Bell, 1989). On the other hand, trophoblast invasion in the human does not induce decidualization in every instance. Pregnancy pathologies that do not show decidualization comprise the following (see Endometrial Stromal Cells and Decidual Cells, above):

- **Tubal pregnancies:** The tubal mucosa does not exhibit any decidual stromal reaction upon implantation and trophoblast invasion; decidua-like cells of the tubal implantation site have been identified by electron microscopy to be invasive trophoblast cells (Spornitz,

1993). Moreover, these tubal implantation sites, in contrast to intrauterine implantation, are largely devoid of large granular lymphocytes (see below) (Vassiliadou & Bulmer, 1998) and of macrophages (own unpublished findings). By contrast, distribution patterns of T cells and B cells are similar in intrauterine and extrauterine implantation sites (von Rango et al., 2001). Trophoblast invasion in this situation is excessive (Kemp et al., 1999).

- **Placenta accreta, increta, and percreta:** Also in these clinical settings, excessive trophoblast invasion is combined with deficient decidualization. Data on leukocyte populations at the implantation site in these cases are not available, to the best of our knowledge.

These data suggest that decidualization is a prerequisite for proper control of trophoblast invasion. It is, however, still an open question whether decidual stromal cells themselves or decidual leukocytes exert this control (see below).

## B Cells and T Cells

B cells and plasma cells are virtually absent from normal decidua and are considered to be irrelevant for trophoblast-decidua interactions (Loke & King, 1995). T cells form a minor portion of the decidual lymphocytes (about 10% of all cells in the decidua; see Composition of Decidua, above) (Marzusch & Dietl, 1994; Loke & King, 1995; King & Loke, 1997). The absence of B cells and scarcity of T cells indicate that there is no important influx of cells of the specific adaptive immune system (Loke & King, 1995).

Overall, decidual T cells show a phenotype that would be in agreement with memory cells or activated T cells (Saito et al., 1994; Loke & King, 1995); it is still an open question whether this activated phenotype is specific for pregnancy or already present during the menstrual cycle. Interestingly, however, according to some earlier studies, decidual T cells do express only low levels of T-cell receptor or none at all, the latter being responsible for recognition of MHC-I molecules (Dietl et al., 1990; Marzusch et al., 1991; Chernyshov et al., 1993; for review see Loke & King, 1995). Recent data question the validity of these findings (Ruck & Marzusch, personal communication). This question is of particular importance since paternal peptides presented by trophoblastic HLA-G and HLA-C molecules, upon binding to T-cell receptors are likely to stimulate T-killer-cell-mediated lysis of the invading trophoblast cells.

The relatively low number of T cells in context with the absence of B cells at the site of implantation renders a classical allorecognition reaction of the trophoblast unlikely. This view is in agreement with the fact that the invasive trophoblast cells do not express classical polymorphic MHC I-molecules (see MHC Class I Molecules, above).

It is still a matter of debate why the number of T cells is reduced and B cells are completely absent from the implantation site:

- Inhibition of lymphocyte proliferation by macrophage-derived PGE<sub>2</sub> is one possible explanation (for review see Hunt, 1998).
- An additional attractive hypothesis has been presented by Munn et al. (1998): Indoleamine 2,3-dioxygenase (IDO) secreted by extravillous trophoblast catabolizes extracellularly tryptophan in the maternofetal junctional zone. Local microenvironments with reduced extracellular tryptophan concentration preclude lymphocyte proliferation and thus may protect the invading trophoblast cells from T-cell-mediated lysis. In accordance with this hypothesis, inhibition of tryptophan catabolism in pregnant mice resulted in rejection of the fetuses.
- Another possible mechanism to locally reduce the number of lymphocytes was published by Hammer and coworkers: Invasive extravillous trophoblast cells secrete Fas ligand (Hammer & Dohr, 2000; Murakoshi et al., 2003) and are thus able to stimulate apoptosis of lymphocytes expressing the Fas receptor. Respective clusters of apoptotic leukocytes were found in the implantation site (Hammer & Dohr, 1999; Hammer et al., 1999).
- Kruse et al. (1999) have analyzed the leukocyte homing events in the decidua basalis, in particular the expression of selectins in the decidual vessels. Their data suggest that selective expression patterns in decidual endothelium associated with microdomain specialization within the decidua basalis may be responsible for the selective access of leukocytes to the implantation site. For further review see Zhou et al. (2003a).

In spite of these local mechanisms to reduce the number of maternal lymphocytes in the implantation site, a considerable number of T cells, capable of attaching the invading trophoblast cells, locally persist throughout pregnancy. The functional role of such T cells at the implantation site in many aspects is still a mystery. Among other aspects, their paracrine activities have raised increasing interest (for review, see Hunt, 1998). The balance of two groups of T-helper-cell-derived cytokines is thought to control the maternal immune response against the fetal semiallograft (for review, see Robertson et al., 1994; Mosmann & Sad, 1996):

- T-helper type 1 proinflammatory cytokines (Th1-type cytokines) comprise IFN- $\gamma$ , IL-2, lymphotoxin, and TNF- $\alpha$ . They are known to activate cytotoxic T cells and are thought to exert adverse effects on trophoblast invasion.
- T-helper type 2 antiinflammatory cytokines (Th2-type cytokines) comprise IL-4, -6, -10, and -13. They are

known to stimulate antibody production by B cells and to support the differentiation of endometrial NK cells (see below), and they are thought to further trophoblast invasion.

Secretion of these cytokines is not specific for T-helper cells. Rather, macrophages also secrete TNF- $\alpha$  and uNK cells, as well as IFN- $\gamma$ . These data indicate that a complex cytokine network regulates the interaction of the immune cells at the implantation site (Marzusch et al., 1997). During normal pregnancy, the Th2-cytokines predominate. Their expression is stimulated by progesterone; by contrast, this hormone inhibits macrophage activation and TNF- $\alpha$  secretion. The action of Th1- and Th2-cytokines on trophoblast invasion is further controlled by endometrial NK cells (Hunt, 1998). Interestingly, invasive trophoblast cells share this type of immune response with invasive tumor cells (Mullen et al., 1998).

It is of particular interest that the course of autoimmune diseases often ameliorates throughout pregnancy but relapses after delivery (Beagley & Gockel, 2003). This raises the question as to the activation of general immunosuppressive mechanisms. As one such possibility Aluvihare et al. (2004) found an increase of regulatory T cells in pregnant mice. Regulatory T cells (CD4<sup>+</sup>CD25<sup>+</sup> cells) inhibit inappropriate activation of T- and B-cell responses. In mice the number of regulatory T cells increased generally from 3% to 5% of the T cell pool (nonpregnant) to 9% to 17% (pregnancy), and in the pregnant uterus even to 30%.

### Endometrial Large Granular Lymphocytes (Endometrial NK Cells and uNK Cells)

These cells have been well known for many years to occur at the implantation site and they were called "Körnchenzellen," K cells, or granular cells (Hamperl, 1954; Hellweg, 1957; Dallenbach & Dallenbach-Hellweg, 1964; Dallenbach-Hellweg, 1971). Today they are mostly called endometrial NK cells or uNK cells.

**Definition:** From a comparative point of view, uNK cells are equivalent to the granular metrial gland cells of rodents for which an abundant literature exists (Bulmer & Peel, 1977; Peel & Bulmer, 1977; Bulmer, 1983; Bulmer et al., 1983; Tarachand, 1985, 1986). The human endometrial large granular lymphocytes (LGLs) are regular constituents of all uterine implantation sites (Durst-Zivkovic, 1978) where they amount to about 40% in the first trimester (see Composition of Decidua. above). They are derived from the bone marrow and are closely related to NK cells (endometrial NK cells, uterine NK cells, uNK cells) (Pijnenborg et al., 1980; Bulmer & Sunderland, 1983; Dietl et al., 1992; Marzusch et al., 1993; for reviews, see Enders, 1991; Spornitz, 1992; Loke & King 1995; Whitelaw & Croy, 1996).

Histologically, they are rounded mononuclear cells of approximately 10  $\mu$ m diameter, with an eccentric, kidney-shaped nucleus. Their typical granular inclusions stain characteristically with phloxine-tartrazine (Pijnenborg

et al., 1980). Sengel and Stöbner (1972) gave a detailed ultrastructural account of these cells. Their appearance within the decidua does not depend on trophoblast invasion but rather is associated with the hormonal conditions of decidualization (Bogaert, 1975; Bulmer et al., 1988a; Pace et al., 1989; Sengupta et al., 1990). Correspondingly, the cells are also present in late proliferative and secretory endometrium.

**Surface markers:** The LGLs express CD56, a marker molecule of NK cells, but they differ from the majority of NK cells in peripheral blood by the absence of CD57 and CD16. Only 1% to 4% of the NK cells in peripheral blood show this CD56-positive, but CD57- and CD16-negative, phenotype, which is presented by virtually all endometrial large granular lymphocytes (Marzusch et al., 1995; King & Loke, 1997). This distribution has raised the question of which factors are responsible for the specific homing of uNK cells to the decidua. Hanna et al. (2003) have analyzed the chemokine receptor repertoire on various NK cell populations and found the receptors CXCR3 and CXCR4 preferentially expressed on CD16-negative NK cells. Moreover, they found the ligand of CXCR4, CXCL12, to be expressed by the invasive phenotype of extravillous trophoblast. These ligand-receptor interactions were suggested to be responsible for specific accumulation of uNK cells in the invasion zone. The fact, however, that in tubal implantation sites, despite the presence of invasive trophoblast cells, uNK cells do not accumulate (von Rango et al., 2001) suggests that CXCR4/CXCL12 interactions alone cannot be made responsible for specific decidual homing of uNK cells.

**Functional aspects:** Different from NK cells of the peripheral blood, endometrial NK cells (LGLs) show only moderate in vitro cytotoxicity against the NK cell-sensitive cell line K562 (Ferry et al., 1990). Accordingly, there has been considerable discussion about whether or not they represent NK cells (Watanabe, 1987; Manaseki & Searle, 1989; King & Loke, 1991; Dietl et al., 1992; Saito et al., 1993b; Welsh & Enders, 1993). Their denomination as uterine or endometrial NK cells reflects these differences. Also, the derivation of endometrial NK cells is not yet completely clear. Loke and King (1995) discussed their origin from a common progenitor cell giving rise to both T-cell and NK-cell differentiation.

The mRNA of a number of cytokines was detected in the endometrial NK cells, namely granulocyte CSF (G-CSF), granulocyte-macrophage CSF (GM-CSF), CSF-1, TNF- $\alpha$ , TGF- $\beta$ , leukemia inhibitory factor (LIF), IL-8, and IFN- $\gamma$  (Saito et al., 1993b, 1994; Jokhi et al., 1994d; Loke & King, 1995). Also, the presence of the proteins was confirmed for many of these cytokines (Saito et al., 1993b; Jokhi, 1994; for review, see Loke & King, 1995; Whitelaw & Croy, 1996).

**Interactions of endometrial NK cells with invading trophoblast cells:** The trophoblastic expression of the non-

classical, nonpolymorphic MHC molecules HLA-G and HLA-E, and of the less polymorphic HLA-C (see MHC Class I Molecules, above) is of special importance:

- Trophoblastic expression of the classical polymorphic MHC-I molecules (HLA-A, HLA-B) would trigger a T-cell-mediated immune response against the allohaploid invading trophoblast cells.
- On the other hand, nonexpression of HLA molecules would cause NK-cell attacks. Generally, surface expression of MHC-I molecules prevents NK-cell-mediated lysis of the respective cell (Ljunggren & Kärre, 1990).
- Thus, expression of minimal polymorphic (without individual specificity) HLA molecules by extravillous trophoblast is expected to prevent both T-cell-mediated classical host-versus-graft rejection (for review, see King et al., 1997) as well as susceptibility to decidual NK cell lysis. Indeed, Chumbley et al. (1994a,b) have shown reduction of NK cell-mediated lysis after HLA-G transfection into HLA-G deficient cell lines.

Endometrial NK cells not only recognize the presence or absence of class I molecules but also appear to be able to recognize some basic polymorphism in class I molecules, although they do not detect fine-polymorphic, individual specific differences like T cells (Loke & King, 1995; King & Loke, 1997). The NK cell receptors do also sense nonpolymorphic HLA molecules. These receptors belong to the p58 family of receptors and are now designated as killer cell inhibitory (or activating) receptors (KIR; KAR) (Gumperz & Parham, 1995; for review, see King & Loke, 1997). Human leukocyte antigen-G binding to KIR is thought to inhibit endometrial NK-cell action, whereas binding to KAR activates the endometrial NK cells. Recently it has been shown that prevention of uNK cell-mediated lysis of invasive trophoblast cells requires much more complex interactions than simply HLA-G or HLA-C expression. In addition to the latter two molecules, invasive trophoblast cells express the nonpolymorphic HLA-E; however, only those HLA-E molecules are exposed at the cell surface, which have bound a nonapeptide derived from the signal sequences of HLA-G or HLA-C. Lytic action of uNK cells against their target cell is only prevented by binding of this HLA-E complex to a dimeric uNK cell receptor (CD94/NKG2) (Borrego et al., 1998; Lee et al., 1998; Llano et al., 1998).

In contrast to the classical intramolecular variability of T-cell receptors, the cell-recognition repertoire of NK cells is defined by varying coexpression patterns of KIR- and KAR-like receptors on one and the same NK cell. In addition, besides HLA-G/C/E binding to uNK receptors, trophoblastic surface carbohydrates are thought to be recognized by additional NK-cell receptors (Yokoyama, 1995; for review, see King & Loke, 1997). The coexpres-

sion of nonpolymorphic HLA molecules jointly with cell surface carbohydrates may be responsible for inhibition or activation of NK cells and thus provides a mechanism for the control of trophoblast invasion. As discussed above, invasive extravillous trophoblast cells express respective cell surface carbohydrates, such as sialyl Le<sup>x</sup> and blood group antigen "i" (King & Loke, 1988; Frank et al., 1995; Huppertz et al., 1996).

With these findings taken together, evidence is accumulating that there is maternal allorecognition of the fetus by endometrial NK cells, ensuring immunologic protection but also control of the fetal allohaploid transplant (for review, see King et al., 2000). This trophoblast-related allorecognition is thus completely different from both the classical lytic NK-cell action and the T-cell-mediated host-versus-graft reaction. Activated endometrial NK cells are likely to exert paracrine actions on B and T cells as well as on macrophages, the latter again controlling the uNK cells. Such paracrine activities may provide the basis for yet unexplained phenomena such as

- the presence of T cells with an activated phenotype, but paucity of T cell receptors;
- the remarkably low number of B cells and plasma cells at the implantation site; and
- the absence of a significant local humoral response to secreted trophoblastic proteins.

## Macrophages

Maternal macrophages are regular constituents of each implantation site and can be demonstrated for instance immunohistochemically by antibodies to CD14 or CD68 (Bulmer & Johnson, 1984; Bulmer et al., 1988b; Vince & Johnson, 1996; Reister et al., 1999; see also Hofbauer Cells in Chapter 6). In spite of their regular presence in the implantation site, only a little is known about the role of macrophages in maternofetal interaction. The recent years have seen a concerted research effort toward the characterization of uNK cells, whereas decidual macrophages have attracted only a little attention.

Macrophages are capable of phagocytosing cellular detritus in the maternofetal battlefield and of clearing immune complexes. Moreover, they are known to be involved in many ontogenetic processes, preferably by paracrine interactions (Werb, 1983). Greater numbers of macrophages are found in the decidua basalis as compared to the decidua parietalis, where trophoblast invasion is limited. This may serve as a hint to so far uncharacterized interactions of trophoblast and macrophages (Oksenberg et al., 1986; Loke & King, 1995).

**Cytokines:** Generally, decidual macrophages produce and respond to a wide range of cytokines and thus may be involved in paracrine networks of the decidua, either

limiting or supporting trophoblast invasion (for review, see Hunt, 1990; Robertson et al., 1994; Loke & King, 1995; Kaufmann & Castellucci, 1997). They may be involved in infection-associated preterm labor (Hunt, 1989); when activated during inflammation, they produce high levels of PGE<sub>2</sub> and TNF, both of which can induce myometrial contractions. Moreover, PGE<sub>2</sub> has a profound inhibitory effect on lymphocyte proliferation (for review, see Hunt, 1998). Triggering of macrophage cytotoxin production has been shown to mediate early embryo loss in murine pregnancy (Baines et al., 1997). In vitro, macrophages have been shown to stimulate IFN- $\gamma$  secretion by uNK cells (Marzusch et al., 1997). Further, macrophage cytokines comprise stem cell factor, which is secreted by invading trophoblast cells. The corresponding receptor (c-kit) is expressed by decidual macrophages (Fig. 9.9A). This pattern raises the question of whether macrophages are attracted and activated by the invasive trophoblast (Sharkey et al., 1992, 1994). Another paracrine loop may be provided by the macrophage-derived VEGF; its receptor (flt-1) is expressed by extravillous trophoblast cells (Sharkey et al., 1993).

**Induction of trophoblast apoptosis:** Also, TNF- $\alpha$  is secreted by macrophages (Hunt, 1989; Todt et al., 1996; Pijnenborg et al., 1998). Its receptor (TNF-R1) is expressed by trophoblast cells (Yui et al., 1996). Interaction between TNF- $\alpha$  and the R1-receptor have been shown to induce trophoblast apoptosis in vitro (Yui et al., 1994). Similar data have been obtained when studying immortalized extravillous trophoblast (EVT) cells in vitro. These EVT cell lines express TNF-R1 (Reister et al., 2001).

We have demonstrated an inverse relation between the number of trophoblast cells in the wall of spiral arteries and the number of macrophages within the vessel wall (Reister et al., 1999):

- In normal pregnancy, the walls of spiral arteries are largely devoid of macrophages and become invaded by trophoblast cells.
- In preeclampsia, deficient arterial trophoblast invasion and increased numbers of apoptotic trophoblast cells around the uteroplacental arteries correlate with large numbers of macrophages in the arterial media. By contrast, in preeclampsia, the number of macrophages in the surrounding interstitium seems to be reduced (Burk et al., 2001).

The positive correlation between activated macrophages and apoptotic trophoblast cells is generally accepted; however, it is still a matter of discussion whether activated macrophages induce trophoblast apoptosis or whether, vice versa, trophoblast apoptosis provides chemotactic signaling for the attraction of macrophages. A later study by Reister et al. (2001) showed that activated macrophages induce apoptosis of invasive extravillous

trophoblast. This effect can only partly be abolished by the simultaneous administration of TNF-R1 antibodies. It therefore cannot exclusively be based on TNF- $\alpha$ /TNF-R1 interaction. Rather, induction of trophoblast apoptosis is a deleterious combination of (1) a TNF- $\alpha$  effect with (2) local tryptophan depletion by macrophage-secreted IDO (see Fig. 9.35).

Macrophage function is inhibited by high doses of progesterone. In particular, expression of iNOS and TNF are reduced (Miller et al., 1996; for review, see Hunt, 1998). This explains why progesterone is one of the many factors that supports trophoblast invasion.

## Glandular Residues

During decidualization, the endometrial glands initially enlarge and they can often be observed in the decidua of first trimester specimens (Fig. 9.15; also see Chapter 3, Fig. 3.1M). Their epithelium actively secretes material that is discharged into the lumen ("uterine milk"). When pregnancy ensues, the epithelial cell nuclei undergo endomitosis, become polyploid, and acquire the feature known as the Arias-Stella (1973) change. Ultimately, the glands atrophy although their remains can still be found in the basal plate and in the placental bed. Their regressive nature in these stages of pregnancy is also underlined by the absence of immunoreactivity for EGF (Hofmann et al., 1991). Due to the atypical structures of these residues they can usually be identified only by staining with immunohistochemical epithelial markers, such as cytokeratin (Bulmer et al., 1986) (see Chapter 3). However, it should be noted that disintegrating residual glands easily can be mixed up with uterine vessels as soon as the latter are invaded by trophoblast cells and their lumen is lined by cytokeratin-positive intraarterial trophoblast.

## Decidual Extracellular Matrix

Extracellular fibrillar material is characteristic of the decidual reaction. It is rich in laminins, collagens, heparan sulfate proteoglycan, and fibronectins (Wewer et al., 1985; Abrahamsohn & Zorn, 1993; Korhonen & Virtanen, 1997). Decidual cells are embedded in a network of type I and III collagens, and enmeshed with collagen V and fibronectins, all of which are produced by the decidual cells and their endometrial stromal precursors. Type IV collagen and laminin prevail in the immediate surrounding of decidual cells. Interestingly, the isoform pattern of laminins changes throughout differentiation; whereas undifferentiated stromal cells secrete preferably laminin 1, following decidualization the newly formed pericellular basal lamina is composed preferentially of laminins 2 and 4 (Church et al., 1996). Antibodies directed against

FIGURE 9.15. Early physiologic change in a spiral artery (bottom) in the placental floor of a normal 33-day twin pregnancy. Little of the Nitabuch's and Rohr's fibrin striae are present as yet. Anchoring villi attach with columns, and the intervillous space is lined mostly with syncytium. The basal plate decidua (pale cells) is densely infiltrated with extravillous trophoblast cells, and the arterial wall (bottom) has undergone fibrinoid necrosis. H&E  $\times 100$ .

osteonectin have shown that the surfaces of mature decidual cells stain heavily with this antibody and that young cells have this protein in their cytoplasm (Wewer et al., 1986).

Kisalus et al. (1987) showed club-shaped processes and secretory bodies on the cellular surfaces of decidual cells containing heparan sulfate that were exocytosed in a merocrine secretory fashion. From our own data we conclude that the ECM surrounding decidual cells is in many places similar in ultrastructure and in immunohistochemical composition to the ECM embedding the extravillous trophoblast cells, the matrix-type fibrinoid (see Fibrinoid, below). Both seem to represent accumulated, modified basal lamina material that is secreted in an unpolarized fashion (Frank et al., 1994; Huppertz et al., 1996). Interestingly, oncofetal fibronectins are found only in decidua that is invaded by extravillous trophoblast (Korhonen & Virtanen, 1997). This raises the question of whether expression of these isoforms reflects a decidual response to invasion or whether

their presence simply points to an admixture of trophoblastic ECM.

In spite of several specific features of both collagen V expression by decidual cells and i-glycosylated oncofetal fibronectins in extravillous trophoblastic ECM, it is still impossible to define the decidual or trophoblastic origin of every matrix component in the junctional zone where matrices derived from both sources intensely mix.

## Fibrinoid

### DEFINITION AND HISTORICAL REMARKS

Fibrinoid, first described by Langhans (1877), is one of the most prominent components of the human placenta. Accordingly, it has always played a remarkable role in placental pathology. It can be easily identified histologically (Figs. 9.16 and 9.17A). According to Grosser (1925, 1927) all placental material of solid consistency and not composed of cells, syncytium, or connective tissue that shows special affinity to acid stains represents fibrinoid (see Chapter 3, Fig. 3.2C,F,H,I). Its light microscopic appearance changes from glossy and homogeneous to lamellar, fibrous, or reticular. In paraffin sections, using hematoxylin and eosin (H&E), and depending on localization and staining conditions, the color of fibrinoid varies from slightly pink to intense red. When Mallory's connective tissue technique is used, the color is (ideally) a light blue but may vary from dark blue to lilac or even red.

The first attempt to clearly differentiate between "fibrin" and "fibrinoid" and to define the latter was made by Grosser (1925). He proposed that the term fibrin be used only for the precipitates of fibrinogen in blood and tissue fluids. Nonfibrous, noncellular, more or less homogeneous products in the placenta, derived from heterogeneous sources such as cellular secretion and cellular degeneration or of unknown origin, were to be described as being fibrin-like, that is, fibrinoid. Because blood clot and secretory products are usually deposited close together and cannot be easily discriminated with every histologic stain, we propose the more general term fibrinoid as appropriate for placental histology. The general use of the term fibrin is not justified.

The following typical localizations of fibrinoid have been described:

1. Fibrinoid at the intervillous surface of the chorionic plate (subchorial fibrinoid, **Langhans' stria**) (Fig. 9.1; also see Fig. 9.23)
2. **Perivillous fibrinoid** (Fig. 3.2H)
3. **Intravillous fibrinoid** (Fig. 3.2F)
4. Fibrinoid deposits in placental septa (Fig. 3.2K)
5. Fibrinoid of cell islands (Fig. 9.17; also see Chapter 3, Figs. 3.1G and 3.2J)
6. Superficial fibrinoid of the basal plate, facing the intervillous space (**Rohr's stria**) (Figs. 3.2I, 9.16)
7. Fibrinoid of cell columns (Figs. 3.2I and 3.4C,D)
8. Uteroplacental fibrinoid in the depth of the basal plate, where maternal and fetal cells come in close contact to each other (uteroplacental fibrinoid, **Nitabuch's stria**) (Fig. 3.2L)
9. **Intramural fibrinoid** of uteroplacental arteries and veins (Fig. 3.1L)
10. Fibrinoid in the membranes (chorion laeve) (Chapter 11, Fig. 11.1)

Unfortunately, most detailed histochemical, biochemical, immunohistochemical, and experimental studies have been performed at only one of these sites of fibrinoid localization. This selection may explain the considerable discrepancies concerning composition, proposed derivation, and functional interpretation. Immunohistochemical, biochemical,

FIGURE 9.16. Basal plate of mature placenta. Above is the intervillous space. The decidua is covered with Rohr's fibrin stria and "placental site giant cells"; basophilic extravillous trophoblast cells are diffusely scattered throughout the paler decidual cells. Atrophied glandular spaces and small maternal vessels are also present. H&E  $\times 100$ .

lectin histochemical, and ultrastructural studies have revealed that fibrinoid is composed of two subtypes that differ regarding genesis and composition (Frank et al., 1994; Lang et al., 1994; Huppertz et al., 1996; for review, see Kaufmann et al., 1996):

- Fibrin-type fibrinoid, which is derived from the coagulation cascade and mainly composed of fibrin;
- Matrix-type fibrinoid, which is a secretory product of extravillous trophoblast cells and mainly composed of collagen IV and glycoproteins of the extracellular matrix.

Generally, both subtypes can be found in all of the above-listed localizations, the only differences being varying proportions.

## Types of Fibrinoid

**Fibrin-type fibrinoid** histologically is a densely stained, partly fibrillar, partly net-like matrix (Fig. 9.17A). Ultrastructurally it is characterized by the presence of a dense meshwork of fibers measuring less than 10 nm in thickness, with the characteristic cross striation of fibrin filaments with an approximately 20 nm periodicity (Fig. 9.18). It never contains extravillous trophoblast cells. Immunohistochemically it shows intense reactivity with fibrin antibodies (Figs. 3.4C and 9.17B) that do not cross-react with fibrinogen (e.g., Immunotech fibrin antibody clone E8, directed against the  $\beta$ -peptide; Hui et al., 1983). Moreover, it contains plasma fibronectins. Typically, basal lamina molecules and interstitial matrix molecules such

as cellular fibronectins, collagens, laminins are absent. For further details see Frank et al. (1994). Furthermore, fibrin-type fibrinoid can be characterized by binding of *Ulex Europaeus* lectin (UEA-I), indicating a reaction with encased and disintegrated remnants of endothelial and blood cells that usually bind this lectin (Lang et al., 1994); *Bandeiraea simplicifolia* lectin (BS-I) and *Lycopersicon esculentum* lectin (LEA) do not stain this type of fibrinoid.

**Matrix-type fibrinoid** is characterized by the presence of single or clustered extravillous trophoblast cells (Fig. 9.17), surrounded by ample glossy extracellular matrix. It never stains with fibrin-specific antibodies (Fig. 9.17B), but it contains immunohistochemically detectable traces of fibrinogen. The most characteristic finding for matrix-type fibrinoid is its immunoreactivity for the basal lamina molecules collagen IV and laminin, as well as for cellular fibronectins, especially the oncofetal isoforms (antibodies BC-1 and FDC-6) (Fig. 9.17C) (Frank et al., 1994). Moreover, admixtures of merosin, a laminin-related protein (Leivo et al., 1989; Ehrig et al., 1990; Damsky et al., 1992), heparan sulfate and vitronectin (Castellucci et al., 1993; Huppertz et al., 1996), as well as of fibrillin (King & Blankenship, 1997) have been found. The presence of oncofetal fibronectins in the surrounding of extravillous trophoblast cells has already been reported before (Feinberg et al., 1991b; Feinberg & Kliman, 1993).

A

C

FIGURE 9.17. A: Semithin plastic section of a fibrinoid plaque attached to a cell island; toluidine blue staining. The right half of the picture shows the intensely staining, heterogeneous, partly filamentous structure of fibrin-type fibrinoid. To the left this is continuous with the mosaic pattern of partly densely stained, partly glossy matrix-type fibrinoid, embedding several extravillous trophoblast cells. Term placenta,  $\times 400$ . B,C: Serial cryostat sections of placental villi and of a cell island (below), 16th week p.m. B: Stained with an antibody directed against

oncofetal fibronectin; this matrix molecule can be found specifically in matrix-type fibrinoid that encases the extravillous trophoblast cells of the cell island (brown staining, lower half), but is largely missing in fibrin-type fibrinoid (light brown staining in the upper half). C: Stained with an antibody that detects fibrin but not fibrinogen; fibrin-type fibrinoid in a perivillous position is specifically stained (brown staining), but not the matrix-type fibrinoid of the cell island.  $\times 50$ .

FIGURE 9.18. A: Perivillous fibrin deposition on the trophoblastic surface of an obviously damaged villus (below). A maternal granulocyte (center) as well as several platelets (upper left corner) are attached to the bundles of fibrin.  $\times 9200$ . B: Higher magnification of fibrin-type fibrinoid from Nitabuch stria from the basal plate. The mixture of granular to fine filamentous material with larger bundles showing typical cross-striation is highly characteristic.  $\times 35,000$ .

According to the lectin binding studies of Lang et al. (1994), matrix-type fibrinoid is further characterized by the presence of binding with LEA and BS-I, whereas UEA-I does not bind.

Ultrastructurally, matrix-type fibrinoid shows a microheterogeneity (Fig. 9.17A). Three different patches of matrix are arranged around the cells in a mosaic-like pattern. These patches are characterized by the following matrix molecules (Huppertz et al., 1996, 1998d):

- Homogeneous, glossy patches are composed of heparan sulfate and vitronectin.
- Fibrillar patches are composed of various fibronectins embedded in heparan sulfate and vitronectin.
- Granular patches are composed of collagen IV and laminins.

Interestingly, in the more proximal invasive zone every large polygonal extravillous trophoblast cell, the main producers of matrix-type fibrinoid, has contact with any of these patches, the integrin distribution in its plasmalemma matching the extracellular distribution of matrix

ligands [see Extracellular Matrix Receptors (Integrins), above]:

- $\alpha 6 \beta 4$  integrins are always in contact with collagen IV and laminin patches.
- $\alpha 5 \beta 1$  integrins are expressed where the fibronectin patches face the plasmalemma.
- $\alpha v$  integrins prevail where the glossy matrix composed of vitronectins and heparan sulfate is apposed (Kertschanska et al., 1997). In the deeper invasive zones where small spindle-shaped trophoblast cells prevail, the integrin distribution within the plasmalemma does not necessarily match the distribution of the surrounding ECM molecules.

Colocalization of integrins and their respective matrix ligands seems to inversely correlate with the invasiveness of the trophoblast; missing colocalization in spindle-shaped trophoblast obviously reflects increasing invasive potential.

**Localisation of fibrinoid subtypes:** The quantitative proportions of matrix- and fibrin-type fibrinoids vary typically between the different locations:

Fibrinoid at the intervillous surface of the chorionic plate (subchorial fibrinoid, Langhans' stria)	Compact layer, facing the chorionic mesenchyme: matrix-type fibrinoid; reticular layer, facing the intervillous space: fibrin-type fibrinoid
Perivillous fibrinoid	Mostly fibrin-type fibrinoid
Intravillous fibrinoid	Highly variable mixture of both fibrinoid types
Fibrinoid deposits in placental septa	Variable mixture of both subtypes
Fibrinoid of cell islands	Superficially thin layers of fibrin-type fibrinoid; centrally around the extravillous trophoblast cells: matrix-type fibrinoid
Superficial fibrinoid of the basal plate, facing the intervillous space (Rohr's stria)	Fibrin-type fibrinoid
Fibrinoid of cell columns	Superficially, facing the intervillous space: fibrin-type fibrinoid; centrally, embedding the invasive trophoblast cells: matrix-type fibrinoid
Uteroplacental fibrinoid in the depth of the basal plate (uteroplacental fibrinoid, Nitabuch's stria)	Highly variable mixture of both subtypes with predominance of fibrin-type fibrinoid close to the separation zone
Intramural fibrinoid of uteroplacental arteries and veins	Mostly fibrin-type fibrinoid
Fibrinoid of the membranes (chorion laeve)	Within the trophoblast layer: matrix-type fibrinoid; at the trophoblast-decidual junction: fibrin-type fibrinoid

As a general rule, fibrin-type fibrinoid, derived from polymerization of blood fibrinogen, lines the intervillous space in all those locations where the syncytiotrophoblast layer is interrupted; moreover, it prevails in zones of contact between invasive trophoblast and decidua. It is always interposed between matrix-type fibrinoid and maternal blood. Matrix-type fibrinoid, a secretory product of extravillous trophoblast, embeds the postproliferative extravillous trophoblast cells and accordingly can only be found where trophoblast migration/invasion takes place.

### Origin of Fibrinoids

Fibrinoid has been shown to react with anti-fibrinogen antibodies in a variety of placental sites (Moe, 1969a,b,c; Gille et al., 1974; Faulk et al., 1975; Johnson & Faulk, 1978), a finding supported by the biochemical findings of Sutcliffe et al. (1982). According to our own experience with anti-fibrinogen binding, it is quite likely that most of the fibrinogen-positive deposits represented **fibrin-type fibrinoid**, even though some immunoreaction for fibrinogen can be found also in matrix-type fibrinoid.

There is no doubt as to the importance of fibrinogen for the formation of fibrin-type fibrinoid. According to Sutcliffe et al. (1982), local, extrahepatic synthesis of fibrinogen is unlikely. Rather, local activation of blood clotting factors must be considered. Indeed, some authors have found enzymes in human trophoblast and uterine cells that were antigenically similar to the blood clotting factor XIII and that were able to polymerize fibrinogen (Chung, 1972; Bohn, 1978).

The typical distribution of fibrin-type fibrinoid lining the intervillous space suggests its origin from maternal blood; however, one cannot exclude that fibrinogen derived from fetal plasma contributes to fibrinoid formation. In particular, in the villous tree, matrix-type fibrinoid is often encapsulated with fibrin from both the intervillous and stromal side, thus suggesting a derivation from both maternal and fetal fibrinogen.

The extracellular matrix molecules found in **matrix-type fibrinoid** are known to be secretory products of epithelial cells (Carnemolla et al., 1987). Castellucci et al. (1993), Hohn et al. (1993), Feinberg and Kliman (1993), and Frank et al. (2000) have provided evidence that also trophoblast cells secrete these matrix molecules. The oncofetal isoforms of fibronectin, containing the ED-B domain, are suitable marker molecules for matrix-type fibrinoid (Frank et al., 1994, 1995). The ED-B domain, which is detected by the antibody BC-1, is not present in plasma fibronectins (Carnemolla et al., 1989). Rather, it is expressed only in oncofetal fibronectins, which are secreted by some fetal and malignant cells, but usually not by normal adult epithelial cells (Carnemolla et al., 1989).

Collagen IV, laminin, heparan sulfate, and cellular fibronectin are secreted also by villous cytotrophoblast together with collagen VI in a polarized manner at their basal surface, constituting the basement membrane (Rukosuev et al., 1990; Castellucci et al., 1993; Nanaev et al., 1993a,b). As a consequence of highly active trophoblastic proliferation in cell columns and cell islands, some of the daughter cells lose the contact with the trophoblastic basal lamina. These extravillous trophoblast cells temporarily stop secretion of detectable amounts of matrix molecules (Castellucci et al., 1993). As soon as the cells are located three or more layers distal to the basal lamina, they start secreting ECM molecules anew, but in a non-polarized manner. At the same time they change their secretory pattern by replacing collagen VI with oncofetal fibronectins (Frank et al., 1994). The matrix molecules accumulate extracellularly as matrix-type fibrinoid, thereby embedding and separating the extravillous trophoblast cells (Figs. 9.4A and 9.9B).

Decidual cells secrete an ECM showing considerable similarities (see below). They have been shown to express various laminins (Church et al., 1996, 1997) and collagen IV (Mylona et al., 1995); moreover, secretion of

heparan sulfate proteoglycan by decidual cells into the surrounding fibrinoid has been described by Kisalus and Herr (1988). These findings raise the question of whether extravillous trophoblast is the only source of matrix-type fibrinoid or whether decidual cells also may contribute to it.

### Interactions Between Matrix-Type and Fibrin-Type Fibrinoid

Matrix-type fibrinoid virtually never directly faces the intervillous space; rather, it is always covered by highly variable amounts of fibrin-type fibrinoid. On the other hand, fibrin-type fibrinoid, in our experience, never directly is in contact with cytotrophoblast but rather is separated from the latter by matrix-type fibrinoid. This typical colocalization of both types of fibrinoid suggests that the processes leading to their deposition are linked to each other.

The interactions between fibrin deposition and secretion of matrix-type fibrinoid become particularly obvious in the case of perivillous fibrinoid. It is a common histopathologic finding that villous cytotrophoblast acquires an extravillous phenotype as soon as the covering syncytiotrophoblast is interrupted (Stark & Kaufmann, 1974). Detailed investigation of such areas has revealed that these denuded villous trophoblast cells rarely directly face the maternal blood. Rather, they encapsulate themselves in matrix-type fibrinoid, which is separated from the maternal blood by fibrin-type fibrinoid. The question remains open, whether fibrin deposition as a consequence of syncytiotrophoblast damage induces the extravillous phenotype with subsequent secretion of matrix-type fibrinoid or whether loss of syncytiotrophoblast causes extravillous transformation of the cytotrophoblast with subsequent apolar matrix secretion and induction of the coagulation cascade.

The presence of collagens, laminin, and fibronectins in matrix-type fibrinoid may represent a possible tie between the formation of both types of fibrinoid. Collagens (Kunicki et al., 1988), fibronectins (Piotrowicz et al., 1988), and laminin (Sonnenberg et al., 1988) are known to initiate coagulation by interaction with platelets (Coleman et al., 1987). Platelet antigens have been described in fibrinoid (for review, see Coleman et al., 1987; Faulk, 1989). Thus, it is likely that matrix-type fibrinoid, once secreted by cytotrophoblast, initiates the coagulation cascade and the formation of fibrin-type fibrinoid in all those positions where it is in contact with maternal or fetal blood. In addition, it cannot be excluded that proteases secreted together with the trophoblast-derived ECM directly initiate fibrinogen cleavage with subsequent fibrin deposition. Such atypical pathways of fibrin formation do not involve the coagulation cascade (for review, see Frank et al., 1994).

### Functions of Fibrinoid

It is no longer justified to classify fibrinoid merely as the result of degenerative processes caused by placental aging or altered blood flow and nutrition. Rather, most authors consider fibrinoid as an unavoidable constituent of the normal placenta (for review, see Fox, 1997). Several functional aspects are under discussion.

- Hörmann (1965) and Kretschmann (1967a,b) pointed to the mechanical importance of the **constructive principle**. Even though we believe that this aspect has never been studied in detail, it appears reasonable that perivillous fibrin, deposited on the stem villi, may increase their mechanical stability. In the same way, mechanically supportive effects can be attributed to fibrinoid deposits lining the chorionic and the basal plates.
- For matrix-type fibrinoid it has been suggested that it represents the “glue” that guarantees **adhesiveness** of the placenta to the uterine wall (Feinberg et al., 1991b; Frank et al., 1994, 1995). This type of fibrinoid occupies most of the interstitium between extravillous trophoblast and decidual cells; it contains several ECM molecules (e.g., fibronectins, laminins, collagens) (Frank et al., 1994; Huppertz et al., 1996) the cellular receptors of which (integrins) have been found in both the maternal and the fetal cells of the junctional zone (Korhonen et al., 1991; Damsky et al., 1992; Aplin, 1993). Matrix-type fibrinoid, which has a protein composition similar to that of basal laminas (pseudo-basement membrane, Aplin & Campbell, 1985; basement membrane-like layer, King & Blankenship, 1994b), may constitute a three-dimensionally arranged giant basal lamina to which all extravillous trophoblast cells and decidual cells of the maternofetal junctional zone are connected. Jackson and coworkers (1993) have added a partly contrasting view. They found that the production of oncofetal fibronectins by trophoblast cells in vitro was stimulated by inflammatory products (endotoxin, lipopolysaccharide) and by inflammatory mediators (IL-1 $\beta$ ). These substances are known to mediate labor by stimulation of prostaglandin secretion. The authors discussed secretion and metabolism of oncofetal fibronectin in relation to the initiation of preterm labor.
- Additional importance may be attributed to fibrin-type fibrinoid as the **regulator of the intervillous circulation** (Stark & Kaufmann, 1974; Becker, 1981; Kaufmann, 1981b). The intervillous space is an open, cleft-like communicating and continuously growing system. In the absence of a clearly defined vascular bed, problems in perfusion are to be expected during the establishment of its maternal circulation. One possibility for continuously adapting the shape of the intervillous space to the maternal blood flow is to obstruct all poorly perfused areas by clotting of blood and fibrinoid deposition. If one were to accept this mechanism, it is then only of

secondary importance whether this is achieved by hemostasis with subsequent coagulation or by trophoblastic malnutrition with subsequent syncytial degeneration and induction of fibrinoid deposition.

- The occurrence of fibrinoid at the maternofetal junction correlates with invasive placentation (Pijnenborg et al., 1981). This consideration has prompted several authors to discuss a functional role of fibrinoid as a **barrier to trophoblastic invasion**. The nature of this influence remains an open question. Badarau and Gavrilita (1967), Wynn (1967a), and Moe (1969a,b,c), have suggested that fibrinoid plays a role as a barrier to limit the invasiveness of the trophoblast. This was supported by findings from tubal pregnancies (Kawagoe et al., 1981). For a long time, one had to counter by suggesting that this conclusion is not in agreement with histologic findings: Considerable numbers of trophoblast cells can be found inside fibrinoid or even below Nitabuch's stria, sometimes even in the myometrium. Our recent findings, however, substantiate that the presence of trophoblast cells is related to only one subtype of fibrinoid, the matrix type. In contrast, the fibrin type is never invaded by extravillous cytotrophoblast (Frank et al., 1994) and may thus have the same barrier function against trophoblastic invasion that Dvorak et al. (1983) have suggested to exist for fibrin against tumor invasion.
- Aplin and Foden (1982) described a placental extract, called the "cell spreading factor," that contains fibronectin and fibrinogen. They speculated about its presence in the uteroplacental fibrinoid to restrict or perhaps even promote trophoblast migration and invasion. This was one of the first suggestions for the presence of **invasiveness-promoting activities**. Later this hypothesis has been further substantiated: Oncofetal fibronectins containing the ED-B domain are known to be present in both, the ECMs of malignant tumors (Carnemolla et al., 1989) and in matrix-type fibrinoid (Frank et al., 1994). This suggests interrelations of extravillous trophoblastic invasiveness with matrix-type fibrinoid. In cell columns, the invasive phenotype of the extravillous trophoblast correlates well with increasing amounts of matrix-type fibrinoid. Whereas fibrin-containing matrices have been discussed as acting as barrier against cellular invasion (Dvorak et al., 1983), the self-secreted matrix-type fibrinoid may provide the appropriate microenvironment for extravillous trophoblastic invasion. This assumption is supported by in vitro data: villous trophoblast explanted on ECMs (Matrigel) comparable to matrix-type fibrinoid achieve an extravillous phenotype and easily invade this matrix (Genbacev et al., 1993a,b,c; 1994; Vicovac et al., 1995a,b). The contrasting functions of matrix-type and fibrin-type fibrinoid described above may interact with each other. One example of this is the morphogenesis of the basal plate, where a barrier of fibrin-type fibrinoid is deposited continuously at the fetal surface. It possibly controls the invasion of trophoblast cells, which themselves secrete matrix-type fibrinoid as a supporting matrix along their invasive pathway.
- Perivillous fibrinoid is discussed as being a **barrier to maternofetal transport processes**. The integrity and completeness of the syncytiotrophoblastic surface of the villi is not perfect. Where the syncytiotrophoblast is interrupted by degeneration or by mechanical forces, the gap is immediately filled by perivillous fibrin (fibrin-type fibrinoid) resulting from the coagulation cascade. Corresponding fibrinoid spots are regular findings in every placenta. Such areas may serve as paratrophoblastic routes for maternofetal macromolecule transfer bypassing the syncytiotrophoblast: Horseradish peroxidase (48,000 d; 3.0-nm molecular radius) was shown to pass through the fibrinoid foci from the maternal circulation into the fetal stroma (Edwards et al., 1991). According to Nelson et al. (1990), these foci of perivillous fibrinoid account for about 7% of the villous surface of the normal human term placenta. They thus possibly provide an effective transfer route for macromolecules amounting to about 1 m<sup>2</sup> of villous surface.
- Matrix-type fibrinoid as well as connective tissue related to both types of fibrinoid shows varying degrees of immunoreactivity for tenascin (Castellucci et al., 1991; Frank et al., 1994). Tenascin is a mesenchymal glycoprotein that facilitates epithelial cell migration during development and is thus involved in many embryonic formative processes (Chiquet-Ehrismann et al., 1986; Aufderheide & Ekblom, 1988). Its presence suggests a **morphogenetic function** of fibrinoids during placental development. Nelson et al. (1990) found evidence that trophoblast-fibrinoid interactions modulate trophoblastic differentiation and proliferation and may be involved in reepithelialization of damaged villous surfaces.
- Most of the classical discussion regarding the functional importance of fibrinoid is related to its possible **immunologic significance**, with many authors discussing an immunologically protective function (Bardawil & Toy, 1959; Kirby et al., 1964; Currie & Bagshawe, 1967; McCormick et al., 1971; Azab et al., 1972; Faulk et al., 1975; Wynn, 1975). A particular immunoprotective role of sialic acid as normal constituent of fibrinoid has been stressed by Currie and Bagshawe (1967). This molecule may mask fetal antigens and thus prevent their recognition by maternal cells; moreover, it is thought to protect fetal cells from already sensitized maternal lymphocytes. It is known from several publications that experimental desialation of tumors by in vitro treatment with neuraminidase significantly increases their immunogenicity (for review see

Bagshawe & Lawler, 1975). Also, heparan sulfate proteoglycan, secreted by decidual and extravillous trophoblast cells into the surrounding uteroplacental fibrinoid (Kisalus & Herr, 1988; Huppertz et al., 1996, 1998d), has been suggested as a molecule that provides immunoprotection. A few publications have defined another immunoprotective function of fibrinoid, that is, its action as an immunoabsorptive sponge. This idea was first put forward by Swinburne (1970). He proposed that the fibrinoid expresses target antigens that bind circulating maternal antibodies, and the resulting immune complexes are then thought to contribute to the deposition of fibrinoid. The same concept was later favored by Chaouat et al. (1983) and by Hunziker and Wegmann (1986). Raghupathy et al. (1981, 1984) added two other findings that may be of interest in this context. They found that fibrinoid-bound antibodies are internalized and degraded within 4 to 6 hours and that the capacity of the antigen sponge is regenerated within 48 hours. Also, Montemagno (1967) opined that parts of the fibrinoid derives from antifetal antibodies. Further insight in this subject has been gained through the studies of Redline and Lu (1988). These authors showed that some of the molecules contained within the basal fibrinoid prevent macrophage movement, a subject that is fully discussed in the context of listeriosis (see Chapter 20).

## Trophoblast Invasion as a Result of Deciduo-Trophoblastic Interactions

Trophoblast invasion in normal intrauterine pregnancies is a tightly controlled process so that trophoblast cells normally do not penetrate beyond the inner third of the myometrium. The control mechanisms, however, are still poorly understood. It is tempting to speculate that controlled invasion is the well-balanced result of trophoblastic invasiveness and decidual defense mechanisms. This view is supported by pathologic findings: local deficiency of decidualization in tubal pregnancies as well as in placenta accreta and percreta usually coincides with enhanced trophoblast invasion. More recent analysis of the decidua-trophoblastic interactions, however, have revealed a much more complex situation characterized by mechanisms supporting and inhibiting invasion provided from both the trophoblastic and the endometrial side.

We have dealt with the various mechanisms separately for extravillous trophoblast, decidua, and ECM (fibrinoids) in the previous chapters. This chapter briefly summarizes the most important interactions between the various tissue components in the light of trophoblastic invasiveness (Fig. 9.19).

The following **trophoblastic features further its invasiveness**:

- Trophoblast cells leaving the basal lamina achieve an interstitial, apolar phenotype that enables the cells to become invasive.
- The invasive phenotype of extravillous trophoblast cells expresses fewer polymorphic (HLA-C) or non-polymorphic (HLA-G, HLA-E) MHC-I molecules, which enable the cells to escape lytic action of T cells and uNK cells.
- The early invasive extravillous trophoblast shows an apolar extracellular deposition of ECM just matching the distribution of integrins along its plasmalemma; this coordinated colocalization is thought to promote migration of the cells.
- Extravillous trophoblast cells are potential sources of relaxin, which is known to stimulate secretion and activation of MMPs by extravillous trophoblast, and to block the MMP inhibitors (TIMPs).
- Invasive trophoblast cells express a broad pattern of MMPs, which enable the cells to degrade the surrounding ECM.
- The ECM secreted by invasive trophoblast cells is partly “i”-glycosylated and thus less susceptible to degradation by proteolytic enzymes than unglycosylated endometrial matrices.
- Invasive trophoblast cells secrete IDO, which catabolizes and reduces extracellular tryptophan; since adequate microenvironmental concentrations of the latter amino acid are required for T-cell proliferation, T-cell-mediated lysis of invasive trophoblast is reduced.

The following **decidual activities promote trophoblast invasion**:

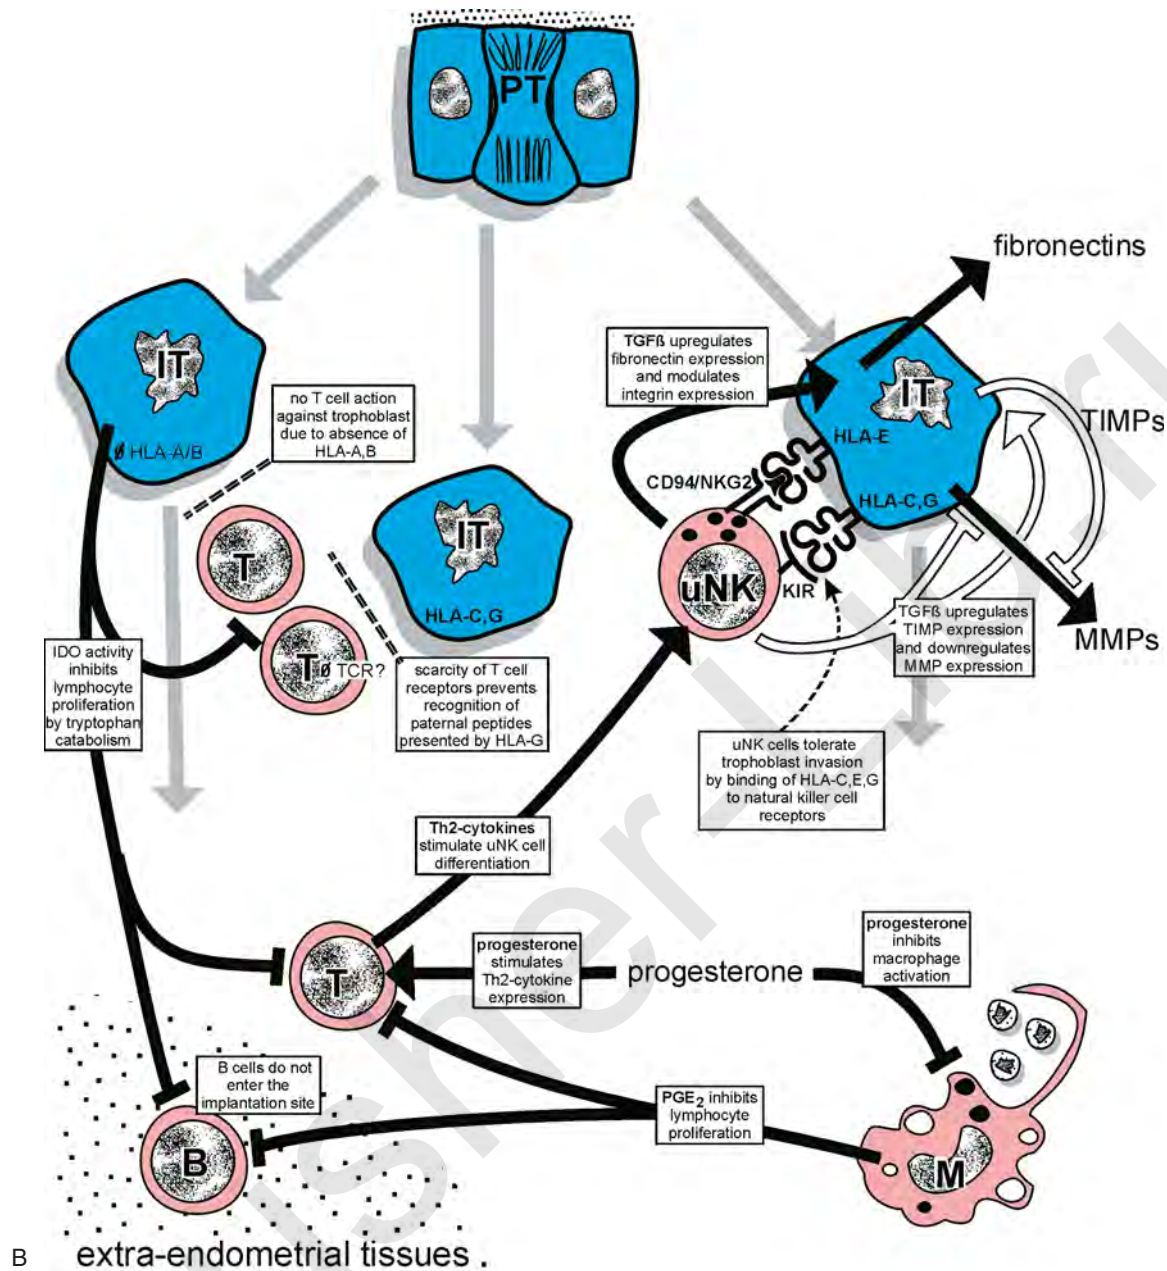

- Decidua cells are a likely source of relaxin, which is known to further MMP action (see above).
- Transforming growth factor- $\alpha$  (TGF- $\alpha$ ) secreted by decidua cells promotes proliferation of the stem cells of the extravillous trophoblast, which express the respective EGFR.
- Endometrial NK cells (uNK cells) have developed receptors (KIRs and the dimer CD94/NKG2) that upon binding to trophoblastic HLA-G, HLA-C, and HLA-E inhibit NK-cell-mediated lysis of the target cells.
- Different from other tissues, T cells at the implantation site possibly express reduced numbers of T-cell receptors (TCRs), which, in other tissues, are used for the host-versus-graft reaction. This reduction may help to avoid lytic action of T cells against extravillous trophoblast cells presenting paternal peptides bound to HLA-G and HLA-C.

The following **trophoblastic mechanisms limit its own invasiveness**:

- Invasive trophoblast cells secrete TIMPs, controlling activation of their self-secreted MMPs.

FIGURE 9.19. *Continued*

- With advancing pregnancy, increasing numbers of highly invasive spindle-shaped extravillous trophoblast cells polyploidize and transform into noninvasive large polygonal trophoblast cells.
- Deeply invasive trophoblast cells tend to aggregate and to fuse syncytially; the resulting multinucleated trophoblastic giant cells are thought to be noninvasive.

The following **decidual activities inhibit trophoblast invasion**:

- uNK cells deliver TGF-β, which downregulates MMP secretion but induces TIMP secretion.

- A subset of invasive trophoblast cells undergoes apoptosis, induced by macrophage-derived TNF-α and by macrophage-induced tryptophan depletion.
- Decidual cells express TIMPs, which inhibit activation of trophoblastic MMPs.

The above very incomplete list of parameters involved in the regulation of trophoblast invasion reveals that promotion and inhibition of invasiveness cannot be allocated to the fetal and maternal tissues, respectively. Rather, every cell type in the maternofetal junctional zone has developed both mechanisms supporting and inhibiting invasion,

resulting in an extremely complex but well-balanced control system. It is of particular interest to note that the immune response to malignant tumors shares many similarities with that to normal trophoblast invasion (Mullen et al., 1998). These similarities suggest that tumor invasion makes use of a kind of “immunologic window” that evolved during phylogeny of mammals in order to avoid host-versus-graft rejection of the allohaploid fetal tissues.

Calcification

The basal plate of the mature placenta often has finely divided deposits of calcium salts. They appear yellow and stippled and occur in irregular quantities. They may be detected by ultrasonography, and placental grading was popular in prenatal sonographic studies. In rhesus monkeys, the degree of calcification seems to be generally related to the stage of pregnancy (Bunton, 1986). Also in the human, immature placentas rarely have any significant amount of grossly visible calcification, whereas post-mature placentas often have a gritty sensation when the knife passes through the floor of the placenta. It is not a reliable sign of postmaturity, however, and sonographers have largely abandoned its grading. These calcium deposits occur not only in the placental floor but also within the internal structure of the placenta, generally accompanying the septa. Calcium deposits are blue in H&E preparations and, as seen in Figures 9.20 to 9.22, the calcium deposits occur principally within accumulations of fibrin/fibrinoid. Occasionally, one finds calcifications in degenerated villi (see Chapter 15). We have also seen a marked increase in calcification in immature placentas in patients with parathyroid adenomas.

The quantity of placental calcium has been studied chemically by Jeacock et al. (1963), who also reviewed the

older literature. These authors found the following calcium concentration in placentas:

Weeks of pregnancy	Mean concentration (mg/g dry tissue)
6–17	4.00
28–36	3.65
37–42	10.26
43–44	10.58

The increment found with postmaturity was small. Binovular twins did not always have the same concentrations. Patients with severe toxemia had higher values when they delivered prematurely but not at term. Still-birth had no effect and infarcts did not have a high calcium content. Rather than the calcium deposits reflecting placental “aging,” Jeacock et al. (1963) suggested that they serve fetal needs.

Fujikura (1963a,b) found that some 15% of placentas had moderate to marked calcification and that it tended to decrease with maternal age; it was most common (in the United States) in placentas delivered between November and February. Fox (1964), who found a significant relation to primigravidity, classified 25% of the placentas as calcified and saw no relation to postmaturity. He emphatically stated that calcification is in no way related to degenerative changes, but that fetal distress and neonatal asphyxia were more common with calcified placentas.

Brown et al. (1988) found by ultrasonographic studies that increased calcification of the placenta occurred in smoking mothers, irrespective of possible fetal weight reduction. When the placenta was studied by radiographic photography, 44% had slight, 30% moderate, and 2% severe calcification (Tindall & Scott, 1965). The manner of deposition varies (see also Hassler, 1969). The findings

FIGURE 9.20. Focal fibrin deposit on the villous surface (with central calcification: dark) covers trophoblast defect on the villous surface. Note that such lesions in the placenta never have any fibrous ingrowth; they do not “organize” in the sense used by pathologists. H&E  $\times 200$ .

FIGURE 9.21. Irregular calcium salt deposits (dark black) in mature placenta. The dark areas are syncytial buds (knots); the light gray areas (arrowheads) represent fibrin in the intervillous space. H&E  $\times 160$ .

of Tindall and Scott indicate that calcium deposits increase steadily from 29 to 43 weeks and that the amounts are related to placental and fetal weights. Placentas of stillbirths had generally less calcification. In contrast to the observations of Fujikura (United States), the placentas of Tindall and Scott (England) had more calcification when delivered from June to October. These authors made ref-

erence to possible physiologic mechanisms that regulate calcium deposition and did not consider the process to be a pathologic event. Russell (1969) found calcium deposits most commonly in the spring and fall and in younger mothers; interestingly, prosperous women also had more calcium deposits in their placentas. The overall incidence, based on radiographic findings, was 18% of placentas

FIGURE 9.22. Mineral salt deposits (arrows) in basement membrane of immature placenta from stillborn fetus. H&E  $\times 640$ .

after 38 weeks. Al-Zuhair et al. (1984) produced excellent scanning electron micrographs of irregular electron-dense attachments to the villous microvillous projections, but the inference that they are calcium deposits needs further proof.

In addition to the typical calcification that is grossly perceptible, the histopathologist often finds granular, purple deposits on the basement membrane of villous surfaces (Fig. 9.22). They have been described by Avery and Aterman (1971) and they are most common in abortions. We are uncertain that the purple granules that they found also in fibrotic villi truly represent calcium. Pathologists have a tendency to assume something to be calcium when it is amorphous, purple, and stains with the von Kossa reaction. The fact is, however, that there is no specific stain for calcium; phosphorus and carbonate salts of all sorts stain with the von Kossa reaction. The murexide stain may be an exception; it may stain calcium more specifically (Kaufman & Adams, 1957).

That such "calcified" basement membranes may represent largely iron deposits has been shown by Birkenfeld et al. (1989) in a patient with  $\beta$ -thalassemia major whose pregnancy came to term. Krohn et al. (1967) addressed the relevance of these deposits when they showed that pregnancies complicated by hydramnios had an unusually high (67%) deposition rate of "calcium" at the trophoblastic border. Iron and phosphates are intermixed and not readily separated by the usual methods. McKay et al. (1958) found it to be a feature of second-trimester placentas.

From chemical analysis, Einbrodt et al. (1973) ascertained that, in a large city, the **lead** contamination of calcium in the placentas had increased from 45% to 65% between 1956 and 1961. In addition to these deposits of minerals, **melanin** has been demonstrated in the basement membranes of villi and in Hofbauer cells (Ishizaki & Belter, 1960). With special stains, these authors identified melanin in 85% of the placentas they examined. It was present as often in Caucasians as in African Americans. They suggested that these deposits occur more frequently in association with chronic skin lesions and called the condition "dermatopathic melanosis of placenta." Melanin-containing macrophages in amnion have also been found in cases of prolonged amnion rupture (Bendon & Ray, 1986). Parmley et al. (1981) demonstrated the "aging pigment" **lipofuscin** in placentas beyond 32 weeks. They used fluorescence microscopy for its demonstration and saw it routinely in the trophoblast. In a discussion of that paper, Wynn remarked that one should not necessarily construe this finding as "aging." We agree with him and the many authors who believe that only maturation, not aging, occurs during normal gestation in placental tissue.

We have earlier stated that sonographers have used the presence of calcium and other structural features to

"grade" the placenta before birth (Hobbins & Winsberg, 1977). Their grades I to III have been correlated with fetal maturity, as judged by the sphingomyelin/lecithin (L/S) ratios (Grannum et al., 1979). These studies have often shown that placental grading is not accurate enough to diagnose pulmonary maturity without the determination of the L/S ratio (Harman et al., 1982; Petrucha & Platt, 1982). They are also not useful for delineating and monitoring postmature pregnancies (Hill et al., 1983; Monaghan et al., 1987) and have generally been given up. There has been a suggestion, however, that they may be useful to predict intrauterine growth restriction (IUGR) (Kazzi et al., 1983).

This chapter is not the place for a detailed review of maternal/fetal calcium relations. Thoughtful reviews have been provided by Pitkin (1975) and Tsang et al. (1976). It has been said that pregnancy induces a maternal "physiological hyperparathyroidism" (Pitkin et al., 1979). High maternal calcitonin levels of pregnancy protect the mother against bone loss (Garel & Barlet, 1978). During the third trimester the fetus requires 100 to 150 mg calcium/kg fetal weight/day for bone apposition (Tsang et al., 1976), and there is also evidence of placental production of vitamin D (Reddy et al., 1983). The paradox of higher serum levels of ionized calcium in the fetus than in the mother may relate to this finding. Despite many safeguards, abnormalities occur. Neonatal tetanus is not rare, particularly in premature infants, and may reflect secondary vitamin D deficiency (Rosen et al., 1974).

Although numerous investigations have been undertaken to clarify transplacental calcium/phosphorus transfer, none can be found that takes into consideration the simultaneous degree of placental calcium deposits. Are they related to homeostasis, or are they merely a reflection of dystrophic mineral deposits in extracellular matrix? Einbrodt and Schmid (1965) did not think that the excessive calcium deposits they found were the cause of an infant's death. They described two successive pregnancies with massive calcification of the placenta (20% to 30% in excess of the normal) in a woman with latent pregnancy tetany. The first pregnancy had been medicated to alleviate these symptoms; the second pregnancy was not treated, yet excessive amounts of placental calcium accumulated. It is not clear that this was the result of the disturbance in maternal calcium homeostasis. The authors cited another case from the literature with similar pathology but without tetany. They identified the placental mineral deposits as hydroxyapatite, not carbonate. The authors made the point that the excessive calcification was not due to mere fibrin absorption of calcium. At present, then, we do not understand the normal mechanisms that lead to calcification of the placenta, let alone when it attains seemingly pathologic quantities.

## Chorionic Plate

### DEVELOPMENT

The development of the chorionic plate begins with the formation of the primary chorionic plate. This process starts as soon as the first lacunae appear in the syncytiotrophoblast of the implanting blastocyst on day 8 p.c. (see Chapter 5). Initially, this layer is composed only of syncytiotrophoblast and cytotrophoblast. It separates the early lacunar system from the blastocyst cavity (see Chapter 5, Fig. 5.1C,D). As soon as the extraembryonic mesenchyme develops and spreads around the cytotrophoblastic surface of the blastocyst cavity (Fig. 5.1D), the primary chorionic plate becomes triple-layered, consisting of mesenchyme, cytotrophoblast, and syncytiotrophoblast. At the same time, the trophoblastic trabeculae that separate the lacunae start proliferating and form the first villous outgrowths into the continuously expanding lacunar system (Fig. 5.1D,E). The trabeculae are henceforth called the villous stems; the lacunar system is transformed into the intervillous space. From this stage onward, the chorionic plate represents the "lid" of the intervillous space and at the same time serves as the base from which the villous trees are suspended into the intervillous space.

The layering of the primary chorionic plate described above is maintained until term (Kaufmann, 1981a). Multifocal tissue degeneration with subsequent fibrinoid deposition, however, may considerably disturb its architecture. Fibrinoid deposits within and along the surface of the chorionic plate are called **Langhans' fibrinoid** (Langhans, 1877; Bourne, 1962). Those parts of the fibrinoid that replace tissues of the chorionic plate are usually compact and largely homogeneous in appearance. Toward the intervillous space, it becomes mostly covered by an inhomogeneous material, fibrin-type fibrinoid that is arranged in more or less net-like fashion. It is thought to be derived from blood clotting in the intervillous space (Bourne, 1962). The syncytiotrophoblastic cover of the chorionic plate is usually replaced by Langhans' fibrinoid, which occurs early in pregnancy.

In some places, the cytotrophoblastic layer also degenerates, whereas in other places it proliferates, resulting in multilayered plaques. These plaques consist of either compact **extravillous cytotrophoblast** or scattered trophoblastic cells surrounded by fibrinoid. The basal layer of cytotrophoblast, which rests on the chorionic mesenchyme, retains the characteristics of a proliferating layer of stem cells. Their highly differentiated, nonproliferative daughter cells (extravillous trophoblast cells) lose contact with the mesenchymal layer and migrate into the neighboring matrix-type fibrinoid. Here they grow in size and achieve the histochemical (Weser & Kaufmann, 1978) and ultrastructural (Wiese, 1975) characteristics of specialized, metabolically highly active cells. They are thus largely comparable to the invasive phenotype of extravillous trophoblast cells in other locations (Kaufmann & Castellucci, 1997).

With advancing gestation, numerous small and large **villi become attached** to the fibrinoid. Through coagulation of blood in their surrounding, and with subsequent transformation into fibrinoid, they may become deeply incorporated into the Langhans' fibrinoid layer. The original Langhans' cells of the incorporated villi commence proliferation following degeneration of their syncytial layer. They then transform into extravillous trophoblast cells, and migrate into the fibrinoid. In places that are devoid of such incorporated villi, the thickness of the chorionic plate rarely exceeds 200  $\mu\text{m}$ , whereas conglomerates of encased villi, together with their derivatives, may measure up to several millimeters in thickness.

The extraembryonic **mesenchyme** that has formed after day 9 p.c. initially completely occupies the blastocyst cavity (see Chapter 12, Fig. 12.1, day 13). During the course of the 3rd week p.c., the exocoelomic cavity is formed, reducing the extraembryonic mesenchyme to thin layers that cover the early embryo as well as the chorionic plate (Fig. 12.18, day 18). In the latter position it establishes the chorionic mesoderm. Toward the exocoelomic cavity, the mesoderm is lined by a single layer of flat mesothelium.

During the course of the 2nd month postmenstruation (p.m.), **fetal blood vessels** derive from the allantois via the connecting stalk and establish contact with the chorionic plate (Fig. 12.1; days 28 and 40). There they spread across the chorionic mesoderm and soon enter the early stem villi (Figs. 5.1F, 5.2, and 12.1). The vessels come into contact with locally formed fetal villous capillaries, resulting in the completed fetoplacental circulatory system. The chorionic fetal vessels soon enlarge to form arteries and veins. It must be pointed out that all these vessels pass the chorionic plate and thus connect the villous trees with the umbilical cord. Capillaries for the nutrition of the various tissues of the chorionic plate are a rare and locally very restricted exception.

At 17 weeks p.m. the amniotic vesicle has become so large that it comes into close contact with the chorionic plate (Grosser, 1927). At this time, the **amnion** is composed of an inner epithelial layer (amniotic epithelium) and an intermediate layer of amniotic mesoderm that, on its outer surface, is lined by amniotic mesothelium (see Chapter 11). Where amnion and chorion closely appose each other, their mesothelial layers slowly regress, resulting in mesodermal fusion. As in the membranes, this fusion is never perfect. Rather, it is a focal attachment, with the formation of net-like bridges between the layers (spongy layer). This structure establishes contact that allows easy gliding of the layers against each other. Attachment of the amnion to the primary chorionic plate transforms the latter into the definitive chorionic plate. Ample folding of the amniotic cover on the chorionic plate is a usual histologic finding (Fig. 9.23A). It is difficult to decide from histologic preparations how far they reflect the in vivo situation and how much is a consequence of the collapse of the amniotic vesicle after delivery because of the easy gliding of the amnion.

### Structure at Term

Only a few publications deal with the structure of the chorionic plate (Langhans, 1877; Grosser, 1927; Singer & Wislocki, 1948; Bourne, 1962; Boyd & Hamilton, 1970; Wiese, 1975; Weser & Kaufmann, 1978; Schiebler & Kaufmann, 1981). Studies that are especially devoted to the chorionic plate concern the cord insertion (Scheuner, 1964), the subchorial Langhans' fibrinoid layer (Geller, 1959), and the chorionic vessels (Nikolov & Schiebler, 1973). Aspects of its cellular composition have been studied twice, on the electron microscopic level by Wiese (1975) and histologically, including enzyme histochemistry, by Weser and Kaufmann (1978).

The layering of the term chorionic plate is consistent with that described during development. The following layers must be distinguished (Fig. 9.24) and are described in greater detail in the following sections:

- Amniotic epithelium
- Compact layer
- Amniotic mesoderm
- Spongy layer, separating amnion and chorion
- Chorionic mesoderm
- Proliferating cytotrophoblast
- Langhans' fibrinoid layer encasing the extravillous cytotrophoblast

### Amnion

The three layers of the amnion, that is, amniotic epithelium, compact layer, and amniotic mesoderm, are struc-

FIGURE 9.23. Paraffin sections prepared to compare the chorionic plate in earlier stages and later stages of pregnancy. A: At the 21st week p.m. B: At the 40th week p.m. The typical layering of the chorionic plate with amnionic epithelium (A), amnionic mesenchyme (AM), spongy layer (S), chorionic mesenchyme (CM), chorionic (extravillous) cytotrophoblast (C), and Langhans' fibrinoid (L) is evident at both time points. The main difference between the two developmental stages is the increased deposition of Langhans' fibrinoid below the chorionic plate near term. Clusters of extravillous trophoblast cells (X) and residues of buried villi (V) are typically incorporated in the mature Langhans' fibrinoid.  $\times 85$ .

turally largely identical with the respective layers described in Chapter 11. Bourne (1962) has given the most detailed review of these layers. Plaques of squamous metaplasia are common findings, especially surrounding the cord insertion. The usually columnar epithelium is here replaced by a squamous, keratinizing type. Sinha (1971) has dealt with this subject in more detail.

Wiese (1975) studied the arrangement of fibers in both connective tissue layers of the amnion by electron microscopy. The compact layer, devoid of cells, is composed of a condensed three-dimensional lattice of collagen fibers. The neighboring amnionic mesoderm differs in two aspects: vertical collagen fibers are lacking, and the remaining two-dimensional loose network is composed only of fibers that are arranged parallel to the amnionic epithelium. Three to four thin layers of filaments alternate with layers of loosely arranged fibroblasts, thus forming an incomplete irregular network. Kratzsch and Grygiel (1972) have histochemically demonstrated the existence

of diphosphoglucose dehydrogenase in these cells, an enzyme that is involved in the production of matrix proteoglycans. For further details see Chapter 11.

### Spongy Layer

The spongy layer (Bourne, 1962) has also been called the intermediate layer (Petry, 1954a,b), jelly layer (Dohrn, 1865), or stratum intermedium (Bautzmann & Schröder, 1955). The layer is structurally similar to the corresponding layer of the free membranes (Chapter 11). It is easier to study at the chorionic plate, however, because here it is less often dislocated by the forces of labor. The spongy clefts that separate amnion and chorion are normally less impressive. The clefts are partially lined by small, rounded cells, which, based on immunohistochemical studies, are likely to be residues of the former amnionic and chorionic mesothelium (Ockleford et al., 1993, 1994; Malak et al., 1993); the latter once lined the exocoelomic cavity

FIGURE 9.24. Layering and cellular composition of mature chorionic plate.

as the so-called Heuser's membrane, prior to fusion of amnionic and chorionic mesoderms.

### Chorionic Mesoderm

The chorionic mesoderm of the chorionic plate presents some peculiarities that have not been described in detail for the chorionic mesoderm of the membranes. Several authors (Scheuner, 1964; Wiese, 1975; Weser & Kaufmann, 1978) have described distinct layers, ranging from "oriented" connective tissue facing the spongy layer to "unoriented" connective tissue near the fibrinoid. In the unoriented layers, the collagen fibers seem to be irregularly arranged, with large polymorphic fibroblasts in between. The oriented layers, on the other hand, consist of thin strata with collagen fibers that are oriented in parallel. The layers are separated by small fibroblasts with long extensions and condensed nuclei. These authors suggested that the unoriented layers are the primitive precursors of the oriented layers, a suggestion that is sup-

ported by the fact that during early pregnancy the unoriented layers are more prominent (Fig. 9.23A).

Bertolini et al. (1969) reported the existence of smooth muscle cells within these layers, in agreement with results of Spanner (1935). Later studies, in particular the detailed electron microscopic investigation by Wiese (1975), did not support this finding. Many of the cells, however, display typical immunohistochemical features of myofibroblasts (see Chorionic Mesoderm in Chapter 11).

The oriented layers of the mesoderm comprise the site of the chorionic vessels, which originate by branching from the umbilical vessels. These vessels have been described in greater detail in Chapter 12 (see Placental Surface Vessels).

### Extravillous Cytotrophoblast

The chorionic mesoderm is followed by an incomplete basal lamina. A layer of extravillous cytotrophoblast is found on its other side. In the central parts of the pla-

FIGURE 9.25. Cryostat survey picture at the 40th week p.m. showing the chorionic plate (CP) with a branching-off stem villus (SV), numerous small villous branches, and a cell island (I). Because of the histochemical reaction for malate dehydrogenase applied to this section, amnionic epithelium, cytotrophoblast, and syncytiotrophoblast show intense staining, whereas connective tissue cells are only weakly stained. Note the immediate relation of the cell island to a large stem villus.  $\times 115$ . (Source: From Schiebeler & Kaufmann, 1981, with permission.)

centa, it is a discontinuous layer of small groups of cells (Figs. 9.24 and 9.25). Near the placental margin, it becomes continuous and is finally multilayered. The location at the exact mesodermal–fibrinoid interface is characteristic for these cells. Where several cells lie close together, their cell membranes show intense interdigitations. They are fixed to each other by desmosomes. Foot-like extensions, equipped with hemidesmosomes, connect the cells to the basal lamina. The latter is absent where the chorionic mesoderm directly faces the Langhans' fibrinoid without interposed cytotrophoblast. The basal ones of these cells present the germinative layer; still, at term, some of these cells can be stained by immunohistochemical proliferation markers (MIB-1, PCNA). Accumulations of proliferating cells up to multilayered groups in the marginal zone of the placenta (Arnold, 1975a,b) account for particular growth activities at the placental margin.

The chorionic plate trophoblast cells lining the chorionic mesoderm were thought in earlier publications to

represent a source for the differentiation of chorionic mesoderm (Hertig, 1935; Wislocki & Streeter, 1938). The histologic studies by Luckett (1978) and experimental findings in chimeric mice (Rossant & Croy, 1985), however, have clearly ruled out this possibility. All placental mesoderm is of fetal origin and invades the chorion.

### Langhans' Fibrinoid Layer

Langhans' fibrinoid layer is a rather constant feature, with a thickness and structure that increase continuously throughout pregnancy. In its early stages, the intervillous surface of Langhans' layer is still mostly covered by syncytiotrophoblast, which becomes completely replaced by additional fibrinoid during later pregnancy.

Abundant scattered or aggregated **extravillous trophoblast cells** can be seen in the fibrinoid. Ultrastructurally (Wiese, 1975), enzyme-histochemically (Weser & Kaufmann, 1978), and immunohistochemically the cells

are comparable to the invasive stages of extravillous trophoblast cells of other origin. The assumption by Bertolini and Klinger (1966) that these cells are decidual cells is no longer tenable but it has to be pointed out that sometimes decidual cells may be present in the chorionic plate, in particular near the placental margin (see below). They are the result of folding of basal plate tissue into chorionic plate tissue and can be interpreted as mild transitional stages toward placental circumvallation (see Chapter 13).

Nearly all earlier authors described the fibrinoid of the chorionic plate as normally composed of two distinct layers that differ in structure: a deep compact layer that, in the mature placenta, is nearly continuous and follows the chorionic connective tissue; and, where present, the chorionic cytotrophoblastic layer (Fig. 9.23). This compact fibrinoid represents **matrix-type fibrinoid** (Frank et al., 1994; Lang et al., 1994). It encases the extravillous trophoblast cells of the chorionic plate, which contribute to its growth by secretion.

This layer is usually covered by a second fibrinoid layer of more reticulated fibrinoid that corresponds immunohistochemically to **fibrin-type fibrinoid** (Fig. 9.23B) (Frank et al., 1994; Lang et al., 1994). The latter had been described as canalized fibrin by Langhans (1877).

The amount of subchorial fibrinoid at term varies considerably. According to our anatomic experience, it is impossible to define the amount that is compatible with normal pregnancy. Note, however, that the most impressive cases of subchorial fibrinoid deposition we have observed occurred in cases of Rh incompatibility. Here the Langhans' stria extended without identifiable demarcation into ample perivillous fibrinoid and numerous subchorial cell islands, occupying up to one half of the placental volume. The subchorial fibrinoid is the basis for the bosselations and the laminated subchorial plaques that vary so much from one placenta to another. The latter are deposits resulting from eddying in the places where the intervillous blood is turned back toward the basal plate.

At times, large **laminated hematomas** are found underneath the Langhans' fibrinoid. Such cases have been reported by Torpin (1960), Shanklin and Scott (1975), and Oláh et al. (1987), with the latter authors diagnosing it even during ultrasonographic examination. The 25 weeks pregnant patient they described suffered a falling hemoglobin level and a rapidly enlarging abdomen. A fatally ill premature infant was delivered by cesarean section. The circumvallate placenta weighed 700 g (28 weeks) and had a 15 × 5 cm laminated thrombus under the chorionic plate. This case is not unlike the classical Breus' mole (tuberous subchorionic hematoma) of earlier abortions, except for the sacculations that Breus delineated (1892). Although Breus thought that these sacculations developed after fetal death, Oláh et al. (1987) cited evidence that the hematoma may be primary, albeit a rare event. A somewhat similar condition was reported by Howorka

and Kapczynski (1971). In their patient, the hematoma was circumferential. It had disrupted the chorion laeve, much as in acute circumvallation. The authors included an interesting diagram that depicts their operative observations. It suggested to them that separate contractions, within sacculations of the uterine fundus were the basis for the detachment. More extensive consideration is given to these "thrombohematomas" in Chapter 11 (see Cysts, Tumors, and Hemorrhage).

## Marginal Zone

The marginal zone is not precisely defined. It consists of the transitional zone of the chorionic plate, the basal plate, and the membranes, and it has characteristics of all three regions. The internal margin, separating it by definition from the chorionic plate (Bühler, 1964), is the line connecting those points where the most peripheral branches of the chorionic plate vessels make their vertical bend to enter the most peripheral villous trees. The outer margin that separates it from the membranes represents the macroscopically visible transition from placenta to membranes (Bühler, 1964). It is largely identical with that line where the intervillous space is occluded by fusion of the chorionic plate with the basal plate.

## Subchorial Closing Ring

Macroscopically, the marginal zone is often represented by a slightly prominent opaque ring which is about 1 cm in width, the subchorial closing ring (Boyd & Hamilton, 1970). An increase in thickness of the marginal zone is represented by the designation "placenta marginata" (Kölliker, 1879). The transposition of the subchorial closing ring nearer to the cord, with origination of the membranes from the chorionic surface of the placenta rather than from the margin, is referred to as "placenta circumvallata" (see Chapter 13). In circumvallate placentas, the intervillous space, together with smaller villous trees peripherally, exceeds the marginal zone. A complete, macroscopically identifiable subchorial closing ring was described by Bühler (1964) in 71% of placentas studied; in 21% it was incomplete, in 8% it was absent.

The structures of the marginal amnion and the marginal chorionic mesoderm are comparable to those of the neighboring zones: chorionic plate and membranes (Arnold, 1975a,b). The structural basis for the prominence and the opaque appearance of the subchorial closing ring is the presence of both an increased number of extravillous trophoblast cells in the Langhans' fibrinoid and local accumulations of decidua cells (Arnold, 1975a,b). The latter usually form a hook-like extension of the basal decidua, which laterally surrounds the placental margin and protrudes into the Langhans' layer.

## Trabeculae

In histologic preparations of the marginal zone, rounded or elongated plaques of connective tissue or trabeculae become apparent. They are nearly uniformly scattered over the Langhans' fibrinoid and extravillous trophoblast layer. They must not be confused with the trabeculae of the early stages of previllous development. Krafft (1973) studied these structures in serial sections and was able to demonstrate convincingly that they are continuous on the one side with encased branches of the most peripheral villous trees. Their peripheral ends extend far into the membranes, where they end blindly at the decidual layer. According to Krafft (1973), they are residues of villous branches that have been incorporated into the marginal zone during regression of the chorion frondosum. They are thought to be important for the mechanical stability of the marginal zone and for anchoring the membranes to the placenta.

## Marginal Sinus

Large maternal veins exist near the placental margin that open into the intervillous space. This coincidence has caused intense speculation regarding the intervillous circulation of blood. Spanner (1935, 1941) described this as the "marginal sinus" and concluded that this sinus drains more or less all of the maternal intervillous blood into the uterine veins. Ramsey (1956) and Arts (1961) called it the "marginal lake." The beautiful studies of Ramsey (1956), Ramsey and Harris (1966), Ramsey et al. (1966), and Ramsey and Donner (1980) showed that this is indeed a prominent area of venous outflow, but also that it does not have the exclusive characteristics attributed to it by Spanner (1935, 1941). Numerous venous openings, scattered over the entire surface of the basal plate, offer sufficient venous drainage at the base of the placenta.

The wall of the initial part of the marginal uteroplacental veins is largely replaced by fibrinoid; in addition, numerous signs of cellular degeneration can be observed in the surrounding tissues (Arnold, 1975a,b). It has been speculated that it is the structural basis for the so-called marginal sinus hemorrhage (Schultze, 1953, 1968), as the peripheral decidual cover is very thin.

In the marginal zone of the placenta, the border between maternal veins and intervillous space is difficult to define for two reasons: First, maternal endothelial cells spread from the venous lumina deeply into the placenta, and there they usually line the intervillous surfaces of the basal and chorionic plates in the entire marginal zone (Nanaev et al., 2000a; see also Lang et al., 1993). Second, the smooth muscle cells of the venous media extend far into the placenta, forming a loosely arranged muscular ring around the placental margin (Nanaev et al., 2000a). This ring has an average width of some centimeters and

extends into both the basal plate and the chorionic plate. The functional meaning of this circumplacental muscular ring is still an open question. Based on the coexistence of maternal endothelium and vascular smooth muscle cells, one may argue that the intervillous space of the marginal zone ("marginal sinus") represents dilated venous openings. This view is in agreement with the finding by Craven et al. (1997) that lateral placental growth takes place by villous "invasion" into the marginal veins with subsequent widening of the maternal venous openings.

## Basal Plate

### TROPHOBLASTIC SHELL AND DEVELOPMENT OF THE BASAL PLATE

The basal plate is defined as the maternal aspect of the intervillous space. It is the most intimate and most important contact zone of maternal and fetal tissues (see Figs. 4.7 and 5.1F). The definitive basal plate is a highly complex structure. It is composed of various tissues, for example, extravillous trophoblast, endometrial stroma with its pregnancy-specific specialization, fibrinoid, residues of degenerating villi, and maternal vessels. General information concerning all of these tissues has been provided separately at the beginning of this chapter.

The early precursor of the basal plate is the **trophoblastic shell** (Fig. 9.26), a particular trophoblastic layer that, in the implanting blastocyst, separates the lacunar system from the endometrial tissues (Fig. 5.1C,D). Its development has been analyzed in detail in the rhesus monkey (Enders, 1995). Because of the intimate relationship between trophoblastic shell and the surrounding endometrium, the first steps in

FIGURE 9.26. Trophoblastic shell of 13-day pregnancy. The cytotrophoblastic columns are covered with syncytium. Placental site giant cells are intermingled with decidua (right). H&E  $\times 300$ .

the formation of the basal plate are coupled with the mechanisms of implantation (see Chapter 5).

Representing the invasive front of the blastocyst, the trophoblastic shell has an irregular surface that interdigitates intensively with the endometrial connective tissue. During early implantation the trophoblastic shell consists merely of syncytiotrophoblast. On day 13 p.c., cytotrophoblast reaches the shell via the trabeculae and splits the syncytiotrophoblast (Fig. 5.1D,E). Because of this, increasing amounts of cytotrophoblast come into contact with the endometrium. As typical sign of their invasive activity, these cells relinquish their closed epithelial formation and commence to invade the stroma as single cells or in small groups (Figs. 9.27 to 9.29; also see Fig. 5.1E,F). It is the first time at which an exact border—one separating the trophoblastic shell and the endometrium—can no longer be defined. An exactly dated, 22-day-old human specimen, described in detail by Larsen and Knoth (1971), illustrated this situation. From this date onward, the term trophoblastic shell is usually replaced by the term **basal plate**, a term that includes the base of the intervillous space together with all placental and maternal tissues that adhere to it after parturition.

The deeper tissue layers of the placental site, which remain in utero and are later discharged as lochia, show a similar admixture of maternal and placental tissues, the **placental bed**. In situ, the placental bed and basal plate cannot be delimited from each other because the demarcation zone becomes visible only shortly before delivery. Therefore, they together composed the **junctional zone** for in situ specimens. They encompass all regions of admixed maternal and fetal composition that lie basal to the intervillous space (Fig. 5.1F). Note that the term basal plate is applicable only to the delivered placenta.

During the first stages of pregnancy, **residual endometrial glands** are still visible in the deep parts of the decidua of the implantation site (see Chapter 3, Fig. 3.1M). So long as these remnants exist, trophoblastic invasion is largely limited to those parts of the compact and spongy layers of the decidua that overlie the glands (Pijnenborg et al., 1980). Only scattered trophoblast cells are found amidst the glands and they are only occasionally closely related to them. During the 15th to 18th weeks p.m., only occasional, isolated fragments of the glands are seen. Most are located in the lateral parts of the placental site, whereas in the central areas the glandular tissue is completely lost. The trophoblast invades the entire thickness of the decidua, down to the myometrium where glands are absent. One may speculate whether the existence of glands prevents trophoblastic invasion or the invasive activities of the trophoblast contribute to the destruction of the glands. We believe the latter to be more likely. Moreover, the prolonged presence of progesterone causes atrophy of the glandular epithelium during advancing gestation.

Much tissue necrosis occurs where maternal and fetal cells come close together. This degeneration has been interpreted as the consequence of proteolytic activity of the invading trophoblast. Large necrotic foci of the decidua in this region may also be a consequence of obstruction of spiral arteries. The necrotic residues of decidua and trophoblast are transformed into fibrinoid with a considerable admixture of fibrin being probable. Two layers of fibrinoid exist. **Rohr's fibrinoid** is a superficial, multiply interrupted, more or less focal layer. It faces the intervillous space (Figs. 5.1F and 9.27B), where it replaces the superficial layer of basal plate syncytiotrophoblast. By contrast, **Nitabuch's fibrinoid** is a layer of uteroplacental fibrinoid. As is expressed by its name, this layer is believed to mark the border of the placental and maternal tissues (Fig. 5.1F) and thus represents the immediate "battlefield" of the tissues (Kaufmann & Stark, 1971). Nitabuch's fibrinoid separates a superficial trophoblastic layer from a deeper decidual layer exactly in only few areas (Figs. 3.2L and 9.27B; also see Fig. 9.31). In other places, the cell types may be intensely intermixed on one or both sides of the Nitabuch layer. Finally, the order of layers can be inverted in exceptional cases, with the decidua nearer the intervillous space and the extravillous trophoblast cells making up the base of the basal plate.

FIGURE 9.27. Developmental stages of the basal plate, paraffin sections. A: At the 8th week p.m. The basal plate is composed of a dense mixture of extravillous trophoblastic and decidual cells, intermingled with a few trophoblastic giant cells (arrows). There is little fibrinoid (F).  $\times 75$ . B: At the 23rd week of gestation. The typical layering of the basal plate is evident. Facing the intervillous space, it is covered by an interrupted layer of Rohr's fibrinoid (R), followed by a nearly complete layer of extravillous cytotrophoblast (X). The latter is largely separated from the decidua cells (D) by a loose layer of Nitabuch's fibrinoid (N).  $\times 85$ . C: At the 37th week p.m. During the last trimester of pregnancy the typical layering of the basal plate is again abolished by trophoblastic cells and decidua cells penetrate the originally separating Nitabuch's layer in both directions. The result is a colorful mixture of fibrinoid and cells of maternal and fetal origin. A few cross sections of a fetal vein (V), lined by innocuous endothelium, can be seen.  $\times 85$ .

FIGURE 9.28. Implantation site of a 13-day human ovum to show the cytotrophoblastic cell columns (C), syncytium (S), intervillous space (IS) without maternal blood as yet and the decidua (D) with infiltrating trophoblastic elements. H&E  $\times 260$ .

**Growth of the basal plate**, laterally as well as in thickness, is largely a consequence of extravillous cytotrophoblast proliferation originating from cell columns. The migration of their daughter cells into tissues of the basal plate can readily be demonstrated (for review, see Extravillous Trophoblast, above). The lateral growth of the basal plate probably is not always accompanied by a corresponding degree of local distention of the uterine wall. This lack may cause a lateral movement and enhance the folding of the basal plate and the uterine wall over each other. Such folding processes result in the dislocation of basal plate tissues into the intervillous space, including all of its normal constituents. The placental septa are thus formed. Detached parts of the septa that are connected to the villous trees only by some interposed fibrinoid make up a subpopulation of the cell islands.

### Layers of the Basal Plate at Term

The mature basal plate is of variable thickness, ranging from 100 $\mu$ m to 1.5 mm. In most places it has lost its typical earlier layering (Fig. 9.27C; also see Fig. 9.31). Only rarely can all of the following layers be identified

in an undisturbed order (Hein, 1971; Kaufmann & Stark, 1971):

**Basal plate syncytiotrophoblast:** The inner surface of the basal plate, which faces the intervillous space, shows residues of the former syncytiotrophoblastic lining in only very few places. These areas are small patches of largely degenerative syncytium and an underlying cytotrophoblast is normally absent. Wanner (1966) reported the existence of **maternal endothelial cells** in the same location that were thought to be derived from the ostia of the uteroplacental veins. According to recent immunohistochemical studies, maternal endothelium lines not only large parts of the intervillous surface of the basal plate (Fig. 9.30; also see Fig. 9.37C,D) but also parts of the septa and of the marginal zone (Lang et al., 1993; Nanaev et al., 2000a). Where syncytiotrophoblast and maternal endothelium are absent, the basal plate is superficially covered by Rohr's fibrinoid.

FIGURE 9.29. Very young placental floor with villi (V) containing connective tissue but no fetal vessels as yet, syncytium (S), intervillous space (IVS) with maternal blood, and the confusing intermixed population of cells in the decidua basalis (DB). The placental site giant cells are largely mononuclear but dark, in contrast to the lighter decidual cells. H&E  $\times 40$ .

FIGURE 9.30. Extravillous trophoblast cells (dark cells) in decidua basalis of a near-term placenta. The arrow indicates a decidua stromal cell. The endothelial cells that are believed to line the basal portion of the intervillous space, above Rohr's fibrin layer, are indicated by arrowheads. H&E  $\times 240$ .

**Rohr's stria:** The superficial fibrinoid layer of the basal plate, Rohr's stria was first described in 1888 by Wolska as superficially located, homogeneous or lamellar material in the basal plate (Fig. 9.27B) that shows structural similarities to a deeper layer characterized 1 year earlier by Nitabuch (1887). A year later, Rohr (1889) dealt with this superficial fibrinoid in some greater detail, pointing particularly to the fact that the superficial fibrinoid layer is less complete and more irregularly structured. His name was later attached to this layer. Rohr's stria is basically similar to Langhans' stria of the chorionic plate. Where villi are attached, it is continuous with perivillous fibrin, engulfing these villi. In most places, Rohr's fibrinoid shows immunohistochemical characteristics of fibrin-type fibrinoid (Frank et al., 1994). Only where Rohr's fibrinoid encases extravillous trophoblast cells, usually in the neighborhood of cell columns, patches of matrix-type fibrinoid can be found that are free of fibrin and rich in other ECM molecules.

**Extravillous trophoblast layer:** The principal layer of the basal plate is highly variable in composition and thickness, measuring 50  $\mu\text{m}$  to 1 mm in thickness. It is composed of **extravillous cytotrophoblast**, patches of **fibrinoid**, loosely arranged **connective tissue**, admixed **decidual cells**, remnants of encased anchoring villi, and

"buried" cell columns. Most of the connective tissue of this region is of maternal origin. It is composed of endometrial stromal cells, small, highly branched fibroblast-like cells, and some macrophages. Because of the presence of maternal connective tissue in this layer, decidualization may also be present. Locally, there may be an admixture of fetal connective tissue cells that are derived from the stroma of encased and degenerating anchoring villi. Both lines of connective tissue cells can easily be distinguished by the application of the enzymatic histochemical reaction for leucine aminopeptidase. It results in positive staining of only the fetally derived connective tissue (Stark & Kaufmann, 1971).

A vast traditional descriptive literature deals in much detail with the structural, ultrastructural, histochemical, and functional aspects of the extravillous trophoblast cells of the basal plate (Wislocki, 1951; Ortmann, 1955; McKay et al., 1958; Thomsen & Willemsen, 1959; Weber, 1961; Dallenbach-Hellweg & Nette, 1963a,b, 1964; Wachstein et al., 1963; Hein, 1971; Kaufmann & Stark, 1971; Stark & Kaufmann, 1971). It has now become clear that these cells represent the largely nonproliferative, invasive portion of the extravillous trophoblast cells emanating from the cell columns (Schindler et al., 1984; Eidelman et al., 1989; Feinberg et al., 1989, 1991a; Loke et al., 1989, 1992a; Wakuda & Yoshida, 1990, 1992; Castellucci et al., 1991; Librach et al., 1991a,b; Damsky et al., 1992; Burrows et al., 1993; Fisher & Damsky, 1993; Mühlhauser et al., 1993; for review see Kaufmann & Castellucci, 1997). We refer the reader to the earlier section on Extravillous Trophoblast in this chapter.

The number of decidual cells present in this layer varies greatly. These cells may be absent or they can represent the majority of cells. For structural features of the decidual cells, see the section on Decidua. Cytotrophoblast and decidual cells may be intensively admixed (Figs. 9.2A and 9.28). According to Wynn (1967a), these cell types never establish direct intercellular contacts; rather, they are separated by fibrillar networks (external lamina of the decidual cells) (Kisalus & Herr, 1988), fibrinoid, or both. This finding is in partial disagreement with the results published by Hein (1971), who found the two types to be in intimate contact. The possibility of such contacts, even though established only occasionally in the human, is supported by findings in rats and mice (Martinek, 1970, 1971).

**Nitabuch fibrinoid layer:** The next layer of the basal plate is a fibrinoid layer (**uteroplacental fibrinoid**), which is a net-like to lamellar structure that is variably interrupted (Figs. 5.1 and 9.27B). It is located in the immediate maternofetal "battlefield" of the junctional zone (see Fig. 5.1). Because of this location, it has commonly been regarded as the site of immunologic processes.

This fibrinoid stria, first described by Nitabuch in 1887, is a rather consistent, more or less uninterrupted layer that is 20  $\mu\text{m}$  to more than 100  $\mu\text{m}$  in thickness. In many

places, the layer may split and rejoin, with trophoblastic and decidual cells or endometrial connective tissue interposed. In its most ideal, but rarely executed situation, Nitabuch's fibrinoid separates superficially positioned trophoblastic cells from more basally located decidual cells (Figs. 5.1 and 9.27B). In these cases, it marks the exact maternofetal border (Wynn, 1967a). Usually, however, the arrangement of maternal and fetal cells is more irregular. Mixed populations of the two cell types on one or both sides of the stria are the commonest finding (Fig. 9.31).

Electron-microscopically and immunohistochemically, Nitabuch's fibrinoid represents a mixture of both, matrix-type fibrinoid and fibrin-type fibrinoid (Frank et al., 1994; Lang et al., 1994; Huppertz et al., 1996, 1998d). Its biochemical analysis by Sutcliffe et al. (1982) showed a prevailing composition of proteins of 48,000 and 105,000d, thus corresponding to components of blood fibrin.

Whether other minor protein bands were of serum or local tissue origin remained an open question. In addition, Kisalus and Herr (1988) found immunocytochemical proof for a decidual secretion of heparan sulfate proteoglycan into the surrounding fibrinoid, and Frank et al. (1994, 1995) as well as Huppertz et al. (1996, 1998d) reported trophoblastic secretion of ECM molecules into it. According to the latter studies, those parts that encase extravillous trophoblast or decidual cells represent largely pure matrix-type fibrinoid. Cell free areas and in particular those layers that cover the basal surface of the delivered placenta are usually composed of fibrin-type fibrinoid. This explains why Sutcliffe et al. (1982) biochemically detected mostly blood clotting products because their material was derived from the basal surface.

Kirby et al. (1964) pointed to the interesting finding that large genetic differences between mother and fetus result in increasing amounts of uteroplacental fibrinoid.

FIGURE 9.31. Cryostat survey section of the basal plate. Enzyme histochemical proof of glucose-6-phosphate dehydrogenase. **The right half of the upper picture is a continuation of the left half of the lower picture. At the upper side of each picture one can see the intervillous space with numerous villi. The ability of the glucose-6-phosphate-dehydrogenase reaction to discriminate between extravillous trophoblast and decidua is used to illustrate the distribution of both cell types in the basal plate.**

The extravillous cytotrophoblast cells can be identified as darkly stained polygonal cells, whereas the decidua is composed of slender, faintly stained cell bodies. Note that there are segments of the basal plate with perfect layering (upper **right**) but also segments consisting merely of decidua (upper **middle**) or extravillous trophoblast cells (lower **left**). A colorful mixture of the two cell types is the most usual feature.  $\times 65$ . (From Stark & Kaufmann, 1971, with permission.)

Consequently, a functionally protective immunological mechanism was proposed. Bardawil and Toy (1959), Kirby et al. (1964), Currie and Bagshawe (1967), Azab et al., (1972), Wynn (1975), and Sutcliffe et al. (1982) suggested a barrier function that protects fetal antigens against identification by maternal cells so as to avoid direct contact of fetal tissues with sensitized maternal lymphocytes. In the same context, Sutcliffe et al. (1982) have pointed to the ample uteroplacental fibrinoid present in human and rodent placentas with invasive implantation, in contrast to the relative lack in artiodactyls and perissodactyls that are characterized by noninvasive implantation with largely intact maternal and fetal epithelial surfaces facing each other.

**Separation zone:** Demarcation and separation of the placenta from the placental bed usually does not take place within Nitabuch's stria, but rather in most cases somewhat deeper. Therefore, some additional tissues may be attached to the placental floor and form the deepest layer of the basal plate. Most cells in this layer are decidual cells and other components of the endometrial stroma, and a certain admixture of trophoblastic elements is a regular finding.

With increasing distance from the intervillous space, the number of multinucleated giant cells (Kölliker, 1861; Boyd & Hamilton, 1960; Hein, 1971; Pijnenborg et al., 1980) increases. These cells are large, highly differentiated, multinucleated elements with diameters up to 100  $\mu\text{m}$ . With the use of serial sections, they appear as slender, branching streamers with syncytial character (Boyd & Hamilton, 1960; Uhlenhuth & Kaufmann, 1979).

This layer is the site of placental separation, a mechanism that is not fully understood. Even when separation is a rapid process, taking place within a few minutes, it must be assumed that tissue changes precede its occurrence. From clinical findings it seems likely that placental separation depends on the existence of decidua at the placental site. Where a decidual layer is lacking, as with an extrauterine pregnancy or placenta accreta, the placenta cannot separate spontaneously. We believe that placental separation occurs primarily on a mechanical basis, the contracting uterus shearing off the turgid placenta at the site of degeneration. In specimens of delivered human placentas as well as of remaining placental beds, decidual changes can be observed morphologically in the future zone of separation. These changes comprise a reduction of collagen fibers, an accumulation of interstitial fluid, and many degenerative changes. Kaiser (1960) reported the preterm reduction in the thickness of the decidual spongy zone from an original 4 mm to 0.2 mm. After placental separation, both surfaces, those of the placental bed and the basal plate are covered by a thin layer of fibrin (Ludwig & Metzger, 1971). This was interpreted by these authors as being a peripartal or perhaps even postpartal phenomenon.

## Uteroplacental Vessels

### Development

The basal plate is traversed by maternal uteroplacental vessels. The uteroplacental arteries are branches or direct continuations of myometrial arteries. As soon as they enter the decidua and the basal plate, they are also called spiral arteries or spiral arterioles because of their spiral course (Fig. 9.32A). Some authors restrict the term spiral artery to the nonpregnant endometrium and rename the vessel after a placenta is established as the uteroplacental artery. In most publications the terms are used synonymously.

The first contacts between maternal endometrial vessels and the intra-placental lacunar system become established around days 11 to 12 p.c. (Boyd & Hamilton, 1970). At this time, the first maternal erythrocytes leave the eroded capillaries and enter the trophoblastic lacunae. For the human there is some doubt whether it results in an effective uteroplacental circulation. Boyd and Hamilton (1970) failed to find openings of spiral arteries into the intervillous space, even in the case of an embryo with 28 somites, which corresponds to the 28th to 29th day p.c. Their earliest specimen with such openings was around 40 days old (10 mm crown-rump length), while Harris and Ramsey (1966) have reported this situation to exist as early as day 30 p.c. (5 mm crown-rump length). Further classical studies concerning this crucial question are summarized in the large study of Harris and Ramsey (1966).

Doppler studies of the uteroplacental circulation have again stimulated the discussion. A provocative and challenging study with ultrasonography, histology, and barium injection of the maternal plate came from Hustin and Schaaps (1987), Hustin et al. (1988), and Schaaps and Hustin (1988). They had earlier observed that chorionic villous sampling (CVS) biopsies are always bloodless. They also found no echogenic evidence of intervillous blood flow before 13 weeks' gestation. Moreover, when they were able to observe the placenta in vivo during the first trimester it was pale, and barium could not be forced into the intervillous space. Furthermore, few maternal blood cells were ever observed histologically in this area. Hustin and Schaaps suggested that the intraarterial trophoblast so much obstructs the arterial lumen (Fig. 9.33) that only filtered plasma reaches the intervillous space before 12 weeks' gestation. Careful inspection of sections from such immature placentas (Figs. 9.12, 9.15, 9.16, and 9.33) shows indeed in many cases the lack of red blood cells in our cases as well.

This **hypothesis of delayed onset of an uteroplacental circulation** has raised a highly controversial debate (Moll, 1995; Hustin, 1995; Jauniaux, 1996; Carter, 1997) and stimulated new, more detailed studies. Enders and Blankenship (1997) showed patent uteroplacental artery lumina in the macaque placenta already in the first month of gestation, even though some arteries may become temporarily blocked; and in the same species, Simpson and coworkers (1997) noted maternal intervillous blood flow from day 20 of gestation onward. When reevaluating human first trimester hysterectomy specimens, Meekins et al. (1997) found maternal blood in the villous space in all stages; moreover, according to their data, total plugging of uteroplacental arteries is a rare event. Also, these authors concluded that uteroplacental circulation is not interrupted in the first trimester.

In the fall of 1997, on the occasion of the European Placenta Group Meeting the authors mentioned in the foregoing paragraph met in Vigsoe/Danmark and discussed their data obtained in human and monkey pregnancies. The members of this workshop reached agreement that the maternal circulation throughout the first trimester may be reduced by

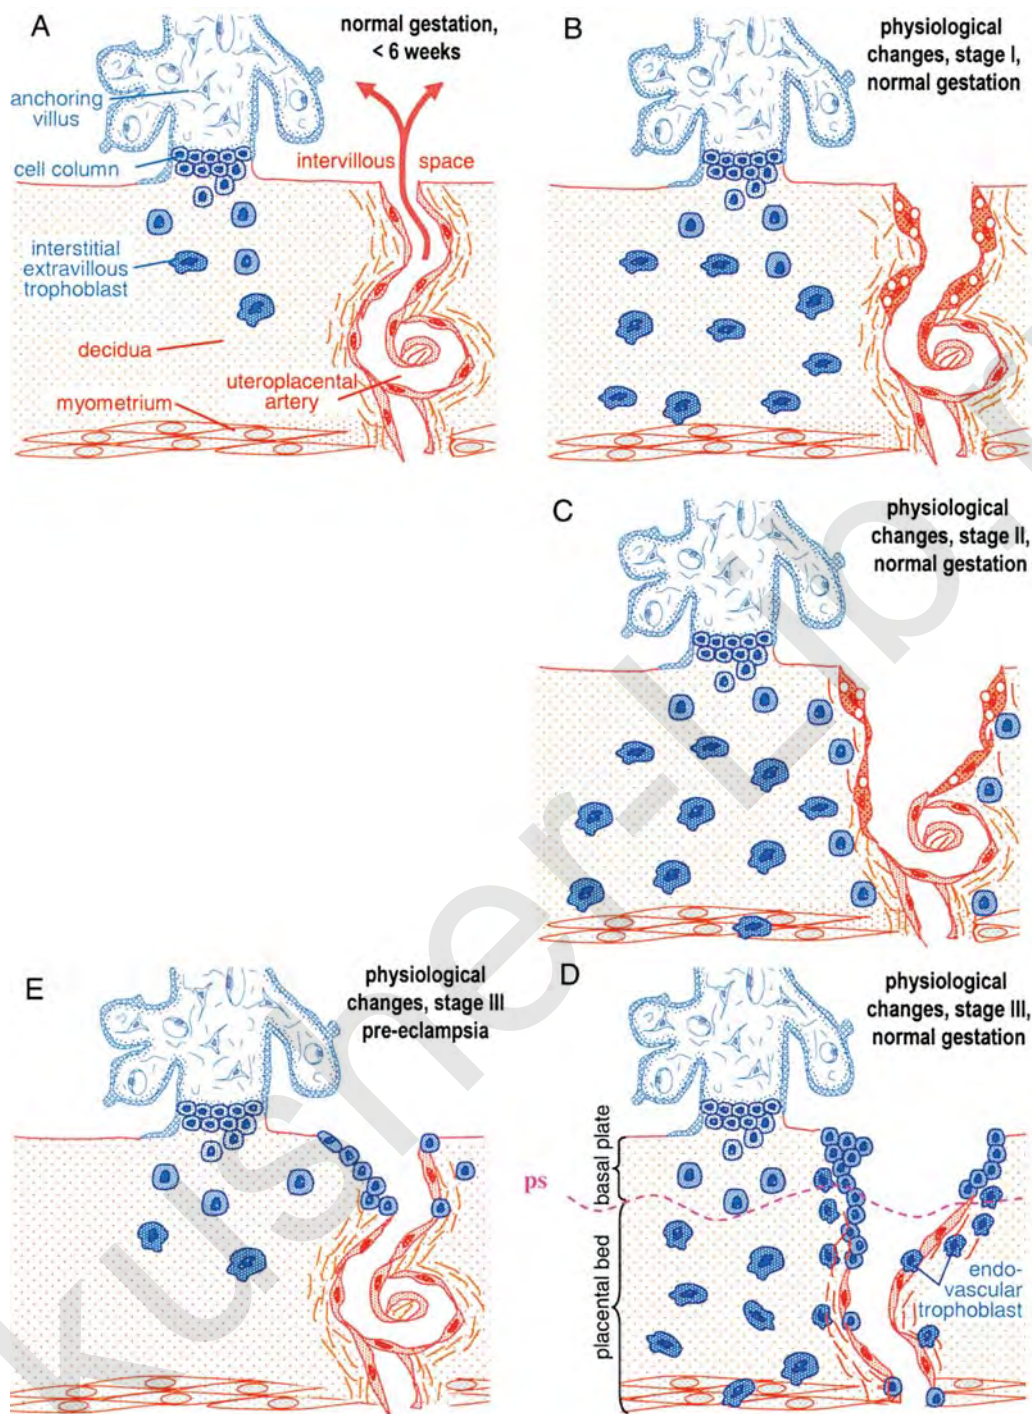

FIGURE 9.32. Schematic representation of interstitial and endovascular trophoblast invasion in human pregnancy. A: Before week 6 of gestation, the uteroplacental arteries are unaltered. B: Stage 1 of the pregnancy-induced physiologic changes of arteries is characterized by generalized endothelial basophilia, endothelial vacuolization, muscular disorganization, and slight lumen dilation. C: After appearance of trophoblast cells in the vascular surrounding, but prior to trophoblast invasion of the vascular walls, in stage 2 of vascular changes, maximum arterial dilatation occurs. D: Only in the final stage of pregnancy-induced changes of uteroplacental arteries, smooth muscle cells and

endothelium of the already maximally dilated arteries are replaced by trophoblast. E: Note that failure of endovascular trophoblast invasion in intrauterine growth restriction (IUGR) and preeclampsia is restricted to the placental bed and does not affect segments of the uteroplacental arteries in the later basal plate of the placenta. Blue, fetal tissues; red, Maternal tissues; ps, zone of placental separation where the basal plate (above, attached to the placenta) separates from the placental bed (remaining in the uterus after delivery). (Source: Modified and extended from Kaufmann et al., 2003, with permission.)

FIGURE 9.33. Arteries in the basal plate in the same placenta as in Figure 9.15. Note the fibrin in the wall, whose muscular coat is destroyed; the vessels are surrounded and thoroughly infiltrated by extravillous trophoblast cells. The paler cells at the bottom are decidual stromal cells; endometrial glands are at bottom right. H&E  $\times 160$ .

partial plugging of the arteries but that it never is completely interrupted. This consensus is in agreement with the low oxygen partial pressures measured in the intervillous space throughout the first trimester; only from week 13 p.m. onward the  $pO_2$  values were raised (Rodesch et al., 1992). These data have interesting implications; for instance, is relative hypoxia an important modulator of trophoblast behavior controlling the balance between proliferation and invasion (Genbacev et al., 1996, 1997)? (See Oxygen-Mediated Regulation of the Invasive Pathway, above.)

The uteroplacental arteries cross the uterine wall almost perpendicularly up to the 8th week p.m. (Pijnenborg et al., 1980). With advancing gestation, as the placental area enlarges, the course of the peripheral arteries becomes more oblique, so that by 10 weeks distal segments are almost parallel to the basal plate. Invading trophoblast breaches these horizontal segments to form new openings into the intervillous space (Harris & Ramsey, 1966). Alteration of the blood flow, which is caused by these new openings, was thought to be the consequence in the most distal segments. Degeneration of the latter can be followed by necrosis of the surrounding decidua. This finding is common in the periphery of the placental site between 8 and 14 weeks of pregnancy. In most instances, obliterated arterial segments can be found within the areas of necrosis. Trophoblastic invasion of the necrotic areas is reduced (Pijnenborg et al., 1980).

The number of spiral arterial turns appears to decrease throughout pregnancy. Intense spiraling, with formation of large loops directly beneath the basal plate, may result in up to seven openings, one after the other, in consecutive loops of one and the same spiral artery. On the other hand, multiple openings of one artery can also be produced by branching in the superficial layers of the basal plate. Both are common findings in early placentas. Near term, most of these additional openings and branches are apparently obstructed by blood clots, resulting in the final finding of one opening per artery. Some smaller branches, arterioles, and venules, may branch off in the deeper layers of the junctional zone and in the superficial myometrial layers. They are nutritional vessels that result in only poorly developed capillary nets.

### Number and Position of the Uteroplacental Vessels

Comparative studies of the maternal circulations of rhesus monkey and human placentas have shown that they are similar. Thus, appropriate deductions can be made from observations in monkeys (Freese, 1968). It is remarkable that, after all these studies, we still do not know the **number of spiral arteries** that perfuse the placenta. Panigel and

Pascaud (1968) reviewed the topic; they wrote that in 1890 Klein found 53 arteries and 31 veins, whereas Spanner in 1934 and 1935 counted 80 to 90 arteries with 488 openings! Franken (1954) described 263 arterial and 79 venous openings. Marais (1962) counted 105 arterial ostia, Reynolds (1966) 40 to 50, and Boyd (1956) 102 to 156 at the end of the first trimester, and about 180 to 320 at term. Brosens (1988) reported 120 spiral arteries for the term placenta, each with a single opening. In contrast to Boyd's observations, Harris and Ramsey (1966) found decreasing numbers of arterial inlets during the course of pregnancy. The final density of arterial openings at term was reported to be one per square centimeter of basal plate surface (Harris & Ramsey, 1966) or 0.5 per square centimeter (Brosens, 1964). Haller (1968) found some 200 to 300 vascular openings in the floor of the delivered placenta; he described their morphology and stated that it was difficult to differentiate between arteries and veins. These conflicting data reflect the methodologic problems when identifying and counting such highly coiled and branched structures. Fewer figures have been given for the **number of venous openings**. Most authors agree that their number is considerably lower than that of the arterial ostia (Franken, 1954; Gruenwald, 1966; Boyd & Hamilton, 1970). All these numbers are in disagreement with those of Borell et al. (1965), who, in cineradiographic studies of pregnant women, observed 25 arteries at term. These authors cautioned that erroneous enumeration of placental lobules causes false numbers of arteries.

Regarding the **position of uteroplacental vessels**, many authors now agree that a single decidual spiral artery delivers its blood into the center of a cotyledon, and on occasion lateral vessels add to the supply. This fact has been amply demonstrated by the injection studies of Freese (1968), Freese and Maciolek (1969), Wigglesworth (1969), Panigel and Pascaud (1968), Schuhmann and Wehler (1971), and Schuhmann (1981). Only Gruenwald (1966), Nikolov and Schiebler (1973), and Brosens (1988)

came to different conclusions. The latter authors found the arteries to open in the periphery of the cotyledons, at the base, or in the lower one third of the septa. The venous openings are thought to be in a more peripheral position of the cotyledons, which is in contrast to the views presented by Spanner (1934, 1935), who concluded that the intervillous venous blood is mainly drained via the marginal venous sinus. This opinion, in turn, has been contradicted by Arts (1961), who found the venous openings more evenly distributed over the basal plate.

It must be pointed out that the idealized arrangement, with one artery opening near the center of a villous tree (see Intervillous Space as Related to the Villous Trees in Chapter 7), is rare. It is seen only at the placental periphery, where the average diameter of the cotyledons or lobules is small. Here the numerical relation of villous trees to basally visible lobes is 1 : 1 (see Chapter 2, Fig. 2.2). Larger lobules, in particular those of the more central parts of the organ, normally contain two to four villous trees that usually overlap partially at the margin (see Figs. 2.2 and 7.26). Here the position of vascular openings, as they relate to the villous trees, is more confusing, and this fact may have contributed to the above controversy.

The villous tissue within the central cotyledonary region, where the maternal “jet” enters, is usually composed of larger, more immature appearing villous types. Here they are separated by wider intervillous clefts (Schuhmann & Wehler, 1971; Schuhmann, 1981; Kaufmann, 1985) (see Fig. 7.26). This can be easily seen when a fresh placenta is sectioned. The area shows apparently empty spaces—the central cavities (Ramsey, 1962; Ramsey et al., 1963, 1966; Gruenwald, 1966, 1971, 1973; Freese, 1968). Wigglesworth (1969) considered this area to be the site where intervillous thrombi most commonly occur, and we agree. Most intervillous thrombi are fresh and apparently result from local stasis of blood flow during labor. At times one can see that their triangular shape originates from vessels in the placental floor. The villous architecture is draped around these central cavities. Serial roentgenographic studies, with injection of radiopaque dyes, demonstrate them adequately. After these spaces are filled, the radiopaque material is dissipated peripherally, producing the familiar and oft-mentioned “smoke rings” (Freese, 1968).

### Importance of Physiologic Changes of Uteroplacental Arteries

The trophoblastic invasion of the uteroplacental arteries and the subsequent alterations have been designated as physiologic changes to distinguish them from the pathologic changes seen in the placental bed vessels of patients with IUGR and preeclampsia (Brosens et al., 1967). The process has been succinctly reviewed by Ramsey (1981), Brosens (1988), and Sheppard and Bonnar (1988).

Trophoblast invasion of uteroplacental arteries with respective physiologic changes is seen in many other species with invasive placentation and is considered to have important ramifications for ensuring placental perfusion. In the course of this process, the spiral arteries are remodeled into low-resistance vessels that are unable to constrict. Because of the absence of local regulatory mechanisms in uteroplacental vessels, the mother cannot reduce the nutrient supply to the placenta without reducing nutrient supply to her own tissues (Haig, 1993).

The physiologic changes according to Brosens et al. (1967) include (1) apparent replacement of endothelium and media smooth muscle cells by invasive trophoblast; (2) loss of elasticity; (3) dilatation to wide, incontractile tubes; and (4) loss of vasomotor control (Fig. 9.32A–D).

The purposes of pregnancy-specific spiral artery remodeling are threefold:

- Maternal blood flow resistance is reduced and uteroplacental perfusion is increased to meet the increasing nutritional requirements of the fetus.
- The loss of contractility and loss of maternal vasomotor control guarantees maximum maternal blood supply to the placenta, irrespective of maternal attempts to regulate the blood distribution within her own body (Moll et al., 1988).
- As already described earlier (see Myofibroblasts in Chapter 6), local loss of maternal vasomotor control enables the fetus to gain control over maternal blood flow resistance and blood flow distribution within the intervillous space.

Deficiency of physiologic changes of the spiral arteries (Fig. 9.32E) has been demonstrated to be abnormal (Feinberg et al., 1991a). It represents a significant characteristic of preeclampsia and of hypertension during pregnancy; it is also typically associated with fetal growth retardation (Brosens et al., 1972, 1977; Sheppard & Bonnar, 1976; deWolf et al., 1980; Brosens, 1988). Khong et al. (1986a) and Sheppard and Bonnar (1988) have even reported complete absence of such physiologic change throughout the length of some of the spiral arteries in cases of preeclampsia and IUGR.

### Stages of Physiologic Changes in Uteroplacental Arteries

Different from earlier views, it is important to note that trophoblast invasion of the arteries is not the primary event, which is responsible for all other pregnancy-specific alterations of the arteries; rather, most of the changes happen already prior to or concomitant with trophoblast infiltration. Trophoblast cells invade already severely altered, physiologically changed arteries. According to structural criteria, physiologic changes of uteroplacental arteries can be subdivided into three subsequent stages:

**Stage 1: Vascular changes preceding trophoblast invasion** (Fig. 9.32B): The initial arterial changes involve a generalized endothelial basophilia and vacuolation, disorganization of vascular smooth muscle, and lumen dilation (Craven et al., 1998). These changes are independent from direct trophoblast invasion and are considered to involve maternal activation of local decidual artery renin-angiotensin systems (Craven et al., 1998). The same authors demonstrated that during intrauterine pregnancies spiral arteries from both implantation and nonimplantation regions display these physiologic changes. Last but not least, in ectopic pregnancies endometrial spiral arteries undergo the same physiologic vascular modifications.

**Stage 2: Vascular remodeling induced by perivascularly located extravillous trophoblast** (Fig. 9.32C): Only after the appearance of the trophoblast invasion-independent changes, the uteroplacental arteries within the implantation region are invaded by extravillous trophoblast cells. As soon as extravillous trophoblast cells approach the uteroplacental arteries, further vascular remodeling starts. This has been analyzed in detail in the guinea pig (Hees et al., 1987; Moll et al., 1988; Nanaev et al., 1995). This second set of changes comprise reduction of media smooth muscle cells and deposition of fibrinoid material prior to infiltration of the media by trophoblast. The question came up as to the mechanisms that drive this second group of changes. Nanaev et al. (1995) analyzed arterial trophoblast invasion in the guinea pig and described arterial dilatation already prior to trophoblastic infiltration of the wall. They found indications for nitric oxide secretion of periarterial trophoblast cells, resulting in maximum arterial dilatation (for further discussion of the role of nitric oxide, see Nitric Oxide and Trophoblast Invasion, above).

**Stage 3: Trophoblast infiltration of vessel walls** (Fig. 9.32D): Only the third and last stage of uteroplacental vascular remodeling is characterized by infiltration of the arterial wall by endovascular trophoblast:

- The uteroplacental arteries undergo further **dilatation** up to several times the original diameter of the lumen (Brosens et al., 1967; Hirano et al., 2002). The increase in luminal width is particularly impressive near the intervillous space, where the spiral arteries may finally reach as much as five times their original luminal diameter. Panigel and Pascaud (1968), Boyd and Hamilton (1970), and Sheppard and Bonnar (1974a,b) reported arterial luminal diameters of about 200  $\mu\text{m}$  in the myometrial segments, compared to 500 to 1000  $\mu\text{m}$  near their opening into the intervillous space. The diameter of the arterial ostia may be as much as 2000  $\mu\text{m}$ . A terminal constriction of the lumens, and in particular a flow-regulating sphincter, as described by Spanner (1935) and Debiassi et al. (1963), have later been refuted by all subsequent authors.

- The trophoblastic infiltration of the arterial media coincides with **loss of elastic fibers** (Robertson, 1976; Robertson & Manning, 1974). The latter authors suggested that even more elastic fibers develop in these vessels throughout gestation; but because of invasion-related degenerative processes, most of these fibers seem to be lost again later. Destruction of elastic fibers usually is attributed to proteolytic activities of the invasive endovascular trophoblast cells. The process has been mimicked in vitro by Aplin (personal communication). Accordingly, the expression of proteases such as interstitial collagenase (MMP-1), gelatinase A (MMP-2), stromelysin 1 (MMP-3), and gelatinase B (MMP-9) was shown (Moll & Lane, 1990; Blankenship & Enders, 1997; Kaufmann & Castellucci, 1997). In this context it is, however, of interest that the two proteinase inhibitors  $\alpha_1$ -antitrypsin and  $\alpha_1$ -antichymotrypsin were found to be expressed only in the intraarterial trophoblast cells, whereas the interstitial subpopulation of invasive extravillous trophoblast cells was negative for both inhibitors (Earl et al., 1989).
- According to Brosens et al. (1967), the trophoblast invasion is paralleled by an increase in **intramural fibrinoid masses**, which cause transformation of the originally flexible vessels into rigid channels.
- Regarding the **media smooth muscle cells**, the original view was that smooth muscle cells are destroyed by invasive trophoblast and become replaced by endovascular trophoblast (Ramsey & Harris, 1966; Brosens et al., 1967; Boyd & Hamilton, 1970; Nikolov & Schiebler, 1973). In fact, Aplin (personal communication) has shown that invasive trophoblast cells in vitro when invading isolated arterial segments, induced apoptosis of vascular smooth muscle cells. In the older literature the vessels were described as being finally more or less devoid of smooth muscle cells (Wilkin, 1958; Brettner, 1964; Panigel & Pascaud, 1969), the loss being less impressive in the decidual portion than at the more superficial levels (deWolf et al., 1973; Nikolov & Schiebler, 1973; Sheppard & Bonnar, 1974b; Brosens, 1988). More recently, it was shown in the guinea pig that at least the majority of smooth muscle cells under the influence of trophoblast cells does not degenerate but rather dedifferentiates to myoblasts (Nanaev et al., 1995). The resulting myoblasts, which are phenotypically similar to trophoblast cells, are the basis for postpartal arterial reconstitution (Nanaev et al., 2000b). The trophoblast cells, in this species only in a secondary step, infiltrated the already maximally dilated and dedifferentiated vessel wall. The data support earlier reports in the same species, which showed vascular changes preceding trophoblastic infiltration (Hees et al., 1987; Moll et al., 1988). Also for the human it was immunohistochemically shown, that  $\alpha$ -smooth muscle actin is still present in segments of uteroplacental arter-

ies that are phenotypically void of smooth muscle cells (Craven & Ward, 1996).

- The **endothelial cells** in the peripheral parts of uteroplacental arteries are largely replaced by a mono-to polylayer of cytotrophoblast (intraarterial trophoblast). The latter partly even form large **trophoblastic plugs**, which locally may obstruct the lumen. It is still an open question whether such trophoblastic plugs may completely block blood flow in certain arteries thus resulting in reduced or even absent perfusion of the intervillous space (Hustin, 1995; Moll, 1995; Jauniaux, 1996; Carter, 1997). One should bear in mind that uteroplacental arteries show final branching before entering the intervillous space (see Number and Position of the Uteroplacental Vessels, above) and that obstruction of single side-branches must not influence intervillous blood flow.

The discrimination between intraarterial trophoblast cells and maternal endothelial cells is not always easy since trophoblast cells, when replacing the endothelium, may achieve an endothelial phenotype. By contrast, also maternal endothelium may contribute to the formation of the intraarterial plugs: When the placental bed was examined with antibodies directed against hCG and factor VIII-related antigens, Tuttle et al. (1985) found that many large endovascular cells had factor VIII activity but no hCG-immunoreactivity, which suggested that they are endothelium, rather than trophoblast.

These problems underline the usefulness of antibodies specifically directed against endovascular trophoblast, such as anti-cytokeratin 17 (Pröll et al., 1997a) or GZ 112 (Hartmann et al., 1997). Application of such antibodies reveals that the majority of cells lining the lumina of the endometrial segments of uteroplacental arteries, and of those parts passing the luminal third of the myometrium, represent intraarterial trophoblast. This is quite different from uteroplacental veins (see below), the maternal endothelium of which becomes replaced only in extremely rare cases by trophoblast.

## Sites and Routes of Endovascular Trophoblast Invasion

Endovascular trophoblast invasion is not a homogeneous process. The density of extravillous trophoblast and the depth of invasion of uteroplacental arteries are most pronounced in the central region of the placental bed. The density and depth of invasion of extravillous trophoblast as well as the degree of invasion of spiral arteries diminish toward the placental margin (Brosens, 1988). Central-region placental bed specimens obtained from normal pregnancies reveal endovascular trophoblast that invaded and dilated uteroplacental arteries up to the first third of the myometrium—a depth similar to interstitial trophoblast invasion in this region.

The anatomic pathways taken by the endovascular trophoblast have been a matter of controversy. Two different

models, the extravasation and the intravasation model, are under discussion.

**Extravasation:** Based on detailed studies on the rhesus monkey, Blankenship and coworkers (1993a) concluded that endovascular trophoblast derived from an unknown source gained access to the arterial lumens via or close to their point of confluence with the intervillous space. Thereafter the cells migrate along the arterial lumens retrograde to blood flow by adhering to the endothelium and replacing it (Fig. 9.34A). Finally a certain number of these cells were thought to leave the lumen (extravasate) and centrifugally invade media and adventitia. This view would imply that endovascular trophoblast cells have a different origin from the interstitial route of trophoblast invasion. And indeed, immunohistochemical markers have been described that allow discrimination of endovascular trophoblast from interstitial extravillous trophoblast (Hartmann et al., 1997; Pröll et al., 1997a).

**Intravasation:** Based on studies in the human, the majority of researchers favor the contrasting concept of intravasation (Pijnenborg et al., 1983; Kurman et al., 1984a; Damsky et al., 1992, 1993; Loke et al., 1992; Fisher & Damsky, 1993; Kaufmann & Castellucci, 1997; Redman, 1997) (Fig. 9.34B). Structural criteria (Pijnenborg et al., 1983) and immunohistochemical data (Damsky et al., 1992; Fisher & Damsky, 1993) suggested that endovascular trophoblast represents an end stage of differentiation of interstitial trophoblast derived from the cell columns. As a sidestep, a subpopulation of extravillous trophoblast cells invade the arterial walls from the surrounding junctional zone and finally enter the arterial lumens. Whether or not the intravasated cells then migrate inside the arterial lumens and even locally may extravasate remains an open question.

A combination of both hypotheses was suggested by Loke's group (Kam et al., 1999). These authors described infiltration and replacement of arterial media and adventitia by interstitial trophoblast, followed by the replacement of endothelium by a separate population of endovascular trophoblast, the derivation of which was not described.

The answer to the question whether extra- or intravasation takes place in uteroplacental arteries is crucial for the understanding of the various hypotheses below. Here it is important to recognize that extravasation was described in the rhesus monkey, a species with a nearly complete trophoblastic shell separating the intervillous space and maternofetal junctional zone. This trophoblastic shell may be a source for intraluminal trophoblast migration. In contrast, the trophoblastic shell of the very early gestation human placenta becomes rarefied to widely spread cell columns not in contact with the terminal structures of the maternal arteries.

In agreement with the extravasation theory, the endovascular trophoblast in the rhesus monkey has been described by King and Blankenship (1993) to maintain proliferation based on PCNA immunohistochemistry (proliferative cell nuclear antigen; antibody PC10). The PCNA displays a long half-life (20+ hours) (Bravo & Macdonald-Bravo, 1987); therefore, cells may remain immunopositive for days after leaving the cell cycle. Human endovascular trophoblast has not been observed to proliferate according to Ki-67 immunohistochemistry, <sup>3</sup>H-thymidine incorporation

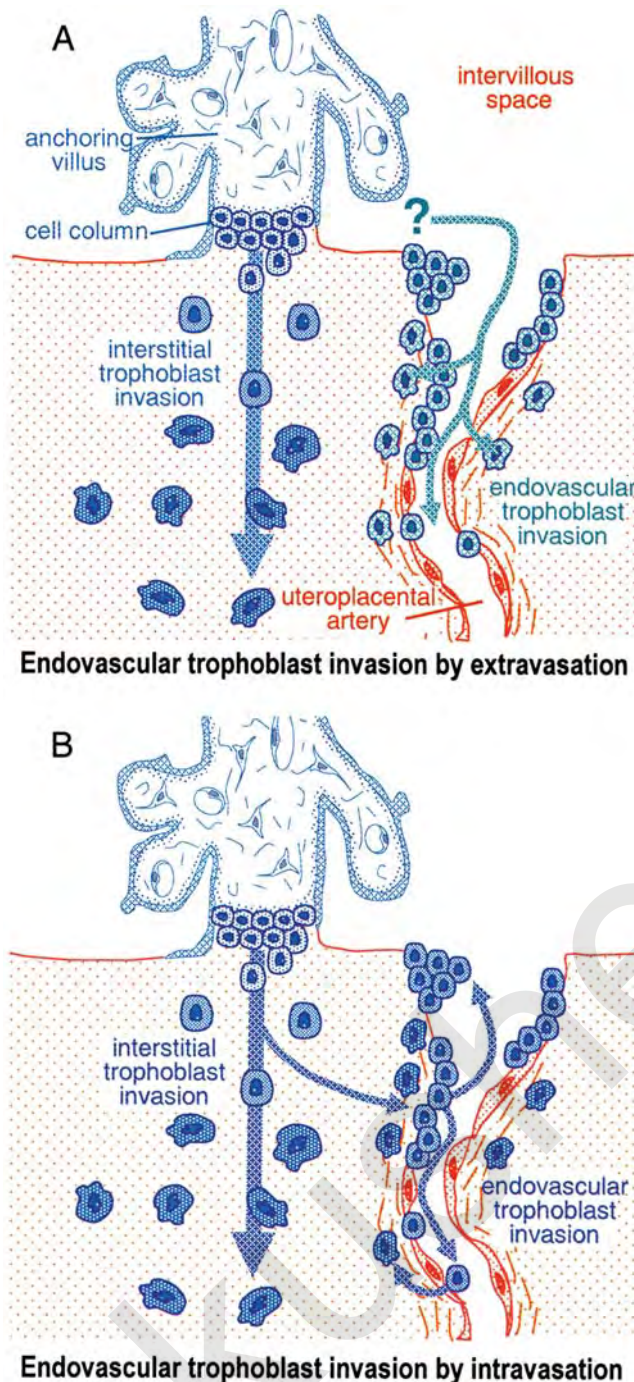

FIGURE 9.34. Hypothetical routes of endovascular trophoblast invasion. Blue: fetal tissues including interstitial trophoblast and its “intravasating” derivatives. Green: extravasation route of endovascular trophoblast. Red: Maternal tissues. Note that in the hypothetical case of “extravasation” (A) the endovascular trophoblast cells invade via the arterial lumen and are derived from an unknown origin. By contrast, in the more likely case of “intravasation” (B), endovascular trophoblast is derived from cell columns via the interstitial invasion route. (Source: Modified from Kaufmann et al., 2003, with permission.)

studies, or assessment of mitotic figures. Proliferation of human extravillous trophoblast has been observed exclusively in trophoblast resting on the basal lamina of cell columns (Kaufmann & Castellucci, 1997).

We conclude from these data that extravillous trophoblast emanating from the cell columns, provides cells for the interstitial route of trophoblast invasion. Cells from the latter route invade (intravasate) uteroplacental arteries and contribute to the remodeling process by replacing arterial media and endothelium (Fig. 9.34B). It may, however, happen that these cells enter the vessel lumina quite early, close to the intervillous space, then migrating along the endothelium against the blood flow to more central portions of the arteries (Enders et al., 1996). In the latter position they may even extravasate again. A similar situation has been observed in guinea pig placenta (Nanaev et al., 1995).

### Trophoblast-Endothelial Adhesion Mechanisms

To understand the pathogenetic mechanisms of IUGR and preeclampsia, there has been increasing interest in the molecular mechanisms behind endovascular trophoblast invasion and concomitant vascular changes. Most of these studies have focused on adhesion mechanisms, which enable the trophoblast to enter the arterial walls and to replace the endothelial lining by a new trophoblastic lining. The expression of cell adhesion molecules is necessary for trophoblast invasion as these molecules enable trophoblast to adhere to the ECM, form colonies, and target cells in the vessel wall. Numerous studies reported that (1) proliferative and early postproliferative cells within the proximal invasive pathway (immunoreactive with proliferation marker MIB-1) express epithelial adhesion molecules, and (2) nonproliferative trophoblast of the distal invasive pathway (immunonegative with MIB-1) acquire an invasive phenotype by switching their repertoire of adhesion molecules to one resembling that of mesenchymal derivatives as, for example, endothelial cells (Vicovac & Aplin, 1996; Merviel et al., 2001).

**Selectins:** The first respective studies on trophoblast-endothelial interactions were performed by the Loke group in Cambridge. These authors found that intra-arterial trophoblast cells express **sialyl-Lewis<sup>x</sup>** (King & Loke, 1988). Expression of this cell surface carbohydrate was already known from various leukocytes. It is the ligand of the lectins **E-** and **P-selectin**, both of which are expressed by endothelium during inflammatory reactions. Interactions between sialyl-Le<sup>x</sup> and selectins enable the leukocytes to attach to the endothelium and subsequently to pass the vessel wall. Interestingly, both selectins were found to be expressed also by maternal endothelium during pregnancy exclusively at the implantation site (Burrows et al., 1994). The authors suggest that sialyl-Le<sup>x</sup>/selectin interaction is used for trophoblast attach-

ment to the arterial endothelium and for trophoblast migration along the vessels lumina. The sialyl-Le<sup>x</sup>-E-selectin interaction is also involved in adhesion of cancer cell lines to human umbilical vein endothelial cells in vitro (Takada et al., 1993).

**N-CAM:** Also the **neural cell adhesion molecule** (N-CAM, CD56) is thought to be involved in the process of vascular invasion. It is a homophilic cell-cell adhesion molecule and permits cells to adhere to ECMs. It is expressed by extravillous trophoblast in nearly all stages of its development (Pröll et al., 1997b; for review, see Kaufmann & Castellucci, 1997). According to data obtained in the rhesus monkey, also intraarterial trophoblast cells are distinctly N-CAM-positive, whereas intramural trophoblast cells and maternal endothelium reveal reduced or no immunoreactivity (Blankenship & King, 1996). The latter authors assign this adhesion molecule a special role of trophoblast/trophoblast adhesion during formation of intraluminal plugs.

**ICAM-1:** According to Ruck et al. (1994), intercellular adhesion molecule-1 (ICAM-1) is expressed by the maternal endothelium at the implantation site. Burrows et al. (1994) found this adhesion molecule not only to be expressed by all maternal endothelial cells, large granular lymphocytes, macrophages, but also by perivascular interstitial trophoblast and endovascular trophoblast. The ligand for ICAM-1 is the  $\beta 2$  integrin heterodimer CD11a/18 (Springer, 1990), which is expressed by large granular lymphocytes/uNK cells (Burrows et al., 1993b) but not by trophoblast cells. These data are partly in contrast to those of Labarrere and Page Faulk (1995), who detected ICAM-1 only in endovascular trophoblast from abnormal pregnancies characterized by arterial malinvasion (IUGR and preeclampsia), whereas endovascular trophoblast from normal pregnancies was immunonegative. It is speculated that expression of ICAM-1 at the implantation site is unimportant for vascular trophoblast invasion itself but rather for local adhesion and subsequent migration of endometrial NK cells (CD56<sup>+</sup> lymphocytes, uNK cells) from the peripheral blood into the decidua.

**Arguments for endothelial mimicry:** Susan Fisher's group (Zhou et al., 1997a,b) introduced the hypothesis that impaired invasion of uteroplacental arteries is due to trophoblastic failure to acquire the vascular repertoire of adhesion molecules. In normal pregnancies these authors reported a generally reduced expression of E-cadherin in extravillous trophoblast, but an upregulation of expression of **VE-cadherin** (endothelial cadherin), **PECAM-1** (platelet-endothelial adhesion molecule-1), **VECAM-1** (vascular endothelial adhesion molecule-1), and  **$\alpha 4$  integrins** (Zhou et al., 1997a). Endovascular trophoblast continues to express these receptors and, like activated endothelial cells, acquires  $\alpha v \beta 3$  (Zhou et al., 1997b). In the latter publication, this group reported that extravillous trophoblast in preeclampsia failed to express most of these endothelial markers and hypothesized that

expression of a vascular phenotype by the trophoblast is required for successful endovascular invasion.

**Arguments against endothelial mimicry:** The trophoblast-endothelial mimicry model has not been supported by other investigators. For example, Lyall and co-workers (2001) studied human placental bed biopsies and found that PECAM-1 expression was not detected in extravillous trophoblast but rather observed only in endothelial cells. Moreover, no differences in cell-type patterns of PECAM-1 expression were observed among normal pregnancy, preeclampsia, and IUGR. Also regarding integrins, the patterns found in normal pregnancies were comparable to those in preeclampsia (Divers et al., 1995). The downregulation of E-cadherin during trophoblast invasion, described by Zhou et al. (1997a,b), was not supported by Floridon et al. (2000). Finally, Jaakkola and coworkers (2000), after studying a broad panel of leukocyte-endothelium adhesion or lymphocyte homing-associated antigens including ICAM-1, ICAM-2, VCAM, P-selectin, E-selectin, L-selectin, CLA-1, CD73, and VAP-1 in the invasion area, concluded that there is no major change in the adhesive properties of the endothelium of the placental bed in preeclampsia.

**Induction of endothelial apoptosis:** Different from the above models, the in vitro data of Ashton et al. (2005) do not require trophoblast-endothelial adhesion, with or without endothelial mimicry, as prerequisites for intra-arterial trophoblast invasion. Rather, based on their data, these authors concluded that trophoblast by means of FasL secretion forces Fas-positive maternal arterial endothelium into apoptosis and thereafter replaces it.

## The Role of Macrophages in the Control of Endovascular Trophoblast Invasion

Maternal macrophages are normal constituents of the placental implantation site and can be demonstrated by antibodies to CD14 or CD68 (Bulmer et al., 1984; Reister et al., 1999). Greater numbers of macrophages are found in the decidua basalis as compared to the decidua parietalis, where trophoblast invasion is limited. This may hint at interactions between trophoblast invasion and macrophages (Loke & King, 1995). Macrophages produce and respond to a wide range of cytokines and may well be involved in local paracrine networks regulating trophoblast invasion (for review, see Hunt, 1989, 1990). Among others, activated macrophages produce high levels of TNF- $\alpha$  (Hunt, 1989). Its receptor TNF-R1 is expressed by trophoblast cells (Yui et al., 1996; Reister et al., 2001). Interactions between TNF- $\alpha$  and TNF-R1 were described as inducing trophoblast apoptosis in vitro (Yui et al., 1994; Reister et al., 2001).

As already dealt with above, in preeclampsia, segments of the spiral arteries located in the inner third of the myometrium and in the deep endometrium are infiltrated by macrophages and do not show any trophoblast

FIGURE 9.35. Defense of endovascular trophoblast invasion (via intravasation) by activated maternal macrophages of the arterial walls in preeclampsia or IUGR. These macrophages force approaching trophoblast cells into apoptosis by secretion of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and indolamine 2,3-dioxygenase (IDO), the latter causing local tryptophan depletion. Blue: fetal tissues including trophoblast. Red: maternal tissues. Lilac: Activated maternal macrophages. Note that in the case of preeclampsia activated maternal macrophages accumulate in the proximal parts of the uteroplacental arteries located in the deeper zones of the placental bed. There they prevent perivascular and endovascular trophoblast invasion and thereby block the physiologic changes of arteries. (Source: Modified from Kaufmann et al., 2003, with permission.)

invasion (Reister et al., 1999). In normal pregnancy, the respective segments are invaded by trophoblast, but rarely show intramural macrophages. Interestingly, the preeclampsia-specific increase of macrophages seems to be restricted to the maternal arterial walls. By contrast, the number of maternal macrophages in the interstitium even was described as being reduced in preeclampsia (Burk et al., 2001).

To analyze the inverse relation between invasive trophoblast cells and maternal macrophages, Reister et al. (2001) have performed in vitro experiments using an immortalized extravillous trophoblast cell line and primary macrophages. The experiments revealed that activated macrophages induce trophoblast apoptosis by the concerted action of two mechanisms (Fig. 9.35):

- By secretion of TNF- $\alpha$ , which binds to the trophoblastic TNF-R1;
- By secretion of IDO, which catabolizes and depletes local levels of tryptophan.

These data explain the immunohistochemically evident inverse relation between the number of endovascular trophoblast and macrophages in the wall of uteroplacental arteries (Reister et al., 1999). The fact that macrophages induce trophoblast apoptosis in vitro renders it unlikely that the increased macrophage population in the arterial walls in preeclampsia is simply due to apoptotic attraction of macrophages. However, combining both possible interactions between macrophages and trophoblast, it could be hypothesized that macrophage-induced trophoblast apoptosis attracts and activates more macrophages leading to a vicious cycle.

### Incompetent Trophoblast Invasion or Exaggerated Maternal Defense as Causes for Maladaptation of Uteroplacental Arteries

Several authors suggest that shallow interstitial trophoblastic invasion results in impaired endovascular trophoblast invasion and leads to maladaptation of uteroplacental arteries. This view is expressed by statements such as “pre-eclampsia is associated with abnormally shallow placentation” (Zhou et al., 1998); “hypoinvasive placental phenotype characteristic of pre-eclampsia” (Caniggia et al., 1999); “shallow trophoblast invasion... predisposing the pregnancy to pre-eclampsia” (Caniggia et al., 2000). In agreement with this view, it is often believed that IUGR and preeclampsia are associated with a generalized impairment of trophoblast invasion that includes both reduced interstitial and reduced endovascular trophoblast invasion.

Recent quantitative studies on interstitial trophoblast invasion in hysterectomized uteri from patients with preeclampsia have revealed in fact that both invasive depth and numerical density of interstitial extravillous trophoblast in this entity are significantly reduced compared to normal (Kadyrov et al., 2003). However, in contrast to previous studies on basal plates from delivered placentas (DiFederico et al., 1999) interstitial trophoblast apoptosis within the placental bed was not increased but rather reduced in preeclampsia (Kadyrov et al., 2003), while endovascular trophoblast apoptosis was increased (Reister et al., 1999).

These contrasting apoptosis features led us to doubt that shallow trophoblast invasion or increased trophoblast apoptosis per se are the cause of impaired endovascular invasion. Mere intrinsic trophoblastic phenomena, such as missing expression of a vascular phenotype, reduced NO secretion by the trophoblast, and altered trophoblast behavior caused by deficient oxygenation (Zhou et al., 1998; Caniggia et al., 2000) are unlikely to be the exclusive causes of malinvasion of uteroplacental arteries with subsequent IUGR or preeclampsia.

Rather, the clinical and basic research data discussed above suggest that maladaptation and malinvasion of uteroplacental arteries characteristic of IUGR and preeclampsia result from a variety of factors interacting with each other in a cascade of events:

- intrinsic factors, namely abnormal biology of the extravillous trophoblast, acting in concert with
- extrinsic, maternal uterine factors operating around the uteroplacental arteries, which might include a.o.
- impaired decidual remodeling (Aplin 1991b; Brosens et al., 2002),
- macrophage-based defense mechanisms (Reister et al., 1999; 2001),
- impaired function of uterine NK cells (Ashkar et al., 2000), and
- maternal endothelial failure to express selectins (King & Loke, 1988; Burrows et al., 1994).

### Structure of Uteroplacental Veins

The structure of the uteroplacental veins differs in some minor aspects from that of the spiral arteries. The muscular coat is even more reduced than that of the arteries, and smooth muscle cells are usually absent near the venous openings (Nikolov & Schiebler, 1973). The discontinuous endothelium is surrounded by some connec-

tive tissue. Trophoblast cells may be locally absent from the vessel walls (Fig. 9.36A) or may show a low degree of infiltration. In the rhesus monkey, trophoblast cells sometimes have been observed even intraluminally to replace the endothelium in venous segments near the intervillous space (Blankenship et al., 1993b).

Wanner (1966) described that maternal endothelium may leave the venous lumina and cover the surrounding parts of the basal plate. This finding has been supported immunohistochemically by applying a panel of endothelium-specific antibodies (Lang et al., 1993). Using an antibody directed against the factor VIII-related antigen we found maternal endothelium not only in the vicinity of the venous openings (Fig. 9.37) but also covering other parts of the basal plate (see Chapter 3, Fig. 3.3C), parts of septa, cell islands, and sometimes even perivillous fibrinoid deposits.

The maternal endothelial lining of the intervillous space is particularly impressive in the marginal zone of the placenta. In this area, maternal veins show funnel-like terminal dilatations that, without clear border, continue into

FIGURE 9.36. Uteroplacental vessels, paraffin sections, 16th week p.m. A: Stained with an anticytokeratin antibody that detects extravillous trophoblast cells (brown). The spiral artery (center) is largely occluded by a plug of intraarterial trophoblast cells. The uteroplacental vein beneath (lower third) shows only few intramural trophoblast cells.  $\times 100$ . B: Stained with MIB-1, which binds to the nuclei of proliferating cells. The tro-

phoblastic plug protruding into the arterial lumen is obviously nonproliferative as are the trophoblast cells lining the upper vessel. The trophoblastic nature of these cells has been proven by anticytokeratin staining of a parallel section. The only positive (proliferating) nuclei (brown) belong to cytokeratin-negative (endothelial) cells.  $\times 250$ . (Courtesy of Dr. Gaby Kohnen, Aachen, Germany.)

FIGURE 9.37. Cryostat serial sections of the basal plate of the mature placenta with a cross section of a spiral artery (lower left); moreover, the basal plate is passed in full thickness by a uteroplacental vein (upper left). A: Stained with H&E, which does not allow one to identify the various cellular components. B: Stained with anticytokeratin, which binds to syncytiotrophoblast of placental villi (right margin), extravillous trophoblast (oval brownish cells in the center) and to the trophoblastic lining of the spiral artery (lower left). C: Stained with antivimentin, a marker for mesenchymal derivatives. It stains decidual

cells (above the spiral artery, lower left) and maternal endothelium lining the venous opening and spreading over the surface of the basal plate (center). D: Stained with anti-factor VIII-related antigen, a specific endothelial marker. Note the absence of staining from the wall of the spiral artery (lower left), but the presence of maternal endothelium at the basal plate surface (center).  $\times 95$ . All sections are counterstained with hematoxylin so that all nuclei appear dark. (Courtesy of Dr. Sonya Kertschanska, Aachen, Germany.)

the chorionic and basal plates. These observations have prompted Craven and coworkers (2000) to study the interactions between lateral uteroplacental veins and placental villi in more detail. They found very often peripheral villi expanding deeply into the openings of maternal placental veins. Some of the villi were attached to venous walls in places where venous endothelial cells expressed vascular cell adhesion molecule (VCAM). And mononuclear trophoblast cells that were integrin  $\beta 4$  positive and  $\beta 1$  negative evaded the villi and started invading the surrounding decidual stroma. Oncofetal fibronectin was present at sites of trophoblast invasion. The authors concluded that the combination of three findings suggests that placental surface expansion throughout pregnancy is at least partly due to **lateral expansion of the placenta** by transformation of marginal veins into intervillous space:

- Dilation of lateral placental veins with transformation into marginal parts of the intervillous space is strongly supported by the fact that marginal parts of the intervillous space are lined by maternal endothelium with smooth muscle cells underneath (cf. Nanaev et al., 2000a).
- Branches of marginal villous trees develop into these newly developed parts of the intervillous trees.
- There they form anchoring villi and cell columns, which are starting points of trophoblast invasion and thus guarantee that also the junctional zone spreads in accord with placental expansion.

On the other hand, not every villous cross section observed in uteroplacental veins is an indication of villous anchorage and points to lateral expansion of the placenta. Rather, peripheral villi may segregate from the villous trees and may be deported with the maternal blood flow into myometrial segments of uteroplacental veins (Fig. 9.38) or even deeper (Fujikura, 2005).

## Intramural Fibrinoid of Uteroplacental Arteries and Veins

Fibrinoid of the uteroplacental arteries is very likely to be composed mainly of fibrin-type fibrinoid. At present, there is no evidence for the secretion of matrix-type fibrinoid by endovascular trophoblast cells. Rather, Sheppard and Bonnar (1974b, 1988) and Bonnar and Sheppard (1977) described typical fibrin with a 200-Å cross-striation in all layers of these vessel walls. They observed intraluminal fibrin thrombi attached to the intimal lining and noted that muscular and elastic components of the vessel walls may be replaced by fibrin.

Whether the deposition is caused by increased fibrin polymerization or by decreased fibrinolytic activity is a matter of dispute. Endothelium is well known to have fibrinolytic activity. The endothelium of the uteroplacental arteries, however, becomes largely replaced by trophoblast during pregnancy. According to Sheppard and Bonnar (1974a), also trophoblast is discussed as being a potent source of antifibrinolytic activity. The latter is said to prevent the enzymatic digestion of fibrin (Kawano et al., 1968).

## Functional Aspects of Uteroplacental Vessels

During the course of pregnancy, uteroplacental flow resistance is decreased by structural widening of the lumens of the uterine and terminal spiral arteries, so that maternal blood supply to the placenta is adjusted to fetal growth. When comparing parameters such as blood flow velocity, arterial widening, and timing of trophoblast invasion in rats and guinea pigs, it was found that the vascular changes proceed normally, even under conditions of reduced blood flow (Moll et al., 1988). They appeared earlier than the

FIGURE 9.38. Paraffin section of a myometrial vein from a 16th week pregnant uterus. The vein is blocked by two placental villi (center), which are lined by trophoblast (dark brown anticytokeratin staining), and by a big fibrinoid conglomerate (left), which contains several cytokeratin-positive (brown) extravillous trophoblast cells.  $\times 80$ . (Courtesy of Dr. Gaby Kohnen, Aachen, Germany).

trophoblastic invasion and could be induced by long-term estradiol treatment. Moll et al. (1988) concluded that the changes in luminal width are not induced by the intra-arterial trophoblast invasion but rather by endocrine/paracrine factors. Later studies of vascular trophoblast invasion in the guinea pig (Nanaev et al., 1995) and in the human (Craven et al., 1998) have supported this view.

The increased arterial diameters are thought to guarantee sufficient uteroplacental blood flow volumes and to prevent excessively high blood pressures in the intervillous space. Only a balance between the intervillous maternal blood pressure and the intravillous fetal blood pressure keeps the fetal vessels open and allows intravillous fetal blood flow (Karimu & Burton, 1994a,b). As is known from experimental studies in the guinea pig (Kaufmann et al., 1982) and in the isolated, dually perfused human cotyledon (Kaufmann, 1985), corresponding elevation of the fetal blood pressure would be an inadequate answer to intervillous pressure increases. Elevation of fetal blood pressure results in filtration through fetal vessels and finally in villous edema. Thus, the only realistic consequence is a reduction of the intervillous blood pressure to that of the fetus. All pregnancy-induced physiologic changes of the spiral arteries must be seen in the light of such considerations.

Failure of physiologic dilatation of uteroplacental arteries due to deficient arterial trophoblast invasion is generally accepted as underlying pathogenetic mechanism in preeclampsia and fetal IUGR (for review, see Brosens, 1988). As discussed above, absent dilation will result in increased maternal flow impedance. From a theoretical point of view, the maternal organism has two different options to adjust to this situation:

- If the maternal blood pressure is kept constant, the increased impedance will cause reduced intervillous perfusion. This directly will impair delivery of oxygen and nutrients into the placenta and into the fetal circulation. The placenta and the fetus become hypoxic (uteroplacental hypoxia, see Types of Hypoxia and Its Effects on Villous Development in Chapter 7).
- If the maternal blood pressure is increased, maternal perfusion of the placenta as well as delivery of oxygen and nutrients into the placenta may be kept constant. This situation, however, will result in increased intervillous blood pressure, which results in compression of the villi, increased fetoplacental impedance, reduced fetoplacental circulation, and reduced oxygen and nutrient transfer to the fetus. The fetus is hypoxic, whereas the placenta may show oxygen partial pressures higher than normal (postplacental hypoxia, see Types of Hypoxia and Its Effects on Villous Development in Chapter 7).

As a consequence, depending on the maternal response to deficient vascular trophoblast invasion, different clinical

features may result such as IUGR with preserved end-diastolic (PED) flow in the umbilical arteries or IUGR with absent or reversed end-diastolic (ARED) flow in the umbilical arteries. Whether or not IUGR is further complicated by preeclampsia very likely depends on the way in which villous trophoblast turnover responds to these changes (see Chapter 15).

## Septa, Cell Islands, and Cell Columns

### Septa

Placental septa are irregular protrusions of the basal plate that are composed of fibrinoid and various cell types (Figs. 9.12 and 9.39). Boyd and Hamilton (1966) gave a detailed historical and analytical description of these structures. As early as in the 6th week p.m. we observed short basal plate protrusions into the intervillous space that were composed of cytotrophoblastic cells, likely precursors of future septa. The septum depicted in Figure 9.40 was found in a placenta from the 8th week p.m.

FIGURE 9.39. Cryostat section of a placental septum (center and above) resting on the basal plate (below). Glucose-6-phosphate dehydrogenase reaction. It becomes evident from this enzyme reaction that the faintly stained decidua (D) extend from the basal plate into the septum. Ample numbers of anchoring villi are attached to the septum. These similarities of basal plate and septum support the theory that the septa are results of folding of the basal plate. 40th week p.m.  $\times 65$ .

FIGURE 9.40. Paraffin section of an early placental septum (middle) during the 8th week p.m. In this stage the septa have a cellular composition similar to that of the early basal plate (see Fig. 9.27). As in the latter, they are largely devoid of fibrinoid and can be interpreted as being extensions and folds of the early basal plate.  $\times 90$ .

Septa can be found in nearly every mature placenta. Absence of septa is a rare event in mature placentas that is usually linked to pathologic conditions (Fig. 9.41). The fetus of the placenta shown in Figure 9.41 had hygroma and X monosomy. True septa are also absent from abdominal pregnancies.

The **shape of septa** is one of irregular plates, or pillars, that partially subdivide the intervillous space. Their position normally corresponds to that of the grooves that are visible at the basal surface of the delivered placenta (Wilkin, 1958) (Fig. 9.42; also see Fig. 2.1)—hence their designation as “intercotyledonary septa.” Many observers, such as Spanner (1935), Stieve (1940), and Stieve and von der Heide (1941), have suggested that septa partly serve as subdivisions of intervillous blood flow. The famous drawings of Spanner and Stieve depicted chamber-like compartments of the intervillous space. In contrast, Becker (1962; Becker & Jipp, 1963) found that septa never subdivide truly functional units of placental tissue. Most often they were found to be rather shallow “vela,” measuring between 12 and 18 mm in height, originating from the floor of the placenta, and rarely reaching the fetal surface. They represent furrows or folds in the maternal surface or basal decidua, rather than complete septations of the villous tissue.

Concerning the **development of septa**, Boyd and Hamilton (1966) suggested that they probably result from buckling of the basal decidua. They envisaged this buckling to be induced by the pressures of expanding villous lobules and found further support for this idea from the relative paucity of villous attachments on only one side of the septa. When the septa are dissected, this side is found to be much smoother than the other. When we studied early specimens from the 6th to 8th weeks p.m. that showed the first signs of formation of septa (Fig. 9.40), we found them to be composed of cytotrophoblast. Anchoring villi can often be observed near their tips (Fig. 9.40). We concluded, therefore, that one of the initial causes of septum formation is traction of these anchoring villi combined with excessive proliferation of their cytotrophoblastic feet. Only later, a considerable admixture of decidua can be found (Figs. 9.39 and 9.42).

As was already discussed, it is likely that the combination of septa with groves in the basal plate (Fig. 9.42) is a consequence of secondary folding of the basal plate along those points where the cytotrophoblastic septal precursors originate. This process can be induced by lateral movements between uterine wall and basal plate and is due to placental growth.

According to this concept of their genesis, it is understandable that the **composition of septa** resembles that of the basal plate. They are composed of both decidual cells and extravillous trophoblast cells embedded in matrix-type fibrinoid, and partly surrounded by fibrin-type fibrinoid. Anchoring villi are attached to the septa by means of cell columns, the latter representing the foci of extravillous trophoblastic proliferation. In addition, the septa may contain all other basal plate constituents like

FIGURE 9.41. Third trimester placenta without septa or folds of the maternal floor. This placenta comes from an 45,X fetus with hygroma.

FIGURE 9.42. Paraffin section of a placental septum, 37th week p.m. Note the numerous anchoring villi inserting at the septum. In its base several vessel cross sections (V) represent uteroplacental veins.  $\times 65$ .

glands (Fig. 9.42) and vessels. Brosens (1988) interpreted the latter to be predominantly spiral arteries, which is in disagreement with current views. Also, the vessels depicted in the septal base of Figure 9.42 are more likely veins. The ultrastructure of septa has been described in much detail by Glienke (1974). Another ultrastructural

study of septa by Demir and Erben (1984) distinguished five cell types but does not draw conclusions as to their origin. Whereas in the early stages of pregnancy (Fig. 9.40) the septa are composed mostly of cells, with advancing gestation trophoblast-derived matrix-type fibrinoid is accumulated and embeds the extravillous

FIGURE 9.43. Intercotyledonary septum with cyst at its tip (top center). The darker cells are extravillous trophoblast cells, which are intermingled with a larger number of decidua cells. Note that Rohr's fibrin stria (at left) follows the outline of the septum. H&E  $\times 80$ .

trophoblast cells. From the intervillous space, fibrin-type fibrinoid is added. At term, both type of fibrinoid are the predominant elements of septa.

Septa are a frequent site of **placental cysts** (Figs. 9.43 and 9.44). Macroscopically identifiable cysts are less

common, but microscopically one finds septal cysts in nearly every placenta. Wieloch (1923) described such cysts as artifacts. Stieve and von der Heide (1941) identified trophoblastic necrosis in the walls of septa and concluded that it is the causal mechanism of cysts. Hörmann (1966) came to similar conclusions. In his studies of what he called "pseudocysts," however, the degenerating cell population is decidua. Also, Schwartz et al. (1973) described the cysts to be the result of cellular necrosis and liquefaction. In many cases, particularly near the base, we found irregular clefts (Fig. 9.42) that can be interpreted to have resulted from laceration of intercellular debris and fibrinoid during labor. On the other hand, cysts with well-developed cellular walls and similar to the cysts of the cell islands (see Fig. 9.47B) are not mechanically induced artifacts.

### Cell Islands

Cell islands are macroscopically round or irregularly shaped white structures connected to either the villous tree or the chorionic plate. Their diameter varies between several hundred micrometers and 3 mm. As the term implies, they are composed primarily of extravillous trophoblast cells (Fig. 9.45) that, with advancing gestation, are encased in increasing amounts of fibrinoid (Fig. 9.46). Fetal or maternal vessels are absent. They resemble septa in structure and composition. When one uses histologic sections, it cannot be excluded that apparent cell islands are, in fact, tangential or cross sections of septa.

The **development of cell islands** never caused much controversy. Most authors agree that cell islands are derived from trophoblast, without an admixture of decidua cells (Spanner, 1935, 1941; Stieve, 1936; Ortmann,

FIGURE 9.44. Septum with cystic centers. H&E  $\times 40$ .

FIGURE 9.45. Placenta from tubal ectopic pregnancy at 5 weeks' gestation. A cluster of extravillous trophoblast cells forming an early cell island is shown above, attached to villi and interspersed with syncytiotrophoblast. No interstitial "fibrinoid" is present as yet. H&E  $\times 240$ .

1955, 1960). Steininger (1978) described a very small number of cell islands in which both decidual and trophoblast cells were present. It is likely that these represent either cross-sectioned tips of septa or former portions of septa that during placental development by traction of anchoring villi have been detached from the septum. Boe (1967) studied trophoblast proliferation in cell

FIGURE 9.46. Cell island at 20 weeks' gestation. The mononuclear cells with dark cytoplasm in the center are the extravillous trophoblast cells. They are surrounded by "fibrinoid." Note that there is no differentiation to syncytium among the extravillous trophoblast cells. H&E  $\times 160$ .

islands in placentas from therapeutic abortions. His view was that the extravillous trophoblast cells derive from the aggregation of "erupted" proliferative masses of cytotrophoblast originating in villous tips. According to Boe's data, cell islands correspond to persistent primary villi that have not been occupied by villous stroma. They are comparable to the basal ends of the anchoring villi, the "cell columns."

This view has been supported by several cell biologic and in vitro studies (e.g., Castellucci et al., 1991; Genbacev et al., 1993c; Mühlhauser et al., 1993). All these studies arrived at the conclusion that the major difference between a cell island and a cell column is the topographical relation: cell islands are freely floating cell columns, and cell columns in the narrow sense are anchored to the basal plate or to septa. A further immunologic difference may be derived from the fact that the extravillous trophoblast of cell columns invades decidual tissues, whereas that of the cell islands only migrates within its own ECM and finally degenerates under formation of cysts (Fig. 9.47).

Krönicher (1975) presented a detailed **ultrastructural description** of the cell islands from early to late pregnancy. He reported different stages of cytotrophoblastic differentiation in the trophoblastic islands. In particular, when studying cell islands from the second and third months, one does not get the impression that they are degenerative or useless groups of cells. Arnholdt and Löhrs (1989, 1991) demonstrated a high mitotic rate in the cells.

The basophilia of the extravillous trophoblast cells, an expression of a richly developed rough endoplasmic reticulum, led investigators to believe that these cells are a potent source of protein hormones, such as hCG (Ortmann, 1955, 1960; Bargmann, 1957; Boyd & Hamilton, 1970). Also, in this respect they are fully comparable to extravillous trophoblast cells of other origin.

## Cell Columns

Cell columns are the massive trophoblastic connections between anchoring villi and basal plate or placental septa. The **development of cell columns** starts around day 15 p.c. when the primary villi become invaded by extraembryonic mesenchyme (see Chapter 5, Fig. 5.1E,F). This process is followed by capillarization of the newly formed villous stroma, which then results in formation of the tertiary villi. Both processes spread from the chorionic plate peripherally but do not reach the basal plate. Rather, the basal parts of the villous stems that connect the latter with the basal plate persist in the primary villous stage. These massive trophoblastic segments of the anchoring villi are called the cell columns. These developmental events are identical to those at some free-floating villous tips, leading to the formation of cell islands.

FIGURE 9.47. Paraffin sections of cell islands. A: At the 37th week p.m., the cell island is largely composed of a fibrinoid matrix in which strings of proliferating cytotrophoblastic cells are embedded. Incorporated decidual cells are rare findings. The surrounding placental villi may be attached to the surface; sometimes they are incorporated into the fibrinoid. Note the heterogeneous structure of the darker superficial patches of fibrin-type fibrinoid as compared to the glossy, lighter matrix-type fibrinoid that

makes up the center of the cell island.  $\times 110$ . B: At the 19th week p.m. In the centers of large cell islands central cavities, or “cysts” are found. They must be considered to be a result of degeneration with subsequent liquefaction. Note two “anchoring villi” attached to this island (above and bottom right). The trophoblast cells lining the border from cell island to anchoring villus represent the proliferating subpopulation, comparable to cell columns.  $\times 120$ . (Source: From Kaufmann, 1981a, with permission.)

The cell columns have been the topic of electron microscopic (Enders, 1968; Larsen & Knoth, 1971; Okudaira et al., 1971, 1991), enzyme-histochemical (Stark & Kaufmann, 1971), immunohistochemical (Okudaira et al., 1971; Feinberg et al., 1989, 1991b; Castellucci et al., 1991, 1993; Librach et al., 1991a,b; Damsky et al., 1992; Fisher & Damsky, 1993; Mühlhauser et al., 1993; Zhou et al., 1993), and numerous in vitro studies, for example by Genbacev et al. (1992, 1993a,b). This particular interest is because they represent the most impressive proliferation zones of extravillous trophoblast, and that the various steps from trophoblastic proliferation via differentiation to invasion cannot be so easily studied anywhere else. All respective data were discussed earlier (see Extravillous Trophoblast). In this context we only briefly discuss some additional **structural features**. Cell columns are composed of a multilayered core of cytotrophoblast surrounded by an incomplete sleeve of syncytiotrophoblast (see Figs. 3.1I and 11.40) (Enders, 1968; Boyd & Hamilton, 1970; Larsen & Knoth, 1971; Okudaira et al., 1971). As soon as cell columns are surrounded by fibrinoid and thus buried in the basal plate, their syncytiotrophoblastic cover becomes replaced by fibrin-type fibrinoid (Fig. 9.48B) (Stark & Kaufmann, 1971). The cytotrophoblastic core continues without sharp demarcation into the Langhans' layer of the anchoring villus at one side (see Fig. 9.4C); on the opposite side, it is con-

nected to loose streamers of invasive extravillous trophoblast.

The border between cell columns and stroma of the anchoring villus is represented by a basal lamina (Fig. 9.4C) (Enders, 1968; Okudaira et al., 1971). It represents the indispensable pad for trophoblast proliferation, and all extravillous trophoblast cells invading the basal plate and the placental bed are derived from this stem cell population (see Fig. 9.1) (Arnholdt et al., 1991; Castellucci et al., 1993; Mühlhauser et al., 1993; Kaufmann & Castellucci, 1997).

As has already been discussed above (see Fig. 9.5), the cell columns function as growth zones for both the basal plate and the anchoring villi. Postmitotic cells derived from the proliferative stem cell population migrate laterally into the villous trophoblastic epithelium as well as basally into the basal plate. With advancing gestation, the cellular layer of the cell columns is reduced by decreasing proliferative activity but continuous migration of the trophoblast (Fig. 9.48). Sometimes there are almost no trophoblast cells left so that anchoring villous stroma and the nearly naked basal lamina directly face basal plate fibrinoid (Figs. 9.48 and 9.49; also see Fig. 3.2I). Because of this situation, Baker et al. (1944) and Ortmann (1960) reported that the cell columns disappear at the end of the third month of pregnancy. But this is certainly incorrect, and with some care one still can find largely intact cell columns even in term placentas.

FIGURE 9.48. Paraffin histology of cell columns. A: At the 15th week p.m. During early stages of pregnancy the anchoring villi (A) are connected to the basal plate (below) by broad or slender feet consisting of cytotrophoblast, the so-called cell columns (C). They are proliferative zones for the villous trophoblast as well as for the trophoblast of the basal plate.  $\times 95$ . B: At the 28th week p.m. During later stages of pregnancy the cell

columns are deeply incorporated into the basal plate by surrounding fibrinoid deposition. Also, its cytotrophoblast is progressively replaced by fibrinoid, indicating reduced proliferative activity of these growth zones. A final stage of this process is depicted in Figure 9.49B.  $\times 95$ . (From Kaufmann, 1981a, with permission.)

FIGURE 9.49. Comparison of a cell column from the 6<sup>th</sup> week of pregnancy (A) with a cell column from the 40<sup>th</sup> week (B). Note the big cluster of early postproliferative and invasive trophoblast cells emanating from the cell column in early pregnancy, as compared to the term anchoring villus, which is connected to

the basal plate by fibrinoid, which contains few barely visible trophoblast cells as remainders of the former cell column. As is typical for this stage of pregnancy, this cell column is “burned out.” H&E,  $\times 300$ .

## Pathology of Trophoblast Invasion

### Placenta Accreta

Placenta accreta is an important condition clinically. It may be life threatening (Manyonda & Varma, 1991). In placenta accreta the villous tissue is in direct contact with the myometrium, and the placental villi are anchored to muscle fibers rather than to intervening decidual cells. The deficiency of decidua prevents normal separation of the placenta after delivery. Normally, the placenta separates from the uterine musculature in a plane just peripheral to Nitabuch's fibrin layer. It is accomplished by the shearing action of contracting myometrium against the stationary, noncontracting placenta and occurs in irregular planes of friable decidual cells. Thus, either the entire placenta is retained, or when the focus of adherence is small, only a portion of placenta is retained. These adherent areas tend

to bleed; fibrin and clot continue to accumulate around such retained placental tissue and, over time, a placental polyp develops that may necessitate operative removal. Lester et al. (1956) found placental fragments to be an unimportant feature of immediate postpartum hemorrhage (4.5%). When hemorrhage occurred in a later stage of the puerperium, however, placental polyp was the cause in 44.4% of affected mothers (see Chapter 10).

Placenta accreta cannot easily be diagnosed from the delivered placenta, but it has been shown that it is often (in 45%) associated with elevated maternal serum  $\alpha$ -feto-protein levels (Zelop et al., 1992; Kupferminc et al., 1993). The placenta may be disrupted during the delivery because of the accretion, and there may thus be missing cotyledons. Occasionally, one can palpate these retained cotyledons by manual exploration in the postpartum uterus. When histologic sections of such a placenta are made, however, the deficiency of endometrium that underlies

placenta accreta is not evident. For such a diagnosis one needs to examine the entire uterus or curettings that include the myometrium. Even then it may be difficult to orient the lesion, and a firm diagnosis may be difficult to render. It is more easily done when whole specimens are available, but this is the less acceptable outcome for the patient. Nevertheless, hysterectomy is a frequent sequel when large areas of placenta accreta exist. If the site of attachment is fixed before trimming the tissues for histology, the lesion is easily diagnosed microscopically (Fig. 9.50). Pathologists must be aware of the difficulties existing in distinguishing the populations of cells that make up the placental floor, especially when they do not examine many placentas. In this differential diagnosis the pathologist must distinguish between the basal decidual cells and the unicellular trophoblast (extravillous trophoblast), cells that are abundant at the site of placenta previa implantation. There is usually an abundance of basal fibrin, and the maternal vessels show the focally deficient physiologic change described by Khong and Robertson (1987). It should also be mentioned that there is a poorly understood increased fetal mortality after 34 weeks' gestation when a prior section had been done (Lumley, 2003; Smith et al., 2003). The increased neonatal problems that are associated with uterine rupture are perhaps more easily understood (Bujold & Gauthier, 2002).

It may be of parenthetical interest here to mention that successful treatment with methotrexate has been undertaken in cervical accretas to destroy trophoblastic cells

FIGURE 9.50. Placenta accreta at term. Villi are attached to myometrium, and the cellular layer at the bottom is composed of only cellular trophoblast (X cells). There is still a large amount of Nitabuch's fibrin layer. H&E  $\times 125$ .

(Oyer et al., 1988; Palti et al., 1989; Bakri et al., 1993). Also, microembolization through the internal iliac artery (Kivikoski et al., 1988) has been used to treat these abnormal implantation sites.

Various antecedents to placenta accreta have been described, such as constitutional endometrial defect, scars, diverticula, cornual implantation, leiomyoma (Fig. 9.51), antecedent cesarean section with placenta previa, and previous curettage (Sumawong et al., 1966). The classic article on placenta accreta is by Irving and Hertig (1937), who studied 18 cases of this condition and reviewed 80 cases from the literature. Their incidence was 1 in 1956 deliveries. Deficiency of endometrium as it was formerly induced by endometrial cautery (e.g., by steam), is no longer a problem, but endometrial defects caused by curettage and by cesarean section have become very prevalent. A familial occurrence was once described to exist in Eskimos, but it has not been confirmed (Schaefer, 1960). Patients successfully treated for Asherman's syndrome (intrauterine adhesions) often develop accretas and other complications (Friedman et al., 1986).

Fox (1972) presented a comprehensive review of this relatively frequent condition and chose to combine all stages of accretion, including increta and percreta. He reiterated that it is a condition of elderly multigravidas, many of whom have uterine malformations (septa) or other complications listed earlier. Of the 622 reported cases covered by his 25-year review, 213 were associated with placenta previa (34%) and seven were placentas membranaceas (vide infra); in only 43 cases were there no predisposing factors. The fact that 57 maternal deaths occurred in these women (9.2%) with 9.6% fetal deaths, attests to the gravity of the condition. Another review of the antecedents to placenta accreta comes from Gielchinsky et al. (2002), whose incidence is higher than usually quoted—0.9% of all deliveries. They affirmed frequent multigravid status, prior section (12%), and placenta previa (10%), but excluded myomas from their review. In their experience, hysterectomy was needed in 3.5% and they had one maternal death. Amazingly, 16% of their patients with accreta had a prior placenta accreta. The rate of maternal complications was higher in the experience of Armstrong et al. (2004), who did hysterectomy in 91%. Similarly, Landon et al. (2004) have evaluated the risk of a trial of labor following prior cesarean section and they enumerate the frequency of maternal and fetal outcomes. The American College of Obstetricians and Gynecologists (ACOG) committee opinion has suggested that there is a 10-fold increase of placenta accreta in the last 50 years (ACOG, 2002) and occurs now with a frequency of 1 in 2500 deliveries.

The frequent antecedent of cesarean section was also stressed by Breen et al. (1977), who reviewed the literature and found an overall incidence of 1 in 7000 pregnancies. This figure is only a rough estimate, however; the higher

FIGURE 9.51. Placenta accreta over a leiomyoma. The leiomyoma (right) was delivered with the placenta at term (see also Cramer, 1987). H&E  $\times 100$ . (Courtesy of Dr. Ralph Richart, New York, New York.)

frequency reported from Thailand (1:540) by Sumawong et al. (1966) was speculated to relate possibly to the higher incidence there of proliferative trophoblastic disease. This argument is unjustified, we believe, as there is no evidence that accretas are the result of an overly aggressive trophoblast. Conversely, all correlations point to a defective uterus. To and Leung (1995) also noted the higher prior section frequency of previas and saw an incidence of 1.18% accreta with placenta previa. Another comprehensive study of placenta accreta comes from Millar (1959), and an overview of the risks were elaborated by Windrim (2005). Millar reviewed not only the morphology of this condition but also its etiology. The decidua was always absent at the attachment site, and it was frequently deficient elsewhere in the uterus, and Comstock et al. (2004) indicated that placenta accreta after prior section can be detected sonographically as early as 15 to 20 weeks' gestation. Fox (1972) pointed out correctly that there is usually a deficiency of placental septum formation with placenta accreta. When septa are present in a placenta accreta, they are composed of uterine muscle. He considered that there may be an endocrine deficiency that fails to support normal endometrial growth. Fox also reported some early cases in which decidua was already lacking. One very young placenta accreta was also found accidentally at hysterectomy

by Begnaud et al. (1965). The histologic features were identical to those of other accretas. An interesting observation was recorded by Cramer (1987). He observed a placenta increta in a patient who had previously needed to be curetted for a placenta accreta. Cramer did not give the patient's prior history and deduced, incorrectly we think, that some placenta have greater invasive qualities than others and do not respect the decidual limitation because of innate qualities.

It has been suggested that the clinical picture associated with placenta previa has been changing (Read et al., 1980); certainly, associated fetal mortality figures have improved. Weckstein et al. (1987) reported a case of placenta percreta and stated their belief that this condition is increasing in frequency because of increased cesarean section rates, which is our observation as well. Importantly, placenta previa can now be diagnosed with some accuracy by sonography, especially with transvaginal probe (Timor-Tritsch & Yunis, 1993; Timor-Tritsch & Monteagudo, 1993). In addition to the diagnosis of the abnormal location, sonography of placenta accreta often displays irregular lucencies in the villous tissue (Finberg & Williams, 1992; Bromley et al., 1995). These "lakes" presumably derive from an abnormal disposition of maternal spiral arterioles to the intervillous space. Their appearance and turbulence within was much enhanced by power amplitude ultrasonographic angiography in a case of placenta previa increta described by Chou and Ho (1997) and reflect the "lacunae" described macroscopically by earlier observers (see above). These authors made a cogent argument for the employment of this methodology for preoperative diagnosis so as to much improve the outcome. The use of magnetic resonance imaging (MRI) has been advocated by Thorp et al. (1998), who were able to make an accurate diagnosis of placenta previa percreta in the first trimester of pregnancy. Fujikura and Sho (1997) studied the occurrence of what they called "cavities" but which correspond to the lacunae of other observers. They found them to be increased primarily in thicker, more voluminous placenta.

Considering the above findings, placenta accreta is a nice example of the importance of endometrial decidualization for proper control of trophoblast invasion. This correlation is further underlined by the fact that the absence of decidualization also in tubal pregnancy coincides with increased trophoblastic invasiveness (see below). At present, the decidual parameters responsible for missing control of invasiveness are still unknown (see Subchapter on Decidua). Several factors are under discussion: deficient decidualization of endometrial stromal cells, absence of endometrial NK cells, paucity of decidual macrophages, presence of B cells, increased numbers of T cells, or a concerted action of all these factors (see Trophoblast Invasion as a Result of Deciduo-Trophoblastic Interactions, below).

## Placenta Increta and Percreta

Many authors, Fox (1972) for instance, do not distinguish accretas from incretas and percretas, and Luke et al. (1966) criticized terms that have become fairly accepted in the medical nomenclature when they recalled 427 cases from the literature of accretas, incretas, and percretas. And we have to admit that the underlying pathogenetic mechanisms are likely to be the same, the only difference being a quantitative one that may be of considerable clinical importance.

In contrast to placenta accreta, in incretas the myometrium is apparently "invaded" by the placental villous tissue, whereas in percretas the villi penetrate the entire wall and the uterus may rupture. This may then become an acutely life-threatening condition. In general, the causes of such "invasive" placentas are similar to those of the placenta accreta vera. These conditions are nearly always present when tubal ectopic pregnancies rupture. Placenta percreta has also been reported to follow tubal reconstructive surgery at the uterine fundus (Stromme, 1963), in septate uteri (Ries & Middleton, 1972), complicating therapy for "missed abortion" (Harden et al., 1990), and through former Cesarean section sites (Berchuck & Sokol, 1983). The "invading" placenta may be intramural in position (Cava & Russell, 1978; Fait et al., 1987), perhaps its rarest site. Although adenomyosis is an attractive and often proposed cause of such unusual cases, it has rarely been found. McGowan (1965) proposed previous instrumental injury as a possibility because he saw two cases that were interpreted to have resulted from curettage. Ayers et al. (1971) have even reported the presence of fetal tissues within placenta increta sites of women who had previously suffered abortion. Dessouky (1980) found viable abdominal villi in the omentum following an instrumental abortion; the patient recovered after resection. Similarly, Davis and Cruz (1996) reported a case of persistent villi in myometrium (placenta increta) following earlier section and tubal ligation.

The most demonstrative pictures of placenta accreta and percreta were produced by Morison (1978). Among a population of 645,000 deliveries from his institution, he found 67 uteri thus affected. Of them, 31 were accretas (14 focal, 17 partial), three were incretas, and three were percretas; 17 were placentas previa accreta, 11 were placenta previa increta, and two were placenta previa percreta. In most of these cases, there was massive hemorrhage. Maternal death (only twice in his series) is a possible outcome; we have seen this also when the accreta had been incompletely removed and subsequent bacterial invasion led to sepsis. The fetus also often dies, but Gribble and Fitzsimmons (1985) described fetal survival (890 g) with such a complication.

Placenta accreta (vera) is usually detected after delivery when the placenta fails to separate or is incompletely

delivered. Incretas and percretas more frequently manifest during earlier gestation because of hemorrhage or uterine rupture. They are now often diagnosed by ultrasonography (Cox et al., 1988; Finberg & Williams, 1992; Hoffman-Tretin et al., 1992; Shapiro et al., 1992). Cox diagnosed the event at 16 weeks, closed the disrupted uterus, and allowed the pregnancy to continue for another 8 weeks. The infant was then delivered by cesarean section. After a stormy course over 2 months, the malformed neonate died. Five other conservatively managed cases were reviewed by Cox et al. as well. Other instances of young percretas have been described at 19 weeks' gestation (deWane & McCubbin, 1981) and 22 weeks' gestation (Bateman, 1967). The etiology of percreta, however, was not always clearly documented. On the other hand, Hassim et al. (1968) treated a mother with uterine rupture that occurred at 26 weeks. The patient expired. Another case involved rupture through a cesarean section scar at 37 weeks' gestation. Percreta with hemorrhage was documented by Hornstein et al. (1984) as occurring during elective termination of a 16-week pregnancy. The mother was 40 years of age and had leiomyomas but no other known risk factor. Rupture of the uterus is sometimes associated with the presence of an intrauterine device (Axelsson & Winblad, 1976), and it has occurred with pregnancy in bicornuate uteri (Zabrieskie, 1962). Zabrieskie reviewed the outcome of pregnancy in 92 patients with malformed uteri; he found that retained placentas occurred in 15% of patients, and that rupture occurred in four. Placenta percreta that invades the bladder and causes hematuria or massive hemorrhage has also been described and it is now seen more frequently with sonography or MRI (Taefi et al., 1970; Silber et al., 1973; Thorp et al., 1992; Leapheart et al., 1997). Nagy (1989) described a primigravida with placenta percreta at 23 weeks' gestation. The placenta had implanted at the fundus and it had spontaneously penetrated. He believed that percretas in primigravidae, at this stage of gestation, are exceptionally rare events.

Two cases of percreta are shown in Figure 9.52. The first was a patient whose erythroblastotic placenta would not separate after delivery. Hemorrhage necessitated hysterectomy. The mother's obstetrical history included five previous cesarean sections. The bulging placenta can readily be seen in Figure 9.52A at the arrows. In this case, only the peritoneum separated the villous tissue from the cul-de-sac. The specimen was much disrupted during the traumatic event. The "invasive" nature of the placenta into the lower uterine segment is seen in Figure 9.52B, it was actually a placenta increta. The placenta shown later in Figure 9.54A, on the other hand, came from what was thought to be an abdominal pregnancy near term with a surviving infant. Most of the placenta had an abdominal position and was attached to a defect in the uterus. The placenta had more or less herniated through a uterine

A

FIGURE 9.52. A: Placenta increta-near-percreta. The patient bled during delivery, and the placenta would not separate, so a hysterectomy was done. At the posterior aspect of the lower uterine segment, one can see the nodular protrusion (arrows) of peritoneum-covered placenta. B: Same specimen as in part

B

A after fixation and sagittal sectioning. Placental outline is indicated by arrows where it is invasive. The blood overlying this area is visible. Also seen are the scars from preceding cesarean sections in the anterior wall (right).

defect. It was covered with old blood and hemosiderin. There was no basal decidua, and there were virtually no free membranes. This case then represented nearly a placenta membranacea with the final implantation on the peritoneum (see Fig. 9.54B); there was significant salpingitis present also. In another nearly fatal case of placenta previa, the pregnancy had followed curettage and therapy for postabortal endometritis. Because such cases usually require hysterectomy, it is not common that one can evaluate possible future reproductive events. We had the opportunity to examine material from a first-trimester percreta that nearly led to fatal hemorrhage. The tissue was excised, and the patient had a successful second pregnancy. In her third pregnancy, however, another percreta developed at 14 weeks, necessitating hysterectomy. Despite careful search, we were unable to identify adenomyosis or other predisposing factors (W.J. Mulligan, personal communication, 1962). Following rupture and hemoperitoneum the  $\alpha$ -fetoprotein levels may be increased (McDuffie et al., 1994). Because of the serious nature of this pregnancy complication, various therapeutic modalities have been advocated for placenta percreta and are reviewed in contributions by Legro et al. (1994), O'Brien et al. (1996), and Dubois et al. (1997). Sono-

graphic diagnosis of this now so much more frequent entity is feasible (Bromley et al., 1995).

The reason why placenta percreta is now so common undoubtedly relates to the greater frequency of cesarean sections. But what is it that causes the percreta? In our view it is the manner in which the uterus is repaired and reconstituted after section. After all, when the section site is closed, the uterus commences a rapid involutionary stage; little regeneration of myometrium can then be expected anyway. Moreover, there is probably little if any myometrial growth after incision, and reconstitution of a normal uterine wall is impossible, we believe. Therefore, when the next pregnancy occurs, the expanding uterus often dehisces at the former section site, and it is not unusual for the obstetrician to witness such dehiscence at repeat cesarean section (Fig. 9.53). Alternatively, when the placenta implants over this previous scar, there is no underlying endomyometrium and, with uterine expansion, the placenta comes to implant on very thin scar tissue and/or peritoneum. Such a condition is seen in Figure 9.54. In this case and others we have witnessed, much distortion of the intervillous space had occurred (lacunae) and there was marked chronic villitis with plasma cells, at this site only. Additionally it needs to be

FIGURE 9.53. Placenta previa in the region of a former cesarean section scar. It necessitated total hysterectomy.

considered that, in the past, closure after cesarean section was accomplished with silk sutures, a practice that has more recently been abandoned, perhaps with dire consequences. The microscopic appearance typical of the placenta accreta in such cases is shown in Figure 9.55.

### Uterine Rupture

The uterus may rupture and expel its contents into the peritoneal cavity, there may massive hemorrhage, or it may be “sealed” by the fetal membranes. Such a case was eloquently illustrated by Murta and Nomellini (2004), in which the former cesarean section scar had dehiscence and the amniotic membrane protruded through the separated uterine wall. These authors cited a number of relevant publications, of which there are many in the obstetrical literature. Only a few are cited here. Aboulafia et al. (1994) found rupture and abdominal hemorrhage in the second trimester and sutured the myometrial defect through which the placenta protruded. They advocated

conservative treatment because they obtained a viable neonate. Endres and Barnhart (2000) were not so fortunate. In their patient a hysterectomy was necessary at 15 weeks’ gestation. Bujold et al. (2002a) examined the rate of rupture after prior transverse cesarean section. When single-layer suture had been performed, rupture in the next pregnancy occurred in 5.6% of cases if the pregnancy took place less than 2 years after prior section; the rate

minimal inflammation at the site of adherence. A: H&E  $\times 160$ . B:  $\times 260$ .

was lower after a longer interval. LeMaire et al. (2001) described fundal rupture necessitating hysterectomy at 16 weeks in a pregnancy in which the uterus had no prior injury or section, although the patient had two previous pregnancies. This and a similar case reported by Caglar and Sezik (2003) must be most unusual events and were considered to be due to a “spontaneous” placenta percreta in an unscarred uterus (Fig. 9.56). Chauhan and colleagues (2003) searched a large database (142,075 patients) and found that 6.2 per 1000 trials of labor after cesarean section led to rupture, and Lin and Raynor (2004) reported

that induction of labor with oxytocin and/or misoprostol was followed by an approximately 1% uterine rupture.

This literature also considers the possible reason for the apparent increase in placenta percreta and uterine rupture. One possibly important aspect as precursor to percretas has been examined by Durnwald and Mercer (2003), for instance. They studied the relationship of single- vs. double-layered suture at hysterectomy. Of 768 women studied, 267 had a single-layer closure, while 501 had a double layer closure of the cesarean section site. The single layered closure was associated with shorter

FIGURE 9.56. Placental site of placenta “percreta.” This was a thin square fibrous scar at the location of previous cesarean section. The placenta was a total previa with expansion from mid-anterior uterus to low-posterior uterus, spanning over the internal cervical os. Focal villitis was present in anchoring villi. H&E.  $\times 160$ .

operative time, slightly less blood loss, less endometritis, and shorter postoperative hospitalization. Importantly, it was not associated with uterine rupture, but there was an increase of what they called “uterine windows,” which is the same as is commonly referred to as placenta percreta (see Fig. 9.53). Bujold et al. (2002b) had found a four-fold increase of uterine rupture after single-stitch repair; however, the ensuing discussion following this paper (Joura et al., 2003; Shipp & Lieberman, 2003; Vidaeff & Lucas, 2003) that discusses the nature of suture material and other controversies should be read to gain full understanding of these issues. Single- vs. double-stitch methods and their history are adequately reviewed by Cohain (2004). That summary recommends sonographic study after a prior cesarean section and the usage of Vicryl as suture material.

Perhaps the most important question for the pathologist is whether there has to be a prior uterine injury for a placenta percreta to occur or whether the placenta can march through the uterus spontaneously. This question is posed because of the enormous number of pregnancies that occur and the real scarcity of reports on spontaneous percretas (uterine rupture from other causes such as abnormal fetal position and arrested labor aside; they are covered by Ofir et al., 2004). We consider that this must be extremely uncommon and at least on occasion explainable by the reduced uterine collagen content in a woman with osteogenesis imperfecta type IA, as demonstrated by Di Lieto et al. (2003).

### Placenta in Ectopic (Tubal) Pregnancy

This topic is relevant here because ectopic pregnancies in many cases are also placentas accreta and percreta, and Fylstra et al. (2002) have even described a case of gestation within a uterine section scar. Additionally, the obstetrician faces interesting issues. For instance, Kemp et al. (1997) reported Doppler sonographic criteria for the viability of (as yet) symptomless tubal pregnancies. They saw two different types: (1) Viable pregnancies characterized by signal-intensive rings of maternal vessels around the gestational sac; these were likely to be followed by rupture if not treated surgically. These are implanted generally on the mesosalpingeal portion of the tubal circumference. (2) Nonviable tubal pregnancies implant on the other side, lack a highly vascularized ring, show little or no trophoblast invasion, and do not require surgical intervention. The authors concluded that differences in maternal vascularization within the tubal wall account for the differences in fate of ectopic pregnancies.

Trophoblast invasion on the mesosalpingeal side of tubal pregnancy is excessive and usually completely penetrates the tubal wall and deeply invades the tubal mesenterium (Kemp et al., 1997, 2002). This invasion behavior is made responsible for the high risk of tubal rupture.

There are no hints that differences in trophoblast biology can be made responsible for this excessive invasiveness. As was already discussed above (see Decidua) the more likely explanation are differences in the tubal host tissue, which largely lacks decidualization, contains only few macrophages, and is completely void of uNK cells (von Rango et al., 2001, 2003; Kemp et al., 2002).

Virtually all mesosalpingeally implanted tubal pregnancies are at least placentas accreta. When they rupture, they do so because the placenta almost always has become a placenta percreta. Overdistention of the tube is not the primary cause of tubal rupture in ectopic pregnancy, which is somewhat in contrast to what has been reported by Philippe et al. (1970). In a review of 112 tubal pregnancies, these authors observed that ectopic implantation is often superficial and that it leads to bleeding at the site of attachment. They did not specifically discuss the rupture. Numerous case reports of viable term fetuses from tubal pregnancies testify to tubal expansibility, and a relevant case is shown in Figure 9.57. McElin and Randall (1951) established criteria for this entity and collected 45 cases from the literature. The placenta they reported was clearly an accreta and was difficult to separate at operation. The fetal mortality in the literature was 75%, and the maternal mortality 10%. Frachtman (1953) also reviewed this topic extensively. He found at least 75 reported cases, to which he added his own. His case had a thin placenta. Large infarcts were found in O’Connell’s case (1952). Sunde (1965) emphasized the need to attempt complete removal of the placenta. Augensen (1983) found the placenta to possess a short cord (22 cm) and observed extensive decidualization of the sac’s wall, as well as many placental infarcts. One wonders if the “decidualization” was truly endometrium or whether it could have been extravillous trophoblast cells. Short cords are expected because of the reduced inability of the fetus to move. Thus, Willemen et al. (1965) recorded 31 cm for the cord’s length, and a case described by Chokroverty et al. (1986) had a 38 cm long cord with a macerated fetus. Many areas of placental degeneration were found as well.

The report by Gustafson et al. (1953) included a color picture of a placenta with velamentous cord insertion. It described a decidual reaction, but it actually depicted a typical placenta accreta with many extravillous trophoblast cells. We believe that, as is not uncommon, these cells were mistakenly interpreted to be decidua. This consideration is an important one that was once specifically studied by Moritz and Douglass (1928). These authors claimed that they regularly found decidua in tubal pregnancies at the villous attachment site “if the chorionic villi are intact.” This finding is contrary to our experience. True decidual transformation is rare in the tubal mucosa and all tubal pregnancies in our patients have been accretas. The connection to the tubal musculature is afforded by extravillous trophoblast cells, or the placental site cells.

FIGURE 9.57. Large ectopic, interstitial pregnancy with placenta accreta.

They often have a superficial resemblance to decidual cells but are of trophoblastic origin. It was for this reason that they were referred to as X cells in the first place, because of the difficulties in differentiating them from maternal tissue elements. Silver stains would quickly delineate the characteristically crisp borders of decidual stromal cells, while cytokeratin stain is useful to distinguish extravillous trophoblast cells.

It is also surprising to find striking contradictions in a study of 90 placentas (young abortions) of tubal pregnancies by Laufer et al. (1962). In their introduction, these authors wrote that decidua was lacking in the tube, but in their summary they stated that, aside from the hydropic degeneration and placental infarcts that are expected, decidua was found in all cases. Not only are tubal ectopic pregnancies accretas, when they rupture (as is commonly the case) they do so because the placenta becomes a placenta percreta with blood issuing from the intervillous space into the peritoneal cavity.

Reports of intraligamentary pregnancy (Vierhout & Wallenburg, 1985) merge with the next topic, abdominal pregnancy. The patient Vierhout and Wallenburg described was presumed to have developed interstitial placentation from rupture of a tubal implantation; the patient suffered severe toxemia, and the placenta was left behind and resorbed spontaneously. Interstitial implantation also occurred in the case described by Schmitt and Dittrich (1973), probably secondary to an abdominal pregnancy. As in so many other abdominal pregnancies, there was no amniotic fluid, and the child had deformations. The placenta had succenturiate lobes, many infarcts and intervillous thrombi. It was small and had unusually thick membranes. Similar cases of “interstitial” tubal preg-

nancy, related to previous tubal surgery, were recorded by Kalchman and Meltzer (1966), and Woolam et al. (1967); these authors reviewed the literature and provided good illustrations.

### Placenta in Abdominal Pregnancy

Implantation in the abdominal cavity, particularly when associated with term fetuses, has long been a topic of heated discussion. It may be associated with tubal disease and contraceptive devices, as in the case described by Tisdall et al. (1970), and Ross et al. (1997) described massive sanguineous ascites in association with it. Early diagnosis is a matter of concern, as it is difficult (Atrash et al., 1987). Ultrasonography and magnetic resonance studies have been advocated (Spanta et al., 1987). This complication of pregnancy is estimated to occur once in 3000 to 8000 births, according to the review of Martin et al. (1988). It also is associated with high fetal (83%) and some maternal mortality, according to these authors. They described nine cases of early and six cases of advanced abdominal pregnancy, and also provided an excellent review of current management. Abdominal pregnancy occurring after gonadotropin-induced pregnancy was reported by Cheng et al. (1994). The young pregnancy was located in the cul-de-sac and easily removed. When both intra- and extrauterine pregnancies exist, we speak of heterotopic gestations, very rare occurrences. Crabtree et al. (1994) reported such a case, a woman who remained pregnant after preterm delivery. After several irrelevant treatments, sonography showed the presence of an abdominal fetus. It was delivered by section; the placenta had an implantation on top of the uterus and was left behind.

Abdominal pregnancy also causes concern because of the unanswered question of how to deliver the placenta (Hreshchysyn et al., 1961), as it does not deliver spontaneously because it is invariably a placenta accreta. There is extraordinary local vascular development in response to implantation. When that tissue is dislodged, exsanguinating hemorrhage may occur. These authors analyzed 101 such cases and found that attempted placental removal was the commonest practice; they also advocated it when it is surgically feasible. They found a high morbidity when the placenta was retained; for example, Caruso et al. (1963) reported a patient who had subsequent bowel perforation.

StClair et al. (1969) intentionally left the placenta in the abdomen and perfused the umbilical vessels with methotrexate. They undertook this measure because methotrexate is highly toxic to trophoblast. The placenta involuted rapidly and the gonadotropin titers fell. They believed that this therapy may have improved the involution, which is otherwise considered to take as long as 50 days. Rahman et al. (1982) have also reported the use of this agent, but they were less enthusiastic about its benefit. These authors reported that 10 cases occurred among 102,000 deliveries. Somewhat similar figures were obtained in other large series dealing with ectopic pregnancy (Hallatt & Grove, 1985). Jaffe et al. (1994), who also left a placenta percreta behind, ineffectively treated the patient with methotrexate, only to have to remove the bleeding tissue 7 weeks after initial surgery.

Many abdominal pregnancies are secondary to tubal abortion; Hallatt and Grove depicted the typical accreta on uterine muscle and provided a distribution of the major implantation sites. The first successful removal of the gestational sac and most of the placenta by laparoscopy was reported by Dover and Powell (1995).

The placenta in abdominal pregnancy is rarely described in detail. It has been mentioned that the placental floor lacks decidua, that a large vascular supply supports the intervillous space, and that the placenta may develop on many maternal organs. Holzer and Pickel (1976) found such a case to have a large succenturiate lobe and a velamentous cord insertion. A remarkable vascular attachment to the mother was described by Norén and Lindblom (1986). Their normal term infant had a thickened placental sac over which many islands of placenta were distributed. The only connection to the mother was a 2 cm wide and 3 cm long vascular pedicle that connected the placenta to the uterine fundus. It was easily ligated. The placenta membranacea had many intervillous thrombi and infarcts. Fetal growth restriction (Shott et al., 1973), anomalies and deformations (Paintin, 1970; Guha-Ray & Hamblin, 1977), and occasionally fetal pulmonary hypoplasia (Cartwright et al., 1986) are often described. Several publications of abdominal pregnancy have appeared in which the condition occurred after hysterectomy (Kornb-

latt, 1968; Niebyl, 1974; Nehra & Loginsky, 1984). The latter authors collected 30 such cases from the literature.

The fate of the retained placenta is also rarely described in detail. When complications such as perforations and adhesions necessitate reoperation, the placental tissue is usually not described. Only sonographic studies of the atrophy are available (Belfar et al., 1986). An interesting report comes from Spinnato et al. (1987), who saw a cyst develop 3 weeks after the term delivery of a normal infant from an abdominal pregnancy. The umbilical cord was tied near its base and the chorion laeve was not removed or closed. Despite the absence of a fetus, the membranes reaccumulated a large amount of fluid. When the mass was finally excised, the fluid was brown and thick. It contained much necrotic debris and the remains of a macerating umbilical cord with its ligature, which were clearly depicted. Regrettably, no histology is available.

Ovarian pregnancies usually abort. The definition of ovarian pregnancy generally follows the strict criteria set in the past. These criteria are often attributed to Spiegelberg (1878), but they were actually delineated by Cohnstein the year before. A term pregnancy has rarely been reported in the ovary, although Williams et al. (1982) described such a case. As expected, the umbilical cord was very short (22 cm), but the placenta was unusually large (1500 g). When sections are made of the implantation site of ovarian pregnancies, the placental villi often insert on the cells of the corpus luteum. The cellular component of the placental floor is the extravillous trophoblast cell, frequently mistakenly identified (Yu et al., 1984). The English-language literature of ovarian pregnancy was reviewed by Boronow et al. (1965), who found 62 cases in 13 years. In other words, it is not a really uncommon entity. They noted that the usual antecedents of ectopic pregnancy (pelvic and tubal inflammation, sterility, and endometriosis) are not important in this disease. The site of implantation often contains much hemorrhage and only some trophoblastic giant cells. True placental tissue is frequently absent, except for some degenerating villi.

## Cysts and Breus' Mole

Placental cysts occur in many normal placentas. They may be found in the placental septa, in cell islands, and under the fetal surface. In addition, there are cystic structures in placental villi. The latter have a completely different pathogenesis and are largely ignored in this context and further considered in Chapters 21 and 22.

Also present and having a somewhat overlapping quality are liquefying hematomas ("Breus' mole"), which may occur in the subchorionic space of the placenta. They are included for discussion here merely for convenience, as they are not related to the common cysts of the mature placenta. A detailed chemical analysis was undertaken of cyst fluid from a large (4 cm) prenatally diagnosed subcho-

ionic cyst by Shipley and Nelson (1993). They compared the content of many components with those of amniotic fluid, cord, and maternal serum. Unusually high concentrations of iron, aspartate- and alanine aminotransferase, and lactic dehydrogenase were found in the fluid.

Placental cysts may be numerous and large (Fig. 9.58). Although the cysts probably have no clinical significance—at least none is recognized as yet—their origin is interesting and has been a matter of controversy. The cells that produce the cysts have also had a varied nomenclature, as they were often mistaken for decidual cells. The cells that produce the cysts and the biochemical features of their viscid, mucin-like product have now been examined more closely. Grosser (1927) considered placental cysts to represent a special form of trophoblastic degeneration. He equated cyst formation with a process of fibrinoid degeneration. Bret et al. (1960) beautifully illustrated these structures in a study of 589 placental cysts and provided an extensive literature review. Cysts have been as large as a fetal head on rare occasion. Sanguineous material is often included and mixed with the normally “serous” content of cysts.

There are thus three principal types of cysts in the placenta. One is a **cystic “degeneration” of villi**. In this form (Fig. 9.59) some villi distend remarkably with fluid. More commonly, however, the villous edema involves scattered areas of the placenta, and the process is related to the hydatidiform mole. It is commonly found in triploid conceptuses and is then referred to as a “partial” mole. Partial moles are considered in Chapter 22.

Next, **cystic “degeneration” of subchorionic intervillous thrombi** occurs. Laminated thrombi form, almost regularly and in small quantities, in the subchorionic space. It is this site where the intervillous (maternal)

FIGURE 9.58. Multiple subchorionic cysts in a near-term placenta. Many cysts were discolored (red, brown, green) due to prior hemorrhage. The placenta had typical “maternal floor infarction” and was the fifth so affected pregnancy of this patient.

FIGURE 9.59. Two variants of villous “cysts,” actually hydropic changes of villi. All are triploid conceptuses at different stages of gestation. The cysts are actually within villous tissue.

blood is deflected backward. Most likely, eddying of intervillous blood accounts for the deposition of the small amounts of fibrin that normally accumulate here. This process leads to the formation of some white patches of subchorionic fibrin and to the “bosselation” (“tessellation”) of the fetal surface of the placenta. The fibrin accumulations increase with maturation, and much more thrombotic material accumulates underneath the chorion in some abnormal placentas.

It is more often found when maternal circulatory disorders exist; we have seen it repeatedly, for instance, in mothers with complex heart disease. These large patches of subchorionic coagulation may protrude on the fetal surface; and when they contract, fluid may be extruded from the clot. In this way, cysts can develop that contain old blood clot (Fig. 9.60). Some of these subchorionic cystic hematomas have been so large that they were diagnosed antenatally by sonography (Kirkinen & Jouppila, 1986). In one of the cases reported by Kirkinen and Jouppila, Doppler velocimetry of blood flow in the umbilical cord identified that the hematoma, having dissected into the base of the cord, caused a venous obstruction to blood flow. It was also the cause of furcate cord insertion. Occasional association with circumvallate placentas has been noted.

On rare occasions, cysts with this macroscopic appearance associate with a fetus papyraceus. This type of cyst is akin to the “**Breus mole**” (Fig. 9.61). Breus (1892) had described these lesions in five cases of missed abortions. He interpreted them as sacculations (“diverticula”) produced by the continued intervillous blood pressure against a decreased amniotic sac pressure. He believed that the

FIGURE 9.60. Term placenta with a large subchorionic intervillous thrombus that had liquefied and produced a protruding cyst. When the cyst was opened, it contained clot, contiguous with the intervillous space.

membranous cover continues to grow after fetal death, and he called the lesion “subchorionic tuberous hematoma,” wanting to differentiate this condition from hydatidiform moles.

The term Breus mole, however, is confusing. It has to do with “mass” rather than the process of molar “degeneration” as seen in hydatidiform moles. Torpin (1960, 1966) referred to these coagula as “hematoma moles” and also related them to circumvallate placentas. He suggested that abnormally deep implantation is their cause. Linthwaite (1963) conjectured that this placental abnormality precedes fetal demise. This view and “excessive implantation” were upheld by Thomas (1964). He cited authors who disagreed with Breus’ opinion, an aspect that was comprehensively discussed in the report by Shanklin and Scott (1975), who studied 10 cases past 25 weeks’ gestation. Seven infants were liveborn, but only

three survived the neonatal period. These findings argue strongly against the view that fetal death is primary in the development of the tuberous subchorionic hematoma. The authors also reviewed case reports that supported their opinion. Their incidence was 1:1200 placentas. Many of their patients had various diseases, including diabetes and hypertension. Despite these observations and their meticulous illustrations, no unified etiology for subchorionic tuberous hematomas emerged from this study.

Breus mole apparently is more commonly associated with monosomy X (45,X, Turner syndrome; Fig. 9.61) (see also Perrin, 1984). It is always a benign condition, and although it correlates with missed abortion, it is not limited to it, as Breus had suggested.

Finally, there are **true cysts** (Figs. 9.62 and 9.63), which are the principal focus of this discussion. These cysts are often blood-tinged, frequently multiple, and most often

FIGURE 9.61. Breus’ mole (subchorionic tuberous hematoma) in an immature placenta from a “missed abortion.” Note the numerous blood-filled protrusions on the surface.

FIGURE 9.62. Multicameral subchorionic cysts issuing from subchorionic deposits of extravillous trophoblast cells in a mature placenta.

FIGURE 9.63. Large subchorial cysts, some discolored by blood, in mature placenta. Note that one of the cysts dissects into the base of the umbilical cord. They may cause compression of vessels.

found in mature placentas. Their frequency is more difficult to ascertain. In our experience, about 5% of mature placentas have surface cysts of varying size. We find a much higher percentage of septal and cell island cysts, provided the placentas are sliced at thin intervals. Paddock and Greer (1927) found 14% in a macroscopic study of 1965 placentas; Carter et al. (1963) found 7% subchorial and 17% septal cysts in 400 mature placentas that they examined for vascular lesions. Cysts may originate below chorionic vessels and elevate them much above the rest of the fetal surface. There is no evidence, however, that this compromises the fetal circulation (Bret et al., 1960).

Subchorial cysts are rarely encountered at the margin of the placenta (Fig. 9.64) and they have not been recorded to occur on the extraplacental membranes. These cysts arise from the same extravillous trophoblast cells at the margin of the placenta that surrounds the entire membranous sac.

FIGURE 9.64. Subchorial cyst on membranes near the edge of the placental disk. It overlies an area of placental atrophy. H&E  $\times 20$ .

Cysts are most commonly found in placental septa (Figs. 9.43, 9.44, and 9.65 to 9.67) and in the cell islands (Fig. 9.47B) of mature placentas. They contain a colorless, thin fluid that is frequently slightly mucinous in character. Real mucin, however, is not found. The fluid is a rich source of major basic protein (MBP). The rich protein content of these cysts is evident by the precipitate found in histologic sections (Fig. 9.68). Paddock and Greer (1927) likened the content of cysts to colloid, while Grosser (1927) wrote of "colliquation necrosis" as the origin of the cystic fluid. It has been the experience of many writers that X-cell cysts are particularly often found in placentas that have fibrinoid degeneration. Thus, in maternal floor infarction, an unusual condition to be discussed later in this chapter, an excessive number of cysts surrounded by extravillous trophoblast are typical (Figs. 9.58 and 9.68). Their lining is irregular and ragged. Spaces develop between the extravillous trophoblast cells during their expansion, and they ultimately coalesce to make cysts.

According to Soma et al. (1991) increased numbers of X-cell cysts can be found in placentas from high altitude (Tibet and Nepal). This finding supports the view that cyst formation is a result of degenerative processes due to malnutrition and hypoxia in the centers of large accumulations of extravillous trophoblast. Further support is derived from the fact that cysts are formed within the

FIGURE 9.65. Placental floor with the origin of a septum of a near-term placenta. The septum shows cystic cavitation in extravillous trophoblast cell deposits. H&E  $\times 60$ .

FIGURE 9.66. Placental septum that reaches the chorionic surface (top). The intercellular substance has been stained dark (purple) with aldehyde-fuchsin (Waidl, 1963). At top left and in the top portion of the septum are small cysts developing in subchorial deposits of extravillous trophoblast cells. Aldehyde-fuchsin  $\times 8$ ; Montage.

extravillous trophoblast of the chorionic plate, the septa, and the cell islands rather than in those of the basal plate, the difference being that in the basal plate the extravillous trophoblast cells are intermingled with macrophages. These macrophages might easily remove degenerative products by phagocytosis and thus avoid liquefaction of degenerative masses.

## Maternal Floor Infarction

In maternal floor infarction (MFI), the floor of the placenta is thick, stiffened, and often yellow. The maternal surface has a corrugated appearance, and the placental septa are prominent (Fig. 9.69). Often, the lesion is associated with excessive proliferation of extravillous trophoblast cells and cyst formation (Fig. 9.70). Frequently, but not always, there is a massive “net-like” fibrin deposition throughout the placental tissue as well, occasionally referred to as Gitterinfarkt or Netzinfarkt in the German literature (Figs. 9.71 and 9.72) (Becker, 1981). The same features occur also in association with villitis of unknown etiology (VUE) (see Chapter 20). The placenta in MFI is often small and firm, and no other major pathologic lesions exist when it is sectioned. Maternal floor infarction is not associated with abruption, but fetal growth retardation is often a sequela. Most importantly, the condition may lead to fetal death, and it recurs frequently in subsequent pregnancies.

One patient seen by us had nine consecutive losses due to MFI. With other patients in whom the lesion had previously occurred, the anticipation of its recurrence has led to intense fetal monitoring, including an evaluation of estriol excretion. Twice, when fetal activity declined, Clewell and Manchester (1983) were able to obtain a living fetus by cesarean section. The placenta had the same changes as those of the original descriptions of MFI (Benirschke, 1961; Benirschke & Driscoll, 1967). This strongly argues against the notion, expressed by Fox (1978), that MFI is a postmortem change of the placenta of stillborns. Likewise, Katz and colleagues (1987) found typical MFI in a patient whose baby survived and did well. That patient had previously had three abortions and one abruptio placentae with stillbirth. All of her placentas had excessive fibrin deposits. The patient had chronic hypertension, and during the last pregnancy there was growth retardation, and a 7.2-fold elevation of  $\alpha$ -fetoprotein.

FIGURE 9.67. Typical septal cyst. Note that it is in the center of the placenta, at the tip of the partial septum.

FIGURE 9.68. Subchorionic “X cell” cyst of the placenta. Note that the cyst contains precipitated protein. H&E  $\times 40$ .

FIGURE 9.69. Maternal floor with maternal floor infarction. The entire decidual floor is thickened, yellowish, and infiltrated with fibrin. The cut section (below) shows the relatively shallow depth of fibrin infiltration.

FIGURE 9.70. Typical maternal floor infarction (MFI) in the placenta of a premature infant who died with hyaline membrane disease. The infant had been reported to “never be active” in utero. The floor and septa have increased fibrin infiltrates, and there are two septal cysts (arrows) in this section. The entire placenta had a firm appearance.

FIGURE 9.71. Massive intervillous fibrin deposition: “Gitterinfarkt.” It was a 34 weeks’ gestation placenta of a growth-retarded infant who did well. The previous pregnancy had also resulted in an infant with growth restriction.

FIGURE 9.72. Case similar to that in Figure 9.71: massive diffuse fibrin encasement of villous tissue in MFI with “Gitterinfarkt.” It was the third stillborn of a healthy mother; the maternal serum MBP levels were markedly elevated.

tein (AFP) was detected from 17 weeks on. She delivered at 34 weeks and the growth-retarded infant eventually did well. The elevated AFP levels were interpreted to result from a disruption at the maternal–fetal interface and at least once a fetal hemorrhage of 4 mL was detected by Kleihauer test. The MBP levels in maternal serum were significantly elevated in one of our patients with MFI, which was established by elevated maternal serum AFP levels; the patient had had two previous stillbirths (G.J. Gleich, personal communication, 1989).

Subsequent evaluation of the possible utility of MBP levels in maternal serum for the anticipation of MFI was not productive (Vernof et al., 1992). Robinson et al. (1989) found a strong correlation between elevated AFP levels and poor pregnancy outcome, even when congenital anomalies and twins were excluded. Thus, MFI and its variants must be entertained in the differential diagnosis of an unexplained elevation of AFP during pregnancy. Mandsager et al. (1993) established ultrasonographic criteria for the diagnosis of MFI and found them useful in anticipating the disease.

It is true that when a placenta has been retained for a long time after fetal death the organ accumulates fibrin and becomes firm. It is not the case, however, with most stillborns. Their placentas usually show no increased fibrin imbibition. Nor have the fetuses of some of the placentas with MFI been dead for especially long periods. As indicated earlier, this condition occurs with liveborn infants as well, especially with growth-restricted infants. Although MFI is a specific entity, it is not always completely expressed; that is, in some placentas, the characteristic fibrin deposition does not involve the entire floor. This variability occasionally makes the diagnosis difficult.

One atypical case has been described in which the fetus ultimately developed microcephaly (Pfeiffer, 1974).

The histologic findings of MFI include a marked increase in fibrinoid deposits of the decidual floor with encasement of many villous tips. Those villi then are sclerotic and avascular. The fibrinoid stains faintly with Congo red, but it is not amyloid by electron microscopic study. There is an increase of extravillous trophoblast (X cells) and septal cyst formation. Occasionally, many subchorionic cysts are found in this condition. Inflammation is usually not present, and the trophoblast in uninvolved areas is normal. The Gitterinfarkt features are shown in Figures 9.71 and 9.72. Villi are encased in masses of fibrinoid and appear to have been strangled, whereas adjacent villi are normal (Figs. 9.73 and 9.74). There is usually no inflammation. In some specimens of MFI, however, there is a moderate degree of lymphoid cell infiltration around the necrotic villi (Fig. 9.75). Plasma cells are absent, and there is usually no villitis. These placentas are also not associated with the decidual vasculopathy (atherosis) of preeclampsia.

It must be emphasized that MFI is macroscopically and microscopically different from common infarcts. No large areas of villous infarction are present; the lesion is usually confined to the floor of the placenta, and the deposition of fibrinoid is an outstanding feature of this entity. Therefore, when studies of the nature and frequency of infarcts are made (e.g., Fox, 1967), this lesion is not encompassed. In considerations of the placenta in placental insufficiency, however, there is more often mention of fibrin-encasement, lesions that apparently represent similar pathologic features. Thus, Wigglesworth (1964) found among the normotensive cases in his study that "the most extensive placental infarction was seen in cases of unexplained stillbirth. The lesions in those placentas were not always pure infarcts but consisted of true infarction and massive arborescent fibrin deposits."

Kubli (1968), in a consideration of chronic placental insufficiency, mentioned that the lesions are variable and comprise cases with "disseminated ischemic necroses with fibrinoid degeneration ('essential' placental insufficiency, prolonged pregnancy)." Ermocilla and Altshuler (1973) found similar lesions, particularly prominent proliferation of extravillous trophoblast cells (X cells) in three growth-retarded infants. They suggested that it would be better if we devoted our efforts to determining the function of X cells than be concerned with their origin. Davies et al. (1984), although not referring directly to MFI, also found an increased amount of fibrin in the placentas of growth-restricted infants.

The only author who has paid more attention to this lesion is Naeye (1985). He attempted to ascertain the incidence of MFI and its significance from the 39,215 placentas examined in the Collaborative Perinatal Study. He found that MFI was reported in 1 of 200 placentas. That figure is much higher than is our experience and

may be related to the variability of observers. The fetuses were stillborn in 17%, and 50% of the patients had had previous stillbirths or abortions (27% of controls had such). He also found chorioamnionitis and twice the expected frequency of fetal growth retardation. His experience of an increased incidence of preeclamptic decidual lesions is not supported by our cases. Smoking had no influence, but women with MFI had higher hemoglobin values. Nickel (1988) also described a case and discussed the recurrence and related diseases.

The etiology of MFI is unknown. We are convinced, partly because of its frequently recurrent nature, that MFI is a specific entity. Naeye (1985), on the other hand, believed that it represents the "final common pathway for a number of disorders, some of which are the result of damage to the decidua." He favored a relation to infection, with which we disagree. It is true that MFI and especially "Gitterinfarkt" are seen in some cases of chronic villitis, but not all MFI placentas have villitis. We have suggested that MFI relates to an abnormal host/placental interaction but not necessarily an immunologic one. Because the lesion has generally been poorly recognized, no further support has been forthcoming for this notion. Be that as it may, it is important for the obstetrician to know of its existence because, as the case reported by Clewell and Manchester (1983) clearly showed, subsequent pregnancies may be salvaged when the disease is recognized to have caused stillbirth or abortion.

We know nothing of the pathogenesis of MFI. The excessive fibrinoid (and perhaps extracellular substances, such as fibronectin) deposits may reduce the flow into the intervillous space and thus be responsible for fetal malnutrition. We have not observed any specific maternal vascular disease in these patients, and lupus anticoagulants have not been present in the mothers. The few clinical correlations and histologic observations have suggested that the fibrinoid deposition occurs relatively quickly. Usually, this situation is the case during the second and third trimesters. With the exception of occasional diabetic patients, the mothers have been clinically normal.

One promising avenue for future study is based on the findings of Robb et al. (1986a,b). Using an immunohistochemical technique, these investigators located what was interpreted as herpes virus antigen in the floor of most specimens diagnosed as having MFI. They suggested that this deposition of antigen may represent a manifestation of latent herpes simplex virus infection. The problematic associated with demonstrating conclusively HSV antigen by immunoperoxidase staining, however, is significant and taints these efforts.

## Decidual Degeneration

Degenerative changes and hemorrhages are frequent features of the decidua in the basal plate and the membranes. The slowly progressive necrosis of the decidua

FIGURE 9.73. Histologic features of Gitterinfarkt. Villi are encased in masses of pale eosinophilic fibrin-like material. Adjacent villi are normal. The encasement usually begins, and is most severe, at the anchoring tips of the villi. H&E  $\times 160$ .

FIGURE 9.74. Case similar to that in Figure 9.73. Fibrin-engulfed clusters of mature villi exist adjacent to normally preserved villi. H&E  $\times 60$ .

FIGURE 9.75. Histologic appearance of a maternal floor infarction. There is an excessive amount of fibrin in the decidua. Many basal villi are dead and are surrounded by chronic inflammatory cells. H&E  $\times 100$ .

capsularis was believed to be the result of progressively decreasing vascularization (Grosser, 1927). The more likely explanation is endocrinologic. One may presume that reduced concentrations of those steroid hormones that induced decidualization occur locally. It may be so because with increasing distance from the placenta decidual degeneration increases (Dallenbach-Hellweg & Sievers, 1975). This view has been supported by the findings of Welsh and Enders (1985), who found decidual involution at the mesometrial side of rodent uteri, opposite the placental site.

Decidual necrosis is often combined with local hemorrhages and may result in prenatal bleeding. McCombs and Craig (1964) reviewed the basal plates of 34 uteri from therapeutic hysterectomies and found decidual necrosis in 81%. In 52% the necrosis was present at some distance from the implantation site. They regarded it to be a normal phenomenon, which is also our opinion. At early implantation sites, hemorrhages of the decidua are normal, although it may be a different matter when they become clinically evident by vaginal bleeding. The latter may be a sign of “decidual angiomas,” according to Bittencourt and Sadigursky (1977). Their finding, however, may merely represent exaggerated dilatation of basal plate vessels with thrombosis.

In the delivered placenta, one often finds small retromembranous hematomas. They appear as patches of adherent brown-yellow clot, which when they are old, look as though they are composed of fibrous tissue (Fig. 9.76). Occasionally, this situation ensues after amniocentesis (Fig. 9.77). Moreover, when an intrauterine device (IUD) remains into pregnancy, it is frequently locally associated with old hemorrhages (see Chapter 1, Figs. 1.4 and 1.5). These IUDs also lead to frequent placental “wandering” (trophotropism) with marginal or velamentous insertions of the umbilical cord.

FIGURE 9.76. Localized retromembranous hematomas in uncomplicated pregnancy. Top: Note the brown patch of old blood in the decidua capsularis. Bottom: There is an old, white retromembranous hematoma in an otherwise uncomplicated pregnancy at term.

Massive hemorrhage during early pregnancy has once been reported to break into the amniotic sac, producing a sonographically apparent umbilical cord mass (Witter & Sanders, 1986). Retromembranous bleeding from venous lakes has also been described to occur, according

FIGURE 9.77. Retromembranous hematoma 4 weeks after amniocentesis. Note the vacuolated trophoblast beneath chorion and the degenerating clot in dead decidua capsularis (below). H&E  $\times 64$ .

to Pozniak et al. (1988), following chorionic villus sampling. They found venous lakes to be uncommon in first trimester uteri and cautioned that they must be avoided in chorionic villus sampling (CVS).

Decidual necrosis and local hemorrhages have been linked to potential adverse effects on embryonic development. Ornoy et al. (1976) found an increase in severe congenital anomalies when prenatal bleeding had occurred, whereas Mau and Netter (1974), in their paired prospective analysis of 5257 pregnancies, found no statistical difference of anomalies occurring in infants of mothers who bled and those who did not. Rutherford (1942) had suggested that prenatal bleeding was an ominous feature. That opinion paved the way for future experimental decidual support with hormone replacement. Javert (1955), who observed that the expansion of the placenta lends itself to decidual bleeding, found administration of vitamin C to be helpful.

## Involution of Placental Site: Retained Placenta

### Involution of the Placental Site

Pathologists rarely obtain a postpartum uterus to enable a detailed study of the involutional changes that take place at the former site of implantation. Therefore, involution of the normal placental site has been studied by only a few investigators. Normally, the postpartum lochia contains the decidual remnants, including perhaps some of the degenerating remnants of the vasculature that had previously undergone the so-called physiologic changes of pregnancy. Only when significant postpartum hemorrhage occurs and hysterectomy is performed, is the pathologist asked to seek the cause of the bleeding. He or she may then find remains of villi, incompletely thrombosed vessels, placental polyps, and some degree of inflammatory reaction. Frisoli (1981) suggested that retained placental tissue is found in about 50% of such cases at curettage. The curettings and postpartum uteri are difficult tissues to study objectively because most pathologists have little experience with the normal, complex process of placental site involution. Williams (1931), in a classic paper, attempted to rectify this situation. His study should be read before any interpretation of such a postpartum uterus is undertaken. It must also be recognized that in 85% of normal, delivered placentas the decidua basalis shows foci of polymorphonuclear leukocyte infiltration (Schneider, 1970). These cells are part of an apparently normal process of implantation and are not considered an expression of deciduitis or infection. Nevertheless, postpartum hemorrhage and subinvolution are nearly always associated with significant inflammation, if only because the cervix remains open and patulous.

The placenta separates from the uterus in the decidua basalis, deep to Nitabuch's fibrin layer. This fibrin layer is usually present in the floor of the delivered placenta but, contrary to some opinions, it does not serve as the cleavage plane. Placental separation probably occurs largely because of the shearing action of the underlying myome-

trium against the noncontractile placenta. One may speculate that detachment might be easier when the placenta is more turgid and still filled with fetal blood, but it is apparently not the case. Walsh (1968) found that when the cord is clamped early and more fetal blood remains in the placenta, postpartum hemorrhage is significantly more common than when this blood was allowed to drain into the fetus.

Immediately following delivery, the uterine surface becomes covered with fibrin and blood clot; the contraction of the uterus clamps the maternal vessels and this stops uterine bleeding. Ludwig (1971), and Ludwig and Metzger (1971) have made elegant electron-microscopic observations of this area postpartum. In their scanning electron-microscopic study, they speak of a "wallpapering" of the endometrial surface with a delicate meshwork of cross-linked fibrin that includes deformed erythrocytes. They had shown earlier that, with the first contraction after expulsion of the placenta, this fibrin is deposited and that it aids hemostasis. There is pronounced furrowing of the inner surface of the uterus following delivery that is bridged by the "tapestry" of fibrin. Mukaida et al. (1975), who also investigated this topic, came to similar conclusions.

Friedländer (1870) found that most of the endometrium degenerates after birth and that regeneration takes place from the glands and stroma in the spongy layer of the endometrium; this process is largely completed by 4 weeks postpartum, at least in the area away from the implantation site. The endometrium of the implantation site itself is not reformed for several additional weeks after delivery. The controversy over what constitutes physiologic changes after birth did not cease until Williams (1931) published his comprehensive study of normal uteri that had been removed up to 4 months after delivery. He showed that the detachment of the placental site proceeded with little inflammation or necrosis. The cessation of blood flow through the endometrial vessels was largely accomplished by contraction of the uterus itself. In the

FIGURE 10.1. Poorly thrombosed uterine vessels of the placental site 2 weeks after delivery of a hydatidiform mole. H&E  $\times 160$ .

absence of contraction, as in cases following former overdistention (e.g., in multiple pregnancy, hydramnios), these vessels may bleed extensively. This uterine atony presents a life-threatening situation that demands emergency attention. Normally then, these vessels are clamped by uterine contraction; they thrombose subsequently (Fig. 10.1), and the vascular placental site eventually becomes a mass of hyaline plaques (Fig. 10.2). The vessels

become “organized” by the ingrowth of fibrocytes and endothelium, and they are later recanalized. This process takes many weeks. One can then readily identify former implantation sites by the presence of these unusual hyalinized vessels and by the remains of some placental site giant cells. These residua of implantation have been demonstrated particularly impressively in several monkey species, in which they form macroscopically visible plaques (Bronson et al., 1972). Although the changes in monkeys are, in general, similar, they differ by involving usually both uterine sides, as their placenta is commonly bidiscoid. Moreover, they are much more massive and persist much longer than the approximately 7 weeks considered to be the normal for women. Also, some calcification occurs in the hyaline areas of simian placental site involution, which is not often the case in humans.

The placental site is then “exfoliated,” as Williams (1931) called it, rather than being absorbed into the myometrial tissue. At least the portions that are central to the myometrium are undermined. Williams considered that the decidual site is undermined by regrowth and by extension and downgrowth of endometrium that originates from remaining endometrial glands and stroma. He described it to be a “conservative” effort of nature to thus dispose of the thrombosed vessels. It must be borne in mind, however, that it applies only to the decidual portions of the placental site; the myometrial part has a much different regressive curve. One mystery of postpartum uterine involution is the rapidity with which the muscle mass is reduced. The average uterus weighs about 1000 g after term delivery and, largely through the dissolution of cytoplasm, it shrinks to less than 100 g, usually within 2 months. An appreciation of this massive involution of myometrium postpartum is especially important in our understanding of the “healing” of cesarean section incisions. Virtually no myometrium repairs the incisional defect. Only a thin fibrous scar approximates the muscle

FIGURE 10.2. Agglomeration of hyaline masses from placental site vessels 6 weeks after normal delivery. H&E  $\times 64$ .

layers. Thus, in subsequent pregnancies the probability of dehiscence exists (see Chapter 9).

The nature of the vascular changes that take place at the placental site postpartum was the topic of a study by Maher (1959). He observed that the elastic membranes of placental site vessels lose their staining qualities for 25 to 30 days. After that, the elastica is restored, but there is persistence of abnormalities in the pattern of the elastic membrane for a long time. Maher described striking involutional and regenerative changes of the placental site vessels and compared them with the much less prominent effect of pregnancy in those portions of the uterus and fallopian tube that are remote from the implantation site.

Anderson and Davis (1968) made the next major contribution to the study of placental site involution. They believed that vascular constriction and occlusion cause necrosis and sloughing of the former decidua basalis. They confirmed the findings of Sharman (1953), which were made from 626 postpartum biopsies and 11 uteri, removed 1 to 9 months after delivery. Anderson and Davis suggested that the absence of necrosis observed by Williams (1931) was due to his lack of appropriate material from days 4 to 7 postpartum. They corrected this deficiency and measured the placental site. Immediately after birth of the infant, the placental site was 18 cm; after the placenta detached, it measured 9 cm (largely because of uterine contraction), and it was 4 mm in thickness. At 8 days postpartum, the placental site measured only 4.5 cm in diameter, and by 8 weeks it had shrunk to 2 cm. The latest time at which a formerly normal placental site was visible macroscopically was 11 weeks after delivery. In contrast to Williams' opinion, a 6-mm-deep area of necrosis of the placental site, extending onto the myometrium, was observed from 2 to 6 days. A mixed "granulocytic and mononuclear inflammatory infiltrate occurred in the slough and the viable endomyometrium." Anderson and Davis described the "physiologic adenomyosis" that occurs in the superficial myometrium, particularly in the center of the former placental site, and they delineated the development of pleomorphic nucleated cells of the endometrial glands. In their experience, placental site giant cells persisted for several days, were confined to the

superficial layers, and did not extend deeply into the myometrium. Villi were found in four early specimens from apparently uncomplicated pregnancies. None of these elements normally persisted past 4 weeks. Vessels were described as thrombosed and showing "endophlebitis." Endothelial proliferation was a particularly prominent feature in the veins. Toward the end of the first week, the veins showed the beginning of organization of clots; arterial thrombosis was not a prominent feature. Because these normal changes are often misinterpreted as possibly being pathologic, a summary of the features of these sequential events is presented in Table 10.1.

Anderson and Davis (1968) were unable to resolve the nature of the placental site giant cells but favored a trophoblastic origin for these cellular elements. They stated emphatically that involution of the placental site does not lead to fibrosis of the uterus. They insisted that the term **subinvolution** must be understood within the framework of these normal involutional processes.

Sharman (1953) found that mitoses of the endometrium first occurred 8 days after delivery. By 16 days, the endometrium was structurally intact again. He also observed an "appreciable number" of plasma cells to be present 6 weeks after birth in 50% of his cases (37% had plasma cells at 3 to 4 months postpartum). This result is surprising, as it implies infection in one half of postpartum patients. It must be reiterated, however, that the inflammatory reaction of the normal placental site involutional process is usually sparse, and in most women it is confined to the first few days. Moreover, this infiltrate is made up of granulocytes and macrophages; plasma cells appear only late in this process.

In step with the involution of placental bed trophoblast are the endocrine signals of pregnancy. Human chorionic gonadotropin (hCG) disappears within 2 weeks from the maternal serum completely, regulated largely by its half-life of 9 to 37 hours (Midgley & Jaffe, 1968; Jaffe et al., 1969). Human placental lactogen (hPL), on the other hand, having a shorter half-life of up to 30 minutes, disappears within a day (Geiger, 1973). The disappearance of other pregnancy markers is less well defined (Tulchinsky & Ryan, 1980). Korhonen et al. (1997) studied the hCG decline in some detail in six women following

TABLE 10.1. Structural alterations in the postpartum placental site

Time	Size (cm)	Slough	Glands	Decidua	Veins	Arteries
Term	9	Hemorrhage	Present	Viable	Hyaline	Fibrinoid

normal delivery. From levels of around 35,000 IU/mL at the end of pregnancy, rapid decline leads to virtual elimination (5 IU/mL) by 21 days after delivery,  $\alpha$ -hCG having a much more rapid decline than  $\beta$ -hCG. Inasmuch as one may see extravillous trophoblast (X cells) for some time following delivery in the hyalinizing placental site, however, it is likely that some of the large quantity of major basic protein (MBP) that exists during gestation can be detected for longer periods, but measurements have not been made.

## Subinvolution

At times the uterus does not involute properly, and the clinical diagnosis of “uterine subinvolution” is entertained. What are the pathologic equivalents of this condition? Khong and Khong (1993) are the most recent authors to have examined this phenomenon, with the evaluation of 169 specimens from “delayed postpartum hemorrhage” that followed a singleton delivery. They provided some reason why such studies should be divided into periods before and after 6 weeks postpartum, not an important issue for pathologists, we believe. Retained placental tissue was most common (45 cases), to be followed by “subinvolution,” that is, widely patent uteroplacental arteries in 30 patients. Endometritis (seven patients) was uncommon and most of the other patients had essentially normal histologic findings. Placental tissue may have been retained because it resulted from placenta accreta, or because the fragmentation of a manually removed placenta was not appreciated at delivery, and a portion of a cotyledon was left behind.

Normally, the uterus shrinks rapidly, with dissolution of the myometrium. Within 2 weeks, its size reduces from about 1000 g to nearly 100 g, and the endometrium and placental site are cast off. With subinvolution this regression is delayed; the uterus remains boggy and edematous and may actually be retroflexed and congested. Often there is bleeding and some remaining placental tissue (“placental polyp”), or an infection may cause uterine subinvolution. Thorsteinsson and Kempers (1970) studied the records of 148 patients with delayed postpartum bleeding, occurring in 1% of deliveries. They found the bleeding most commonly resulted from subinvolution of the placental site. Curettage was done in 94 patients, and 78 were found to harbor microscopic fragments of placental tissue; seven additional patients had grossly visible placental remains. Curettage cured most patients. It is interesting to note here also that most of the patients (135) were said to have had normal placentas at delivery.

According to Stamm (1961), incompletely removed placentas have been the cause of litigation. For that reason, others had suggested that placentas be injected for completeness. Stamm, however, believed that the

evaluation for completeness of the placenta through the injection of milk is inaccurate, and that it should not become a routine procedure. Tears in the placenta often occur, which makes it difficult to ascertain with certainty that removal was complete. Stamm suggested that manual exploration of the uterus is necessary when one is uncertain whether a placenta has been removed completely.

## Placental Polyps

Placental polyps were described in three patients by Hoberman and his colleagues (1963), who also reviewed the sparse English-language literature on this topic. Placental polyps are usually made up of remnants of villous tissue that have become encased in layered clot. At times, one finds that the villi are directly attached to the myometrium; they are thus focal placentas accretas, but because of degenerative changes this diagnosis is often impossible to verify.

When these “polyps” are removed, the symptoms usually abate. If they are not removed, life-threatening bleeding may occur. This possibility was emphasized in the study of placental polyps undertaken by Dyer and Bradburn (1971). They decried that this important complication of the puerperium is rarely mentioned in modern textbooks. Dyer and Bradburn described the “immediate type” of polyp, which occurs during the first month after delivery, and the “delayed type,” where the tissue may be discovered months or even years later. They acknowledged that accretas may be part of the problem but believed that other, unrecognized factors play a role as well. Finally, they speculated that such retained fragments are the possible sites of future trophoblastic tumors. In our opinion, there is little evidence for the latter speculation, even though the placental site trophoblastic tumor has become a delineated entity (see Chapter 23). It is true, however, that an exaggerated placental site may pose as tumor and the differential diagnosis is not always easy (Benirschke, 1997). Philippe et al. (1968) claimed that a deficient arterial occlusion at the site of involution is a probable cause of postpartum hemorrhage. After studying and depicting the normal vascular occlusions, these authors showed hugely distended vessels with poorly organized thrombi, as well as increased hyaline masses, to be a cause of the bleeding that may take place later, when early postpartum hemorrhage has occurred. Philippe and his colleagues speculated that these vascular changes may result from inadequate hormonal effects on these vessels during the immediate postpartum period. They also suggested that therapy with 17-hydroxyprogesterone caproate may resolve the condition and that hysterectomy is not always indicated. Rutherford and Hertig (1945) showed placental polyps in three postpartum patients who had neither placental remains nor

inflammation, but had hugely dilated, improperly occluded, placental site blood vessels. Perhaps this situation constitutes the “true” subinvolution, a process whose etiology is yet to be clarified. Most recently, late bleeding has been associated with the discovery of hyalinized masses (placental-site nodules); when stained with antibodies to hPL, these masses were found to contain positively staining placental-site giant cells (Young et al., 1990) (see Chapter 23). The authors cautioned that these masses are benign remnants of placentation that must not be mistaken for tumor. Suffice it to say, retained placental villi are not always present in patients who experience postpartum hemorrhage. Incomplete occlusion of vessels alone may be the cause of subinvolution, as also may be an idiopathic failure of trophoblastic placental site cells to involute.

In addition to these features of subinvolution, there is the postpartum endometritis, “puerperal fever,” an infection caused by a variety of microorganisms. Its prototype, however, is caused by group A streptococci. The histologic features may be similar to those seen with other subinvolutional events, although there are additionally pronounced acute inflammation, infiltration with plasma cells, phlebothrombosis, and often colonies of bacterial organisms. All are life-threatening processes that may also lead to pulmonary embolism. Various aspects of a placental polyp, symptomatic 9 years after abortion of the last known pregnancy, were reported by Lawrence et al. (1988). At that time the patient had undergone sterilization. The polyp was composed mostly of “necrotic and hyalinized villi, without identifiable trophoblast.” A few syncytial cells exhibited hCG immunohistochemically, and abundant X cells were present with the hPL reaction. Regrettably, the authors did not report on the status of the ovaries so as to rule out a possible recent pregnancy. They also reviewed the few case reports and case series

FIGURE 10.3. Myometrial remnants of a former placental site with hyalinization, 2 years after normal delivery and death for unrelated reasons. H&E  $\times 160$ .

from the literature, which included a placental polyp 21 years after pregnancy.

In our experience, the hyaline scars of former placental sites may persist in the uterus for much longer than has been indicated in most of the literature cited here, much as the corpus albicans persists for years in the ovary. The myometrial remnants of former placental site vessels are shown in Figures 10.3 and 10.4, assuredly 2 years after the

FIGURE 10.4. Finding similar to that in Figure 10.3 but deeper in the myometrium. H&E  $\times 160$ .

FIGURE 10.5. Composite of implantation site with endometrium above. This patient had retained placental tissue for 16 weeks (see Fig. 10.6), and many of the placental site giant cells (dark)

persist deep in the myometrium. No vascular thrombosis had occurred. H&E  $\times 16$ .

last pregnancy. Figure 10.5 shows the uterus of a patient with retained placental tissue who died 16 weeks postpartum. Numerous trophoblastic cells can be seen throughout the myometrium of the placental site. Most, but not all, villi were completely necrotic in this patient (Fig. 10.6).

Somewhat related to these rare pathological findings are the observations made by Craven and Ward (1997)

on placental bed biopsy. This was done after cesarean section delivery of a multiparous patient for a study of preeclampsia. Microscopically, squamous epithelial masses, undoubtedly of vernix origin, were embedded in endomyometrium and maternal vessels. There was intense inflammation also present, and the authors considered this to be the result of membrane rupture.

FIGURE 10.6. Live and necrotic villi forming the placental polyp of the uterus shown in Figure 10.5, 16 weeks after delivery. H&E  $\times 64$ .

## Involution of a Remaining Placenta

Involution of a remaining placenta is conveniently dealt with at this point because some of its features resemble the findings of retained placental tissue and placental polyps. When fetectomy had been performed in rhesus monkeys between the 10th and 23rd weeks of pregnancy, it was alleged that the placenta was later delivered "on time" (Van Wagenen & Newton, 1943), that is, at term for this species. Lewis and Hertz (1966) found that most of the monkeys developed degenerated placentas when fetectomy was done between the 14th and 35th days of gestation. They had expected to find hydatid swelling, perhaps molar transformation, but it did not occur. In similar, larger experiments, Panigel and Myers (1972) also did not find hydatid changes following either fetectomy or ligation of the vessels that extend to the monkey's second placental disk (the "bridging vessels"). They observed that some villi remained structurally normal for several weeks, although their fetal capillaries and red blood cells soon disintegrated. The maintenance of some fine structural detail in these surviving villi is indeed remarkable. The villi become usually more compacted, rather than hydropic. Detaching a disk of the placenta and thereby interrupting the maternal perfusion in monkeys, however, led to placental infarction (Myers & Panigel, 1973). In many ways the villous changes found after prolonged retention of the placenta resemble those encountered following fetal demise (Fox, 1968). They are initiated by syncytial knotting, stromal fibrosis with loss of capillaries, and fibrosis of major stem vessels. Calcification and complete villous hyalinization are end stages.

When investigation of the factors that initiate labor required reexamination of the role of fetectomy, specifically as it relates to the role played by the fetal adrenal and pituitary glands, Lanman et al. (1975) restudied the placental changes following fetectomy in the rhesus monkey. In the 13 animals examined by these authors, fetectomy was performed between 65 and 143 days, term being 168 days. Nine of the placentas remained in situ beyond the expected date of delivery, two delivered near term, and two delivered prematurely. Histologic study revealed empty vessels, stromal fibrosis of villi, hyalinization, and calcification 17 to 108 days after fetectomy. X-cell hyperplasia was prominent in two placentas. The placental weights were similar to what was expected at the time of fetectomy, but they were much smaller than expected for the gestational age of the placenta. Somewhat different results were obtained by Nathanielsz et al. (1992). These authors were unable to obtain the placentas for dissection but, from the endocrine changes that occurred after fetectomy, they decided that a functional fetal circulation is necessary for normal gestational control.

The anatomic results just reviewed have also been the experience with retained placentas in women whose fetus has died or when only one fetus of twins survives. The placental tissue remains structurally intact for a long time. It first loses its fetal vasculature and undergoes fibrosis, and much fibrin accumulates, particularly in the intervillous space. The trophoblast continues to be perfused by the maternal circulation and so survives longer. The placenta eventually atrophies and comes to resemble an infarct. The result is not a true infarct, because an infarct occurs only after interruption of the maternal intervillous circulation.

# 11

## Anatomy and Pathology of the Placental Membranes

### Overview

The term **membranes** is usually taken to be synonymous with the amnion and the chorion laeve. The membranes represent the “bag of waters” that encloses the fetus. The membranes are distinct from the chorion frondosum, which is the actual placental tissue and forms a specialized, thickened part of the membranes. In other usage, placental membranes is occasionally also used as denoting the entire afterbirth. The true membranes normally insert at the edge of the placenta and contain the amniotic fluid and fetus. Membranes rupture during delivery owing to stretching or because of the mechanical force of the accoucheur. Several distinct layers are present in the membranes, and the structure and function of the membranes have received considerable attention primarily because of an interest in the turnover of the water they contain. Enzymatic activity of the membranes during the initiation of labor has been of additional interest. Most recently, the composition of the various extracellular connective tissue components has come under scrutiny (for review, see Bryant-Greenwood, 1998). Comprehensive surveys of many of these aspects, particularly the structural nature of the membranes, are found in Bourne’s (1962) and Schmidt’s (1992) books on the topic. Millar et al. (2000) measured the surface of the entire membranes in preterm and term placentas sonographically. It was 1037cm<sup>2</sup> between 25 and 29 weeks; 1376cm<sup>2</sup> from 30 to 34 weeks, and 1876cm<sup>2</sup> at term. The measured surface area of expelled membranes, however, was only 737cm<sup>2</sup>, 855cm<sup>2</sup>, and 1115cm<sup>2</sup>, respectively, from which they deduced that the membranes are stretched in utero. The structural basis for premature rupture of the membranes was reviewed by Malak and Bell (1996). Amniotic fluid dynamics were reviewed comprehensively by Barnes and Seeds (1972), and they have been modeled by Mann et al. (1996). The turnover of amniotic fluid has also been reexamined by Gilbert et al. (1997) in rhesus monkeys undergoing chronic catheterization. The absorption of

technetium-99m from the fluid led these authors to conclude that much fluid turnover occurs through the placental membranes. Measurements of tensile strength with determination of gene regulation of membrane rupture were provided by Nemeth et al. (2000a,b), who constructed a special apparatus for the purpose. They found upregulation of interleukin-8 and pre-B-cell colony-enhancing factor by distention.

There are three distinct layers of the membranes. Their origin and interdependence must be understood if one wishes to comprehend their complexity (Fig. 11.1; also see Fig. 11.6). The inner layer is the **amnion**. A thin, avascular layer of epithelial cells and connective tissue, it is derived from the fetal ectoderm by cavitation within the embryonic knot (Luckett, 1973) and is contiguous, over the umbilical cord, with the fetal skin. Confirmation of its epidermal origin has come from the studies of Nanbu et al. (1989), who demonstrated the fetal differentiation antigen CA 125 in the fetal periderm (outer layer of epidermis) and the amniotic epithelium.

The amnion is passively attached to the next layer, the **chorion laeve**, by the internal pressures of amniotic fluid. The chorion laeve, a much more complex tissue, is composed of connective tissue within which there are the fetal (chorioallantoic) blood vessels. The villi of the chorion frondosum originate from the chorion. At the parietal, free surface of the membranes, one finds their atrophied remains, even in term pregnancy specimens. These former villi then are round balls of connective tissue, usually lacking trophoblastic cover and possessing no vessels. On the outer surface of the chorion rest also the remains of the cytotrophoblastic cells of the trophoblastic shell. They undergo much change with advancing gestation; they are somewhat vesicular and often atrophy. Small cysts are often found in these cell collections that are similar to the X-cell cysts in the placental tissue (see Fig. 11.13).

These cells, as the remaining villi, are intimately intermingled with the outermost layer, the **decidua capsularis**.

FIGURE 11.1. Microscopic appearance of normal “membranes.” Amnion epithelium (A) sits on a thin layer of connective tissue that is separable from chorionic connective tissue (C) in an ill-defined plane (P) representing the so-called spongy layer (see Fig. 9.20). The following layer of extravillous trophoblast cells (T) is irregularly studded with atrophic “ghost villi” (V). At the periphery one finds the decidua capsularis (D) with maternal vessels (M) and frequent fibrinoid (F) deposits. H&E  $\times 16$ .

FIGURE 11.2. A–C: Uterus of a first trimester pregnancy with a 7.5-cm fetus in situ that was removed because of carcinoma of the cervix. Note the large myometrial vessels and the distance of the implanted placenta from the endocervix. The arrows

point to the “marginal sinus.” P, placenta. D: The membranes have been elevated from the decidua vera (DV) to show the fact that the decidua vera and decidua capsularis (DC) do not “grow together.” The cervix has been removed.

The decidua, representing modified endometrium, is the only maternal component of the membranes. A variety of trophoblastic cells are present within this area, and it is essentially impossible to obtain “clean” decidual cells from this tissue for experimental work. The decidua capsularis also normally contains a few maternal blood vessels, some phagocytes, and other inflammatory cells. At the placental margin, this decidua capsularis is contiguous with the decidua basalis and here delimits the marginal sinus. The tissue at the base of the actual placenta, to which the normal villous tissue is anchored, is the maternal floor. One often finds degenerative processes and inflammation at this location, and hemorrhages are also frequent at this site. They have been referred to as being the result of a marginal sinus thrombosis, a term that is no longer defensible. When one stretches the edge of the membranes away from the placenta, one can see the friable tissue that constitutes this marginal decidua. When it is disrupted, one enters the intervillous blood space, the marginal sinus. In Figure

11.2, the margin of the placental membrane attachment is seen in situ. The uterus depicted also clearly shows a lack of fusion between the decidua capsularis and the decidua vera (or parietal decidua), as is similarly shown in Figure 11.3.

For the purposes of this presentation, we start with a brief summary of the development of the membranes. In the following sections we discuss each layer separately and identify the associated pathologic processes. This organization of material is not meant to suggest that these structures are independent; often they have substantial interactions. There is, however, much misunderstanding of the perceived unity of the membranes, particularly in biochemical studies. It is thus important that one clearly distinguishes between these different structures.

#### DEVELOPMENT

The trophoblast of the implanting blastocyst can be subdivided into one early implanting half (the cells surrounding the implantation pole or the

FIGURE 11.3. Membranes and decidua vera at term. The membranes of this placenta had a “plaque” attached to their external surface that was a portion of the decidua vera from the opposite side of the uterus. There is a space between decidua capsularis

and decidua vera; the latter is covered by well-preserved uterine epithelium. True “fusion” between the two deciduas has not occurred. H&E. A  $\times 10$ ; B  $\times 240$ .

basal chorion) and one later implanting half (that surrounding the anti-implantation pole or the capsular chorion) (see Figs. 4.1B,C and 12.1). The developmental processes, described in Chapter 5, are valid for the basal chorion. With the appearance of the first villi, the basal chorion becomes the chorion frondosum, the forerunner of the later placenta (Fig. 11.4). The capsular chorion, which implants a few days later (see Fig. 5.1B,C), initially undergoes a corresponding although delayed development. It proceeds with the identical processes of lacuna formation and consecutive transformation of the trabeculae into small villous trees, as those that take place at the implantation pole. At this stage, it is called the **capsular chorion frondosum**. Within a few days, however, beginning at the end of the 3rd week postcoitus (p.c.), the first degenerative changes at the antiimplantation pole can be observed. These result in the regression of newly formed villi, a process that slowly spreads laterally over the blastocyst surface (Hamilton & Boyd, 1960). As soon as the villi degenerate, the surrounding intervillous space obliterates. Finally, the primary chorionic plate of the respective region, the obliterated intervillous space together with its villous remnants, and the trophoblastic shell fuse (see Fig. 12.1), forming a multilayered compact lamella, the **smooth chorion (chorion laeve)** (Fig. 11.4). The first patches of the smooth chorion are formed roughly opposite the implantation pole. From there they gradually spread over about 70% of the surface of the chorionic sac. This process continues until the fourth lunar month, when it slowly comes to a halt (Wynn, 1968; Boyd & Hamilton, 1970).

The differentiation process into chorion frondosum and chorion laeve is paralleled by changes in the surrounding maternal tissues. The superficial layer of the endometrium, which is characterized throughout implantation by the transformation of endometrial stromal cells into decidual cells, is henceforth called the decidua. Depending on its spatial relation to the implanting chorionic sac, the decidua is subdivided into several segments (Fig. 11.4). The decidua below and lateral to the blastocyst or, later, that below the placenta, is called the **basal decidua (decidua basalis)**. With complete interstitial implantation, the decidua closes over the blastocyst. This protruding layer is called the **capsular decidua (decidua capsularis)**. All those parts of the decidua that line the uterine cavity without being in contact with the blastocyst (i.e., at the opposing uterine wall) are called the **parietal decidua (decidua vera)**. With increasing diameter of the chorionic sac, the capsular decidua focally degenerates, so that in such places the external surface of the smooth chorion (trophoblast cells) borders the uterine cavity (Fig. 11.4C). This surface finally touches the parietal decidua (Fig. 11.4B,C). Between the 15th and 20th weeks p.c., the smooth chorion, together with its attached residual capsular decidua, locally fuses with the parietal decidua, thereby largely obliterating the uterine cavity (Fig. 11.4C). From this date onward, the smooth chorion has contact with the decidual surface of the uterine wall over nearly its entire surface and may function as a paraplacental exchange organ. The efficiency of this exchange, however, is limited by the absence of fetal vessels within the smooth chorion.

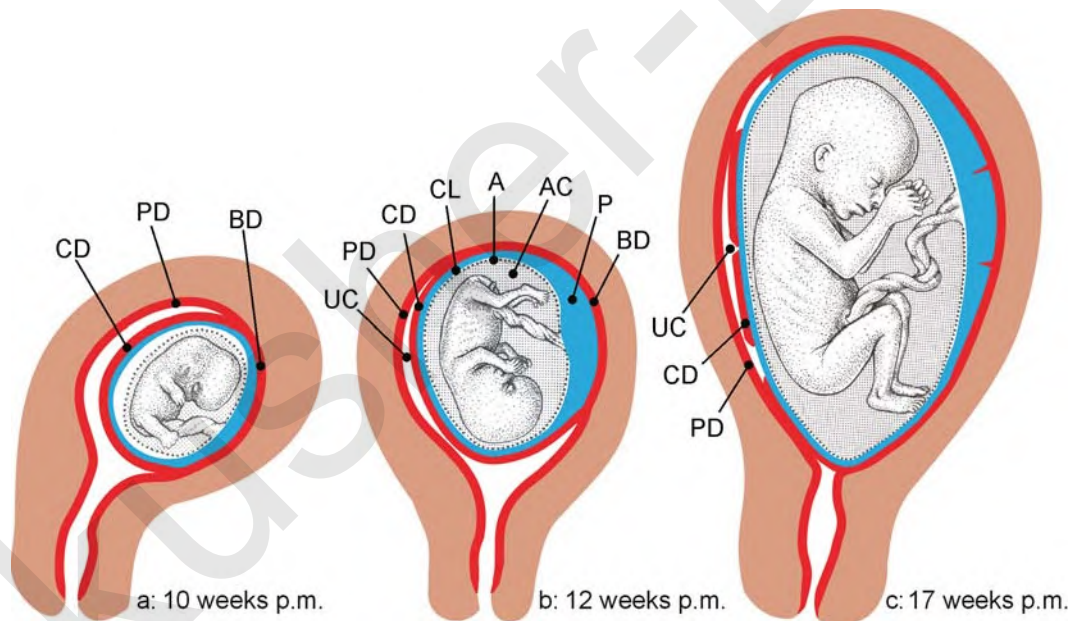

FIGURE 11.4. Late stages of the development of the fetal membranes. Fetus and amnion: black. Trophoblast: blue. Decidua: red. Myometrium: brown. A: Until 10 weeks postmenstruation (p.m.), the embryo is surrounded by a unit of chorion frondosum (blue); its later specialization into chorion laeve and the placenta is indicated by a slight increase in thickness only. The capsular part of the chorion frondosum is covered by the capsular decidua (CD), which is continuous with basal decidua (BD) at the placental site, and with the parietal decidua (PD), which lines the uterine cavity. The amnion (black dotted line) is not fused in most places with the chorion frondosum. B: Two weeks later (12th week p.m.), the original chorion frondosum

has differentiated into the thick placenta (P) and the thinner fetal membranes that surround the inner amniotic cavity (AC). At this stage, the membranes are three-layered, composed of inner amnion (A), intermediate chorion laeve (CL), and outer capsular decidua (CD). Because of the embryo's small size, the uterine cavity (UC) is largely open. C: From 17 weeks on, the membranes come into close contact with the uterine wall. The remainder of the capsular decidua (CD) fuses with the parietal decidua (PD) and largely closes the uterine cavity (UC). From then on, the chorion laeve contacts the parietal decidua. (Source: Modified from Kaufmann, 1981.)

A third tissue, the amnion, contributes to the development of the membranes. During the first steps of implantation, an enlarged intercellular space between embryoblast and neighboring trophoblastic cells can be observed. Some small cells that line the inner surface of the trophoblast in this particular region have been named the amniogenic cells. They are the forerunners of the **amniotic epithelium**; the cleft separating them from the embryoblast is the early **amniotic cavity** (Hertig & Rock, 1941; Starck, 1975; Hinrichsen, 1990) (see Fig. 12.1). Because of its continuous expansion, the amniotic cavity slowly surrounds the embryo from all sides and finally covers the umbilical cord. In addition, through fetal growth and the production of **amniotic fluid**, the amniotic cavity is expanded.

Extraembryonic mesoblast, formed in the lacunar stage (see Chapter 5; Fig. 5.1D), not only lines the inner surface of the blastocyst cavity but also covers the external surface of the amniotic epithelium, thus giving rise to the **amniotic mesoderm**. Amniotic mesoderm and the extraembryonic mesoblast covering the trophoblast (**chorionic mesoderm**) are separated by a cavity called the exocoel (see Fig. 12.1) (Hertig, 1945, 1968). Those mesoblast cells that line the cavity are transformed into a mesothelium (Heuser's membrane). Fluid accumulation within the amniotic cavity causes its expansion so that it slowly compresses the exocoel. During the 6th to 7th week p.c., the amniotic vesicle has become so large that its mesoderm locally fuses with the chorionic mesoderm (see Fig. 12.1). This process starts in the areas surrounding the cord insertion at the chorionic plate and is largely completed after another 5 weeks (until the 12th week p.c.). The amniotic vesicle then completely occupies the exocoel (see Fig. 11.4) (Boyd & Hamilton, 1970). Only cleft-like remnants of the latter may be detectable in later stages of pregnancy, although one can always detach the amnion from the chorion. There is some sonographic indication that complete fusion may be delayed in pregnancies with trisomy 21 (Down syndrome) (Appelman et al., 1998). According to Grosser (1927), the mesothelium of both mesoderm layers disappears as soon as they come into contact with each other or even fuse. Fusion is never perfect, and amnion and chorion can always easily slide against each other. There are numerous clinical descriptions of "double sacs", that is, the presence of more fluid than expected between the amnion and chorion (e.g., Borlum, 1989). Generally, they have no relevance and are not

pathologic. Histologically, they even seem to be separated by a system of slender, fluid-filled clefts (see Intermediate Zone of Chorion, below). Bundles of connective tissue fibers exist, crossing from one to the other layer; however, they are locally restricted and are laterally surrounded by these clefts. Differing from the situation in the membranes, the expanding amnion not only becomes closely attached to the surface of the cord but firmly fuses with it. It cannot be dislodged from the cord.

As soon as the amnion is attached to the surfaces of the placenta, umbilical cord, and the chorion laeve, its nomenclature becomes specified. The terms **placental amnion**, **umbilical amnion**, and **reflected amnion** are widely used. Although histologically the reflected amnion and chorion laeve are evidently separate structures, macroscopically they are summarized under the term **membranes**.

In spite of the considerable expansion of the amniotic cavity (Fig. 11.5), the structure of the membranes generally remains constant from the 4th month until term (Petry, 1962; Schmidt, 1992). Their mean thickness after separation from the uterine wall during labor is from about 200 to 300mm, with a slight tendency to increase closer to the placenta. Because of local edematous swelling of the amniotic mesoderm, considerably thicker membranes are sometimes observed (Bourne, 1962). After birth, the following layers can be seen histologically (Fig. 11.6):

1. Amniotic epithelium and basal lamina (20–30µm in thickness)
2. Amniotic mesoderm (about 15–30µm in thickness)
3. Intermediate zone (highly variable in thickness)
4. Chorionic mesoderm (15–20µm in thickness)
5. Trophoblast (10–50µm in thickness)
6. Decidua (up to 50µm in thickness)

## Amnion

The amnion is composed of an inner layer of epithelial cells, planted on a basement membrane that, in turn, is connected to a thin connective tissue layer by filamentous strands (Danforth & Hull, 1958). When the membrane is allowed to fix while stretched, the surface appears flat; when it is allowed to contract, many folds appear. It is a translucent structure that is frequently detached from the rest of the membranes by the forces of labor. It can almost always be easily separated from the underlying chorion, with which it never truly fuses, cellularly speaking.

As mentioned, this “fusion” of amnion and chorion completes around the 12th week of development (Boyd & Hamilton, 1970). Before that time, the amnion forms a separate bubble within the chorionic sac; it is surrounded and separated from the chorion by chorionic fluid, the magma reticulare, a viscous and thixotropic gel within which some stellate cells are dispersed (Fig. 11.7). It is important to recognize that the amnion does not possess its own blood vessels, in contrast to the opinion expressed by Donskikh (1957), who believed them to be present in early embryos. His drawings, however, are not convincing.

The amnion obtains its nutrition and oxygen from the surrounding chorionic fluid, the amnionic fluid, and the fetal surface vessels and, during early gestation, from the magma reticulare. It is of parenthetical interest here to note that magma reticulare-like differentiation has been described in yolk sac tumors, and that these elements stain positively with antibodies to vimentin and cytokeratin, thus displaying both mesenchymal and epi-

FIGURE 11.7. Intact placenta and fetus at 8 weeks of pregnancy, the chorion laeve having been opened. The arrows point to the amnionic bubble within the magma reticulare. Note also the early spiraling of the umbilical cord.

thelial characteristics (Michael et al., 1988). The latter is valid also for the amnionic epithelium. Despite its clearly epidermal origin, the cells not only express epidermal markers such as CA 125 (Nanbu et al., 1989) and such general epithelial markers as cytokeratins (Beham et al., 1988), but also vimentin staining is observed (Beham et al., 1988; Wolf et al., 1991). The latter is thought to be a marker for mesenchymally derived cells.

It is of historical interest also to note that Cane (1888) considered the amnion to secrete the amnionic fluid, which then was said to mold the early amnionic membrane. He also considered that it was responsible for the supply of oxygen by its rhythmic contractions, deemed to be analogous to the condition prevailing in birds. These hypotheses can now be laid aside.

## Amnionic Epithelium: Different Cell Types or Cell Degeneration

The amnionic epithelium is a highly variable tissue, composed of a single layer of flat, cuboidal to columnar cells (Bautzmann & Schröder, 1955; Hempel, 1972; Schmidt, 1992). Columnar cells normally have been observed near the insertion of the membranes at the placental margin (Bou-Resli et al., 1981), whereas the cells generally flatten further in the periphery. Despite the diversity in shape, there appears to be only one single, uniform cell type (Sinha, 1971; Hempel, 1972; King, 1980). Previous findings by Thomas (1965), Armstrong et al. (1968), and Wynn and French (1968) resulted in the suggestion of the existence of different cell types, such as Golgi and fibrillar cells, or light and dark cells. These types could not be verified, however, in later studies.

According to Hoyer (1972), an artifactual genesis of the previous findings (due to inappropriate fixation and inappropriate osmolality of the fixative) may be the explanation. The differences in nomenclature may also result from different amounts of fluid content. Thus, Hebertson et al. (1986) noted in their electron microscopic study of the epithelium that the normal thickness was much increased (to 18–56  $\mu\text{m}$ ) in diabetic pregnancies, channels (see following) were reduced in hydramnios, and other changes could be correlated with oligo- and polyhydramnios. Moreover, as discussed by Wynn and French (1968), a certain structural diversity of the cells may result from degenerative processes. These authors suggested that the often-present vesicles may reflect pinocytotic events. Histologic examination of the amnionic epithelium shows it to exhibit many different appearances. Often it is tall and columnar, whereas in other specimens it is flat and more squamous (Fig. 11.5). The varied appearance of the epithelial cells may be the result of different methods of fixation during preparation for

microscopy, and it may also result from different amounts of fluid content. Numerous gaps in the amnionic epithelium may be signs of such an expulsion of dying cells from the epithelium into the amnionic fluid, resulting in frequent defects of the epithelial layer. The remains may be the channels that Bourne and Lacy (1960) interpreted to be channels for preferred fluid exchange. Similar channels and complex cellular arrangements of the amnionic epithelium have been identified in the surface by the electron-microscopic studies of King (1982). This investigator also drew attention to the significant differences in the epithelial structure of the amnion when it is obtained from the free membranes or represents that of the cord. The development of micro-“blebs,” frequent cell shedding, and the importance of the basal membrane for the maintenance of the integrity of the sac have been emphasized in the studies of Herendael et al. (1978). The influence of labor on the structure of the amnionic epithelium has been studied by Sonek et al. (1991).

## Cytologic and Functional Aspects of the Amnionic Epithelium

During early pregnancy the bulging apical surfaces of the cells are covered by loosely scattered microvilli (Hoyer, 1968a; Lister, 1968; Ludwig et al., 1974). The number of microvilli increases later in pregnancy. The microvillous surface is characterized by a densely packed glycocalyx with a high concentration of anionic binding sites (King, 1982). Intracellularly, a pronounced rough endoplasmic reticulum, numerous lipid droplets, and glycogen stores are evident. The ultrastructural findings are thought to favor intraamnionic lipid synthesis, rather than a degenerative origin of the droplets (Armstrong et al., 1968; van Bogaert et al., 1978; King, 1980). So far, however, there is no explanation for such a possible secretion. According to Benedetti et al. (1973), the lipids cannot be explained as the result of absorption from the amnionic fluid because the respective hydrolytic enzymes are absent. Most authors favor the view that the lipids are derived from the maternal circulation and, after some chemical changes, are secreted into the amnionic fluid (Polano, 1922; Szendi, 1940; Schmidt, 1965a,b, 1967; Armstrong et al., 1968; Pomerance et al., 1971; Schmidt et al., 1971). It is, however, difficult to understand how such quantities of maternally derived lipids should pass all layers of the membranes, and accordingly not all findings are in agreement with this concept. Some point to a fetal origin of the lipids and thus to their resorption from the amnionic fluid. According to Polishuk et al. (1965) and Pritchard et al. (1968), the intraamnionic lipids are chemically similar to those of the vernix. Vernix caseosa is derived from fetal sources, that

is, secretory products of the fetal skin mixed with desquamated skin cells (Brusis et al., 1975). Even the degenerative character of the lipid droplets is still under discussion, although there is no ultrastructural evidence to support degeneration. The amount of lipid droplets increases throughout pregnancy (Yoshimura et al., 1980); maximum amounts have been reported following fetal hypoxia (Bourne, 1962; Bartman & Blanc, 1970) and fetal death (Yoshimura et al., 1980).

Substantial evidence exists to suggest a significant role for prostaglandins in the initiation and maintenance of uterine contractions (Smieja et al., 1993). Among the sources of prostaglandins for parturition, the amnionic epithelium seems to play a pivotal role because of its strategic anatomic location, with its close relation to amnionic fluid, myometrium, and uterine cervix. With the onset of labor, production of prostaglandins increases (Olson et al., 1983; Kinoshita et al., 1984; Skinner & Challis, 1985; Lopez Bernal et al., 1989; Mitchell, 1988). Moreover, amnionic epithelium is the nearly exclusive source for prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) (Okazaki et al., 1981a). The release of the latter hormone is regulated by intrinsic stimulatory properties of the membranes, but not of the villous chorion (McCoshen et al., 1986).

In this context, several questions arise: Do the membranes have the lipid precursors (arachidonic acid) for the synthesis of prostaglandins, and where are these metabolites manufactured and located? Foster and Das (1984) have contributed relevant studies. They separated amnion from chorion of normal membranes that they obtained following the normal onset of labor and analyzed the lipid content. This investigation contrasts with earlier studies that used combined membranes. It must be mentioned that the chorion was not freed from its decidual investment and that inferences drawn with respect to the precise localization of prostaglandin precursors cannot be made from this study alone. Nevertheless, the chorion had considerably more lipid (in milligram per deciliter) than the amnion, as can be seen in the following summary of their findings:

Lipid components	Amnion (mg/dL)	Chorion (mg/dL)
Total lipid	470	1530
Nonpolar lipids	319	1042
Cholesterol esters	44	263
Cholesterol	71	210
Triglycerides	160	416
Free fatty acids	44	153
Phospholipids	150	488

Olson and Smieja (1988) studied the incorporation of arachidonic acid into amnion and found that there was no difference, regardless of whether labor had preceded.

Enzymes involved in prostaglandin biosynthesis include phospholipases, prostaglandin synthase, and prostaglandin endoperoxide synthase (or cyclooxygenase). They have been found in human amnion (Okazaki et al., 1981b; Bryant-Greenwood et al., 1987; Smieja et al., 1993; Toth et al., 1993; Toth & Rao, 1992). Interestingly, the enzymes are regulated by human chorionic gonadotropin (hCG) (Toth & Rao, 1992), the receptors of which are found on the amnionic epithelium (Rao & Lei, 1989; Reshef et al., 1990; Toth et al., 1993). The complexity of the intraamniotic regulatory mechanisms is increased by some additional findings: corticotropin-releasing hormone (CRH) (Jones & Challis, 1989) and glucocorticoids (Gibb & Lavoie, 1990) modulate prostaglandin production; CRH messenger RNA (mRNA) was demonstrated in the amnion of term pregnancies (Okamoto et al., 1990). Its production is modulated by glucocorticoids and progesterone (Jones et al., 1989).

Interleukins also are well known to regulate prostaglandin biosynthesis. According to the *in situ* hybridization and polymerase chain reaction studies by Rote et al. (1993), explants of normal amnion and chorion laeve produce interleukin-1 $\beta$  *in vitro*; the application of endotoxin induced additional expression of interleukin-6. In conclusion, the authors speculated that intraamniotic infections induce production of interleukins that increase prostaglandin production. Much additional investigation relates to prostaglandin initiation during the process of chorioamnionitis and is covered in Chapter 20. 15-Hydroxyprostaglandin dehydrogenase as a prostaglandin-metabolizing and -inactivating enzyme was found in membranes and villous trophoblast (Cheung et al., 1990). Casey et al. (1989) found prostaglandin dehydrogenase in the decidua capsularis and proposed that it regulates levels of prostaglandin therein as well as in the amnionic fluid, uterus, and blood.

The interactions between prostaglandins and oxytocin in the regulation of uterine contractions are only poorly understood. In humans, oxytocin acts as the myometrial contraction stimulator, but only when it is combined with increased levels of PGF<sub>2 $\alpha$</sub>  (Fuchs et al., 1982). The production of the latter is stimulated by oxytocin through a receptor-mediated process (Roberts et al., 1976). Benedetto et al. (1990) were able to demonstrate the oxytocin receptors in the amnion as well as in the chorion laeve. Finally, leukotrienes, another cytokine group derived from arachidonic acid, are produced by the amnion (Rees et al., 1988). The authors stated that these cytokines may affect uterine contractility besides their function as mediators of immune reaction and vasodilation.

From a functional perspective, perhaps more interesting are some findings concerning the intercellular junctions and the basal lamina of the amnion. The amnionic cells are connected to each other by numerous desmosomes that focally bridge the long, winding lateral inter-

cellular spaces; some additional gap junctions have been observed in the laterobasal region (King, 1982; Bartels & Wang, 1983; Wang, 1984). Tight junctions occluding the lateral intercellular spaces, and thus limiting paracellular transport, could not be observed between the cells, with the exception of a few during the first months of pregnancy (King, 1982; Bartels & Wang, 1983). Consequently, the intercellular clefts may represent an effective route for paracellular transfer, as has been demonstrated by tracer studies (King, 1982; Matsubara & Tamada, 1991). This point is of particular importance, as there are no hints of an effective transcellular pathway for macromolecules.

There are, however, some findings concerning the basal lamina that restrict the relevance of these interpretations. The amnionic cells have a highly folded basal surface that interdigitates intensely with the basal lamina to which they are fixed by numerous hemidesmosomes (Danforth & Hull, 1958; Verbeek et al., 1967; King, 1980, 1982; Bartels & Wang, 1983; Wang, 1984). According to the histochemical studies of King (1985), the basal lamina contains large quantities of proteoglycans, rich in heparan sulfate. The latter substance may serve as a permeability barrier to anionic macromolecules. Also, Klima et al. (1991), Wolf and Schmidt (1991), and Singhas (1992) have described by means of lectin-binding studies the presence of glycoconjugates in the amnion and discussed the influence of these substances on amnionic fluid transfer. These findings are in agreement with two other studies. Liotta et al. (1980) observed restricted permeability of an isolated basal lamina preparation of human amnion to a 60,000-dalton protein, and Sutcliffe (1975) reported that the amnionic fluid contains a much smaller amount of protein than is found in fetal and maternal serum. Thus, the amnionic basal lamina must also be considered to participate in the barrier function (King, 1985).

Concerning the regulation of transamnionic fluid transfer, Beham et al. (1988), Wolf et al. (1991), and Ockelford et al. (1993) have studied the distribution of cytoskeletal filaments within the amnionic epithelium. Actin,  $\alpha$ -actinin, spectrin, ezrin, cytokeratins, vimentin, and desmoplakin have all been found. The specialized arrangement of this intracellular filament system indicates a role in the structural integrity and modulation of cell shape as well as in junctional permeability (Wolf et al., 1991). Casey et al. (1991) demonstrated that amnionic epithelial cells produce endothelin-1 and are thus one of the potential sources for endothelin in the amnionic fluid where it appears in concentrations exceeding those of the blood plasma by 10- to 100 fold. Epidermal growth factor, interleukin-1, and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) increased amnionic endothelin production. Amnionic endothelin may be involved in the regulation of amnionic fluid homeostasis as it is known to promote water transfer across the epithelia of other organs.

The amnion is involved in the turnover of the amnionic fluid. There is great immunohistochemical activity of carbonic anhydrase isoenzymes CA-1 and CA-2 (Crescimanno et al., 1993; Mühlhauser et al., 1994); this enzyme is involved in bicarbonate-carbon dioxide exchange. This fact makes it likely that the epithelium is responsible for regulating the pH of the amnionic fluid, keeping it constant at about pH 7.10. In doing so, the amnionic epithelium is at least partly involved in fetal pH regulation because the fetus delivers considerable amounts of protons and bicarbonate via his or her kidneys into the amnionic fluid. In addition, aquaporins may be involved in fluid balance, as they are found in amnion and chorion of the human placenta (Mann et al., 2002). These authors suggested that the presence of aquaporin may be responsible for the rapid water turnover from amnionic fluid to the fetal circulation (400 mL/day).

Amnionic epithelium participates not only in fetal CO<sub>2</sub> clearance but also in the clearance of fetal vasopressin, for instance, which is excreted via the fetal urine. It is removed from the amnionic fluid by diffusion- and swallowing-independent mechanisms (Uyehara & Claybaugh, 1988). It is likely that the degrading peptidases are active in the amnionic epithelium as well as in the amnionic fluid. In this context it may be of interest that Gossrau et al. (1987) described dipeptidylpeptidase IV activities in the amnionic epithelium and speculated about its hydrolytic action, both intracellularly as well as in the amnionic fluid.

Epithelial participation in the secretion of amnionic fluid and in its resorption has long been under discussion (Bourne, 1962; Armstrong et al., 1968; Kratzsch & Grygiel, 1972; Smadja et al., 1974; Weser & Kaufmann, 1978), but until now this secretory activity has been speculative. It is generally accepted that the sources of the amnionic fluid are multiple and that the role of the amnion in maintaining its composition is still uncertain. The general functional description of the amnion as an epithelial lining that is contributing to the homeostasis of the amnionic fluid is supported by many clinical findings (see following), but they add little to the resolution of the precise interactions. Several groups of investigators have detected, by immunohistochemical means, hormones such as hCG and somatotropin (hCS) in the amnionic cells (Thiede & Choate, 1963; Kim et al., 1971; de Ikonoff & Cedard, 1973). It is likely, however, that these hormones are the result of resorption from the amnionic fluid with subsequent degradation, rather than reflecting any local hormone synthesis.

The structural studies support the view that the amnionic epithelium is metabolically highly active throughout gestation. This point is also supported by the histochemical proof of high activity of various enzymes (Weser & Kaufmann, 1978). The histochemical study of enzymes related to energy metabolism suggested a predominating

anaerobic glycolysis caused by restricted oxygen supply (Benedetti et al., 1973). The absence of vessels in the mesenchymal layers of the amnion raises the question concerning the source of its nutrients and oxygen. They may be supplied by diffusion from the deeper layers of the uterine wall or via the amniotic fluid from the fetus. Wolf and Desoye (1993) have described the presence of glucose transporter protein-1 and -3 predominantly at the apical surface of amniotic epithelial cells, whereas glucose transporter protein-4 and insulin receptor could not be detected. Thus, it is quite likely that these cells cover their glucose requirements from the amniotic fluid with an insulin-independent mechanism. Furthermore, Bourne (1962) reported a monochorionic, diamniotic twin pregnancy in which the ipsilateral amnion in the “dividing membrane” degenerated following the death of one fetus. This finding can be explained in different ways; it simply may be an indicator that the fetus is important for supplying the amnion with nutrients and gases or, alternatively, the degenerating fetal tissues may affect adversely the epithelium.

The question of possible repair mechanisms of amnion epithelium and the mesenchymal cells after mechanical injury was studied in vitro by Bilic et al. (2004). They produced monolayers of epithelial and mesenchymal cells and then injured them. Repair of the epithelium was generally complete within 40 hours but less efficiently so in mesenchymal cells, although it was more extensive in preterm than term tissues. The addition of platelet-derived growth factor (PDGF) and TNF- $\alpha$  had no beneficial effect on cell proliferation.

#### AMNIONIC FLUID

It is commonly accepted that the amniotic fluid is derived from multiple sources: (1) possible secretory processes of the amniotic epithelium; (2) filtration of fluid from maternal vessels via the parietal decidua and the chorion laeve; (3) filtration from the fetal vessels via the chorionic plate and via the umbilical cord; (4) urination by the fetus; and (5) during earlier stages of pregnancy, by filtration from intracorporeal fetal vessels via the fetal skin. Its composition is influenced by continuous resorptive processes by the fetal digestive tract and the amnion and by pressure-dependent fetomaternal filtration across the membranes. The volume of the fluid is not static, varying among the stages of pregnancy as well as among individuals. A careful determination of the development of amniotic fluid volumes throughout pregnancy by a dilution method during amniocentesis has been presented by Queenan et al. (1972) (Fig. 11.8). The results showed a wide range of volumes, with a mean of 239 mL at 15 to 16 weeks postmenstruation (p.m.), a maximum mean of 984 mL at 33 to 34 weeks p.m., and a slight final decrease to term (836 mL). After term (41 to 42 weeks p.m.), the mean volume was reduced to 544 mL.

The composition of the amniotic fluid has been described in detail by Schmidt (1992) and is reviewed only briefly here. The pH is usually 7.10, with maximum values of 7.40; the osmotic pressure is about 255 mOsm. Further constituents include:

- Glucose (5–20 mg/100 mL)
- Amino acids

FIGURE 11.8. Volume of amniotic fluid during gestation in 187 determinations. Mean values  $\pm 1$  SD. There is a wide range, with a final decrease during the last 4 weeks of gestation. (Source: Modified from Queenan et al., 1972.)

- Proteins (280–780 mg/100 mL) ( $\alpha_1$ -albumin;  $\alpha_2$ -albumin;  $\beta$ -globulin;  $\gamma$ -globulins: immunoglobulins IgA, IgG, IgM;  $\alpha_1$ -fetoprotein; lipoproteins); the recent identification of elevated S100B protein levels by Florio et al. (2004) was used to anticipate fetal demise at mid-gestation; similarly, elevated maternal  $\alpha$ -fetoprotein levels anticipated sudden fetal demise (Smith et al., 2004).
- Lipids (40 mg/100 mL), largely as lipid droplets measuring 1 to 30  $\mu$ m in diameter, composed of cholesterol, triglycerides, diglycerides, free fatty acids, phospholipids (among the latter, the ratio of lecithin to sphingomyelin (L/S ratio) as performed during prenatal diagnosis is thought to be a reliable parameter in determining pulmonary maturity; it has also been suggested that surfactant may stabilize the amniotic sac) (Hills, 1994); Longo et al. (1996) found no lecithin/sphingomyelin but a substance with similar migratory pattern and may thus be confusing.
- Urea (20–40 mg/100 mL)
- Uric acid
- Creatinine
- Bilirubin

In addition, a broad variety of hormones has been found in the amniotic fluid (Schindler, 1982):

- Progesterone, estradiol, estriol, testosterone, aldosterone, cortisol
- Luteinizing hormone (LH), follicle-stimulating hormone (FSH), hCG, human placental lactogen (hPL), prolactin, adrenocorticotrophic hormone (ACTH), human growth hormone (hGH), somatomedin, thyrotropin (thyroid-stimulating hormone, TSH)
- Thyroid hormones, parathyroid hormone, oxytocin, glucagon, insulin, hypothalamic-releasing hormones, neurophysin. We have had an interest in the presence of endorphin in amniotic fluid (Gautray et al. (1977)). This central nervous system (CNS)- or pituitary-derived hormone was present late in gestation, has its source in fetal urine, and was elevated in amniotic fluid of gestations with gastroschisis (Akgur & Olguner, 2004; Mahieu-Caputo et al., 2004). We speculate that variations in levels may indicate different levels of response to pain by the fetus, as for instance in osteogenesis imperfecta.

Numerous enzymes have been found, most of which, according to Schmidt (1992), are thought to be derived from the membranes by secretion or by cell shedding. Among the activators and inhibitors of proteases are tissue-type plasminogen activator (tPA) and urokinase-type plasminogen activator (uPA), as well as their respective inhibitors PAI-1 and PAI-2 (Kjaeldgaard et al., 1989). They regulate the fibrinolytic and proteolytic activities of amniotic fluid plasminogen, which is considered to be involved in the etiology of membrane rupture (Jenkins et al., 1983) (see following).

After staining with Nile blue (Nieland et al., 1970), hematoxylin and eosin (H&E), Giemsa, or Papanicolaou stains, a variety of amniotic fluid cells can be observed, their number steadily increasing throughout pregnancy and reaching values at term to 80 cells/mm<sup>3</sup>. Their origin has not been satisfactorily determined in every case because, after exfoliation from their tissue of origin, they usually undergo structural changes (Schmidt, 1992). The following cell types have been classified by Schmidt (1992):

- Large anuclear flat cells (diameter 40–50 mm), probably exfoliated keratinocytes
- Nucleated squamous epithelial cells (diameter 30–50 mm): type b originating from the oral mucous membrane, type c possibly originating from the amniotic epithelium of the cord, type d derived from the fetal vulva and vagina
- Small round to oval cells (diameter 18–25 mm), originating from the fetal urinary tract
- In addition, a variety of special cell forms such as polynuclear cells from the urinary tract (transitional epithelium) and others have been found. This has included neurogenic cells (Prusa et al., 2004) whose origin may be the fetal hair follicles (Sieber-Blum & Grim, 2004).

#### CHROMOSOMAL DETERMINATIONS

Bautzmann et al. (1960) and other students of the amniotic membrane have often made flat membrane preparations for investigation. These preparations allow one to see more clearly the squamous nature of the epithelium and to demonstrate its occasional defects. These preparations also lend themselves to observing the lipid droplets in the epithelium whose numbers increase with maturation (Bautzmann & Hertenstein, 1957; Danforth & Hull, 1958; Schmidt, 1963). Occasional giant cells ("colossal cells") with large vacuoles are seen to include large vacuoles. Such preparations also show relatively frequent polyploid nuclei. The epithelial cells, however, divide under normal conditions by regular mitosis (Schwarzacher & Klinger, 1963). Multinucleated cells, particularly binucleated cells, are most commonly found in newborns. Mitoses become rare after the sixth gestational month. In cytophotometric measurements, Schindler (1961) showed, in specimens from early gestation, that the polyploid cells are tetraploid and octoploid, with a concomitant increase in their cytoplasm. These observations have assumed greater significance as the use of amniocentesis for chromosomal determination of the fetus has been more widely practiced. The finding of mixed cell populations (mosaicism) is here of concern; it demands an explanation (Kalousek & Dill, 1983). These authors studied 117 specimens and concluded that the mosaic (aneuploid) cell populations they found invariably came from the membranes. Aneuploid cells were not found in fetal lymphocytes when these were studied after birth. They had only 47 completely successful cultures with two aneuploid admixtures, but it is not clear that they grew amnion epithelium, as opposed to chorionic fibroblasts. Nevertheless, they reviewed other reports of mosaicism of cell lines from amniotic fluid culture (origin of these cells also unknown), where the fetus was eventually found to be normal.

Similarly perplexing mosaicism has been detected in chorionic villus sampling (CVS) biopsy by a number of investigators. Linton and Lilford (1986), for instance, found complex XY/XXY mosaicism, and all 14 metaphases contained an extra chromosome 16q. It was associated with a karyotypically normal fetus in a case described by Breed et al.

(1986). In parallel cultures of amniotic fluid cells and samples from CVS, Verjaal et al. (1987) also found discrepancies and warned that great care must be taken when interpreting such abnormalities. Their findings supported the view of Hogge et al. (1985) that such errors occur as often as in 2% of CVS. Schulze et al. (1987) had experience with two aneuploid mosaics (46,XX/47,XX + 3; 46,XX/47,XX + 15) and normal 46,XX newborns. Crane and Cheung (1988) suggested that postzygotic nondisjunction of chromosomes in the cytotrophoblast is the most likely cause of such mosaicism. They described 15 cases of mosaicism in CVS, identified in direct preparations from the biopsy, thus ruling out an artifact of tissue culture. They suggested that the processing of multiple individual fragments of tissue might avoid mistaken diagnosis. Further consideration of confined placental mosaicism is to be found in Chapter 21. The most recent methodology for the evaluation of the fetal genotype and for the study of differences in the genetic contributions of fetus versus placenta involves a molecular analysis of the DNA extracted from both tissues. Butler et al. (1988) studied 50 paired samples from these sources and found differences in the hyper-variable regions of repetitive DNA in four pairs, whereas they were alike in the others. This finding may indicate that mitotic crossing-over or other mechanisms of chromosomal segregation occur. These points must be considered for a meaningful interpretation of cytogenetic studies from placenta and amniotic fluid. Furthermore, mitotic errors in the delicate amniotic membrane of early gestation might be one mechanism that leads to defects in its structure and thus to the future amniotic band development. Additional discussion of this important topic is found in Chapter 21, on abortion.

Another still poorly understood feature of the developing membranes is that the X inactivation ("lyonization") of its cells appears to be non-random. Ropers et al. (1978) reviewed the studies on this topic and analyzed the glucose-6-phosphate dehydrogenase (G-6-PD) activity of heterozygotic females. Preferential activity of the maternal X chromosome-derived isozyme activity was found in the membranes of the placenta, analogous to earlier observations made in rodents (Frels et al., 1979; Rastan et al., 1980). Confirmation of these results has come from the study by Harrison and Warburton (1986). They also used the variants of G-6-PD as markers for "lyonization," but the mechanism (DNA methylation) leading to this preferential expression of the maternal allele ("imprinting") and the possible reasons for it are unknown at present.

## Cellular Metaplasia and Glycogen

Metaplastic processes are frequent in the amniotic epithelium. They are present in at least one fourth of mature placentas, most prominently around the umbilical cord; they must not be confused with amnion nodosum. We refer to them as "squamous metaplasia," a misnomer, as Bourne (1960) noted. The amnion is squamous, and these areas of metaplasia do not form in response to some chronic irritation or inflammation, as for instance in the bronchus of smokers. They merely betray maturity and are not found in immature placentas. This so-called squamous metaplasia of the amnion is actually only the focal keratinization of the epithelium (Figs. 11.9 and 11.10). It is a regular feature of the amnion in many other species, such as whales and sheep, in which nodules of keratin stud the cord and amnion. Some species even have melanin pigment in these structures. In the term human placenta these areas of squamous metaplasia are visible

FIGURE 11.9. Squamous metaplasia of the amnion. At left is a surface view showing the concentric layers of keratin. At right one sees the tiny nodules of keratin irregularly present over vessels and chorion, different from amnion nodosum.

as hydrophobic foci of tiny, concentric elevations. They are most commonly found in the vicinity of the cord insertion. Squamous metaplasia occurs in up to 60% of term placentas. Sinha (1971) and Nieland et al. (1970) provided a detailed electron-microscopic study of squamous metaplasia. In animals, these plaques (occasionally referred to as pustules) may be 15 cells thick. They may have no similarity to amnion cells but more resemble the epidermis and usually include keratohyaline granules and melanin. In this context, one must recall the developmental and structural continuity (see Fig. 12.1) of amnionic epithelium and the squamous fetal skin.

An interesting consideration is whether, in cases of ichthyosis congenita, the amnion participates in the excessive keratinization that is seen in the epidermis. One report of marked plaque formation in ichthyosis has come from Coston (1908). He observed a large placenta whose cord and amnion were covered with ichthyotic patches. This finding has not been our experience. The placenta of the X-linked type of ichthyosis (the commonest form of this disease) is structurally normal. A biochemical study by Bedin et al. (1981) of the steroid sulfatase in placentas from heterozygous women has shown that the locus (localized at Xp22.3) determining this critical enzyme for the disease is not inactivated by lyonization. It can now be identified by fluorescent in situ hybridization, and deficiency should be suspected when abnormally low estriol values are found in pregnancy

(Ahmed et al., 1998). Garcia et al. (1977) observed the concurrence of amnion nodosum and congenital ichthyosis in four cases. Amnionic plaques of the membranes were correctly interpreted to result from oligohydramnios, rather than from excessive squamous metaplasia. Our conclusion is that the amnion, although ectodermal in origin, does not have the capacity to exhibit the lesion of ichthyosis congenita. In a case of severe, fatal lamellar ichthyosis seen by us, the amnion was attached to the fetal skin because of oligohydramnios, but its remnants, located around the cord insertion, were free from keratinization. There was some excessive squamous metaplasia on the cord surface, with prominent desmosomes but lacking keratohyaline granules and true keratin. Moreover, no macroscopic plaques were present despite severe fetal skin involvement. A case of harlequin (lamellar, collodion) ichthyosis was described in detail by Shareef et al. (2000), but the placental findings were not noted. Interestingly, after adequate neonatal care of this severely affected neonate, its skin was normal at 2-month follow-up. An unresolved question is the cause of the common oligohydramnios in these pregnancies and the concomitant fetal deformities. The latter are frequently much in excess of those found with Potter's syndrome and are presumably a part of the genetic abnormality ichthyosis. Moirrot and colleagues (1990), on the other hand, suggested that polyhydramnios is frequent in lamellar ichthyosis cases. They also found no typical changes in

FIGURE 11.10. Squamous metaplasia, typical of mature placenta (top), and amnion epithelium (bottom). H&E. Top  $\times 160$ ; bottom  $\times 250$ .

amnion, only keratinization. The fluid was found to be yellow and “flocculent,” and the placenta edematous. Keratinization was also found to be absent in the rare harlequin fetuses of the Neu-Laxova syndrome (Karimi-Nejad et al., 1987), in which hyperkeratosis is a prominent feature of the infant’s skin.

During early pregnancy, the amnionic epithelium contains cytoplasmic glycogen, and it is not significantly increased in the placentas of women with diabetes. Increased amounts of glycogen in the placentas of diabetics have been found to occur only around the major fetal vessels (Robb & Hytten, 1976). Other vacuoles are frequently present in the epithelial cells; they may be engaged in transport activity (Fig. 11.11). In cases of fetal death, the epithelium shows extensive degeneration, particularly when studied by electron microscopy (Mukaida et al., 1977). For a consideration of the vacuolization of amnionic epithelium, see the following section.

## Amnionic Mesoderm

The amnionic epithelium rests on a basal lamina that is mainly composed of collagen IV fibrils (Yurchenco & Ruben, 1994), laminin (Aplin et al., 1985), and heparan sulfate proteoglycan (Foltz et al., 1982). It is associated with the basal cell surface by means of fibronectins. Its functional influence on transamnionic transfer has been discussed earlier. The lamina is fixed to the neighboring stroma by anchoring plaques containing collagen IV, which are attached to anchoring fibrils in the surrounding tissues that contain collagen VII (Keene et al., 1987). In addition, collagen V appears in the area immediately surrounding the basal lamina (Modesti et al., 1984). Proteoglycans embedding the collagen fibers can imbibe water and swell, leading to sliding of the amnion over the chorion; this might provide a short-term sealing mechanism of ruptured membranes (Behzad et al., 1994; Bryant-Greenwood, 1998).

The following layer, the compact stromal layer, has a varying thickness. It contains collagen types I and III (Madri et al., 1983) and fibronectins (Linnala et al., 1993) that are largely secreted by the amnionic epithelial cells. The distribution of the different collagen types in the various mesenchymal layers of the amnion has been described in detail by Malak et al. (1993). The compact stroma is composed of bundles of 50-nm collagen fibrils that are intermingled with 18-nm fibrils (Aplin & Allen, 1985). The three-dimensional structure of these fibrils and their association with the basal lamina as well as with the basal surface of amnionic epithelium has been beautifully illustrated by Campbell et al. (1989). The two types of fibers together form a coarse meshwork of bundles, in which, according to Bourne (1962), some elastic fibers can also be integrated. The latter finding has been contested by Aplin and Allen (1985), so that it remains an open question whether the well-known elasticity of the amnion results from the presence of elastic material or the arrangement of the collagenous bundles.

A characteristic layering of the amnionic mesoderm, as it has been described for the amnion of the **chorionic plate** (Bourne, 1962), is less pronounced in the **amnionic membrane**. The ability to identify several distinct layers of connective tissue probably depends to some degree on the state of its contraction and fixation, as well as on one’s imagination. It is evident, however, that the compact, collagenous layer nearer to the epithelium is largely devoid of connective tissue cells. Ockleford et al. (1993), based on immunohistochemical studies, have suggested that it represents a giant lamina reticularis making up the inner part of a basal membrane and thus belongs to the amnionic basal lamina.

The deeper part of the amnionic mesenchyme, also called the fibroblast layer (Bou-Resli et al., 1981), contains a more or less dense network of branched fibroblasts. Bartels and Wang (1983) failed to observe intercellular junctions connecting these cells. Additionally, some macrophages can be observed as early as in the

7th week of gestation (5- to 6-mm embryo). Schwarzacher (1960) likened them to Hofbauer cells. In electron microscopic studies of the amnion, Hoyes (1968b) suggested that these macrophages derive from the epithelium and that they decrease in number toward term. In light of the modern findings regarding the biology of placental macrophages (see Chapter 6), however, there are no longer arguments regarding an epithelial derivation. The bundles of collagen fibers are arranged in clearly separated layers of varying fiber orientation (Bou-Resli et al., 1981). Aplin and Allen (1985) described the synthesis of collagens I, III, and IV, as well as of laminin and fibronectin, by amniotic epithelial cells in culture. From these findings, they concluded that the epithelium not only produces the basal lamina but is also involved in the synthesis of the stromal fibers, at least of the compact layer, which is largely devoid of fibroblasts.

#### A MEDLEY OF THEMES

The sex chromatin (Barr body) of amniotic epithelial cells and of the underlying connective tissue is easily observed. Using this marker, Klinger & Schwarzacher (1962) demonstrated in a fetus with XY/XXY mosaicism that the amnion was also mosaic. Some areas were sex chromatin-positive and others were sex chromatin-negative. Moreover, they showed clearly that the connective tissue underlying one type of epithelium occasionally had a different karyotype. This observation proved, once and for all, that these tissues have different embryologic origins. We indicated earlier that we believe the peripheral connective tissue of the amnion is a condensation of the cellular elements that are dispersed in the magma reticulare of the primitive chorionic sac. Parenthetically, it may be noted that an improved method for the histologic detection of sex chromatin in formalin-fixed tissues has been described (Davis & Penny, 1981); it employs pronase and acid hydrolysis before quinacrine staining. Perhaps the earliest time sex chromatin can be observed in human embryos is on day 13. Thorburn (1964) identified the Barr bodies readily in trophoblast. The sex chromatin in membranes

and trophoblast has also been described by Bohle and Hienz (1956) and Verma and Ghai (1971).

Efforts to study the possible existence of smooth musculature in human amnions have usually employed flat, surface preparations of membranes. From studies in chicken and reptiles it is known that an orderly arrangement of a smooth muscle plexus in the amnion produces regular contractions, possibly to ensure mixing of fluid and rocking of the embryo (Bautzmann & Schröder, 1953; Bautzmann, 1956). Such structures have not been found in mammals. In early human amnions, only net-like fibrocytic cell arrangements are identifiable in the connective tissue of the amnion; muscle is absent.

There are also no nerves, lymphatics, or blood vessels in the amnion. Because the amnion is avascular, it must subsist on the nutrients and gaseous exchange of surrounding fluids and structures. As mentioned earlier, this point is particularly well demonstrated by the large portions of amnion that are apposed as the "dividing membranes" in diamniotic monochorionic twins. Here the large stretches of amnion are kept alive by the amniotic fluid surrounding them. Consequently, when one fetus dies, that portion of its amniotic surface dies as well. The epithelial cells undergo necrosis, as shown in Figure 11.12A (see also Bourne, 1962). It is surprising that the living amnion from the opposing twin's side is not able to sustain this portion of membrane, as the dividing membranes are so thin and delicate. Although it is also possible that the death of the amniotic epithelium in these circumstances comes about by the liberation of noxious substances from a macerating fetus, it is unlikely. The amnion overlying the placenta proper takes much longer to die; it is obviously being kept alive by the oxygen gradients from the persisting intervillous circulation.

#### CLINICAL AND RESEARCH APPLICATIONS

Because the amnion can be so readily separated from the chorion, and because it is so widely available, it has often been used as dressing for burns and other wounds (Editorial, 1984; Redmond, 1984). This practice appears to have special merits in that the epithelium does not possess human leukocyte antigen (HLA)-type antigens and even fails to elicit an immunologic reaction when transplanted (Akle et al., 1981). Moreover, antibacterial properties of the amnion are well documented. The antimicrobial effect is thought to be related to the close adherence of the membrane to the wound surface (Talmi et al., 1981).

FIGURE 11.12. Two sets of "dividing membranes" (A,B) of diamniotic, monochorionic twins with one twin having died days before birth. Note the necrosis of the epithelium on the right sides at various stages of degeneration. H&E. A  $\times 160$ ; B  $\times 250$ .

Amnion has also been a favorite cellular material for virologists in that it can readily be established in culture, particularly when it is obtained from young pregnancies and from patients with toxemia of pregnancy (Jonas & Caunt, 1965). When such cultures are treated with cortisone, profound changes occur in the membranous surface of the amnionic epithelial cells (Polet, 1966). It is also worthy of note that the injection of transformed human amnion cells into cortisone-treated mice induces tumor growth with cartilage and bone formation, presumably by stimulating host cells to undergo this differentiation (Anderson et al., 1964). In other studies, the amnion has been used to serve as a substratum for axons in tissue culture (Davis et al., 1987) and for the cultivation of trophoblast; after removal of the epithelial cells, the remaining connective tissue matrix, together with the epithelial basal lamina, serves as an excellent substratum for the monolayer culture of cytotrophoblast, even allowing syncytial fusion of the latter (Bullen et al., 1990).

## Chorion Laeve

The chorionic membrane is a tough fibrous tissue layer that carries the fetal blood vessels. The villi arise from its outer surface; on the inside of the chorion is the amnion, which is only loosely attached. It has been convenient for many authors to speak of the “placental chorion,” the membrane that covers the placental disk proper. In agreement with the anatomic literature, we call it the chorionic plate. On the other hand, the “reflected chorion” is the chorion laeve or extraplacental membrane (Bourne, 1962), which is the tissue that we discuss in greater detail in this chapter.

## Intermediate (Spongy) Layer

When studying the membranes after birth, one realizes that the reflected amnion and chorion can easily slide, separating the two membranes from each other. This phenomenon is due to the existence of the spongy layer, which results from incomplete fusion of amnionic and chorionic mesoderm during early pregnancy. This intermediate layer is composed of loosely arranged bundles of collagen fibers with a few scattered fibroblasts, separated by a communicating system of clefts (Schmidt, 1956; Petry, 1962; Bou-Resli et al., 1981). The clefts are remainders of the formerly existing and now largely obstructed exocoel (see Fig. 12.1). This view has been corroborated by immunohistochemical/confocal laser studies by Ockleford et al. (1993).

It is difficult to decide whether accidental cells lining these clefts are also fibroblasts or whether they are the remainder of the original amnionic and chorionic mesothelium. The presence of collagen type IV in this zone (Malak et al., 1993; Ockleford et al., 1993), which is a typical basal lamina molecule, means that a mesothelial origin of these cells is quite likely (Ockleford et al., 1993). In addition, macrophages have been observed (Schmidt, 1956).

## Chorionic Mesoderm

The spongy layer continues without sharp demarcation into the next connective tissue layer, already belonging to the chorion laeve.

This connective tissue is derived from the embryo (Luckett, 1971). When restudying human and rhesus monkey embryonic material, Luckett found that the extraembryonic mesoderm comes from the primitive streak. It develops on day 12 from the caudal pole of the embryonic shield and differentiates in human embryos on about day 14. He interpreted this to mean that the cells of the primitive streak move peripherally; there they form the cores of the primitive villi. Luckett did not totally exclude the idea that there may be some minor contribution derived from trophoblast, but in our view this is unlikely. For example, even well-differentiated choriocarcinomas never produce connective tissue, which would be expected at least occasionally; as such behavior is seen with virtually all other neoplasms. The meticulous study by Enders and King (1988) referred to below clearly shows now that the connective tissue of the placenta derives ultimately from the “epiblast.”

Another reason for asserting that chorionic connective tissue has an embryonic origin comes from the embryologic studies on reconstituted mouse embryos (Rossant & Croy, 1985). Rossant and Croy took inner cell masses of mice with distinct isoenzymes and in situ genetic markers and placed them into different trophoblastic shells. They then followed the placental development and deduced that only 4% of the mouse placenta was derived from the embryo. This portion was composed primarily of fetal capillaries. Mouse placental tissue has generally little connective tissue.

The formation of the extraembryonic mesenchyme has been studied in exquisitely prepared electron micrographs from early rhesus monkey ova from days 19 to 60 (Enders & King, 1988). This is an important topic as inferences made from various divergent cytogenetic procedures (CVS, amnionic fluid study, fetal biopsy) have often yielded findings that are difficult to interpret unless this is understood. These authors found that the first evidence of mesenchyme was peripheral to the primitive endoderm, the “hypoblast.” They showed convincing evidence that the rough endoplasmic reticulum of this mesenchyme has intracisternal densities that are not shared by other connective tissue. This feature allows one also to determine its origin. It could be followed into the early villous structures on day 13. Also arguing against a trophoblastic origin of villous mesenchyme is the finding that there is always a complete basal lamina underlying the trophoblast. The meticulous study of Enders and King showed that the earliest blood vessel formation comes from this villous mesenchyme, which differentiates focally into endothelium as early as on day 13 but more actively later.

The composition of the chorionic mesoderm is similar to that of the fibroblast layer of the amnion, consisting of a coarse network of collagen bundles intermingled with finer argyrophilic fibrils. The distribution of the various collagen types I, III, IV, V, and VI has been detailed by Malak et al. (1993). Hessle and Engvall (1984) and Hessle et al. (1984) focused on the distribution of collagen VI. Fibroblasts and macrophages are regular findings. According to Wang and Schneider (1982) and Bartels and Wang (1983), many of the fibroblasts are likely to represent myofibroblasts. They are connected to each other by gap junctions, which allow intercellular coupling. McParland et al. (2003) found thickening and expression of smooth muscle actin in the region overlying the internal os. Most of the studies that concern collagen composition and

tensile properties of the membranes (Aplin et al., 1986; Teodoro et al., 1990; Manabe et al., 1991; Malak et al., 1993) consider both the mesenchyme of the amnion and that of the chorion. For details we refer the reader to these papers. It is very likely that both layers equally contribute to the mechanical stability of the membranes. Meirowitz et al. (2002) found an increase of collagen I/XIV mRNA ratios in premature rupture of membranes that was not associated with infection.

The structure of the chorion laeve has been extensively studied by Hoyes (1970, 1971). His earlier contribution, although specifically dealing with the mesenchyme of the amnion, has two important features. Hoyes stated that, before the attachment of amnion to chorion, the mesenchymal cells have a continuous configuration with highly developed endoplasmic reticulum. Later, these cells disintegrate into dispersed elements. Hoyes believed that the Hofbauer cells found during later development resulted from degenerating connective tissue elements, a notion that is no longer in agreement with the modern views regarding the derivation of the placental macrophages (see Chapter 6). It appears to us more likely that these cells take their origin from the fetal vascular compartment. Santiago-Schwarz and Fleit (1988) described a population of cells in cord blood that, upon culturing, developed into macrophages. In a later paper, Hoyes (1971) described the mesenchymal elements. He considered them to be similar to those of the amnion.

The connective tissue is followed by a basal lamina that is highly variable in terms of thickness and structure. It is composed of laminin and collagen IV and shows accumulations of fibronectin and collagen III in its immediate surrounding (Aplin & Campbell, 1985). Near the basal lamina, increased amounts of extracellular debris can be observed (Lister, 1968). Fetal vessels exist up to the 6th month; they are branches of the umbilical vessels, extending via the chorionic plate into the mesoderm of the former chorion frondosum. During the last trimester, these vessels are usually absent (Hoyes, 1971). Band-like groups of cells that are rich in lipid droplets and glycogen stores (found between the collagen bundles) have been discussed to be residues of the former capillary endothelium (Hoyes, 1971). This author traced the development of those capillaries that are present up to the 3rd month; they thrombose and gradually disappear. Lister (1968) claimed to have found some capillaries in abnormal placentas near term, but this observation was shared by neither Hoyes (1971) nor us.

From histochemical studies of fetal membranes, largely periodic acid-Schiff (PAS) and similar reactions, Sala and Matheus (1984) concluded that the membranes are not merely a container for the fetus, but that because of their polysaccharide content they participate in the exchange of water and electrolytes. They found that more neutral polysaccharides were present in the trophoblastic shell of

term placental membranes and decidua than elsewhere; the acid mucopolysaccharides were most prominent in the connective tissue layers and decidua.

## Trophoblast Layer

A highly variable layer of trophoblast cells persists until term. These cells are the only residues of the former villi of the chorion frondosum, intermingled with the trophoblastic residues of the primary chorionic plate and the trophoblastic shell.

The trophoblast is separated from the chorionic mesoderm by this basal lamina, on which it rests as a more or less uninterrupted, mostly even, multilayered stratum. Toward the uterine wall, the trophoblast interdigitates intensely with the decidua. Near the placental margin, the trophoblast splits into two layers, flanking an intermediate fibrinoid lamella of increasing thickness. Ghost villi may be encased in the fibrinoid, which consist of clearly identifiable villous stroma surrounded by fibrinoid with some scattered trophoblast cells (see Figs. 11.1 and 11.6). At the placental margin, transition of the ghost villi into intact villi, surrounded by maternal blood, may lead smoothly to the placenta (Bühler, 1964). In other cases, abrupt changes from placental margin into a uniform trophoblast layer of the chorion laeve are observed.

The trophoblast cells of the membranes, together with all the other cytotrophoblast residing outside the placental villi, are now subsumed under the term **extravillous cytotrophoblast**. This summarizing term is justified because all these cells show the same behavior despite their different locations (chorionic plate, basal plate, cell columns, cell islands, septa, membranes). The structure of the trophoblast cells of the membranes is variable (Bou-Resli et al., 1981), as it is in all other extravillous trophoblast populations. Several stages of differentiation can be found, including proliferating, undifferentiated rounded cells with large, oval nuclei and scarce organelles resting on the basal lamina that incorporate <sup>3</sup>H-thymidine (Kaltenbach & Sachs, 1979) and nonproliferating, differentiated, large polygonal cells with highly irregular, invaginated nuclei and condensed cytoplasm, with ample rough endoplasmic reticulum, lipid droplets, and glycogen. These cells have a highly active energy metabolism and express alkaline phosphatase (Petry, 1962). Some of the latter cells that are located nearer the decidua are obviously degenerative in nature. Foci of matrix-type fibrinoid can be observed between the cells. It is probably identical with the amorphous material described by Bou-Resli et al. (1981).

The trophoblast cells are separated from each other by a system of partly dilated intercellular clefts, bordered by a few microvilli and irregular cytoplasmic processes. The clefts are filled with a largely amorphous material

(Bou-Resli et al., 1981), with some loosely arranged collagen fibers, and with bundles of a fine fibrillar material. Immunohistochemically, this material contains laminin, collagen IV, and heparan sulfate proteoglycan, all three known to be usual basal lamina constituents; in addition, oncofetal fibronectin but no fibrin is present. Thus, the area corresponds to the matrix-type fibrinoid described by Frank et al. (1994) and Huppertz et al. (1996), which is a secretory product of trophoblast rather than a blood-clotting product as postulated for fibrin. These secretions are frequently found in small cysts that correspond to the cysts in the placenta, the so-called X-cell cysts (Fig. 11.13). The content is, in part, major basic protein. The presence of fibronectin in this trophoblastic layer has also been described by Yamaguchi et al. (1985) and that of collagen IV and laminin by Aplin and Campbell (1985), Malak et al. (1993), and Ockleford et al. (1993); the latter authors pointed to the similarity with basal lamina material.

The trophoblast cells are connected to each other by desmosomes (Bourne, 1962; Lister, 1968; Bou-Resli et al., 1981; Bartels & Wang, 1983; Wang & Schneider, 1987). In addition, occluding junctions and gap junctions have been described (Bartels & Wang, 1983). The function of the occluding junctions is still open to question. As concluded from their focal arrangement and from physiologic studies

(Battaglia et al., 1968; Lloyd et al., 1969; Chez et al., 1970; Seeds et al., 1977), the junctions cannot limit the permeability of the chorion laeve; physiologically, this layer must be regarded as a leaky membrane. The extracellular matrix may be involved in the permeability properties (Bartels & Wang, 1983), as discussed for the amnionic epithelium. This assumption, however, also cannot explain why the layer seems to be permeable for placental lactogen with a molecular weight of about 22,000 daltons (Chez et al., 1970), whereas it was found to be impermeable to the much smaller inulin molecule (5500 daltons) (Battaglia et al., 1962).

Another interesting view has been stressed by Bartels and Wang (1983). The existence of gap junctions between the trophoblast cells suggests that these cells are coupled metabolically. Gap junctions could not be detected between the individual cells of the villous cytotrophoblast or between villous cytotrophoblast and syncytiotrophoblast (Metz et al., 1979; Reale et al., 1980). Large amounts of renin have been detected immunohistochemically within the cytotrophoblast of the chorion laeve (Symonds et al., 1970; Poisner et al., 1981), and it has been demonstrated in other tissues that renin-producing cells are coupled by gap junctions (Boll et al., 1975; Forssmann & Taugner, 1977). The probable renin synthesis attributed to these cells is the only concrete functional finding, although there are some vague histochemical hints that the trophoblast of the smooth chorion is also involved in steroid biosynthesis (Benedetti et al., 1973) and that some cells at the trophoblastic decidual interface express hPL (Sakbun et al., 1990b). Another finding makes it likely that the trophoblast cells of this site are more than mere residual or even degenerating elements, as they bind epidermal growth factor to such an extent that they must be designated a real target tissue of this growth-stimulating and growth-regulating molecule (Rao et al., 1984).

Trophoblast cells of the membranes are an easily available source for the isolation of extravillous trophoblast cells for *in vitro* purposes because extravillous trophoblast cells are the only cells of epithelial origin within the membranes after stripping off the amnion (Lewis et al., 1996; Gaus et al., 1997).

## Decidua

The decidual layer that is attached to the membranes after birth is largely derived from the parietal decidua (see Fig. 11.4), with some additional residual elements of the capsular decidua. Whether the individual cells are derived from one or the other layer cannot be distinguished. Because the capsular decidua usually undergoes degeneration early and becomes discontinuous (Fig. 11.4C; compare Fig. 11.3), it is likely that the remaining cells are mostly of parietal origin.

FIGURE 11.13. Subchorionic cysts in extravillous trophoblast. H&E  $\times 250$ .

In most morphologic descriptions of the membranes, the decidua is only peripherally discussed or is not mentioned at all. Therefore, it is difficult to decide if it is structurally different from the basal decidua, which has been the subject of numerous studies. The only modern description of the parietal decidua is based on rhesus monkey membranes (King, 1981). As far as can be determined from the early descriptions by Petry (1962) and Bourne (1962), the results can be extrapolated to humans. The cells of this layer obviously do not comprise a uniform population. They all have elongated cell bodies surrounded by more or less prominent and partly condensed meshworks of fine fibrils. Most of the cells have well-developed granular endoplasmic reticulum, numerous mitochondria, and a prominent Golgi apparatus. The cell surfaces of many cells are characterized by stalk-like cytoplasmic processes that contain secretory granules, which are also well known in the decidua basalis (Wynn, 1974; Kisalus & Herr, 1988).

The cells are surrounded by a basal membrane-like material that contains various collagens (Wewer et al., 1985; Malak et al., 1993), heparan sulfate proteoglycan (Kisalus & Herr, 1988), and laminin. Charpin et al. (1985) studied laminin distribution. They considered laminin to be the protein that was demonstrated around decidual cells by Wynn (1974). Because laminin has never been found in nondecidualized endometrium, they suggested that it is deposited under hormonal control. The same is probably valid for the other basal lamina molecules. Because laminin has an adhesive quality, they proposed that it may be involved in the attachment and nesting of the blastocyst.

In their delineation of placental villi with immunofluorescent antibodies directed against complement C3 breakdown products (C3d), Leivo and Engvall (1986) observed a strong localization in the trophoblastic basement membrane and decidua but none in the basement membranes of villous capillaries. They considered it possible that the complement originates from maternal plasma, as none was found in fetal capillaries, and it was also not produced by trophoblast. Because C3d has been found in glomeruli, its immunologic relation to placenta, amply demonstrated in studies of the past, may have a new explanation. Laminin has a strong affinity for C3d, and it may be for this reason that it is bound at these sites. Some of the decidual cells have been shown to express relaxin, a hormone, however, that is secreted also by cyto- and syncytiotrophoblast of different origin (Sakbun et al., 1990a).

The deeper layers of the parietal decidua, which remain in utero, are richly supplied with maternal blood vessels (Arts, 1961). In the superficial parts of the decidua that are attached to the membranes after birth, maternal vessels are the exception. If there are any vessels here, only some capillaries, smaller arterioles, and venules can be identified.

## Tensile Properties of the Membranes

Some investigators have wondered why the relatively thin amnion withstands pressures so readily, and many have conducted measurements of its tensile strength. Independently, Polishuk et al. (1962, 1964), Laufer et al. (1966), and MacLachlan (1965) developed an apparatus to measure the tensile strengths of amnion and whole membranes. The tensile strength of amnion is greater than that of chorion. According to Klima et al. (1989), it is the amount and arrangement of fibers of the compact layer of amnionic mesenchyme that are primarily responsible for the tensile properties. The tensile strength of the amnion was estimated to be even greater than would be needed for a successful gestation, and they found that the strength is greater still during early gestation than near term (see also Wyatt-Ashmead and Ashmead, 2004).

The average thickness of the membranes is 0.56 mm, the amnion making up one third. The average tensile strength is 205 g/cm (50–500 g/cm) (Lavery et al., 1980). More recent studies have pointed out that the membranes have a great ability to withstand trauma. They can expand to twice normal size during pregnancy and labor; their physical properties are both viscous and elastic, and these properties are believed to explain the various unusual physical features (Lavery & Miller, 1977). Kanayama et al. (1985) were unable to demonstrate the presence of elastins in any membranes, a finding that was contradicted by the results of Malak and Bell (1994a) and Hieber et al. (1997).

## Pathology of the Membranes

### Preterm Rupture of the Membranes

Studies of details in membrane strength in prematurely ruptured sacs have supported earlier findings (Danforth et al., 1953). They pointed out that the membranes thin out appreciably at the site of rupture, but that their possibly reduced strength is not the explanation for rupture (Artal et al., 1976). Surprisingly, amnions from pregnancies with premature rupture of membranes had even higher tensile strengths than those with timely membrane rupture (Lavery et al., 1980).

It is not logical to deduce from a study of the membranes in general what the nature of the membranes may be at the site of rupture. It seems that it is not so much the general membrane strength that is important but rather that a local alteration occurs near the site of the membranes overlying the endocervix in the process that leads to their rupture. Malak and Bell (1994b, 1996) have reported local reduction of trophoblast, absence of decidua, and edematous swelling of connective tissue ("zone of altered morphology") as well as local activation

of a variety of proteinases (see following). Moreover, Lei et al. (1996) have shown in the rat placenta that the amniotic epithelium undergoes apoptotic cell death followed by degradation of collagen I before the onset of labor. In contrast, older morphologic studies indicated that widespread apoptosis and degeneration do not occur in humans (Aplin et al., 1985). Nonetheless, the latter group did not exclude that weakening of the membranes may result from more localized changes in the tissue (Streuli & Aplin, 1996).

Amniotic epithelium and the few neighboring fibroblasts continue to synthesize and to deposit basal lamina and interstitial collagens and other matrix molecules until term, depending on the presence of vitamin C (Aplin et al., 1986). When collagen content of amniotic membranes was quantified, it was found to decrease significantly during the last 8 weeks of pregnancy; it may be reduced in membranes from prematurely ruptured sacs (Skinner et al., 1981). According to Teodoro et al. (1990), the membranes of patients with premature rupture have 44% less collagen than is normal. In contrast, Evaldson et al. (1987) and Al-Zaid and colleagues (1980) found no decrease but rather a dissolution of fibers near the site of membrane rupture. This change was examined electron microscopically by Ibrahim et al. (1983). From samples taken at cesarean section at the cervical and opposite sides of membranes, they showed that disruption of the collagen fibrils occurs near the site of membrane rupture. In spite of these contradictions, the role of connective tissue fibers in the pathogenesis of premature rupture is illustrated by the Ehlers-Danlos syndrome. Infants affected with this inherited, generalized disorder of the connective tissue have a greatly increased incidence of preterm prelabor membrane rupture (Barabas, 1996).

It must be said that the crucial point is not the overall content of collagens, but rather the distribution of isoforms, their cross-linkage, and the availability and activity of the respective cleaving enzymes. Several publications underscore this view. Kanayama and colleagues (1985) analyzed the collagen isoforms of normal and prematurely ruptured membranes. They recognized types I, III, and V in these extracts and found altered ratios between the types in specimens from prematurely ruptured membrane cases. There was a particular reduction in collagen type III, and they deduced from their analysis that it related to an increase in trypsin content and a decrease in  $\alpha_1$ -antitrypsin. The findings were generally supported by Keene et al. (1987), Malak et al. (1993), and Bryant-Greenwood (1998), who concluded that collagens I and II together with smaller amounts of collagens V, VI, and VII are involved in the tensile properties.

Not only is the presence of the various types of collagen fibers critical for the mechanical properties but so is their cross-linkage. Availability of copper ions is required to cross-link collagen fibers. King et al. (1997) have shown

that amniotic expression of metallothioneins and amniotic fluid levels of this  $\text{Cu}^{2+}$ -binding peptide are increased in smokers. These data suggest a reduced availability of copper for cross-linking of collagens and may help explain the increased incidence of premature rupture of membranes in smokers. Shimizu et al. (1992) provided an additional, closely related explanation for the obvious correlation between smoking and preterm membrane rupture: fibronectins are also involved in the tensile properties of connective tissues by cross-connecting collagen filaments. These authors found inhibition of fibronectin expression in smokers.

Lower collagen/hexosamine ratios reduce tensile strength. Meudt (1966) found that meconium exposure had the same effect but offered no quantitative data. Lavery et al. (1980) provided such data and noted that although tensile strength is reduced, the presence of meconium does not correlate with premature rupture of membranes. In an attempt to explain why the membrane rupture occurs frequently away from the internal uterine os, Lavery et al. (1982) constructed a complex rheologic model. From it they suggested that local flaws develop under the stress of Braxton-Hicks contractions and with labor. Opitz and Bernoth (1962) examined the site of rupture with polarizing optics; they observed the development of parallel "rupture lines" of collagen. The ability of the amnion to slide over the chorion is probably partly responsible for the variations in membrane rupture. This is enhanced, as Schwarzbacher (1960) pointed out, by residues of magma reticulare [see Intermediate (Spongy) Layer, above] between amnion and chorion that exist to term. This remnant of extraamniotic fluid is presumably also responsible for the sonographic "tenting" of some amnions seen after failed amniocentesis (Platt et al., 1982). It is also possibly the reason why, with repeated amniocentesis, the amnion often detaches from the chorion and thus allows the collection of amniotic fluid underneath. This mechanism probably led to the retained chorion of the patient reported by Stempel and Nelson (1982). The studies by Wynn et al. (1967) with pig amnion suggested that "healing" of earlier defects may result from the regenerative processes in the amnion. They may also explain cessation of fluid leakage in such pregnancies. These authors are the only ones who clearly stated their opinion that the amnion is nourished by amniotic fluid.

Studies of active and latent collagenases (matrix metalloproteinases) have shown that during labor the placenta, cervix, and maternal serum contain high levels of the active enzymes whereas the levels in the umbilical cord are markedly lower (Rajabi et al., 1990). By incubating membranes in "pseudoamniotic fluid" and studying the biomechanical properties with and without the addition of enzyme inhibitors, Artal et al. (1979) suggested that membrane rupture is perhaps regulated by enzymes.

FIGURE 11.14. Amniotic cyst surrounding the umbilical cord. The cyst (left) contained 5 mL of clear fluid. There was no evidence of a vanished twin. H&E  $\times 160$ .

According to Jenkins et al. (1983), amniotic fluid plasminogen must also be considered as an etiologic factor in preterm rupture. Its proteolytic activity is regulated by tPA and uPA and their respective inhibitors (PAI-1 and PAI-2) (see earlier discussion). Plasminogen as well as its activators and inhibitors were detected in amniotic fluid (Kjaeldgaard et al., 1989). Other studies showed that proteases, presumably released from bacteria, reduce the strength and elasticity of membranes (McGregor et al., 1987). This finding is relevant because of the well-known fact that premature rupture occurs with chorioamnionitis (Naeye, 1982) (see Chapter 20).

The studies and reviews by Vadillo-Ortega et al. (1995, 1996), Fortunato et al. (1997), and Bryant-Greenwood (1998) attributed a special role to the broad variety of matrix metalloproteinases (MMPs) and their inhibitors (tissue inhibitors of metalloproteinases, TIMPs) within the membranes. Furthermore, Bryant-Greenwood (1998) reported that activation of MMPs by relaxin decreased the tensile strength of the membranes. For the first time, these data point to the existence of a local autocrine-paracrine signaling system coordinating the local events during membrane rupture.

### Cysts, Tumors, and Hemorrhage

Localized edema with resultant cyst formation is occasionally seen on the amniotic surface. It is not usually associated with clinical problems (Fig. 11.14). Occasionally, such cysts are amniotic epithelial inclusions. No real tumors have been described to develop in the amnion. To be sure, rare nests of cartilage, skin, or bone may be found underneath the amniotic epithelium (Fig. 11.15), but they are not generally neoplastic. Some of these structures may represent the remains of aborted (“vanished”) twins. This possibility is unlikely because vanished twins (discussed in Chapter 25) have usually a different microscopic appearance. An unusual case of an epidermoid cyst

is seen in Figure 11.16. Other investigators have described teratomas in the membranes (e.g., Fox & Butler-Manuel, 1964; Joseph & Vogt, 1973; Nickell & Stocker, 1987). These “tumors” have usually had the appearance of acardiac twins, also discussed in greater detail in Chapter 25. Although these authors stated emphatically that no umbilical cord attached them to the membranes, a feature

FIGURE 11.15. Subamniotic mature cartilage in normal placenta. H&E  $\times 100$ .

FIGURE 11.16. Subamniotic squamous epithelium-lined cyst with keratinization in normal placenta. H&E  $\times 160$ .

that is usually held to be a *sine qua non* for acardiac twins, the appearance of the lesions described is that of acardiacs. Smith and Pounder (1982) came to the same conclusion. They described a  $3.0 \times 2.0 \times 1.5$  cm mass at the edge of a placenta, covered with skin, and broadly attached to the chorion (not decidua, as they stated). It also contained glia, intestine, cartilage, and fat. They referred to other, similar cases that were originally described by Küster (1928) and suggested that the lesion was most similar to an amorphous acardiac twin, under which heading this topic is further developed (see Chapter 25). Despite the lack of organization of such “teratomas,” a feature that is also found in some bona fide acardiacs, some recognizable structures are depicted in most of the foregoing descriptions. The difficult decision as to whether such a lesion represents a teratoma or an acardiac twin has been pursued since Küster (1928) described a walnut-sized lesion composed of external skin, bone, cartilage, connective tissue, nerves, fat, glands, and smooth muscle; she leaned toward a diagnosis of teratoma. Unger (1989) has reconsidered this problem, but there is no resolution. To invoke their origin from aberrant germ cells seems unwarranted without further supportive evidence. Other teratomas of the placenta fall into the same category. See further details in Acardiac Twins in Chapter 25 on multiple pregnancy.

Hemorrhage into areas underneath the amnion most commonly originates from chorionic vessels. It is seen in many placentas when they are examined by the pathologist because the attendants in the delivery room have collected blood for the determination of fetal pH and blood groups and to undertake other laboratory tests. Rarely is such subamniotic blood of prenatal origin, and the age-old question of whether the placental surface can be damaged by the fetus (scratching) has remained unresolved. Shanklin and Scott (1975) found subamniotic

hemorrhages in 1 of 400 placentas. They preferred to call them hematomas and indicated that inappropriate traction on the umbilical cord by the accoucheur to be the common cause of this hemorrhage. There are, however, ultrasonographic observations before birth that suggest the occurrence of subamniotic and, certainly more frequently, **subchorionic** hematomas, representing intervillous thromboses. It is normal to find small laminated fibrin deposits beneath the chorionic plate at term, presumably accumulating from eddying in the intervillous circulation. These deposits may acquire major proportions, however, and they then represent a pathologic feature. Sonographers have been much interested in this topic, as it is readily demonstrable with their equipment. It must be cautioned, however, that so-called subchorionic hematomas, seen sonographically as often as in 60% of pregnancies, may represent merely some blood eddying rather than representing the typical “thrombohematomas.” The differentiation may not be easy and the consequences may differ materially. Nyberg et al. (1990) found that marginal abruptios “tend to dissect beneath the placental membranes,” resulting in subchorionic hematomas. This site is by far the most common type of abruptio seen by sonography (91% before 20 weeks) and may mimic other placental sonographic masses, such as angiomas. In addition, these authors recognized what they termed “preplacental hematomas,” deposits between placenta and amniotic fluid. They are considered to be subchorial or subamniotic in location; some authors believed that they may originate from ruptured vessels (DeSa, 1971) and large ones possibly correspond to the Breus’ mole (Shanklin & Scott, 1975).

Anechoic placental “lakes” beneath the chorionic plate are common and probably of no significance, as most disappear with delivery. It was found that 80% of the subchorial hematomas that were recognized before 20

weeks result in normal term delivery and that their size is the most important prognostic determinant. Thus, Abu-Yousef (1987) found significantly large hematomas to have a grave prognosis, and also that they always extend to the placental margin. Pearlstone and Baxi (1993) reviewed 14 studies and found that these lesions are common (occurring as often as in 4% to 48% of pregnancies), that their etiology was still undetermined, and that a risk for premature delivery exists with large thrombi. One such large thrombus was shown in an early publication by Cooperberg et al. (1979). Oláh et al. (1987) delivered a normally grown fetus at 28 weeks with a huge subchorionic "thrombohematoma" that appeared sonographically as a placental tumor. The neonate succumbed at 5 days of age. The placenta weighed 700 g (!) and was circumvallate; the hematoma was 15 × 5 cm. Conversely, Pedersen and Mantoni (1990), while also finding subchorionic hematomas with great frequency among threatened abortions that had vaginal bleeding (18%), stated that their presence did not enhance the frequency of abortion. Large preplacental hematomas (Pedersen and Mantoni observed hematomas of 2 to 150 mL) may produce clinical symptomatology similar to abruptio, and fetal demise can occur when the hematoma is large enough. Some authors believe they can compress the umbilical cord. The various controversies about this entity were discussed by Spirt et al. (1993). Dickey et al. (1992) also found these hematomas commonly by sonography and related adverse outcomes only to cases with vaginal bleeding. Fleischer et al. (1988) found a correlation with elevated  $\alpha$ -fetoprotein levels, as did Bernstein et al. (1992). Because of the presence of antinuclear antibodies in three of five patients with subchorionic hematomas, Baxi and Pearlstone (1991) recommended that these

patients be screened for such antibodies, irrespective of the obstetric history. We have seen a number of such hematomas among midtrimester losses. They differ from Breus' moles in that they are not focal and the chorionic plate is uniformly elevated rather than, as in Breus' moles, in pockets. When fetuses survive, they often become growth retarded. Al-Nuaim et al. (1996) found an 8.5% incidence of sonographically diagnosed subchorionic hematomas in patients with bleeding in early pregnancy, with a 20.7% abortion rate, a frequency similar to that of other studies.

True amnionic cysts are rarely present on the placental surface. The most common cysts found here are located underneath the chorion; they take their origin from extravillous trophoblast cell deposits in which central liquefaction has occurred. Bleeding into such cysts may occur, and the cysts may also be large and multiple. The associated fetus or newborn may be normal or small for gestational age; growth restriction occurs occasionally because extravillous trophoblast cells are especially prevalent in placentas with severe, extensive ischemic degeneration. These features are discussed further in Chapter 9.

Many term placentas exhibit the remnants of yolk sac as small yellow-white, calcific plaques beneath the amnion (Fig. 11.17) and there may even be on very rare occasions the remains of an omphalo-mesenteric duct present (Fig. 11.18).

## Amnionic Fluid Embolism

### *Vernix Dissection*

Vernix caseosa often dissects underneath the amnion. Indeed, the occasional rupture of only the amnionic sac

FIGURE 11.17. Placental surface with remnant of yolk sac beneath amnion at arrow. There is also extensive amnion nodosum.

FIGURE 11.18. Subamniotic remnant of omphalo-mesenteric (vitelline) duct. H&E  $\times 160$ .

can lead to the formation of “double sacs,” a condition seen also in patients with “high leaks.” Such accumulations of vernix also occur occasionally in large patches of greasy material that may be mistaken for a vanished twin (Fig. 11.19). Jacques and Qureshi (1994) summarized 18 cases of subamniotic vernix collection and emphasized that no cellular reaction to this material had taken place. There were also no clinical events that suggested a mechanism leading to this benign subamniotic vernix accumulation. Spontaneous amniotic membrane rupture seems

to have occurred as the initiating mechanism, as was observed by Yang (1990) in his study of amniotic bands. In placental bed biopsies, vernix has also been observed; indeed, vernix can then lead to an inflammatory reaction, as shown by Craven and Ward (1997). They found vernix with neutrophilic reaction in the myometrium and decidual bed at incidental placental bed biopsy. It was also found in uterine veins, associated with thrombi in this postpartum patient. Patients who have had clinical fluid discharge and in whom later intact membranes were observed have similar membrane ruptures. Reisfield (1958) considered it to result from a congenital defect, but this conclusion is probably not valid. This rupture may occur before delivery, presumably when the amnion breaks before the chorion does. Amniotic fluid with cellular debris (squames, fat, hair) can then be pushed underneath the amnion (Fig. 11.20), at times in impressive amounts. This material appears as white flakes that can be moved back and forth under the amnion. In general, this finding has no significance whatsoever; earlier students of the matter, however (Leary & Hertig, 1950), considered that such subamniotic vernix may gain access to the maternal vascular space and thus initiate the clinical spectrum of amniotic fluid embolism. Indeed, some of their pictures showed squamous cells in the intervillous space and within the decidual sinusoids. Whether the vernix got there by dissection from the subamniotic space is a matter of conjecture. This separation between amnion and chorion can also occur spontaneously before birth, and amniotic fluid may then enter this space, a feature that is sometimes recognized sonographically

FIGURE 11.19. Large, white accumulation of pasty vernix caseosa beneath (dissected) amnion. It is much larger than a yolk sac remnant and must not be mistaken for a fetus papyraceus.

FIGURE 11.20. Dissection of vernix underneath the amnion. H&E. A  $\times 64$ ; B  $\times 125$ ; C  $\times 400$ .

(Borlum, 1989). Borlum emphasized that such “chorio-amniotic separation” is not a contraindication to amniocentesis.

Amnionic fluid embolism has been recognized as an important cause of maternal deaths. It occurs most commonly after tumultuous labor, occasionally during cesarean section, and rarely after amnioinfusion for the treatment of thick meconium (Maher et al., 1994). Steiner and Lushbaugh (1941) first reported this entity. It occurred in 70% of cases during labor, in 11% after vaginal delivery, and during cesarean section in 19% (Clark et al., 1995). Clinical features include severe dyspnea, shock,

and afibrinogenemia. Amnionic fluid embolism may lead to death; indeed, Clark et al. (1995) found it to have a 61% mortality. At autopsy one finds fragments of vernix caseosa, fat, squames, and fetal hair, as well as thrombotic material in the pulmonary capillaries (Fig. 11.21). The problem is well illustrated in an authoritative study by Landing (1950b). Although the diagnosis of amnionic fluid embolism is often suspected, it is only occasionally diagnosed with accuracy during life (Resnik et al., 1976; Haddad, 1985). The pathologic interpretation of vernix in pulmonary capillaries is frequently difficult, particularly when it is attempted from blood smears of living patients.

FIGURE 11.21. Pulmonary blood vessels containing various elements of vernix in a fatal amnionic fluid embolism. On the left is a squame (arrow), in the middle a hair (arrow), and on the right squames with meconium pigment (arrow heads). H&E  $\times 240$ .

It must be realized that the embolization is probably a relatively brief event, wherein circulating vernix is quickly filtered out in the periphery and lung. Contamination of specimens by dandruff (during handling or staining) simulates the microscopic appearance closely. Squames are often contained in the histologic staining solutions and so simulate the true vernix that one must make a positive interpretation with great circumspection. The finding of vernix in blood smears, however, is absolutely diagnostic. It seems unlikely that vernix enters maternal vessels by dissection of the amnion. It probably enters large veins that are opened during cesarean section or tumultuous labor, and in patients with placenta previa accreta. Similarly opened uterine vessels were considered by Landing (1950b) to be sites of entry. Bendon and Ray (1986) reported five cases of prolonged amnionic fluid leakage; they believed that the squames they found in and underneath the chorion represented vernix. In one, it had elicited a foreign-body giant cell reaction. Although it was certainly not the cause of the chorioamnionitis in that case, their Figure 2 clearly showed that the squames had access to the maternal intervillous space.

Amnionic fluid embolism is fatal in more than 60% of cases. The clinical diagnosis is thus of considerable importance (Tuller, 1957; Philippe et al., 1961; Guidotti et al., 1981). Cases have been reported after repeated amniocentesis (Paterson et al., 1977) and even in undelivered patients with cord entanglement that had led to abruption of the placental margin (Corridan et al., 1980). Amnionic fluid embolism causes not only pulmonary hypertension when the lung capillaries are plugged but also shock, hypotension, and uncontrolled bleeding. The "consumption coagulopathy" that follows the disseminated intravascular coagulation event has been thought to result from the thromboplastin-containing liquor. Many coagulation studies on amnionic fluid have been published (Beller et al., 1963). The principal coagulative protein in amnionic fluid appears to be tissue factor (Lockwood et al., 1991). It must be cautioned again, however, that the accurate diagnosis of embolism may be difficult during life; afibrinogenemia more often results from abruption, the dead fetus syndrome, and other complications of pregnancy than from embolism with liquor. Moreover, it must be appreciated that several studies have supported earlier notions of the possible involvement of arachidonic acid and leukotrienes in the catastrophic process that follows amnionic fluid embolism (Clark, 1985, 1988; Azegami & Mori, 1986). Although a central focus of past considerations has been the presumed pulmonary hypertension in this condition, Clark et al. (1988) have shown convincingly that left-sided heart failure is the principal cause of death in this devastating disorder. Clark et al. (1995) later reviewed data from a National Registry with 46 cases and found that the disease simulates the clinical picture of septic shock. Many

patients in their review had histories of allergic reactions and atopy. For all these reasons, they suggested that anaphylactic shock may be an important underlying mechanism. Importantly, during the lengthy discussion of this presentation, Clark et al. indicated that, as the clinical picture is not of the nature of an embolic event, the identification of fetal squames may not be a reliable indicator of the amnionic fluid embolism. Benson and Lindberg (1996) reviewed suggestions that amnionic fluid embolism initiates anaphylaxis in the patient. Because tryptase is a reliable indicator of mast cell degranulation, they suggested that it be measured in future embolic events to obtain more insight into the disease.

Even greater care must be exercised in the diagnosis of amnionic fluid embolism during early pregnancy. The overwhelming evidence suggests that the fluid before 20 weeks is unable to cause coagulation. Vernix is not found in any quantity before the third trimester, certainly not at times of genetic amniocentesis. Also, Clark et al. (1986) made the point that blood obtained from pulmonary arteries of pregnant and nonpregnant patients often contain squamous cells. They assumed that this cellular material originates from venous puncture, rather than from amnionic fluid. Although this statement may be true, it is our opinion that these cells usually derive from contamination with debris contained in fixing or staining solutions and, most commonly, from dandruff of technicians.

## Meconium

Meconium is the bile-stained intestinal content of the fetus. It is often admixed with mucus. Meconium is present in the small bowel of fetuses long before mid-gestation but is usually not eliminated until after birth. Its chemical composition has been partially determined by the early studies of Rapoport and Buchanan (1950). These investigators found it to contain mucopolysaccharides, blood group antigens and some small amount of protein. In infants with cystic fibrosis, there is more protein (nitrogen) than in normal infants, presumably because of the absence of trypsin digestion. When meconium is discharged before parturition, the baby and placenta may be meconium stained and deeply green. It is a common event. In consecutive placental examinations, we have found in San Diego that macroscopic meconium staining occurred in 17.81% of 12,951 placentas, whereas Nathan et al. (1994) found it in 19%. In addition, in our material there were 130 hemosiderin-stained placentas (1%); thus there was a total of 5% hemosiderin staining of the stained placentas overall. Fujikura and Klionsky (1975) reviewed the 42,000 placenta examinations of liveborn infants that were enrolled in the oft-cited large, prospective Collaborative Perinatal Study that was conducted in the 1960s. These authors identified staining in 10.3%, and

18.1% of neonatal deaths had meconium-stained placentas. Their case material, however, contained many instances of erythroblastosis, a condition that is now rarely encountered. Therefore, many of the placentas may well have been stained with hemolyzed blood pigments rather than with meconium. Kallakury et al. (1993) found that 19 of 23 discolored placentas (of 100 consecutive organs examined) contained meconium and even more contained iron pigment. They concluded that no relation to fetal well-being could be identified. This result is contrary to the opinions published by Spinillo et al. (1997), who correlated “meconium-stained amniotic fluid” with cerebral palsy in infants born from 24 to 33 weeks. Regrettably, it is impossible to ascertain whether truly meconium rather than hematin or hemosiderin discolored the fluid. As we will see, this is an important and occasionally difficult differential diagnosis.

The reason for the discharge of meconium is complex and has been reviewed in some detail in the past (Benirschke, 2001). One early review of this intestinal content of the fetus comes from Antonowicz and Schwachman (1979) when intestinal functions in patients with cystic fibrosis were dominant. When intestinal function was studied sonographically in fetuses between 15 and 41 weeks of gestation, Cajal and Martinez (2003) concluded that all passed material through a dilating anus at one time or another and considered discharge to be physiologic. When it occurs, it usually takes place during the last month of pregnancy and with an even greater frequency in postterm pregnancies. It may be of some importance to differentiate various types of meconium staining of the fetal surface of the placenta. Such differentiation is represented in a simplified fashion as follows:

Gross features	Clinical outcome
Acute meconium staining: blue-green, glistening placenta, covered with green, slimy meconium	Typically normal
Subacute meconium staining: slippery, edematous membranes with dark discoloration	High risk of association with asphyxia and cerebral palsy; meconium aspiration syndrome
Chronic meconium staining: dull and diffuse, muddy, cord sometimes stained throughout	Some of the infants with brown-green discoloration later manifest placental and membranes damage, assumed to be secondary to prenatal hypoxia sometimes later manifest

In a study conducted by Usher et al. (1988) of 5915 pregnancies 1 week before term, 1408 pregnancies lasting 1 to 2 weeks past term, and 340 pregnancies lasting more than 42 weeks, meconium staining was observed in 15.3%, 27%, and 31.5%, respectively. Although meconium

discharge was also positively correlated with fetal distress, meconium staining occurred without fetal distress in 10.9%, 18.8%, and 16.2% in the respective groups. Similarly, Rogers et al. (1990) found no good correlation between meconium discharge and neonatal blood pH determinations. Trimmer and Gilstrap (1991) unsuccessfully attempted to correlate the thickness (the “meconiumcrit” of Weitzner et al., 1990) of meconium-stained fluid with outcome. Despite these findings, meconium has assumed great importance in medicolegal pursuits (see Chapter 26 and below).

Meconium is moved in the intestinal lumen by contractions of the intestine’s muscular wall. This movement is regulated by a variety of hormones. Because of the difficulty of passage in Hirschsprung’s disease, various neurogenic factors have been implicated. These are reviewed by Acosta et al. (2005), who studied the cholinergic influences and electromechanical aspects in sheep. Others have suggested that muscarinic acid receptors may be playing a role in fetal intestinal transport. Yet another motility factor is motilin, a 22-amino-acid polypeptide. Motilin is released during the fasting period and induces movement of the “activity front” of the small intestine. In a variety of experimental animals and in human volunteers, the infusion of this polypeptide caused intestinal motor activity that can be interrupted by high doses of gastrin and insulin (Vantrappen et al., 1979). When motilin was measured in the umbilical cord blood of neonates, it was found that those with fetal distress had levels elevated above the normal 32 to 127 pmol/L (Lucas et al., 1979a). Lucas et al. suggested that meconium discharge was the result of elevated motilin levels, which in turn were induced by fetal distress. In subsequent studies (Lucas et al., 1979b), it was found that six of eight gastrointestinal hormones were also elevated in cases complicated by fetal distress. This finding suggested to these investigators that these hormones may be powerful mediators in the many complications that follow fetal distress.

Immature fetuses had significantly lower levels of motilin than did mature infants. This conclusion, however, has been challenged by the report on motilin levels by Kowalewska-Kantecka (1995). She found only small and statistically nonsignificant lower values in premature infants. Our own studies of motilin levels in mature infants with and without meconium discharge are also somewhat different (Mahmoud et al., 1988). In part, the different findings may have occurred because we used different antibodies. We found that motilin levels of infants who had passed meconium were 177 pmol/L of cord blood, whereas those who did not pass meconium had only 111 pmol/L. No relation to fetal distress was found in this study. Because of the underdeveloped production of motilin in immature fetuses, it may be easily understood that meconium discharge is rare in premature

infants, whereas it is common in postmature infants. Whether fetal distress is a primary signal for an increase in motilin and for meconium discharge is still uncertain. It is certainly true that many term stillbirths never have discharged meconium despite prolonged periods of distress that eventually lead to their demise.

Putative meconium presence in greenish amniotic fluid of very premature infants often results from hematoidin and other blood-derived pigments that have the same spectral absorbance when amniotic fluid is studied. It must be said that it then may be very difficult to properly define meconium staining of amniotic fluid. For instance, Falciglia et al. (1993) described a 610-g infant with intrauterine meconium aspiration syndrome and pigmented material in the lung at autopsy. It is not clear to us that this green-stained fluid and the yellow pigment of the lung truly represented discharged meconium, as other pigments have similar spectral characteristics. In fact, we have never seen meconium discharge at that young gestational age. However, Kearney (1999), Scott et al. (2001), and others have reported meconium discharge to occur in immature gestations. In fact, the worst effect on the umbilical cord I have ever seen occurred in a 34-week premature infant and is shown in Figure 11.22. There were numerous meconium macrophages in cord and membranes, and part of the Wharton's jelly had disintegrated to allow the fetal vessels to lie free. Remarkably, the neonate did well. We may need to have a better definition for the material in the amniotic fluid and lungs. For each of the cases of midtrimester amniocenteses with meconium-stained liquor, Karp and Schiller (1977) suggested that a reason for fetal distress could be envisaged. Three times it had been caused by significant prenatal bleeding, once there was marked hypertensive disease in the mother, and twice unsuccessful amniocenteses had preceded it. These investigators did spectrophotometric studies and found absorbance peaks at 405 nm, which is

usually considered to be diagnostic of meconium but can be mimicked by other bile pigments. Their fetuses did well, and the pigment may have been hematoidin.

Golbus and Stephens (1979) did similar spectrophotometric studies on fluid obtained from genetic amniocentesis. Discolored fluid had a large 405- to 415-nm peak, shared with meconium and oxyhemoglobin, as well as peaks at 540 and 575 nm. The latter peaks were the result of blood pigments, believed to derive from disintegrating old blood. Allen (1985) found a 1.67% incidence of "meconium"-stained fluid among 4709 midtrimester amniocenteses, with a 5.06% fetal mortality. He excluded fetuses with brownish amniotic fluid from the analysis. In the discussion that followed his paper, various data were summarized and a consideration of the difficulty with the use of spectrophotometry as a sole determinant of meconium was given. In studies of brown and green fluids from amniocenteses, Hankins et al. (1984) found that brown and green fluids had similar absorption spectra; the authors concluded that the staining at mid-gestation is more likely secondary to hemolysis than to meconium discharge. We concur with that assessment. We have seen only one case of meconium discharge before 30 weeks (courtesy of Dr. C. Kaplan); this occurred in a 29-week gestation stillbirth in a mother with uncontrollable hyperthyroidism, allergy to propylthiouracil, and thyroidectomy during the second trimester. The fetus had 242 nucleated red blood cells (NRBCs)/100 white blood cells (WBCs) and the membranes had a massive meconium macrophage population; iron stains were negative. Moreover, the umbilical arterial walls were focally necrotic and had mural thrombosis. One may assume that the maternal hyperthyroidism stimulated fetal motilin production, but that remains speculative, although meconium discharge is more frequent in maternal hyperthyroidism. Legge (1981) detected the presence of hemoglobin in brownish fluids by chemical means. Alger et al. (1984)

FIGURE 11.22. Umbilical cord of a 34-week fetus. The 24-year-old mother had been "hyperthyroid" and was treated with radioactive iodine and was on Synthroid medication. The neonate did well. The dissolution of Wharton's jelly and isolation of fetal vessels is remarkable. (Courtesy of Dr. S.L. Pedron, Tucson, Arizona.)

made a determined effort to differentiate among the pigments of second-trimester "meconium-like" substances. They studied 123 fluids, irrespective of their gross discoloration, finding that 91% of the clear fluids had an absorption peak at 405 nm, which is that of a pigment generally absent at term. The presence of this peak was not correlated with fetal outcome but it had a higher frequency in the presence of circumvallate placentas and in those with abruptio placentae. The substance was identified as methemoglobin. The authors emphatically denied the ability of a fetus to be able to discharge meconium before 20 weeks; they reviewed what is known of early fetal intestinal motility and anal innervation. Abramovich and Gray (1982), on the other hand, went so far as to suggest that the fetus routinely defecates until 16 weeks but ceases to do so by 18 to 20 weeks.

Boué et al. (1988) found the appearance of intestinal "microvillar enzymes" in amniotic fluid as early as at 12 to 13 weeks' gestation and suggested that this occurred as the anal membrane ruptured. When fetal anal sphincter control is established (18 weeks), however, the enzyme disappears quickly. Whether this evidence should be considered as "defecation" is moot. Ostrea and Naqvi (1982) found that the passage of meconium was strongly dependent on gestational age. Eighty percent of their premature neonates with meconium staining were older than 34 weeks' gestation, even when they had presented as breeches. Their overall incidence was only 6.5%. Recall that although the tensile strength of meconium-stained membranes is reduced, the frequency of premature rupture of membranes is not increased with meconium staining (Lavery et al., 1980). Franquoual et al. (1986) identified coproporphyrin and hemoglobin chemically in stained fluids. Zorn et al. (1986) also studied midtrimester staining to rule out the presence of true meconium. Bilirubin staining of amniotic fluid has been associated with intestinal obstruction and hydramnios (Grimes & Cassady, 1970); these authors suggested that the pigment may derive from disturbed placental exchange. Could it not equally well derive from prenatal vomiting of bile-stained gastrointestinal content? This situation certainly occurred in two of our cases with duodenal or jejunal obstruction, which was complicated by hydramnios. The fetal surfaces of the placentas were diffusely yellow, rather than green as in meconium discharge. Griffiths and Burge (1988) found three similar cases with intestinal obstruction and bile vomiting in utero. Yellow fetal surfaces, especially in the loose connective tissue next to the fetal vessels, are often caused by hematoidin (bilirubin) from hemolysis, as in rhesus incompatibility. We have also seen it complicating Bart's hemoglobinopathy ( $\alpha$ -thalassemia) and associated with an abnormal hemoglobin.

The conclusion that can be reached from all these investigations is that meconium discharge of immature pregnancies is rare and that it is unreliably assessed by current

technology. The reason is that hemoglobin is the common precursor of all these pigments. It may be more useful to determine if hemosiderin is present as iron-containing crystals in histologic preparations of the discolored placental surface. This test would be a more reliable indicator of decomposed blood. The formation of pigments in vivo has been a long-standing investigative challenge for pathologists. In particular, it has been questioned whether extracellular formation of hemosiderin and hematoidin is possible. This topic was fully reviewed by Muir and Niven (1935), who experimented with the injection of red blood cells and hemolyzed blood into rodents and rabbits. Generally speaking, hemosiderin was formed within cells only after about 24 hours; hematoidin, in crystal form, followed in about 7 days. Muir and Niven did not find it in extracellular sites. They assumed that it derives intracellularly from hemosiderin after removal of the iron. This moiety is the same as the bilirubin of meconium. We believe that hematoidin and bilirubin cannot be reliably distinguished from each other at present by either light microscopy or spectrophotometry.

For some reason, meconium has become the "red flag" for obstetricians and for the law profession as well (Sepkowitz, 1987). Meconium, so it is often portrayed, is the result of preceding fetal distress and hypoxia (Mitchell et al., 1985; Zorn et al., 1986). Numerous studies, on the other hand, indicate that correlations between meconium discharge and fetal pH or with tocograms are poor (Steer et al., 1989; Richey et al., 1995), although elevated erythropoietin levels are recorded (Manchanda et al., 1999; Jazayeri et al., 2000). The finding of meconium during labor is in fact a complex topic. The amount of gastrointestinal hormone accumulating in the fetus may reach an optimal quantity at the normal 40 weeks' gestation; when gestation continues beyond that time, meconium discharge becomes increasingly likely. Meconium is thus perhaps correlated with postmaturity (or "postdatism") more closely than with distress (Ostrea & Naqvi, 1982). This is not to say that postmature babies infrequently suffer some distress. Their discharge of meconium, however, may merely reflect the maturation of the system (see also Usher et al., 1988). As mentioned earlier, many term stillbirths never have discharged meconium, despite prolonged periods of distress that eventually lead to their demise. Yeomans and colleagues (1989) correlated meconium in amniotic fluid with fetal acid-base status. They concluded that "meconium-stained amniotic fluid correlates poorly with infant condition at birth as reflected by umbilical cord acid-base measurements." Their report also provided a valuable review of the views, pro and con, that meconium relates to fetal hypoxia. It must be appreciated that the mere presence of meconium at the time of birth may be irrelevant, while the prolonged presence in utero with staining of membranes and cord may signal significant problems to have existed. The important ques-

tion is, How are we to separate what is meaningful meconium staining from its accidental presence? Some answers have been provided by Phelan et al. (1994, 1999), Redline and O'Riordan (2000), Kaspar et al. (2000), and Spinillo et al. (1998) that suggested a relationship to neonatal impairment and the presence of meconium at birth. Further, the experimental studies performed by Blackwell et al. (2004) found minor CNS learning deficiencies in rats that had been exposed in utero to meconium late in gestation. None of these studies, however, is designed to show that fetal hypoxia is the cause of meconium discharge; it could as well be its consequence.

Meconium has deleterious sequelae when it is aspirated by the fetus (Byrne & Gau, 1987) and on the amnion and umbilical cord as well. A deleterious effect on the conversion of surfactants has been demonstrated by Kakimoto et al. (2002). Nathan et al. (1994) reviewed the impact of meconium-stained fluid in a very large sample and concluded that the impact on fetal morbidity and mortality is small and primarily related to the meconium aspiration syndrome. An increased viscosity of the meconium-stained amniotic fluid also was not apparently related to a worse outcome. At times, the meconium is quickly expectorated when aspirated and has then no untoward consequence, whereas at other times it leads to fatal pulmonary complications despite proper airway management (Davis et al., 1985). Thureen et al. (1997) found that much of the pulmonary damage had usually a prenatal onset and that significant placental abnormalities were frequent. Dooley et al. (1985) studied outcome in infants who had meconium present below the vocal cords and related its discharge to intrapartum events; they found that no change in therapeutic maneuvers would have saved the infants (see, however, Falciglia, 1988). The quality of meconium differs from case to case. In some infants, mucinous material may be present that the newborn's respiratory tract finds more difficult to eliminate. Likewise, it must be appreciated that not all babies born from a meconium-containing amniotic environment suffer meconium aspiration. They may have ceased to breathe in utero as a result of chronic distress (Kaplan, 1983). Thus, the problem is complicated and must be evaluated on individual merits. One must also consider the possibility that aspirated meconium causes degenerative changes in the alveolar epithelium similar to those seen in the amniotic epithelium. Thus, the meconium aspiration syndrome may represent a form of chemical pneumonitis with acute respiratory distress syndrome. Others (Katz & Bowes, 1992) have suggested that the deleterious pulmonary effect of meconium aspiration may be initiated by asphyxia. Kearney (1999) impressively demonstrated the production of subpleural plaques and infarcts with inspissated meconium, and later (2000) found eight "unequivocal intrauterine meconium aspirations" in midtrimester fetuses. How controversial the

topic is may be learned from the study of Ghidini and Spong (2001), who concluded that most so-called meconium aspiration syndromes are the result of prenatal asphyxial and infectious problems. Many experimental studies have been conducted with meconium inhalation before and after birth; some have yielded conflicting results. Goodlin (1968), for instance, found that there was little difference between saline and meconium in his rabbit experiments. Wiswell et al. (1992) observed the changes in piglets, and Goetzman (1992) summarized all aspects of the meconium aspiration syndrome. Yoder (1994) reviewed treatment regimes and reemphasized that not all meconium is equal. Of what element exactly the noxious quality of meconium consists, however, is unknown. It is possible that bile acids constitute the toxic material, as reported in maternal sclerosing cholangitis (Nolan et al., 1994) and in the cholestasis of pregnancy (Sepulveda et al., 1991). It should be noted, however, that experimental infusion of cholic acid during gestation into fetal lambs did not appear to be toxic (Campos et al., 1986). Alternatively, perhaps it is trypsin that causes the toxicity. Thus, Maradny (1994) showed that fetal urine and amniotic fluid contain urinary trypsin inhibitor-related (UTI-R) substance, that it can be demonstrated immunochemically in amnion epithelium, and speculated that it may have a stabilizing effect on intracellular calcium. Resolution of this question is desirable as it may lead to effective therapeutic measures for the meconium aspiration syndrome. The investigations by Uotila and Kääpä (1998) showed that meconium dose-dependently stimulates the expression of cyclooxygenase-2 in monocytes. These authors suggested that, if a similar stimulation of alveolar macrophages occurs in response to meconium exposure, perhaps their production of prostaglandins participates in the creation of the meconium aspiration syndrome.

Meconium is noxious in other ways (Rubovits et al., 1938). When meconium has been present in the amniotic cavity for many hours, the amniotic epithelium begins to show degenerative changes. Vacuolation, heaping up, loss of cells, and eventually necrosis are seen (Fig. 11.23). Moreover, muscle cells of the umbilical vessels of the umbilical cord, and their ramifications on the placental surface may degenerate when meconium presence has been long-standing (Figs. 11.22 and 11.24). This change was first described by Altshuler and Hyde (1989), who also provided evidence that damage to the fetal vascular tissue may exacerbate fetal cerebral hypoperfusion and thereby augment possibly existing fetal hypoxia. When they experimentally exposed segments of umbilical veins obtained from cesarean sections to meconium solutions, the muscular wall contracted markedly and rapidly. In addition, necrosis of vascular walls was believed to be a consequence of meconium exposure. Exactly how long this exposure must have existed before visual vascular

FIGURE 11.23. Heaping and degeneration of amnionic epithelium with meconium macrophage (arrows) after 20 hours of exposure (right) to meconium. H&E. Left  $\times 160$ ; right  $\times 400$ .

alterations occur is not known, but we estimate that it is many hours. In subsequent studies, Altshuler et al. (1992) examined 1100 meconium-stained placentas among which they found 10 with vascular necrosis; two placentas had ulcerated cords. It is also common that the fetal surface blood vessels suffer damage and may contain mural thrombi. Holcberg et al. (1999) confirmed the vasoconstrictive result by injecting variable concentrations into isolated placenta cotyledons and found a concentration-dependent effect. Moreover, when they dialyzed the meconium-containing amnionic fluid, the constrictive effect vanished. Sienko and Altshuler (1999) found interleukin- $1\beta$  in the meconium-containing macrophages, and specifically ruled out inflammatory reactions of the placentas studied. Hsieh et al. (1998) found no relation of meconium discharge and interleukin levels but detected interleukin- $1\beta$  in meconium. The degenerative effect of meconium on cord smooth muscle was studied *in vitro* by Lembel et al. (2000) and essentially confirmed. This topic is further discussed in Chapter 12.

It is incorrect to assert, however, that meconium causes chorioamnionitis (Dominguez et al., 1960; see also Lauweryns et al., 1973) although, when it is present simultaneously, the neonatal outcome is poorer (Rao et al., 2001). To be sure, when degenerative changes in the surface do occur, they are sometimes followed by inflammation, but the amnionic sac infection syndrome is not caused

by meconium. We believe this to be true despite the observations by Beaufort et al. (1998) that meconium contains interleukin-8 and also demonstrated some leukotactic activity. Bacterial cultures from meconium-stained fluid, however, are more frequently positive than those from controls (Romero et al., 1991; Mazor et al., 1995). Meconium additionally inhibits neutrophil performance (Clark & Duff, 1995), thus further decreasing fetal defense. In the retrospective study undertaken by Burgess and Hutchins (1994), the authors thought not only that meconium induces the typical arterial necrosis of the cord but also that inflammation may result in membranes and fetal lung from meconium. Their inflammation of the membranes was less severe than that usually seen in chorioamnionitis. We often see deeply meconium-stained placentas, obviously having been exposed to meconium for many hours that do not have any inflammation. A study by Novak and Kokomoor (1988) found meconium in about 13% of 1024 consecutive placentas, 30 of which came from prematures. The latter had 53% “chronic staining” in contrast to 17% in the term placentas. Also, 60% of the premature infants had inflammation with the staining; it occurred in only 26% of the mature neonates. Villous edema was also more common in the prematurely delivered infants’ placentas, and the authors concluded that meconium-stained placentas come from populations with different characteristics. It is likely

FIGURE 11.24. Degenerating muscle of umbilical cord blood vessel after chronic meconium exposure. H&E. Left  $\times 64$ ; right  $\times 160$ . (Courtesy of Dr. G. Altshuler.)

FIGURE 11.25. Viscous, mucinous fluid beneath the amnion is a frequent feature of prolonged meconium exposure. Note the heaped, dissociated amnionic epithelium. H&E  $\times 250$ .

that the more immature babies had chorioamnionitis independent of the meconium discharge because inflammation is much more common in prematures in any event.

It has been our experience that, after meconium has been present on the placental surface for some time, it leads to an accumulation of a viscous fluid between amnion and chorion. It is readily apparent histologically (Fig. 11.25)

The pigment of meconium can be seen in cells of the membranes. It is not only the pigment that is found; phagolysosomes are full of debris when examined ultrastructurally (Fig. 11.26). For routine purposes, it suffices to make light microscopic observations. When hemosiderin is to be ruled out, a Prussian blue stain quickly differentiates between these two pigments. Meconium-laden macrophages are large, ovoid, or round cells in amnion and later in the chorion that have a yellow-brown-green

FIGURE 11.26. Meconium macrophage filled with lipid and lysosomes in a patient also having gastroschisis. Some lysosomes contain membranous debris and other heterogeneous material. Transmission electron micrograph.  $\times 15,200$ . (Courtesy of Dr. M. Grafe.)

content (Fig. 11.27). They are often vacuolated (Fig. 11.28). It is our opinion that these macrophages usually “lie in waiting” in amnion and in chorion, and that they are normally inactive and unoccupied. When meconium or other substances come by, they spring into functional

activity. Although iron stains (Prussian blue) readily differentiate hemosiderin, the only other significant pigmentation, the bile in meconium is not readily confirmed positively. Its association with fine vacuoles helps, but a Luna-Ishak stain (Luna, 1968) may be necessary to

FIGURE 11.28. Different types of meconium macrophages in membranes after prolonged exposure. Note that the amnion is degenerated in all sections, and only the right membranes show minimal inflammation. Left: Vacuolated cells with pigment.

confirm the pigment on occasion; it stains the bile a greenish color. The stain is not always easily performed. Bourne (1962) showed some photographs suggesting that meconium may stream through passageways of the epithelium, but it is more likely that these areas represent already damaged epithelium. In detailed studies of the ultrastructure of placenta and membranes, Lister (1968) concluded that the meconium appears as electron-dense granules that are associated with debris and frequent cellular degeneration. There are, however, also rare circumstances in which the membranes definitely do not have green meconium staining and histologically have pigmented macrophages that do not stain with iron stains. This finding was prominent in a placenta of a case of characteristic  $\alpha$ -thalassemia that we saw. Hemolysis was not clinically observed and the nature of the pigment was not determined. One can always speculate that meconium had been discharged days earlier, but there was no evidence for this. Further, in a child with anal atresia and rectourinary fistula we saw meconium staining because of meconuria. In other cases, bile vomiting may be the cause of such pigmented macrophages (Vijayakumar & Koh, 2001). Not only that, Ohyama et al. (1999, 2000) described a number of newborns with ulcers of umbilical cords in which there was atresia of the intestines below the papilla of Vater. They concluded that this results from vomiting of the upper intestinal content.

When meconium is discharged a short time before birth, it may be wiped or washed off the surface without leaving a stain. Later, it stains the amnion, and thereafter the chorion stains permanently. When studies were done to estimate the time interval for the staining to become permanent, it was found that one may find histologic meconium-stained macrophages in the amnion within 1 hour of exposure; staining of the chorion occurred after 3 hours (Miller et al., 1985). Poggi et al. (2003), however, deduced from their experiments that it takes much longer (~12 hours) for the staining to take place. When it has been present for longer times, it cannot be dated reliably. From their review of the literature, Fujikura and Klionsky (1975) estimated 4 to 6 hours before meconium reaches the chorion. These figures are estimates only, because it is difficult to undertake such observations prospectively in vivo. Similar timetables have been established for the staining of fingernails and vernix. Desmond et al. (1956) found that it took 4 to 6 hours of bathing the toes of neonates in meconium-containing fluid before the nails were stained, and 12 to 14 hours for the vernix to be stained. The further progression of meconium staining of the membranes is the following: Bile pigment stains the center of the umbilical cord, usually without being contained in many macrophages, and the amniotic epithelium degenerates. The meconium is then handed to macrophages that reside within the decidua. With very

long-standing meconium exposure and when the rare uterus with attached placenta becomes available for study, one may even observe meconium-stained macrophages within the myometrium. It is possible that some meconium is ultimately completely removed by this exchange, by swallowing, and by in utero inhalation of the material. It is also conceivable that, in some instances, fetuses discharge meconium repeatedly. This fact further complicates our ability to assign firm time sequences of placental meconium staining. It must also be remembered that the staining quality of meconium is reduced or eliminated when slides that contain meconium macrophages are exposed to light for longer periods of time (Morhaime et al., 2003). This is similar to the effect of exposure of jaundiced neonates to ultraviolet (UV) light. The frequent meconium discharge in postterm fetuses and its effect on the fetus is complicated by the increasing incidence of oligohydramnios after term. The volume of amniotic fluid decreases significantly near term and thereafter (Clement et al., 1987). Suggestions that indomethacin induces both (Itskovitz et al., 1980) have not yet been confirmed. Prophylactic amnioinfusion with saline in thick meconium discharge has sometimes been beneficial in the ultimate outcome (Macri et al., 1992; Uhing et al., 1993). The overall benefit of this procedure, however, is still controversial (Dye et al., 1994; Usta et al., 1995). Importantly also, several cases of maternal amniotic fluid embolism have been reported following this procedure (Maher et al., 1994). Many of the outstanding questions regarding meconium have been addressed in a searching contemporary contribution (Benirschke, 1994).

It is essential that hemosiderin be differentiated from meconium. It derives from hemolyzed red blood cells and is commonly found in association with circumvallate placentas, in the placentas of erythroblastotic infants, with abruptio placentae, and with thromboses and other circumstances wherein bleeding has occurred. Although such placentas often have a brownish tint, they may be green and simulate meconium macroscopically, except that the membranes are not then slimy. Clayton et al. (1969) spectrophotometrically studied the fluid pigments of hydropic fetuses and those with hemolyzed blood; they emphasized the difficulties of differentiating these moieties. Hemosiderin is composed of granular particles, and it has a characteristic sheen (refringence) when the focus of the light microscope, or its substage, is changed (Figs. 11.29 and 11.30). Hemosiderin is strongly positive with iron stains but, as mentioned earlier in this chapter, hematoidin cannot be reliably distinguished from the bilirubin of meconium. Finally, one should be aware that the bilirubin that stains the macrophages laden with meconium bleaches when it is exposed to the light of the laboratory.

FIGURE 11.29. Circumvallate placenta with extensive hemosiderin staining. Although it looks green, it is all hemosiderin, not meconium. Disrupted fetal vessels are shown at white arrows.

### GASTROSCHISIS

The amnionic epithelial cells in gastroschisis have a characteristic fine, uniform, extensive vacuolation (Ariel & Landing, 1985) (Figs. 11.31 and 11.32). Although this association was startling when first found, it is now known to be regularly present, is virtually diagnostic of gastroschisis, and is not found in fetuses with omphalocele. The fine vacuoles of amnion in gastroschisis contain lipid when examined by electron microscopy (Grafe & Benirschke, 1990), but the origin of the lipid is still obscure. When young pregnancies (>20 weeks) are studied, the vacuolization of the epithelium is not yet present; only later in gestational age does it accumulate, and the lipids then stain intensely with oil red O and other lipid stains. It is possible that the lipid comes from the opened abdominal cavity of the fetus, but that possibility should be ascertained by future studies. This assumption is somewhat contradicted by the finding that the fibrin/fibrous coating of intestines in this condition apparently contains no lipid (Tibboel et al., 1986). As was summarized earlier in this chapter, lipid has been found in small quantities by histochemical staining of the amnionic epithelium during early pregnancy, but particularly in specimens from term pregnancies. Moreover, the quantity of cel-

lular lipid content in amnionic fluid cells was formerly used reasonably successfully to estimate the length of gestation (van Bogaert et al., 1978). Schmidt (1963) studied lipid removal from the amnionic sac in the chick embryo and concluded that lipid injected into the extraembryonic coelom of the chick is absorbed by amnionic epithelium. Later, lipid in amnionic cells again becomes a component of the amnionic fluid, from where it reaches the fetal intestine. Schmidt considered similar pathways for the human embryo. Pritchard et al. (1968) found the composition of the lipid in amnionic cells to be similar to that of the amnionic fluid and to vernix; they suggested that most of the lipid in vernix is produced by amnionic epithelium. We believe that the reverse occurs, and that vernix is derived from fetal sebum, which becomes incorporated into amnionic epithelium. The difference of normal versus gastroschisis amnionic epithelial vacuolation is evident in the dividing membranes of discordant dichorionic twins (Fig. 11.32).

### EPIDERMOLYSIS BULLOSA

Epidermolysis bullosa, a rare condition, has been associated with amnionic lesions. Faulk et al. (1988) reported that a term newborn with

this disease had an amnionic surface with multiple polypoid protrusions that were covered by epithelial cells. We saw a 26-week premature infant with this disease and with duodenal atresia. Its amnion also had lesions similar to those described by Faulk et al. (1988). There were apparent protrusions of the connective tissue through epithelial defects. Thus, polyp-like excrescences were produced that were partially covered by amnionic epithelium (Fig. 11.33). There was no inflammation but many pigmented macrophages existed in the connective tissue of the

membranes. Thus, it would appear that the amnion shares the immunologic features of this disease with the skin.

### Amnion Nodosum

Amnion nodosum, a relatively common condition, was first so named by Landing (1950a) when he observed small granules on the placental surfaces from pregnancies that were complicated by severe oligohydramnios. The lesion had been known since Pilgram (1889) and was described in the German literature as *Amnionknötchen*, so termed by Franqué (1897). Blanc (1961) assigned the term **vernix granulomas** to it and expanded on the pathology of associated fetal lesions in a later contribution (Blanc et al., 1962). The term **vernix granuloma**, although denoting its relation to vernix, was not adopted because the lesions are clearly not granulomas.

Amnion nodosum is most commonly found in the placentas of fetuses with renal agenesis or following premature and prolonged amniorrhea, in the placenta of the donor twin of the twin transfusion syndrome (the “stuck twin”), in diamnionic acardiac twins, characteristically in sirenomelia, and with some other disturbances that lead to prolonged oligohydramnios. It is clearly the result of deficient amnionic fluid over a prolonged period of time. The nodules are most pronounced on the placental surface, but they may rarely extend onto the membranes as well. They are only very rarely found on the umbilical cord surface. Most cases of amnion nodosum show fine

granules that are best seen in oblique light (Fig. 11.34). They are quite different from the granules of squamous metaplasia, which is typically more plaque like, patchy, and hydrophobic. Amnion nodosum is frequently brown-yellow and not shiny. The nodules are composed of squames and hair intermixed with sebum. They are from vernix that has been "rubbed" into defects of the amnionic surface. Probably the first event is that the amnionic epithelium becomes defective because of absent fluid; this then allows vernix to attach to the defect (Figs. 11.35 and 11.36). There is no inflammatory or other tissue reaction of the amnion to the presence of the vernix. At times, the edges of the granules become covered with regenerating amnionic epithelial cells.

Electron-microscopic studies have shown that most of the nodules are composed of acellular debris, degenerating cellular walls, hair fragments, and squamous cells. Bartman and Driscoll (1968) discussed the possibility, originally sug-

gested by Bourne (1960), that the nodules originate from the amnionic epithelium, but Salazar et al. (1974) clearly demonstrated their origin from vernix. The later authors described many cell types present within the nodules; these also contain remnants of cells, old cell walls, and fibrillar material. The centers of amnion nodosum are positive with PAS and Alcian blue stains. Salazar et al. (1974) laid to rest the notion of the cellular origin from squamous hyperplasia and metaplasia. Surprisingly, they saw some nodules covered by thin, symplastic amnionic epithelium that they considered as possibly having regenerated.

Amnion nodosum develops during late fetal life. There is not enough vernix during early pregnancy to produce this lesion. Although oligohydramnios has been verified as early as at 16 weeks in the case of urethral obstruction reported by Wagner and Tygstrup (1963), the amnion was still normal. Alternatively, as shown in Figure 11.35, in such gestations the amnion shows only minute foci of cellular

FIGURE 11.34. Macroscopic appearance of amnion nodosum in a child with renal agenesis. Note the uniform presence of fine granules, mostly sparing the vessel surfaces and not present on the cord.

FIGURE 11.35. Early stages in the development of amnion nodosum. Focal ballooning, necrosis, and apposition of debris are present in therapeutic abortions performed for recognized oligohydramnios caused by renal agenesis or renal cystic disease. H&E  $\times 400$ .

degeneration. When renal anomalies exist in only one of monoamniotic twins, as in the sirenomelia described by Kohler (1972) and substantiated by many subsequent cases, there is no amnion nodosum. Not only does amnion nodosum not develop in such monoamniotic twins, but the pulmonary hypoplasia that is so characteristic of newborns associated with severe oligohydramnios is also prevented. Brown et al. (1978) described two cases of oligohydramnios secondary to amniorrhea, similar to that originally delineated by Bain et al. (1964). In Brown et al.'s two cases, amnion nodosum was present in only one, a fetus of 1000 g; the other, weighing 600 g at 27 weeks, lacked amnion nodosum. The explanation for such apparent discrepancies is that at that early age little vernix exists to allow amnion nodules to develop. It needs not be hypothesized, as did Bain and colleagues, that the vernix had drained out with the amniorrhea, or that real "trauma" or very close contact with the fetal surface is necessary to produce the nodules, as has been suggested. The nodules are much too finely distributed to have derived from trauma of scratching or from close fetal contact with the amnion. We believe that it forms by apposition of vernix debris to foci of dying amnion epithelium—areas of epithelium that are no longer sup-

ported by the nutrition and oxygen normally contained in amniotic fluid. If the amnion had ruptured earlier, as in cases with amniotic bands, similar nodules may develop on the chorionic surface, something we have termed "chorion nodosum" in a case of congenital high airway obstruction syndrome (CHAOS) (Welsh et al., 2000).

There are numerous other reports of amnion nodosum, itemized in the contributions of Thompson (1960), Masson et al. (1966), Fitch and Lachance (1972), and Wentworth and Turnbull (1969). A comprehensive study of 100 cases of oligohydramnios may be found in the poorly accessible thesis of Déglon (1978). These studies also considered the pathogenesis of pulmonary hypoplasia and the fetal deformities associated with oligohydramnios. The dispute here is whether pulmonary hypoplasia follows the inability of the lung to inhale normal amounts of liquor, or whether it is a phenomenon caused by compression from life in a too-tight uterus. Breathing motions alone do not determine the future of lung development; it is the availability of amniotic fluid that is a prerequisite for useful breathing expansion of the lung (Wigglesworth & Desai, 1982; Kilbride et al., 1988). This claim is supported by experimental studies of fluid withdrawal from the amnion

FIGURE 11.36. Late stages of amnion nodosum. Left: One nodule. Phosphotungstic acid hematoxylin (PTAH). Right: A larger plaque. Both contain squames, fat, and hair. Left: PTAH  $\times 1160$ . Right: H&E  $\times 200$ .

of rats (Symchych & Winchester, 1978). Lung fluid production may be another important facet, as derives from rare and complex anomalies.

The poor prognosis of fetuses associated with oligohydramnios and identified sonographically during the second trimester has been the topic of articles by Barss et al. (1984) and Mercer and Brown (1986). Wong and colleagues (1985) criticized this mode of detection if it is not followed up by confirmation through amniocopy or amniocentesis. An additional consideration regarding pulmonary development is the secretion of fluid by the respiratory tract. When laryngeal atresia exists, the fetal lung may overexpand owing to this secretion, with hydramnios ensuing from obstruction to venous return (Silver et al., 1988).

### Amnionic Bands

The existence of amnionic bands as a cause of amputations and other fetal debilities can hardly be disputed, although such doubts are expressed in the literature with regularity. These doubts began with Streeter (1930), who believed the defects to be of "germ plasm" origin. Others have shared this doubt in the primacy of amnion disruption (Patterson, 1962; Woolnough, 1987; Lockwood et al., 1989). Doubt has been expressed particularly with cases involving major congenital anomalies, such as exencephaly, ectopia cordis, and spinal disruptions (Chaurasia, 1978). These cases are frequently associated with broad amnionic adhesions. Several reviews of these cases have suggested that we may be faced with two or three distinct entities: (1) amnionic bands (with constriction possible of fingers, extremities, or umbilical cord but a generally normally formed fetus); (2) amnionic sheets (usually attached broadly to the skull and often the facies); and (3) the limb-body wall complex (with amnionic sheets and gross disruptions). The last word has not been spoken on this complicated issue, especially as to etiology and pathogenesis. Two considerations in the literature have suggested that amnionic bands and the limb-body wall complex are two distinct entities (Martinez-Frias, 1997a,b). It is also clear that the amnionic sheets are very frequently associated with many other fetal anomalies [e.g., exencephaly, meningocele, bony defects, single umbilical artery (SUA)], which is not the case with the typical bands that entangle the fingers. There may be overlaps, as also suggested by Moerman et al. (1992). These authors provided a useful differentiation between these features and suggested that the latter two categories are associated with disturbances of early embryogenesis, thus leaving the amnion attached to the forehead in a broad sheet. Numerous cases of constriction of umbilical cord, limbs, and fingers have been presented that leave little doubt, however, that true bands from disruption of the amnionic sac do occur, that these can cause amputations, even fusion of fingers and toes, and that they may cause fetal death by encircling the

FIGURE 11.37. Spontaneous abortion at 15 weeks with amnionic bands encircling a constricting umbilical cord and tips of fingers.

cord (Hong & Simon, 1963; Ashkenazy et al., 1982). Baker and Rudolph (1971), who reported on 13 cases, believed that bands occurred only rarely, once in 10,000 births. Bands can be a cause of spontaneous abortion with macerated fetuses, which must be carefully inspected to arrive at the correct diagnosis (Figs. 11.37 to 11.39). Kalousek

FIGURE 11.38. Case similar to that shown in Figure 11.37, with encircling of extremities and cord. Aborted fetus. (Courtesy of Dr. G. Altshuler. Source: Altshuler & McAdams, 1972, with permission.)

FIGURE 11.39. Surface of the placenta of a term fetus with an amnionic remnant issuing from the base of the cord. The band had encircled the leg and nearly amputated it (see Fig. 11.41). Note the opacity of the membranes.

(1987; Kalousek & Bamforth, 1988) found amnionic bands much more frequently. They occurred as often as 1 per 53 previable fetuses compared to 1 per 2500 to 10,000 liveborns.

At times, it has even been witnessed that a smaller limb is delivered with a fetus. We have seen a newborn with foot amputation whose placenta was accompanied by one small macerated foot. The gestational age of the foot was estimated (from its length) to be 20 weeks. The term neonate suffered osteomyelitis later in the amputated stump. These findings indicated to us that amputation had occurred at an earlier fetal age. Such was also the case in the patient reported by Torpin and Faulkner (1966). Shipp et al. (1996) observed fetal decapitation caused by amni-

onic bands. Remarkably, the fetus continued to grow for 7 weeks after decapitation. The fetus also had clubbed feet and hepatic calcifications, presumably from hypoxia. Doubtless, the fetus moves and becomes entangled in these remnants of amnion; because the fingers move most actively it is probable that amputation of fingertips is the most common sequel in amnionic bands. Most fetuses with amputations caused by amnionic bands are otherwise normal, and the placental surface is usually completely devoid of amnion. In such cases, one usually finds remnants of amnion only around the umbilical cord whence the bands originate (Figs. 11.39 and 11.40) (Patterson, 1962). The amnion is so firmly attached to the cord

FIGURE 11.40. Placental surface of an infant with an amputated arm. The tiny remnants (clamp) of amnionic bands were initially not recognized at inspection after delivery. The importance of recognizing bands cannot be overemphasized if proper clinical counseling is to occur.

surface that it does not detach from it and is not capable of disruption with band formation. The placental surface is usually somewhat opaque owing to infiltration with enlarged macrophages. This situation is particularly true when the amnion has been missing for long periods (Fig. 11.39). The entire topic of amnionic disruption and bands has been exhaustively treated by Torpin (1968) in a book that has innumerable references and illustrations. Not only did Torpin collect more than 400 cases from the literature, he also gave a detailed account of the many cases he had himself encountered. This volume should be consulted with respect to the history and other aspects of this relatively common cause of fetal anomalies. Moreover, it was Torpin who first contradicted the theories of Streeter and assigned a later amnion rupture as the etiologic event. Constriction of extremities is perhaps the most common or best known feature (Fig. 11.41). We believe that the mobility of hands and feet is responsible for this. It should be cautioned, however, that not every case of amnionic rupture necessarily leads to entangling and constrictions.

Another comprehensive review of most aspects of amnionic bands is that of Seidman et al. (1989). These authors bemoan that the syndrome is surely underdiagnosed and emphasize that no two cases are alike. This is especially so when one includes the limb-body wall complex. Single umbilical artery and short umbilical cords were found to be common associations. The karyotype of associated fetuses has almost always been normal, and the etiology is still disputed. This other type of amnionic disruption leads to very different fetal deformities. These have been assumed to be associated with **early** amnion rupture, although different interpretations exist. Indeed, the sheets are so large and often so well shown in sonography (they are contiguous with the ectoderm of the face and other parts of the body) that one should

question the association with amniotic disruption. The anomalies are characterized by more profound defects commonly involving the face, skull, and abdomen. Often exencephaly, clubbed feet, and a variety of other features are observed. Although these disruptive events were once also held to be sequelae of amnion rupture, the mechanism that produces them is surely different from the typical bands. Yang (1990) has reviewed the topic well, added a number of band cases and sheets to the literature, and believed that amnionic bands were doubtless the result of early amnion rupture. He also highlighted the fact that not all ruptures lead to band constrictions and that vernix is often incorporated into the membranes after rupture. Shephard et al. (1988) conjectured that the frequent facial disruption of these fetuses may result from the "stickiness" of these areas in early embryos. This is highly unlikely. Stickiness would not produce the large variety of other anomalies, nor would it be associated with a sheet of amnion whose epithelium is contiguous with the facial ectoderm. Incomplete embryonic folding and neural tube closure are more likely the mechanism. Because of fetal growth retardation and hydramnios, these "limb-body wall complexes" (Patten et al., 1986) are often recognized antenatally. Pysher (1980) described such a case that affected only one of monozygotic twins, and Woolnough (1987) described it in a dizygotic twin. We have seen it in one of presumably monozygotic but dichorionic twins. It had broad amnionic adhesions and many other anomalies (truncus, short bowel, ureteromegaly).

In observations of amnionic bands described by Lockwood et al. (1989) and their review of the literature, emphasis was laid on the fact that only one of monozygotic (rarely a dizygotic) twins may be affected, thus making an external cause such as infection unlikely. Hartwig et al. (1989) reviewed this limb-body wall mal-

FIGURE 11.41. Note the extreme constriction of the right foreleg by the amnionic bands shown in Figure 11.39. The infant also had several amputated toes.

formation complex more completely and concluded that only some cases have broad amnionic adhesions and that others cannot be explained by this mechanism. They favored other, more complex disturbances of early embryogenesis as their etiology. It was especially deemed to be so because apparently unrelated anomalies (e.g., truncus arteriosus) were sometimes encountered in such fetuses. It must be cautioned, however, that delivery often disrupts the areas of amnionic adhesion, and reconstruction may be difficult. Characteristic of the limb-body wall complex is that the amnion is contiguous with some portion of the body wall, often either the abdomen or the skull (Fig. 11.42). This interesting spectrum of anomalies has therefore received attention since the beginning of the 20th century (e.g., Ballantyne, 1904; Woyton, 1961; Torpin, 1968; Chaurasia, 1978; Higginbottom et al., 1979; Bieber et al., 1984; Seidman et al., 1989). Most commonly it has been assumed that these gross malformations result from an "early amnion rupture" but truthfully the exact differences of etiology between it and the more classical amnionic band syndrome are not known. We prefer to see them as a different entity and consider amnionic sheets separately from true bands.

Figure 11.42. Abnormal skull and partial exencephaly secondary to broad amnionic adhesions. (Courtesy of Dr. Cynthia Kaplan. Source: Kaplan, 1980, with permission.)

For these reasons and because "amnionic intrusion" (Fort, 1971) (i.e., the prenatal intraamniotic invasion by perinatologists) is now so common, many investigators have attempted to understand these features by experimental reduction of amnionic fluid and disruption of the fetal sacs. After doing this in mice, Trasler et al. (1956) found a high incidence of cleft palate, which is also a common feature of this syndrome in humans. De Myer and Baird (1969) found similar defects and skeletal abnormalities in rat fetuses when amniocentesis was done between days 14 and 16; Kino (1972), Singh and Singh (1978), and Houben and Huygens (1987) observed that limb defects follow focal hemorrhages in the limbs after amniocentesis in rats. None of these experiments, however, produced adhesions. Whether they bear any relation to the massive anomalies seen in the limb-body wall complex is doubtful. Lockwood et al. (1989) suggested that these hemorrhages are a primary agency in the formation of amputations and the band syndrome in general. Among the 2300 amniocenteses reported by Porreco et al. (1982), adverse outcomes usually related to complications from anterior placentas; amnionic adhesions were not recorded (see following). In at least one case that we have seen with many amputations, cleft face, and skull adhesion, the mother had been a heavy user of intoxicating drugs. She had fallen onto her abdomen from a second-story window during her second month of gestation. Whether this was the cause of amnionic rupture remains speculative but should stimulate the detailed review of patients' histories. Moreover, it instills doubt into the hypothesis that these conditions (amnionic bands and facial disruptions) are etiologically different.

It has been noted that pregnancies complicated by apparent bands as identified with ultrasonographic techniques often have a benign outcome, without fetal adhesions present; at birth, no amnionic bands can be found (Wehbeh et al., 1993). The discrepancy was first noted by Mahony et al. (1985) and further elaborated on by Randel et al. (1988) in their sonographic study of 17 patients. In the patients with this condition, the membranes were intact, and the apparent bands represented indentations of the free membranes by endometrial synechiae or were the sequelae of former endometrial trauma. In most patients there is a history of repeated therapeutic abortion, myomectomy, or infection. Presumably, such history has led to the formation of endometrial synechiae, around which the amnion expands; sonographically it appears as bands. In two cesarean sections of patients with amnionic sheets, however, no uterine anomalies were identified. Such a case is shown in Figure 11.43. During sonography, a peculiar "stalk" was seen near term. This 36-year-old patient had a transverse lie with primary cesarean section. Although she was multiparous, no other risk factors were ascertained. The decidual adhesive band is clearly visible. There were no other pathologic findings or complications.

FIGURE 11.43. “Amnionic sheet.” This stalk was identified sonographically as a stalk. It represents an adhesion in the uterine cavity.

Future studies are needed to clarify this condition. For clinical purposes, it is important to distinguish it from true amnionic bands. These uterine adhesions have also been termed amniotic sheets, but they are different from the sheets discussed earlier in the limb-body wall complex. It is unfortunate that the two names have been used for quite different conditions. It has occasionally been questioned whether ruptured amnion may heal or if it always must lead to defects and bands. Behzad et al. (1994) have attempted to answer this by causing laser-induced amnionic defects and immediately fixing the tissues in a controlled manner. They observed that the amnion tends to slide in its spongy layer over the chorion, thus possibly sealing the defect. We have also observed that typical constriction of a limb, undoubtedly formed by a band, can be associated with an apparently normal placenta. In such a case the amnionic surface of the chorion frondosum was entirely normal but, over the chorion laeve, the amnion was necrotic over long distances, amnion nodosum existed, and, most challenging, there was extensive vernix caseosa in the decidua capsularis. Undoubtedly a focal rupture had occurred, vernix and a limb had extruded, and thus the band-like constriction took place.

When sections are made of amnionic bands, the bands are found to consist of normal-appearing amnionic epithelium with its connective tissue. There are few signs of degeneration, and inflammation is absent; there is also no evidence that bands may derive by a mechanism of “adhesions,” as suggested by Lockwood et al. (1989). Because the amnion does not completely attach itself to the chorion until the 12th week (Boyd & Hamilton, 1970), we assume that in the typical amnionic band syndrome cases the rupture of the amnion occurred before the 3rd month. It would then allow the fetus to escape into the chorionic sac and to become entangled in the amnionic remains when moving. The amnion, whose growth it appears is mediated by stretching of an enlarging sac, shrivels when

ruptured; its remains then produce the amnionic adhesions. The fetus may not always entangle, but one finds only rarely spontaneously denuded placentas without fetal amputations. They then usually relate to the disruptions occurring in the process of labor, and the entire amnion is present and not, as in the band syndrome, only small portions thereof. Torpin (1968, 1969) made the point that it is at times difficult to identify band formation on the placental surface. He advocated that the placenta be studied under water, which enhances the detection of placental structural abnormalities. He also described the case of a fetus from whose mouth a 94-cm-long piece of amnionic band was extracted (Torpin et al., 1964).

The etiology of these bands has stimulated the interest of obstetricians and dysmorphologists. We and others have questioned patients extensively as to possible traumatic or other significant events of early pregnancy, always with negative results. We have seen a set of twins who may shed some light on this question. A woman with previous salpingectomy had in vitro fertilization with transfer of five ova. Three of the ova “took,” and the pregnancy was followed closely by sonography. At 6 weeks an abdominal catastrophe was diagnosed as uterine rupture from placenta percreta of one triplet that had nested near the tubal stump. It was resected, and the pregnancy went to term. One placenta was normal; the other had an opaque surface and the remnants of a shriveled amnion around the cord with a small extension of band. The newborn had a single finger constriction. It was speculated that the amnion disruption occurred at the time of uterine rupture or during its repair. Many of these aspects were well discussed in Torpin’s book (1968) and by Street and Cunningham (1964). Rarely have toxins such as lysergic acid diethylamide (LSD) been implicated (Blanc et al., 1971). As a rule, the mothers do not recall anything unusual in their pregnancy. The few exceptions of antenatal trauma have been well documented in Torpin’s classic book (1968). It must

be emphasized that the event typically occurs spontaneously. It is an open question whether excessive fetal activity or defective amnion development are causes of such rupture. Garza and colleagues (1988) concluded that amnionic bands are not hereditary. Only one study suggested that it may rarely occur in families repetitively (Lubinsky et al., 1983). These authors described two families with possible band-related amputations and reviewed the sparse literature. Torpin (1968) also suggested from his large experience that recurrence would be an exceptional event. Hereditary collagen defects (Ehlers-Danlos syndrome and osteogenesis imperfecta) were implicated by Young et al. (1985), but we have seen several cases of both conditions with entirely normal membranes; moreover, in one reported case of Ehlers-Danlos type III no untoward membrane complication was reported (Atalla & Page, 1988).

It must be cautioned, however, that it is the **fetus** who must be affected with this collagen defect to exhibit possible ill effects from this condition. There is thus the report by Barabas (1966) that reviewed the gestational history of 18 patients with this syndrome. In his series, 14 of 18 patients (78%) were born prematurely secondary to premature rupture of the membranes. This large number suggests strongly, as did the author, that membrane integrity in this genotype may be adversely affected. Likewise, Levick (1989) found an increased number of miscarriages and intrauterine fetal deaths in families, even in those where the father had the disease. She studied three families with this defect and attributed miscarriage to "cervical laxity or premature rupture of fetal membranes." In neither report were bands described. Most authors consider that amnionic bands represent a sporadic event without recurrence risk; the usual discordance in monozygotic twins is further support. Some authors have described occasional families with possible band-related recurrent amputations, but it is exceptional (see also Lockwood et al., 1989). The notion that once the amnion has ruptured in early life the chorion allows fluid transfer and oligohydramnios, as suggested by Lockwood et al. (1989), has no merit. Nor has their suggestion that possible ensuing oligohydramnios leads to fetal skin abrasions. Amnionic bands have been described in monkeys at least twice (Tarantal & Hendrickx, 1987), and we have been shown a chimpanzee with typical finger amputations.

The nomenclature of modern dysmorphologists refers to these anomalies as the ADAM complex (amnionic deformities, adhesions, mutilation). The **incidence** of amnionic bands is difficult to assess. An epidemiologic study was undertaken in Atlanta to identify the prevalence of TEARS (the early amnion rupture sequence). It was found to be 1.16 per 10,000 births among 388,325 live births assessed (Garza et al., 1988). These authors identified 45 cases of these severe, disruptive injuries. The

incidence was higher in blacks and correlated with low maternal age. There was a 30% mortality rate. On occasion, amnionic bands have been recognized by sonography; more commonly, however, the amnionic sheets are seen sonographically. It has also been suggested that amniocentesis might be the cause of early amnion disruption and of bands (Rehder & Weitzel, 1978; Moessinger et al., 1981), but this must be uncommon. Amniocentesis is also generally done too late in gestation to detach the amnion from the chorion. Christiaens and colleagues (1989) provided evidence that CVS may occasionally be held responsible for such injury. Although this point has been debated in the literature, it is the sense that only very early CVS may be related to this anomaly (see Chapter 21). Seeds et al. (1982) also described such occurrence. Moessinger et al. (1981) found an arm constriction in an aborted fetus after complicated CVS with chorioamnionitis ensuing. Lage et al. (1988) have also been skeptical of the role of amniocentesis in the causation of amnionic bands. Moreover, the experimental studies just cited suggest that the sequelae of early fluid withdrawal differ from what is observed clinically in this syndrome, which is frequently referred to as "Streeter's bands," after his early (1930) description. There are also bands that completely encircle the abdomen or an extremity (see Fig. 11.41), and that have caused deep furrows and produced sloughing of skin. Finally, there are cases in which the circulation of the umbilical cord has been interrupted by bands composed of amnion (see Figs. 11.37 and 11.39) (Kohler & Collins, 1972; Ashkenazy et al., 1982; Yang, 1990). Furthermore, in some cases bands have caused fusion of fingertips, with a space remaining at their base. All these varieties cannot be rationally explained by "germ plasm defects"; the primacy of the simple bands from sac disruption makes much more sense. We admit that the limb-body wall complexes do not have similar amputations and, as a rule, they lack amputations. Their pathogenesis is different, and the broad amnionic sheet adhesions are surely the reason for their short umbilical cords. Some authors have suggested that short cords are not a related feature, but that has not been our experience and it is certainly not the case in the review by Moerman et al. (1992). The complete review of pathogenesis and associated features provided in the report of two cases by Seidman et al. (1989) should be consulted. Lockwood and his colleagues (1988, 1989) provided suggestions on how to make the diagnosis of amnionic bands in twins, and they also considered their pathogenesis. They reviewed 15 cases of amnionic bands in twin gestations, all of them in monochorionic ("identical") twins. The absence of this syndrome in dizygotic (dichorionic twins), and other considerations led these authors to reject an "exogenous" etiology. The spectrum of anomalies in these twins, however, makes it clear that no single entity is being discussed.

FIGURE 11.44. Extramembranous pregnancy. A, amnion; C, chorion; AS, amnionic sac. (Source: Perlman et al., 1980, with permission from the American College of Obstetricians and Gynecologists.)

## Extramembranous Pregnancy

Not only may the amnion rupture, with the fetus developing outside the amnion although still contained within the chorion, but also the entire chorion (laeve) may rupture. The fetus then lies in the endometrial cavity, and the pregnancy is referred to as “extramembranous” (Fig. 11.44). Although several previous cases were well described, the first observation made in situ was by Hofbauer (1929), who provided an excellent picture. The patient had hysterectomy for mistaken diagnosis and gave a history of repeated prenatal hemorrhage to have been a major problem. Torpin (1968) collected 100 such cases and illustrated them well. These cases are rare circumstances, usually associated with prolonged “amniorrhea” (actually representing periodic fetal urination). Commonly there are severe positional deformities of the fetus associated with extramembranous gestation, and pulmonary hypoplasia is a characteristic sequela (Benirschke, 1977). Occasionally, such fetuses have survived, as in the cases reported by Perlman et al. (1980) (Fig. 11.44). These authors collected the few cases reported since Torpin’s (1968) review; we witnessed three cases during the 1980s and have seen others since then. We are impressed with the uniformity of the placental findings. The placenta is typically circumvallate (Fig. 11.45); the cords are short, and in the membranes one finds substantial quantities of posthemorrhagic hemosiderin. There may be sparse amnion nodosum over the placental tissue, but it is not striking. The remaining edge of the membranes is relatively normal, as was depicted by Perlman and his colleagues (1980). Most of these pregnancies abort or terminate prematurely. They are occasionally associated with infection. Evidence that the fetus must have escaped out of the membranes much earlier is manifested by the diminutive hole that usually remains in the membranes. The hole may barely admit the umbilical cord, let alone fetal parts (Fig. 11.46). As in the other cases of bands and membrane rupture, the etiology

remains obscure. It is nevertheless interesting to reflect on fetal life within the endometrium and to ponder the pathogenesis of circumvallate placentation. The placental membranes that have folded over appear essentially normal (Fig. 11.47), with the exception of some minor degree of amnion nodosum and hemosiderin. Panayiotis and Grunstein (1979) have reported that one of dichorionic twins suffered prolonged amniorrhea and was born with severe growth retardation (1600 g) and typical Potter syndrome-like features. The placenta was characteristically circumvallate, and the co-twin (2150 g) survived. Extramembranous development was reported by Vago and Chavkin (1980) as having occurred after amniocentesis that led to amniorrhea. Despite deformities and some pulmonary hypoplasia, the 1520-g neonate survived. The placenta was typical. Occasionally, extramembranous pregnancy occurs with multiple gestations. Baergen et al. (1995) have described such a case in dichorionic twins. The unusual feature of that case was that the extramem-

FIGURE 11.45. Extramembranous pregnancy. Note the circumvallate nature of the surface and the diminutive opening through which the cord emerges. Infant died of pulmonary hypoplasia.

FIGURE 11.46. Extramembranous pregnancy with fetus. Note the size of fetus and the membrane opening. There is a circumvallate placenta and marked pulmonary hypoplasia.

FIGURE 11.47. Membrane insertion in the extramembranous pregnancy shown in Figure 11.46. Below is villous tissue; membranes are folded at the right, and the fetus lay in space F. Much necrotic debris and inflammatory exudate are present at the margin. A, focal amnion nodosum. H&E  $\times 64$ .

branous twin had significantly less evidence of prenatal compression, presumably because of "cushioning" by the second, fluid-filled amniotic sac.

# Anatomy and Pathology of the Umbilical Cord

## DEVELOPMENT

The development of the umbilical cord is closely related to that of the amnion (see Chapter 11). Throughout the last days of the second week postcoitus (p.c.), the blastocystic cavity is filled by a loose meshwork of mesoderm cells, the extraembryonic mesoblast, which surrounds the embryoblast (Fig. 12.1, day 13). The embryoblast at that time is composed of two vesicles: the amnionic vesicle and the primary yolk sac. When these two vesicles are in contact with each other, they form the double-layered embryonic disk. During the following days the extraembryonic mesoderm cells are rearranged in such a way that they line the inner surface of the trophoblastic shell as chorionic mesoderm. They also cover the surface of the two embryonic vesicles (Fig. 12.1, day 18). Between the two mesoderm layers the exocoelom cavity forms. It largely separates the embryo and its mesodermal cover from the chorionic mesoderm. The exocoelom is bridged by the mesoderm in only one place, which lies basal to the amnionic vesicle. This mesenchymal connection is referred to as the connecting stalk (Fig. 12.1, day 18). It fixes the early embryo to the membranes and is the forerunner of the umbilical cord. During the same period (around day 18 p.c.), a duct-like extension of the yolk sac, originating from the future caudal region of the embryo, develops into the connecting stalk. This structure is the transitory allantois, the primitive extraembryonic urinary bladder. Heifetz (1996) estimated that some 20% of umbilical cords at term contain remnants of allantoic or omphalomesenteric duct, primarily near the fetal end.

The three subsequent weeks are characterized by three developmental processes:

1. The embryo rotates in such a way that the yolk sac vesicle, originally facing the region opposite the implantation site, is turned toward the implantation pole.
2. The amnionic vesicle enlarges considerably, extending around the embryo.
3. The originally flat embryonic disk is bent in the anteroposterior direction and rolled up in the lateral direction. It thus "herniates" into the amnionic vesicle. As the embryo bends, it subdivides the yolk sac into an intraembryonic duct (the intestines) and an extraembryonic part (the omphaloenteric or omphalomesenteric duct), which is dilated peripherally to form the extraembryonic yolk sac vesicle.

Both the allantois and the extraembryonic yolk sac extend into the mesenchyme of the connecting stalk (Fig. 12.1, day 22). Between days 28 and 40 p.c., the expanding amnionic cavity has surrounded the embryo so far that the connecting stalk, the allantois, and the yolk sac are compressed to a slender cord, which is then covered by amnionic epithelium (Fig. 12.1, day 28). They thus form the umbilical cord. The

cord lengthens as the embryo "prolapses" backward into the amnionic sac (Hertig, 1962). During the same process of expansion, the amnionic mesenchyme locally touches and finally fuses with the chorionic mesoderm, thus occluding the exocoelomic cavity. This process persists until the end of the first trimester when, at approximately 12 weeks, the amnionic cavity completely occupies the exocoelom so that amnionic and chorionic mesenchyme have fused everywhere.

During the 3rd week p.c. the extraembryonic yolk sac, the omphalomesenteric duct that connects with the embryonic intestines, and the allantois become supplied with fetal vessels. All mammals use either allantoic or yolk sac vessels for the vascularization of the placenta. The human allantoic vessels, two allantoic arteries originating from the internal iliac arteries, and one allantoic vein that enters the hepatic vein, invade the placenta and become connected to the villous vessels. The allantoic participation in placental vascularization is the reason for the term **chorioallantoic** placenta. In contrast, in the choriovitelline or vitelline placentation (e.g., that of rodents and bats), the yolk sac vessels establish fetoplacental vascular connections.

The development of the cord has been treated in detail in the classical text by Cullen (1916). Unfortunately, this book is so inaccessible that it is rarely cited, let alone read. Another major review with special reference to comparative anatomy is that by Arvy and Pilleri (1976a). This volume brings together an enormous amount of material and is of particular interest because so many features considered to be abnormal in human placentas are normal features in some other species. Thus, many animals have pronounced squamous metaplasia on the cord's surface and nodules, not only near its abdominal end, that make the surface feel somewhat sandy. Blackburn and Cooley (1993) have also contributed a major review of all aspects of umbilical cord anatomy and pathology that should be consulted for additional considerations. It is richly illustrated and has major relevance to the relationship of cord anomalies to congenital malformations of the fetus.

## Amnionic Epithelium

The cord is covered by amnionic epithelium. Near the umbilicus, a largely unkeratinized, stratified squamous epithelium provides the transition from the abdominal wall to the cord's surface. Farther away from the umbilicus, the epithelium transforms into a stratified columnar epithelium (two to eight layers) and finally into a simple columnar epithelium (Hoyes, 1969; Sinha, 1971; Hempel, 1972). The latter continues developing into the simple

columnar to cuboidal epithelium of the placental amnionic surface. The basal cells of the stratified parts of the amnion resemble the amnionic epithelium of the membranes, whereas the superficial cells sometimes are squamous, poor in organelles, and pyknotic (Bourne, 1962). Parry and Abramovich (1970) found two principal cell types, with intermediates. In contrast to earlier theories, they suggested that these cells do not have any water-regulatory function. Thus, if there is larger water content in the proximal portion of the cord it must have other underlying causes. In this context it is interesting to note that Gebrane-Younes and coworkers (1986), based on the ultrastructure of the umbilical endothelium and other wall components, have suggested a considerable fluid transudation out of the umbilical vessels into the amnionic fluid.

In general, the amnion of the cord is structurally similar to that described in the membranes; and there are no indications that this is different for its basic functions (see Chapter 11). In contrast to the amnion that covers the chorionic surface of the placenta, however, and that of the membranes where it is easily detached, the amnion of the cord grows firmly into the central connective tissue core. It cannot be dislodged.

## Wharton's Jelly

The connective tissue of the cord, or Wharton's jelly, is derived from the extraembryonic mesoblast. McKay et al. (1955) referred to this jelly-like material of the exocoelom as a "thixotropic gel" because it liquefies when touched (see also Bacsich & Riddell, 1945). The incorporation of this mesenchyme into the cord substance and the subamnionic layers probably accounts for their mucoid and compressible structures. The importance of this faculty was stressed by Reynolds (1952). He likened the compressed (by distended fetal vessels) Wharton's jelly to erectile tissue. It is clearly true that a filled umbilical cord is a relatively firm, rigid structure and that, with expansion and contraction of the vasculature, its thickness and turgidity vary. Strong (1997a) reviewed this protective function of Wharton's jelly. This jelly is composed of a ground substance of open-chain polysaccharides (hyaluronic acid: Graumann, 1964; carbohydrates with glycosyl and mannosyl groups: Yamada & Shimizu, 1976), distributed in a fine network of microfibrils. Immunohistochemically, the interstitial collagens types I, III, and VI, as well as the basal lamina molecules collagen type IV, laminin, and heparan sulfate were found (Nanaev et al., 1992, 1997). Immunoreactivities for these extracellular matrix molecules were accumulated around cleft-like territories ("stromal clefts") in Wharton's jelly; the stromal clefts themselves were occupied by homogeneous ground substance, which was devoid of collagens and basal lamina

molecules but probably contained ample proteoglycans. These fiber-free stromal clefts must not be misunderstood as lymphatic vessels that exist neither in the cord nor in the placenta.

Wharton's jelly contains evenly distributed spindle-shaped fibroblasts with long extensions (Parry, 1970) and numerous mast cells. These cells can be stained selectively, surround the vessels densely, and are also found underneath the cord surface (Moore, 1956). Electron microscopic and immunohistochemical studies by Takechi and coworkers (1993) revealed that the stromal cells embedded into the collagen meshwork were myofibroblasts rather than typical fibroblasts. Myofibroblasts are fiber-producing cells that have contractile properties similar to those of smooth muscle cells. These data were supported and further extended by Nanaev and coworkers (1997). According to these authors, the stromal cells of Wharton's jelly depending on their location within the cord, show different degrees of differentiation from mesenchymal cells to myofibroblasts:

- The most immature, still proliferating cells are located close to the amnionic surface. These undifferentiated cells very likely correspond to cells isolated from Wharton's jelly, which proliferate well in vitro and contain stem cells that differentiate into neurons and glia (Mitchell et al., 2003).
- With increasing distance of the amnionic surface, the stromal cells acquire cytoskeletal features of contractile cells, including desmin,  $\alpha$ -smooth muscle actin and partly also  $\gamma$ -smooth muscle actin.
- In close proximity to the umbilical vessels highly differentiated myofibroblasts expressing additionally smooth muscle myosin were found.

The myofibroblasts and their less differentiated precursors line the jelly-filled, stromal clefts of Wharton's jelly (Nanaev et al., 1997). The authors speculated that jelly-filled stromal spaces together with the surrounding meshwork of contractile cells serve as a mechanism for turgor regulation of the cord, avoiding compression of umbilical veins and counteracting bending of the cord.

There are surprisingly few macrophages in the umbilical cord. Even when the cord is deep green due to meconium staining and when meconium-filled macrophages are readily seen in the membranes, only relatively few activated and pigmented macrophages are seen in the cord substance. Similarly, after intrafunicular bleeding, hemosiderin is not formed in situ.

The tensile properties of the cord have been reported by Ghosh et al. (1984). No significant differences in the tensile parameters with respect to the sex of the baby were found, but there was a significant positive correlation between the tensile breaking load and the birth weight of the baby. The average tensile breaking load is

2.49 times the weight of the baby at birth. Additional biomechanical data on the mechanical strength of cord vessels and Wharton's jelly may be found in the paper by Pennati (2001).

Recent studies by sonographers have concerned the variable thickness (diameter) of the umbilical cord as it varies considerably and, at times, can be shown to have prognostic value. Needless to say, the diameter increases with gestational age to about 32 weeks (Ghezzi et al., 2001a) and has led these investigators to create nomograms (Ghezzi et al., 2001b). The same group of obstetricians has also found that chromosomally abnormal fetuses and those with other placental abnormalities had larger volumes of cords (Ghezzi et al., 2002; Raio et al., 2004). Cysts, for instance may cause much enlargement (*vide infra*) and make the cord heavier, and in many placentas of pregnancies in diabetics the cord appears thicker and more water-logged. Cysts are relatively frequent (2.1% according to Ghezzi et al., 2003) and may be single (good prognosis) or multiple (aneuploidy, miscarriage).

## Structure of Umbilical Vessels

There are normally two arteries and one vein in the human umbilical cord (Fig. 12.2). An originally developed second umbilical vein atrophies during the second month of pregnancy. In rare cases—1% according to Boyd and Hamilton (1970)—there is only one umbilical artery (*vide infra*), an anomaly that may be associated with multiple fetal malformations (Lemtis, 1966, 1968). Local fusion of the two arteries has also been reported (Kelber, 1976). The arrangement is different in many other species. For example, two arteries and two veins are found in the nine-banded armadillo, with many subtle variations (Benirschke et al., 1964) and, as indicated earlier, other animals may have an admixture of yolk sac (vitelline) vessels. Cats may have four vessels of each type. The notion of a

FIGURE 12.2. Cross section of mature umbilical cord, near its placental insertion. Wharton's jelly is compressed by the expanded umbilical vein (V) and two arteries (A). (Source: Schiebler & Kaufmann, 1981, with permission.) H&E  $\times 10$ .

“double umbilicus” (Reeves, 1916) is based on a single observation of a somewhat displaced, doubled umbilical vein found in an adult, with puckering of the skin. In another case, described by Murdoch (1966), there were two umbilical veins, and a portion of the cord was separated, giving it a partially split appearance. Hill and associates (1994b) also described the persistence of a second (right) umbilical vein within frequently (18%) malformed fetuses. They did not report upon the possible persistence of a second vein in the umbilical cord itself, however. Thus, the findings are limited to sonographic intrafetal findings. The topic was reviewed by Bell et al. (1986), who found a second vein in a severely anomalous fetus but it was not present in the umbilical cord. The mean intravital diameter of the arteries is around 3 mm, with a slight tendency to increase toward the placenta. The venous diameter is around twice this size (Fig. 12.2).

Human umbilical vessels differ in many ways from the major vessels of the body. The endothelial cells of both the arteries and the veins are unusually rich in organelles

FIGURE 12.1. Simplified representation of the development of the umbilical cord and amnion. Day (d) 13 postcoitus (p.c.): The embryonic disk consists of two epithelial layers: the ectoderm (E), which is contiguous with the amnionic epithelium (AN), and the endoderm (ED), which partially surrounds the primary yolk sac cavity (PY). Both vesicles are surrounded by the extra-embryonic mesoderm (EM). Day 18 p.c.: At this stage, the endoderm has become closely applied to the periphery of the yolk sac; and at the presumptive caudal end of the germinal disk, the allantoic invagination (A) has occurred. In the extraembryonic mesoderm, the exocoelom (EC) has cavitated. A mesenchymal bridge, the “connecting stalk” (CS), has developed that will ultimately form the umbilical cord. Day 28 p.c.: The embryo has begun to rotate and fold. The primary yolk sac is being subdivided into the intraembryonic intestinal tract and the secondary

(extraembryonic) yolk sac (SY). Secondary yolk sac and allantois extrude from the future embryonic intestinal tract into the connecting stalk. The amnionic sac largely surrounds the embryo because of its folding and rotation. Villous formation has occurred at the entire periphery of the chorionic vesicle, forming the chorion frondosum (CF). Day 40 p.c.: The embryo has now fully rotated and folded. It is completely surrounded by the amnionic cavity and is attached to the umbilical cord. The latter has developed from the connecting stalk as it has become covered by amnionic membrane. The exocoelom has become largely compressed by the expansion of the amnionic cavity. At the abembryonic pole of the chorionic vesicle, the recently formed placental villi gradually atrophy, thus forming the chorion laeve (CL). Only that portion that retains villous tissue, that which has the insertion of the umbilical cord develops into the placental disk.

(Parry & Abramovich, 1972; Las Heras & Haust, 1981) and thus structurally different from the endothelium of the villous vessels. Gebrane-Younes et al. (1986) have given a careful account of the ultrastructure of the endothelium. They described ultrastructural evidence that transudation of fluid through the umbilical vessel walls contributes to the formation of amniotic fluid.

Despite all differences among umbilical and villous endothelium, human umbilical vein-derived endothelial cells (HUVECs) are often used for cell culture as models for "placental endothelium." The findings by Lang et al. (1993) suggested to us that we should be careful with the interpretation of such experiments. The latter authors described considerable differences among umbilical and villous endothelium with respect to cell surface markers and receptors for transferrin and immunoglobulin G (IgG).

Slender endothelial extensions, penetrating the basal lamina, may interdigitate with the neighboring muscle cells and form an endotheliomuscular system (Nikolov & Schiebler, 1973). The arteries possess no internal elastic membrane and have much less elastica in general than other arteries (Boyd & Hamilton, 1970; Nikolov & Schiebler, 1973). The vein, on the other hand, has an elastic subintimal layer (Fig. 12.3). The muscular coat of the arteries consists of a system of crossing spiraled fibers (von Hayek, 1936; Goerttler, 1951; Scheuner, 1964). Desmin-positive smooth muscle cells are largely concentrated on the outer layer of the media (Nanaev et al., 1991). In contrast, the inner media smooth muscle cells are poorly differentiated with few myofilaments (Meyer et al., 1978; Sexton et al., 1996). They hardly can contribute actively to postpartal closure of the cord arteries. The venous muscular coats are thinner than those of the arteries and composed of more separate layers of longitudinal or circular fibers. Media smooth muscle cells of the cord and adjacent chorionic vessels are major placental storage sites for glycogen; only minor quantities were found in

the surrounding stromal myofibroblasts. Glycogen levels showed a strong direct correlation with fetal birth weight (Mvumbi et al., 1996).

Cardoso and colleagues (1992) have analyzed the extracellular matrix of isolated umbilical arteries. In general, hyaluronic acid was increased, whereas heparan sulfate and chondroitin 4- and 6-sulfate were reduced in normal umbilical arteries as compared to normal adult systemic arteries. Following hypertension in pregnancy, the total glycosaminoglycan and collagen content of the umbilical arteries were reduced; these changes were unlikely to impair the hemodynamic properties of the cord vessels. Each umbilical vessel is surrounded by crossing bundles of spiraled collagen fibers that form a kind of adventitia. The umbilical vessels of human umbilical cords lack vasa vasorum. Fetuses beyond 20 weeks of gestation, however, have vasa vasorum in the intraabdominal portions of their umbilical arteries (Clarke, 1965).

#### INNERVATION

There is general agreement about the findings by Spivack (1943) that no nerves traverse the umbilical cord from fetus to placenta, and that the placenta has no neural supply. A number of investigators, however, have since investigated this apparent lack of nerves, and some have come to different conclusions. Thus, Kernbach (1963) studied the amnion with Cajal stains and considered the powdery Nissl substance of extravillous trophoblast cells to represent sympathicoblasts with nerve fibers. He also believed that he had identified nerves in the amnion (Kernbach, 1969). Ten Berge (1963) reviewed the older literature on this topic and found only three authors who claimed to have demonstrated nerves by "persevering techniques." Ten Berge was unable to obtain convincing preparations with a variety of stains. He believed, however, that the responsiveness to oxygen perfusion and a variety of pharmacologic agents argues in favor of innervation. Fox and Jacobson (1969) stained various segments of umbilical cords from abortuses and term placentas with methylene blue and observed fibers in all segments of all cords. The fibers were most easily seen in Wharton's jelly but surrounded and entered the vascular walls. Fox and Jacobson interpreted the fibers to be neural elements. It is possible that these structures relate to the vagal fibers described in embryos by Pearson and Sauter

FIGURE 12.3. Umbilical cord sections of a stillborn with necrosis (from thrombosis) of one umbilical artery (right) and a normal artery (middle) and vein (left). In these sections, one may observe the presence of a delicate subendothelial elastica only in the vein at left. von Gieson  $\times 160$ .

(1969), which are thought to be instrumental in closing the ductus venosus after birth. The same authors subsequently investigated the sacral portions of embryos and found convincing evidence of neural supply of umbilical arteries (Pearson & Sauter, 1970). Some neural elements terminate before entering the cord, whereas others penetrate it. This report was contrary to the older literature, which was reviewed.

Ellison (1971) then took up the topic and studied the cords with a thiocholine technique. He demonstrated acetylcholinesterase-positive nerve endings in the proximal 20 cm of umbilical cord, but the placental side invariably gave negative results. The illustrations of tiny nerves present around the umbilical vessels appear convincing. Because they frequently showed degenerative changes, they were interpreted as having a primarily prenatal function. Ellison (1971) was unable to confirm the assertion by Fox and Jacobson (1969) of a subamniotic neural plexus and interpreted it as an artifact. Electron-microscopic search for innervation of the human umbilical cord has generally been negative (Nadkarni, 1970). Fox (1978), who cited other studies, believed that the topic may be controversial because of the paucity of fibers. Lachenmayer (1971) examined guinea pig and human cords, as well as the intrafetal portions of vessels for formaldehyde-induced fluorescence, considered to be specific for catecholamines. He found no evidence of nerve fibers in the cord vessels, but they were present within the fetus and the immediate vicinity of the umbilicus. He considered the cord to be a model of a nerve-free effector organ. Later studies, for example those by Nikolov and Schiebler (1973), Papaloucas et al. (1975), and Reilly and Russel (1977), have corroborated this view. Immunohistochemical examination of cords obtained from the first, second, and third trimester and using a panel of antibodies directed against neural and glial structures, also failed to identify any nerve tissues in the middle and placental segment of the human umbilical cord (Fox & Khong, 1990).

## Contractility of Umbilical Vessels

There has been much interest in the mechanisms of closure of umbilical vessels after birth (Editorial, 1966). Yao et al. (1977) observed umbilical cords after delivery and witnessed that irregular constrictions of arteries occurred at irregular intervals. Davignon et al. (1965) showed that increased transmural pressures exerted on the umbilical arteries led to vasoconstriction. This finding is usual in the guinea pig also. Throughout the last 2 weeks of pregnancy, the cord vessels show increasing responsiveness to mechanical irritation, which is not present during the preceding periods of pregnancy. This response and other mechanisms indirectly confirm the absence of a neural mechanism operating in cord vessels (Shepherd, 1968).

Electron-microscopic observations led Röckelein and Scharl (1988) to the assumption that an endotheliomuscular interaction, mediated by the endotheliomuscular interdigitations (Nikolov & Schiebler, 1973), may play an important role. As a consequence of muscular contraction, the authors described a cytoplasmic prolapse of smooth muscle cells into the endothelial cells, thus causing a kind of “hydrops” of the latter. Seemingly hydropic endothelial cells of umbilical arteries deeply protruding into the arterial lumens and partly occluding those have

been seen by many authors. Sometimes they have been interpreted as a pathologic finding, for example, in the allantoic vessels obtained from HIV-positive mothers (Jimenez et al., 1988). According to Röckelein and Hey (1985; Hey & Röckelein, 1989) this phenomenon is more likely to be a result of either postpartal muscle contraction or even an artifact due to delayed fixation. And this is our experience as well.

The vessels are exquisitely sensitive to various endocrine mediators, such as serotonin, angiotensin, and oxytocin (LeDonne & McGowan, 1967; Dyer, 1970; Winters, 1970). Moreover, smooth muscle contractility of the vessel walls is influenced in paracrine loops by substances produced within the neighboring endothelial cells. Among these mediators, prostaglandins have been shown to be produced within the umbilical vascular endothelium. Despite earlier observations to the contrary, it is now known that the endothelium of the umbilical vein produces far more prostaglandins than does that of the arteries (Harold et al., 1988). There is, however, little production of prostaglandins in placental surface vessels. Karbowski and coworkers (1991) have cultured umbilical vein endothelial cells from smoking and from diabetic mothers, and they found that the synthetic rate of prostaglandins PGI<sub>2</sub> and PGE<sub>2</sub> was significantly reduced as compared to those from normal control mothers. Because both prostaglandins are potent vasodilators and platelet aggregation inhibitors, the authors concluded that impaired placental perfusion in smoking and diabetic mothers may be mediated by the altered umbilical endothelium. Ulm et al. (1995) observed similar defective prostacyclin production of umbilical arterial response in cords delivered to cigarette smoking mothers. McCoshen et al. (1989) found by incubation experiments that the cord (presumably its amniotic surface) is the major source of PGE<sub>2</sub> in the gestational sac during labor.

Another vasodilator that has attracted much attention is nitric oxide—identical with the endothelium-derived relaxing factor from the older literature (Pinto et al., 1991; Mildenberger et al., 2003)—which is produced from the conversion of L-arginine to citrulline by nitric oxide synthase (NOS). This enzyme has been detected immunohistochemically not only in villous syncytiotrophoblast but also in fetal villous and umbilical endothelium (Myatt et al., 1993). A reduction in this enzyme's activity has been correlated with abnormal umbilical artery waveforms (Giles et al., 1997). Atrial natriuretic peptide (ANP) is another potent vasodilator that additionally seems to be involved in fetal fluid hemostasis. Its binding sites have been detected in umbilical smooth muscle cells (Salas et al., 1991). Immunoreactivity for the peptide itself and its messenger RNA have been found in the umbilical endothelium (Cai et al., 1993a,b) even though Inglis and colleagues (1993) questioned the local umbilical synthesis. They suggested an endocrine action of the

peptide that would be released from the fetal heart into the circulation (for review see Macara et al., 1993); messenger RNA for ANP is present in cardiomyocytes of fetuses as early as 19 weeks (Gardner et al., 1989).

Vasoconstrictor substances found in umbilical endothelium comprise angiotensin II, 5-hydroxytryptamine (5-HT) and thromboxane (see Macara et al., 1993), neuropeptide Y (NPY) (Cai et al., 1993a), as well as endothelin-1 (Hemsen et al., 1991). Gu and coworkers (1991), however, detected endothelins-1 and -2 only in fibroblasts and amnionic epithelium of human cords rather than in endothelium. Bindings sites for endothelin-1 have been described in the media of umbilical vessels, the activity of the arteries exceeding that of the vein (Rath et al., 1993). The functions of these vasoconstrictors are still under discussion. NPY and angiotensin II, which are found most abundantly in the endothelial cells, cause relatively weak or no responses on the term umbilical artery in vitro (White, 1989). When White compared the effects of various vasoactive agents on the arteries in premature and term placentas, significant differences were found. Immature vessels were more sensitive to angiotensin II, arachidonic acid, and oxytocin; term vessels reacted more to vasopressin, norepinephrine,  $\text{PGD}_2$ , and  $\text{PGE}_2$ . In vitro, 5-HT and endothelin-1 were found to be powerful vasoconstrictors on all levels of fetoplacental circulation (Maclean et al., 1992). The latter substances are also under discussion as mediators of closure of placental circulation at birth (Hemsen et al., 1991).

These findings shed new light on the highly complex mechanisms of autoregulation, not only of the umbilical circulation, but also of the villous circulation, as most of these mediators have been described also in the walls of the larger chorionic and villous vessels (for reviews see Macara et al., 1993; Okatani et al., 1995). Further studies will have to elucidate the complicated interactions of these substances, as they are very likely to be involved in abnormal conditions, such as intrauterine growth restriction (IUGR) and a high Doppler resistance index.

The vessels of patients with preeclampsia, growth-retarded fetuses, and diabetes, as well as those of smoking mothers, show reduced prostacyclin production (Busacca et al., 1982; Dadak et al., 1982; Jogee et al., 1983; Mäkilä et al., 1983). Similar effects have been found in vitro by Karbowski et al. (1991). Degeneration of endothelium from umbilical vessels had earlier been shown to occur in smoking mothers (Asmussen & Kjeldsen, 1975). Other effects of smoking on the placenta have been discovered as well; most are discussed in Chapter 19. One example is that the steroid production is altered (Mochizuki et al., 1984); others are trophoblastic degeneration, microvascular changes, and several other effects have been observed (Wigger et al., 1984). Although it is attractive to consider that prostaglandins are the principal mediators of umbilical vascular responses, some evidence has been adduced

that there may be considerable differences among species (Dyer, 1970). Alcohol leads to a dose-dependent contractile response in umbilical arteries in vitro (Yang et al., 1986). Estrogens dilate the vessels (de Sa & Meirelles, 1977).

## Hyrtl's Anastomosis, False Knots, and Hoboken Nodes

An important macroscopic feature of umbilical arteries is the presence of an anastomosis between the two arteries near the surface of the placenta. The older literature (Hyrtl, 1870; Fig. 12.4) and more recent studies have shown that 96% of cords have some sort of arterial anastomosis (Priman, 1959; Arts, 1961). Most were seen 1.5 cm from the placental insertion and were either truly anastomotic vessels, or the two arteries fused. On rare occasions, two such communicating vessels exist. Fujikura (2003) measured the distance of the anastomosis from the placental surface—0.5 to 6 cm. Like Hyrtl (1870), who attached much importance to this communication, we believe it to be meaningful for an equalization of flow and pressures between the two arteries and for the uniform distribution of blood to the different lobes of the placenta. A better understanding of the functional importance of Hyrtl's anastomosis has come from numerous sonographic studies that employed Doppler flow evaluation. These have taken on a significant importance in prenatal evaluations now and have, for instance, detected a difference in the size of the two arteries (Dolkart et al., 1992) and are commonly used to anticipate fetal growth and its impairment (e.g., Raio et al., 2003). In a study to evaluate Hyrtl's anastomosis, Raio et al. (2001) showed that it was present in 36 of 41 cases they studied, and a fusion existed in the remaining five. Greater impedance occurred when the anastomosis was oblique rather than straight across the arteries, and they also came to conclude that it served as a means to equalize pressures and circulation. Ullberg et al. (2001) studied 67 placentas and found an anastomosis in 60, two connections in one, and absence of four cords. Its relevance to an understanding of single umbilical artery, the commonest macroscopic anomaly of the placenta, is discussed below. Young (1972), who provided an admirable review of the literature, studied this anastomosis in many primate species and prepared an elaborate classification scheme for the different types observed. He found that "lower" primates (e.g., lemurs) lacked it; New World monkeys had it in some 30% of cords, and Old World monkeys showed an 80% incidence. It is apparently a recent evolutionary development. Ullberg et al. (1994) studied 83 placentas with barium sulfate injection and found 76 to have an anastomosis. Of the seven others, three had a single umbilical artery and four had true absence. They found

FIGURE 12.4 Various arrangements of Hyrtl's anastomosis between the two umbilical arteries near their placental insertion. [Injection studies of Hyrtl (1870); reproduced with permission.© Wilhelm Braumüller, Wien 1870.]

no correlation with fetal growth. When Predanic et al. (1998) sonographically studied blood flow velocities in parallel umbilical arteries, they found a substantial number with markedly different flow and arterial resistance. This was more pronounced at earlier gestational ages and tended to diminish toward term. They speculated that the aberrant cases may have lacked Hyrtl's anastomosis, but did not examine for its presence.

Often the looping of umbilical vessels is the cause for "false knots" of the cord. In most cases, local loops of the arteries, or sometimes even the vein, cause knot-like dilation of the cord. Sometimes focal varicosities of the veins or perivascular accumulations of connective tissue result in a similar external appearance. Finally, there are the "valves (nodes) of Hoboken" (Hoboken, 1669; Spivack, 1936), named after a 17th-century Dutch anatomist.

Malpas and Symonds (1966) concluded that these crescentic folds in the inner wall of umbilical arteries are present after delivery, but that they do not exist in vivo. Reynolds (1952) was not so sure and depicted some of these vascular indentations. He speculated that they resulted from muscular constriction, a view that has been corroborated by electron-microscopic studies. Thus, Röckelein and Scharl (1988) and Röckelein et al. (1990) speculated on the occurrence of some interference with postnatal closure of the cord vessels. On the other hand, most other observers believe that the folds have no physiologic significance, as was inferred by Spivack (1936). They cautioned that incisive observations have to be made immediately after cesarean section because the folds form quickly. Ideally, their presence in vivo should be studied with sonography before birth.

## Allantois

The allantoic duct, a minute connection to the fetal bladder is frequently found in the proximal portions of the umbilical cord. Remnants may exist discontinuously throughout the cord. Complete obliteration of the duct is normally achieved by 15 weeks' gestation (Janosco et al., 1977). In the fetus, the rudiment is referred to as the median umbilical ligament. The remains of this connection in the umbilical cord are always located centrally between the two umbilical arteries, and they usually consist of a collection of epithelial cells without lumens (Fig. 12.5). The epithelium, when present, is generally of the transitional, bladder type. Mucin-producing epithelium is also found occasionally, perhaps because of the proximity to the yolk sac during development. Rarely is the allantoic tissue accompanied by muscle and even more uncommonly is the duct patent. Nevertheless, urination from the clamped umbilical stump has been reported, and cysts may even persist into adult life (Kreibich, 1947). A patent duct ("urachus") on the abdominal wall may complicate pregnancy. Nielsen et al. (1982) reviewed 12 such cases from the literature and reported on an additional patient. Their patient had a discharge from the umbilicus during pregnancy. Her bladder became infected, and pyelonephritis ensued. Infection is a common complication of this rare condition. An abscess of the allantoic duct remnant was described by Baill et al. (1989). It was found in the placenta of a 22 weeks' gestation placenta that was involved with chorioamnionitis and funisitis.

The allantoic remnant may be symptomatic at birth, presenting as a "giant umbilical cord" (Ente et al., 1970). In one of the two patients of these authors, the cord was tense and swollen to a 5-cm diameter. Urine discharged from it. The second patient also had an enlarged cord but only after the cord had separated during the neonatal period did urine pass through the duct. The authors

FIGURE 12.5. Two remnants of allantoic duct: left patent, right obliterated. Note the absence of the muscular coat. H&E  $\times 525$ . (Courtesy of G.L. Bourne.)

stressed the association with a tense, "giant" cord swelling and contrasted it to that found with omphalomesenteric remnants. That was also the finding in a case reported by Chantler and his colleagues (1969), where a single umbilical artery ("fusion") was an associated anomaly. Browne (1925) described a cyst in the umbilical cord originating from the allantois that is very similar to the one depicted here. It measured 14 cm in diameter and weighed 300 g. The neonate did well after initial depression. De Sa (1984) described a small cyst and likened its appearance to the cell nests of von Brunn, which are characteristic for bladder epithelium. Such a case is shown in Figure 12.5. This stillborn had a prenatally diagnosed swelling at the abdomen. At delivery, the "giant", edematous cord (Fig. 12.6) weighed 180 g (the average normal weight of the cord is 40 to 45 g). Sections showed that the urachus extended deep into the umbilical cord; it was accompanied by normal bladder musculature and was located in its usual place between the two arteries (Fig. 12.7). The remarkable feature of this umbilical cord was that it had numerous vasa aberrantia. These vessels cannot be classified as vasa vasorum because they were similarly distributed around vessels and the urachus. Normally, vasa

FIGURE 12.6. Edematous umbilical cord of a 32-week fetus with a large urachal extension into the cord. It was correctly diagnosed by sonography before birth. This cord weighed 180 g (compared with a normal weight of about 40 g). (Courtesy of Dr. S. Kassel, Fresno, California.)

FIGURE 12.7. A: Histologic appearance of the umbilical cord shown in Figure 12.6. The urachus is at the arrow. Note the presence of small vessels and vasa aberrantia around the vein and one artery. H&E  $\times 6$ . B: Vasa aberrantia around the umbilical vein in the same case. H&E  $\times 64$ .

vasorum are confined to the intraabdominal portions of these structures. Furthermore, around all these small vessels were numerous islands of extramedullary hematopoiesis. The fetus presumably died because venous return was compressed by this large cyst in the cord.

Even if there are no macroscopic or clinical suggestions for the presence of allantoic vestiges, careful histologic examination may reveal their presence. When studying the placental extremities of 1000 cords, Jauniaux and coworkers (1989a) found such remnants in 14.6% of the cases. The overall incidence of a truly patent urachus, however, is estimated as uncommonly as once in 200,000 births, and it is more frequent in males (Costakos et al., 1992). Remnants have also been described as presenting with a cord cyst. Such a case was recognized sonographically in a case of trisomy 18 by Ramirez et al. (1995), although the true nature of the cystic cavity was not described.

#### OMPHALOMESENTERIC DUCT

The omphalomesenteric (vitelline) duct arises through the lengthening of the umbilical stalk when the embryo retracts ("herniates" or "prolapses") into the amniotic cavity. While the embryo is folding and the cord becomes established, the connection between the gut and the yolk sac lengthens. From the primary yolk sac develops the secondary structure that is connected to the fetal intestines. Gonzales-Crussi and Roth (1976) and Ukeshima et al. (1986) have provided detailed morphologic descriptions of the intact, nonregressive yolk sac during the early stages

of pregnancy. The yolk sac has a three-layered wall, consisting of an inner resorptive endodermal epithelium and an outer mesothelium that are joined by some mesenchyme. Erythropoiesis was found in the mesenchyme from 6 to 8 weeks of gestation (Jones et al., 1993).

When the gut rotates and withdraws to its original cavity, this duct atrophies. Atrophy is usually complete by the 7th to 16th weeks (Janosco et al., 1977). Jones et al. (1993) described generalized degenerative changes for the 10th week. Meckel's diverticulum, a small outgrowth of the ileum, is a frequent remnant of this connection in the fetus. Only in exceptional cases can a larger duct be found. It then connects the ileum with the proximal part of the cord. Having thus an endodermal origin, it is not surprising that in remnants of this duct one may find liver, pancreas, stomach, and intestinal structures.

Minute vitelline ducts are frequently found on histologic study in the umbilical cord. At the placental extremities, the incidence seems to be lower; of 1000 mature cords studied, only 1.5% showed remnants of the omphalomesenteric duct, whereas vitelline vessels were present in about 7% (Jauniaux et al., 1989b). Clinically, these vestiges are unimportant unless the occasional direct communication with fetal bowel is explored by curious investigators (Hinson et al., 1997). The blood vessels that may accompany the vitelline duct are always tiny and may even contain red blood cells. It is noteworthy, however, that these vessels always lack a muscular coat; this, we believe, develops only under the influence of blood pressure. Thus, when in sirenomelia the omphalomesenteric artery is probably converted to the sole umbilical artery (because the allantoic vessels failed to develop), this vessel acquires a "normal" muscular investment. Usually, vitelline vessels are composed only of endothelium. There are other points of view with respect to the single artery in sirens, and they are discussed at the end of this chapter.

Cysts of vitelline origin have been described many times. In contrast to the allantoic duct remnants, they often have muscular coats (Fig. 12.8) and may occur in duplicate (Fig. 12.9). True intestinal walls,

FIGURE 12.8. Omphalomesenteric duct remnant at left with mucus-producing epithelium and a small amount of musculature in the wall. At right are the remains of the vitelline vein. H&E  $\times 100$ .

including ganglion cells, may be present. Browne (1925) referred to a report of one such cyst as having caused fetal death, presumably due to compression of the allantoic vessels. Three cases were reported by Heifetz and Rueda-Pedraza (1983a), one of which had many other anomalies. These authors reviewed six previously described cases and extensively discussed the embryology. Heifetz and Rueda-Pedraza made the point that the cysts (0.4 to 6.0 cm) are frequently surrounded by a plexus of small vessels (Fig. 12.10) and that they usually lie in the proximal portion of the cord. Males outnumber females 4:1. Although these vitelline remnants are not particularly common and usually have no clinical significance, this is not always the case, and the question of what to do when such an anomaly is found is not always easy to answer. Heifetz and Rueda-Pedraza (1983a) thought that exploration of the neonate's abdomen is not indicated. Schellong and Pfeiffer (1967), however, described a child with intestinal obstruction that developed after the umbilical stump had fallen off. A "wart-like" swelling had developed at the navel. Because it was later identified as the severed intestine that had entered the cord for some distance, they favored exploration when such structures are found.

Remnants of distended omphalomesenteric ducts can be associated with atresia of the small intestine and can be a rare cause of abdominal distension (Petrikovsky et al., 1988). One experienced obstetrician stated to me that he had severed the normal-appearing cord of a neonate who was later found to have nearly the entire length of small bowel within that cord. King (1968) described similar cases and

referred to them as ileal "prolapse," a normal feature in early embryos (Fig. 12.11). Such remnants of intestine may be seen on the surface of the umbilical cord. Lee and Aterman (1968) reported an intestinal polyp arising 5 cm from the end of the cord. Dombrowski et al. (1987) described intestinal epithelium on the surface of the umbilical cord that was associated with a hemangioma of the cord. Harris and Wenzl (1963) reported the only other similar case, in which they found pancreatic tissue within the anomaly. No islets of Langerhans, however, were present in that pancreatic remnant. In neither case was abdominal exploration necessary. Fetal death occurred as a rather unusual complication of such an embryologic remnant in the interesting case described by Blanc and Allan (1961). Ectopic adrenal tissue, liver, and nevus cells were identified in umbilical cords by Sotelo et al. (2001). Ulceration of the cord with fetal hemorrhage has been observed by Ohyama et al. (2000) in several cases, some associated with intestinal atresia. Bile acids were found in amniotic fluid and the authors suggested that bile vomiting may have been responsible. Prenatal exsanguinating hemorrhage had taken place into the amniotic sac from a "tear" in the umbilical cord, near the fetal surface. Because of the proximity of vitelline structures, including gastric mucosa, it was inferred that the umbilical vein had ulcerated owing to erosive activity within this location. Calcific masses accompanied this lesion. On other occasions, a fibrous band has emanated from the end of Meckel's diverticulum and neonatal demise with obstruction of intestines. Two such cases were described in detail by Pfalzgraf et al. (1988). When there is per-

FIGURE 12.10. A plexus of small vitelline vessels accompanies the duct remnants (bottom center) in term cord. At top right is the dilated allantoic duct. H&E  $\times 64$ .

FIGURE 12.11. Cross section of an umbilical cord of a 4-cm crown-to-rump embryo from a tubal pregnancy. At left bottom is the umbilical (allantoic) vein. H&E  $\times 25$ .

sistence of the vitelline duct and it opens upon the abdomen, a fistula with bowel discharge may develop and can be demonstrated radiographically (Ankola & Pradham, 2000).

The finding of liver tissue at the umbilicus (Shaw & Pierog, 1969) is rare and probably relates more to exomphalos (omphalocele) than to the vestiges herein described. Patel et al. (1989) reported a newborn with a markedly swollen umbilical cord (70-mm circumference) at its abdominal attachment that contained herniated bowel. Because of having seen this case, they determined the normal circumference of the umbilical cord in 191 neonates at different fetal ages and of various weights. The normal circumference was found to be  $37.7 \pm 7.3$  mm. They cautioned that clamping large cords may cause bowel obstruction.

After regression of the omphalomesenteric duct, remainders of the detached yolk sac persist in many cases and can be found as 3- to 5-mm white-yellow disks in the chorionic plate (see Chapter 11). Meyer (1904) found them to measure up to 15 mm and wondered how such atrophic structures could become so large while degenerating. The yolk sac remnant is almost invariably located near the margin of the term placenta. It lies underneath the amnion and has a somewhat pasty consistency. This vestige must not be interpreted as being abnormal or

perhaps as representing the site of former inflammation. Histologically, it stains deeply purple with hematoxylin. It appears to be calcified but is probably mostly a deposit of pasty calcium phosphates (Fig. 12.12). The calcareous nature of this material was discussed at length by Meyer (1904). Our own x-ray microanalysis studies (courtesy Dr. Lee Hagey) revealed the predominance of calcium phosphates in the remainders of the yolk sac. The yolk sac can be visualized as a small sac during early pregnancy (Reece et al., 1987). Ferrazzi et al. (1988) reported an overall success of 97% with this visualization, at 7 weeks' gestation. Minute omphalomesenteric vessels may also accompany these yolk sac remnants. They can be seen coursing toward the umbilical cord (Fig. 12.13). The yolk sac can be visualized as a small sac during early pregnancy (Reece et al., 1987). Ferrazzi et al. (1988) reported an overall success of 97% with this visualization, at 7 weeks' gestation.

It is now well recognized that the vessels are exquisitely sensitive to various mediators, for example, serotonin, angiotensin, and oxytocin (LeDonne & McGowan, 1967; Dyer, 1970; Winters, 1970). The cord and certainly the placenta are here considered as having no functional neural investment, a conclusion that is shared by most authors (e.g., Lauweryns et al., 1969).

### Spiral Turns of the Cord

The umbilical cord is usually spiraled, a quality referred to as “chirality” (Fletcher, 1993). A counterclockwise spiral (left) exceeds that of the opposite direction by a ratio of 7:1. The helices may be seen by ultrasonographic examination as early as during the first trimester of pregnancy (Figs. 12.14 and 12.15; Dudiak et al., 1995). Lacro et al. (1987) have studied this phenomenon in greater detail, efforts that evidently are not appreciated by everyone. For instance, Eastman (1967) stated, “As far as I am aware, knowledge about these helices is of no practical value whatsoever.” Helices are readily seen by the 9th week of gestation. They usually number up to 40, but as many as 380 turns have been described. The number is already well established early in pregnancy, and it increases only insignificantly during the third trimester.

It therefore follows that the cord length grows not by increased spiraling but by increasing the pitch between each turn of the spiral. It is uncommon to find an absence of spirals in the cord but when this occurs, it has an ominous prognosis (Strong et al., 1993). These authors found that 4.3% of newborns lacked cord twists and that these had a significantly higher increase in perinatal mortality and other problems. Later, the same authors suggested that the umbilical coiling index (number of coils divided by length of cord; average 0.21/cm) may identify the fetus at risk (Strong et al., 1994). When the index fell below the 10th percentile, more chromosomal errors, fetal distress, and meconium staining were identified. A subsequent study by Rana et al. (1995) examined this proposition. They found that excessive coiling was associated with cocaine usage and increased frequency of premature labor. Reduced coiling was a predictor of problems

FIGURE 12.14. Sonographic appearance of a left umbilical helix in one of monozygotic twins with the transfusion syndrome at 22 weeks' gestation. (Courtesy of Dr. G.R. Leopold.)

FIGURE 12.15. The helical nature of the distended blood vessels in the umbilical cord is shown in this sonograph of a pregnancy at 38 weeks' gestation. (Courtesy of Dr. G.R. Leopold.)

with labor and delivery. Uncoiled cords were present in 4.9%; their mean coiling index was 0.19/cm, and the cords of the uncoiled specimens were not unusually short. Del Valle et al. (1995) had similar results and suggested prenatal sonographic detection of chirality as an important desirability (see Degani et al., 1995; Lewinsky et al., 1996). In the study undertaken by Weeks et al. (1995), it was found that black patients had significantly less coiling than white patients. Infants with fixation of their bodies to the placental surface (due to amnionic bands) have not only relatively short cords but also few or no umbilical helices (Spatz, 1968). Likewise, Drut and Drut (2003) described a complex fetal anomaly with undercoiled, short umbilical cord and suggested decreased fetal motion to have occurred. The same is true for species with elongated embryos in elongated uterine horns (e.g., whales), a situation that hinders embryonic rotation (Slijper, 1960; Arvy & Pilleri, 1976b). This point causes us to infer that the turns must be induced by fetal rotations. Furthermore, because the left spirals outweigh the right spirals by approximately the same frequency as the distribution of handedness, Lacro et al. (1987) reasoned that the cerebral organization is the cause of the direction of spirals. The authors subsequently found that this hypothesis is incorrect, and that there was no correlation between the handedness of the fetus (and that of the mother) and the direction of spirals (Table 12.1). Furthermore, twins were found to have spirals in the same or opposite directions, although in general they had fewer twists than singletons and a different ratio. Monozygotic twins may have helices in different directions, an observation often made before. Only infants with single umbilical arteries had a significant reduction of spirals. No other anomalous development correlated, and one or the other twist was not more commonly associated with perinatal morbidity or mortality. It is interesting that an occasional cord may have helices in opposite directions (Fig. 12.16). Shen-Schwarz et al. (1997a) found that cords were more often not coiled

FIGURE 12.16. Umbilical cord with helices pointing to the right and left directions. Normal infant, 52-cm cord, circumvallation.

in twin gestations, irrespective of their chorionicity. The spirals of the cord have been studied in 5000 cords by morphometry and histology (Blackburn et al., 1988). A left twist was found in 79% with a left/right ratio of 3.7:1.0; in twins, the left direction was found in 61%, and mixed spiraling occurred in 26%. In contrast to the findings of Lacro et al. (1987), Blackburn et al. (1988) always found identical twins to spiral in the same directions. Fetuses with single umbilical arteries had a 1.5:1.0 left/right ratio. These authors also gave figures for cord dry mass and weight/length ratios. Fletcher (1993) found a 76.5% left-handed spiral in patients at Abu Dhabi, a right-handed twist in 15.5%, mixed in 6.5%. They found no sex difference. When Atalla et al. (1998) correlated neonatal acid-base findings with cord status, they found that there was a linear relation between venous and arterial pH, PCO<sub>2</sub>, and length of cord, spiraling index, and other macroscopic characteristics of the cord structure.

Most authors have concluded that spiraling of the cord is the result of some fetal activity, and that the lack of spiraling may reflect fetal inactivity and possibly central nervous system (CNS) disturbances. Thus, reduced coiling has a poor prognosis (Strong et al., 1993). We have seen absent twists not only in many stillborns but also in various chromosomal errors and congenital syndromes such as the Pena Shokeir syndrome, and others. Another suggestion for the occurrence of spirals is that they are governed by the earth's rotational forces and that, like the familiar bathtub vortex (Sibulkin, 1983), there are differences in the chirality of cords between the hemispheres. This postulate has been disproved by our study of chirality in the Northern and Southern hemispheres. Edmonds (1954) and Lacro et al. (1987) considered in detail the various theories that are the basis for umbilical cord spiraling. The causes remain unknown. In our experience, Schordania's (1929a) notion that long cords are

TABLE 12.1. Distribution of the direction of the umbilical cord helix

Source of cord	Direction of the cord helix			
	Left (%)	Right (%)	None (%)	Left/right ratio
Live-born singletons	7.8	83	12	5
All twins (combined data for 290 sets)	3.7	66	18	11
Monochorionic twins	7.8	82	11	7
Dichorionic twins	4.8	77	16	8
Intrauterine deaths	8.7	73	8	18
Single umbilical artery (SUA)	2.8	63	22	15
SUA with problems	1.1	44	39	17
SUA without problems	5.2	72	14	5.2
Placental singletons (n = 14,070)	7.5	75	10	15

more spiraled is correct, although it contradicts the findings of Chaurasia and Agarwal (1979), who studied only a small number of specimens. The higher fetal mortality seen with intense spiraling (Fig. 12.17) has been discussed.

The fact that frequently, but not always, the spirals represent distended umbilical arteries is well seen in Figure 12.18. This helical arrangement of vessels has been helpful in the diagnosis of fetal death, as in some such pregnancies gas can then be visualized in an helical arrangement (Gruber, 1967). Several investigators have suggested that differential pressures of different-size umbilical arteries are the forces that produce the helices. The findings on single umbilical arteries (Lacro et al., 1987) tend to negate this notion. It may be that we are failing to differentiate true umbilical cord twists from changes in which the umbilical arteries are merely wound around a less spiraled vein. Whether arteries are wound around the vein (Smart, 1962) or the vein winds around arteries (Potter, 1961) is irrelevant. Both arrangements can be seen in the same cord (Fig. 12.18). The many arrangements that exist have been depicted by Hyrtl (1870) and Arvy and Pilleri (1976a), among others. These authors made numerous corrosion preparations of cords to investigate these features. Dado et al. (1997) deduced from their perfusion studies of cords that coiling had little effect on resistance when external pressure was applied or the cords were stretched. They felt that "differences in morbidity associated with umbilical cord coiling should not be attributed simply to mechanical factors, and other mechanisms should be sought."

FIGURE 12.17. Term placenta of a stillborn infant with an intensely twisted umbilical cord. The cause of death was inferred to be the twisted cord as there were no other findings. Note also the remains of the yolk sac (arrow).

FIGURE 12.18. Umbilical cord with true and false knots in a live infant. The arteries wind around the vein (left arrow); in the knot, the vein winds about the artery. False knots with vessels (top arrow) and with only Wharton's jelly (central arrow) are apparent as well.

### Length of the Cord

The length of the umbilical cord has been the topic of numerous studies. Most authors agree that excessively short and long cords correlate well with a variety of fetal problems and have been adequately summarized by Gilbert-Barness et al. (1993). The normal length at term has been cited by Grosser (1927), who utilized data from various older studies, but standards for measuring the length were supplied later (e.g., Mills et al., 1983). These authors and Naeye (1985) used the very large number of cord measurements from the Collaborative Perinatal Study and provided smoothed curves from 34 to 43 weeks' gestation. These data are not significantly different from ours (provided at the end of this book in tabular form). The mean length of 59.44 cm was determined by one of us (8000 measurements, ranging from 24 to 146 cm); another author found it to be 66.54 cm (12,000 measured). When circled once about the neck the cord was 76.5 cm long, and when circled twice about the neck it was 93.5 cm. Thus, wide variations were detected. As was suggested by Leonardo da Vinci, the umbilical cord has usually the same length as the baby. Figure 12.19 gives values for cord lengths as determined by a variety of authors. Mancini et al. (1993), however, found that the length of the cord shrinks up to 7 cm in the first few hours following delivery. Thus, accurate recording at birth is preferable.

There have been numerous other studies. Malpas (1964), stimulated by the birth of a baby with a 129-cm-

FIGURE 12.19. Length of umbilical cord as determined by different authors. When exact numbers were not given, the approximate number was entered.

long cord, measured 538 normal cords at term. He found a normal distribution, with an average length of 61 cm (30 to 129 cm). There was slight correlation with fetal and placental weights. Gardiner (1922) obtained an average length of 55 cm for normal cords. He considered less than 32 cm as “absolutely” short, and more than 32 cm as “relatively” short. He also suggested what the length of the cord *should* be if it were to allow a normal delivery with cephalic or breech presentations with looping (he also gave quantitative accounts of the frequency of coiling). He assumed that the length of the cord was determined by the amount of amniotic fluid and depended also on fetal movements. The complete findings of Malpas just cited supported the notion of Walker and Pye (1960) (average 54.1 cm, maximum values ranging from 17.8 to 121.9 cm) that most of the cord’s length is achieved by the 28th week of pregnancy. During the 41st day p.c., the developing cord, the amniotic covering of which is still incomplete, has a mean length of about 0.5 cm. By the 4th lunar month it has grown to between 16 and 18 cm and, by the 6th month, to between 33 and 35 cm. It was also suggested that there may be a relation to umbilical arterial pressures, but this point was not well supported. In a series of 37 pairs of monozygotic twins studied, little difference was found when they were compared to singletons. Naeye (1985) based his findings on the measurements of cords at birth from the Collaborative Perinatal Study (35,779 cases) and found that the cord grows progressively from 32 cm at 20 weeks to 60 cm at term. Although growth slowed progressively, it never ceased. Ultrasonographic measurements have also been published that describe the length of the umbilical cord in early gestation. Thus, Hill et al. (1994a) studied 53 normal fetuses and 15 with fetal death between 6 and 11 weeks’ gestation. The cord lengths of 60% of the dead fetuses was significantly shorter. These findings suggested to the

authors that demise is preceded by reduced fetal activity. The normal fetuses’ cords grew linearly. The measurements are depicted in tabular form in Chapter 28. Weissman et al. (1994) studied the diameters of cord and its vessels of 368 normal gestations of between 8 and 40 weeks and ascertained smooth curves of growth for all data. More recently, the recognition of a relationship between fetal movements and fetal well-being have resulted in “kick-counts”; the results are summarized in an early contribution by Grant et al. (1989) and in many publications since. They have also been charted extensively and followed with advancing gestational age (ten Hof et al., 1999). These studies are difficult and analysis is complex because of the irregularities in the occurrence of movements, the minor and major bursts that occur, the length of observation, etc. Increased length between bursts was observed with advancing age.

## Abnormal Length, Nuchal Cord

Although it is known that short cords (less than 40 cm) are correlated with neonatal problems and depressed intelligence quotient (IQ) values, the essential question, however, remains whether the length of the cord is determined by prenatal CNS problems or whether the CNS problems that are so well correlated, result from perinatal problems attending the delivery with a short cord. This question is of interest because it has been shown not only that short cords are more common with a variety of congenital anomalies but also that the length of the cord is usually determined by fetal movements in early fetal life. When the fetus is constrained, as occurs for instance with amniotic adhesions and in ectopic pregnancies, the cord is short (Miller et al., 1981). The possible relation between long cords and excessive fetal movements is more difficult to assess because of the deficiency of quantitative data on prenatal movements. It would also be of great interest to obtain more information as to whether children associated with long umbilical cords remain to be “hyperactive” in later life; the contribution by Naeye and Tafari (1983) suggests that this may be so.

Moessinger and his colleagues (1982) have investigated the question of the cord’s length experimentally in rats. They injected curare (short cords), placed the rat fetuses in an extrauterine position (long cords), and produced oligohydramnios (short cords). It has also been learned that infants with Down syndrome (trisomy 21) have significantly shorter cords (45.1 cm versus 57.3 cm for controls), speculated to be due to the reduced fetal activity in utero (Moessinger et al., 1986). Likewise, with breech presentations, the cord is shorter by some 4.5 cm than with births from a vertex presentation, and 7.9 cm shorter in twins (Soernes & Bakke, 1986). These authors also confirmed other investigators’ findings that males have

slightly longer cords than females (58.46 cm versus 56.90 cm in vertex; 53.78 versus 52.51 cm in breech). Snider (1997) examined the length of umbilical cords associated with lethal bony malformations such as osteogenesis imperfecta. All had significantly reduced cord lengths. Four additional cases with similar findings came from Dr. M. Grafe (personal communication, 1997) and many more cases have since come to our attention. It was inferred that because the presumed pain felt with movements the fetuses did not move normally. This is also one explanation for the pulmonary hypoplasia (lack of chest movements) and reduced motion is also the finding during sonography of such fetuses. In Chapter 11 we discussed the possible relationship of pain to endorphin levels in amniotic fluid, and suggested that such studies should be encouraged to be pursued in the future. Correlations such as these have led to experiments in animals, where it was found that prenatal alcohol administration to rats shortens the cords (Barron et al., 1985), as does atenolol (a beta-blocker) given to rabbits (Katz et al., 1987). Shorter cords have since been found in offspring who suffer the fetal alcohol syndrome (Calvano et al., 2000). Contrary to these views, Fujinaga et al. (1990) have opined that the "stretch hypothesis" is faulty. Their findings verified that umbilical cords of humans and rats steadily increase with gestational age, but in some of their cases with oligohydramnios long cords were found. Moreover, their tenet was that the amount of amniotic fluid decreases with advancing gestational age and that, therefore, "fetuses should be less active." This is not the place to argue extensively over the merits of one or the other theory; suffice it to say that oligohydramniotic fetuses may be just as active as those in normal environments and thus may be able to stretch their cords. It is also important to know how long

the oligohydramnios had existed and how severe it was. Moreover, because cords grow substantially early in fetal life (before for instance endorphin secretion in cases of osteogenesis imperfecta (OI) and urinary deficiency may have influenced the growth of cords, the finding of longer cords in some cases of oligohydramnios is not surprising. Further data are definitely needed. Naeye and Tafari (1983) found that neonates with long cords were relatively hyperkinetic when compared with those that had shorter cords. Malicki et al. (1997) analyzed retrospectively data from 38,224 placental studies and concluded that excessively long cords (3.95%) were significantly more common with right spirals, with excessive spiraling, true knots, thromboses in fetal vessels, congestion, and meconium staining. Male fetuses were also overrepresented. Kalish et al. (2003) also found a deleterious effect of right twisting (placenta previa and hemorrhage).

An interesting study of equine abortions comes from Hong et al. (1993). They found that torsion of an excessively long umbilical cord is an important cause of fetal wastage in horses, making up some 4.5% of 1211 cases. The normal cord length in horses was found to be 52 cm whereas that of abortuses with torsion was 72 cm. Excellent photographs accompany this description and are further considered below.

There are rare cases of "achordia", which have mostly been associated with abdominal wall defects (Giacchia, 1992), as in Figure 12.20, or with acardiac fetuses (see Chapter 25). Most of these infants actually have a diminutive cord rather than no cord at all. Rupture of short cords and of cords with entanglement have been reported by Szécsi (1955). Several authors have delineated a "short cord syndrome" that includes a variety of associated anomalies (Gilbert, 1986; Grange et al., 1987). In the

FIGURE 12.20. Excessively short umbilical cord at term with an abdominal wall defect (gastroschisis).

latter study, cords less than 15 cm were often associated with abdominal wall defects and evisceration, spinal and limb deformities, and other lesions. The authors thought of it as a "primary malformation."

An excessively long cord poses problems because the fetus may become entangled in it or the cord may prolapse, especially after the membranes rupture. The successful clinical management of gestations with long cords has been detailed by Katz et al. (1988). In general, long cords have more pronounced spiraling and it may be inferred from this fact also that the excessive length results from increased fetal movements. Umbilical cords measuring up to 300 cm have been reported (Arvy & Pilleri, 1976a). The greatest length we have measured was 165 cm. One would think that such excessively long and spiraled cords would also require greater perfusion pressure, but this has not been confirmed, and some studies suggest that it is not true.

Looping about the neck and extremities was found in 23% of overall obstetrical cases by Earn (1951) and it was more common with excessively long cords. He once found the cord to be wound eight times around the neck. The fetus in Figure 12.21 had died because its cord was entwined around the neck three times; there was obstruction of venous return from the placenta. The constriction of the cord shown in Figure 12.22 led to its reduced size. It had been wound around the arm and the depression of the arm was clearly discernible and bore testimony to this entwinement having caused the fetal death. We have subsequently seen similar compression of an extremity due

to cord pressure, but the fetus survived. Although it simulated grossly the constriction of amniotic bands, it was much wider. Nelson and Grether (1998) found that a statistically significant correlation exists between the presence of tight nuchal cords at delivery and the occurrence of otherwise unexplained spastic cerebral palsy (quadriplegia, not diplegia), to be discussed next.

To find an entanglement of cords with extremities and bodies of young fetuses establishes that these abnormalities are not just features of labor and term pregnancy. Javert and Barton (1952) also made such observations. They studied 1000 spontaneous abortions, of which 297 cases had sufficiently well-preserved cords for study. Of these, 104 (35%) were abnormal, compared with a rate of 4.8% in a control group of "therapeutic" abortions; 13.4% were of excessive length and had looping. In those cases, excessive fetal activity had often been observed before fetal death occurred. A case reported by Williams and colleagues (1981) is of considerable interest here. They had a patient with fetal growth retardation at 38 weeks' gestation in whom an emergency cesarean section was performed because of flat fetal heart rate tracings. The normally long umbilical cord was wound five times about the severely compressed and bruised neck. Various clinical findings, including oligohydramnios and a lack of fetal movements led them to suspect that this cord entanglement had been present for at least 2 months. Lin et al. (1999) showed an impressive indentation of the abdomen of a monoamniotic twin neonate due to encircling by the umbilical cord. It disappeared spontaneously.

FIGURE 12.21. Stillborn fetus with cord wrapped three times about its neck. Death presumably came about by obstruction to venous return from the placenta, not by obstruction to vessels of the fetal head. Note the congestion of the head.

FIGURE 12.22. Umbilical cord and arm of a stillborn fetus. There is marked constriction of the arm and cord where the latter had wound firmly about the arm. The specimen was received with the amnion unruptured, so fetal motion alone must have caused the entanglement.

There have been numerous investigations to ascertain whether nuchal cords may cause fetal death or asphyxia during labor. Crawford (1962) found its incidence to be as high as 34% in vaginal vertex deliveries. He surmised that the significantly increased morbidity was related to deprivation of placental perfusion after expulsion of the fetus. In later analysis of his data, Crawford concluded that the incidence of nuchal cords rises steeply after 38 weeks of gestation, perhaps secondary to greater fetal activity or because of decreasing amniotic fluid volume (1964). A somewhat similar incidence of nuchal cords and its complications was found by Kan and Eastman (1957) (one coil 20.6%, two coils 2.5%, three coils 0.5%), Reiss (1964), Horwitz et al. (1964), and others. McCurdy et al. (1994) were able to identify the presence of nuchal cords sonographically, confirming other radiologists' impressions. In their study, the presence of nuchal cords led to more admissions to the neonatal intensive care unit (NICU) and to cesarean section. Schaefer et al. (1998) saw nuchal cords in 26 of 316 (8.23%) sonographically examined fetuses at 10 to 14 weeks' gestation, but most had disappeared at term. Collins et al. (1991) and Collins (1997) separated two types of nuchal cords, to be distinguished at delivery, much as Giacomello had done (1988): "Type A encircles the neck in an unlocked pattern; Type B encircles the neck in a locked pattern." Type B is found to be associated with breech delivery and is considered to be as having more severe consequences for fetal

outcome (see also Collins, 2002). In 850 deliveries, type B was found three times, two of whom had fetal distress and one was stillborn. In another study of nuchal cords of 231 prenatally studied patients, Collins et al. (1995) found that nuchal cords can be present as early as at 20 weeks' gestation. Of 36 cases, 11 resolved before delivery, one with triple encirclement resolved to a single loop around the neck. A nuchal cord may form, they found, when the umbilical cord is four fifths as long as the fetus. That nuchal cords may be associated with or cause fetal growth restriction was demonstrated by Soernes (1995) in 11,201 deliveries. In 19% of deliveries one encirclement was found, 5.3% had two loops, 1.2% had three, and 0.2% had four cord encirclements. In statistical analysis, Soernes found a detrimental effect of nuchal cord encirclement upon fetal weight and a similar relation to increasing length of the umbilical cord. From this he inferred that encirclement must have existed for long periods in utero and cautions that inferences of poor fetal outcome with nuchal cords may reflect long-standing prenatal events (see also Nelson & Grether, 1998).

Some authors, however, deny any relation to fetal distress and poor fetal outcome from problems of cord length. Sinnathuray (1966) and Kan and Eastman (1957) found no increase in perinatal mortality. Dippel (1964) wrote that nuchal cords are much "maligned" and observed only a significant increase in the frequency of irregular fetal heart rates and the need for resuscitation when they were present. He opined that a hasty delivery is rarely required. Spellacy and coauthors (1966) studied this phenomenon in 17,190 deliveries from the Collaborative Perinatal Study. They concluded that nuchal coils occurred in 20.4% of deliveries and that there was entwinement about the body in 2%, and knots occurred in 1%. There were more complications with long cords, and with "tight" cords, that is, cords that were functionally short. Entanglement was the cause of depressed 1-minute Apgar scores but did not cause low 5-minute scores. Length of cord was also not correlated with the 1-year neurologic status; stillbirths, though, were increased with true knots. McLennan et al. (1988) undertook a prospective study of 1115 vaginal deliveries to ascertain the frequencies of knots and encirclement. Six knots (0.5%) and 158 cases with encirclement (14.2%) were found, with cords ranging from 27 to 122 cm in length. No warning of such knots or entanglements was identified in the gravidas, and the offspring had no problems, although the authors admitted that they are the cause of 10% of fetal deaths above 2500 g. In their experience, the average cord length was 52 cm, the 10th percentile was 40 cm, and the 90th percentile 69 cm. Giacomello (1988) reported the detection of nuchal cord in a large proportion of breech presentations by ultrasonography. He cautioned that an assessment of the postdelivery incidence of nuchal cords is unreliable and minimally requires description of the nature of the nuchal cord. He

depicted two types, locked and not locked, much as Collins (1997) did subsequently. The following photographs impressively demonstrate the consequences of severe spiraling that led to thrombosis of surface vessels with fetal demise (Figs. 12.23 and 12.24).

In recent years, obstetrical care has frequently involved extensive monitoring of fetal heart rates. Cord entanglement, the now uncommon cord prolapse (Panter & Hannah, 1996), and other abnormalities during labor have thus become better correlated with compromised cord perfusion. Rayburn et al. (1981), for instance, reviewed some of these findings. They studied 536 term deliveries in an effort to correlate the findings of fetal heart rate monitoring with cord length. They defined a short cord as all cords measuring less than 35 cm in length and a long cord as measuring more than 80 cm. Of the 32 cases with "cord accidents," 20 (62.5%) were found with long cords. The monitor tracings had cord compression patterns. These authors advocated measuring cord length routinely after delivery, a recommendation since strongly repeated (Benirschke, 1991). Fribourg (1981) objected to this measurement as an idle enterprise because there are "no current means of performing measurements before the fact." But this situation is changing with improved sonographic techniques and with the development of velocimetry (Feinstein et al., 1985; Guidetti et al., 1987). A better understanding of the correlations just described is deemed especially important for infants whose poor outcome is otherwise unexplained. This consideration particularly concerns medical litigation.

It was mentioned earlier that infants born with nuchal cords are more often deprived of placental blood transfusion because their cords are severed by the obstetrician before extraction. Shepherd et al. (1985) identified that newborns with nuchal cords are significantly more anemic

than controls, presumably because of reduced venous return from the placenta secondary to compression of the umbilical vein. Vanhaesebrouck et al. (1987) suggested that tight nuchal cords may be the cause of hypovolemic shock of the newborn. They observed two newborns with anemia and cord entanglement and suggested that entanglement occurs as often as in some 20% of births. That nuchal cord entanglement may have serious sequelae for the fetus was shown in the retrospective study of Nelson and Grether (1998). They found cerebral palsy as a probable consequence of this prenatal problem. Fetomaternal hemorrhage was ruled out by Kleihauer stains on maternal blood to have caused the anemia. These authors also suggested that problems of venous return from the placenta allowed pooling of blood in the placenta. Thus, "fetoplacental" hemorrhage is the mode they used to explain the neonatal anemia in their cases. Anagnostakis and coauthors (1974) conjectured that the two neonatal deaths with pulmonary hemorrhages they saw may have resulted from increased pulmonary perfusion because of tight nuchal cords. This argument is difficult to accept, as nuchal cords are so common and lethal pulmonary hemorrhages rare.

Premature separation of the cord with fetal bleeding may occur with short cords and when a "relative" short cord is induced by entangling. An interesting suggestion has been made by Akiyama et al. (1981), who were concerned with ascertaining clinically when the placenta had detached from the uterus so as to allow its delivery. When they clamped the cord immediately after delivery of the infant, pinched the placental end of the cord, and then squeezed the blood toward the placenta for 10 to 15 cm, they could assess the backflow of blood in their fingers when slowly releasing the pressure. When backflow was sensed, the placenta had not yet separated.

FIGURE 12.23. Marked spiraling of umbilical cord with surface vessel thrombosis (see next figure). Intrauterine fetal demise.

FIGURE 12.24. Marked spiraling of umbilical cord with surface vessel thrombosis (see previous figure). Intrauterine fetal demise. The partially calcified thrombosis of surface veins is indicated by arrows.

Eastman and Hellman (1961) emphasized that the absolute and relative lengths of cords are the important factors, not the actual measurement of the cord length. It is obvious that a long cord, wound about the neck five times, may in fact be a relatively short cord during fetal descent with delivery. Dislodgment of the placenta may then occur, which may cause bleeding. In the case described by Corridan and coauthors (1980), this complication was associated with fatal amniotic fluid embolism. The reader is also referred to Fox's (1978, 1997) book on the placenta for additional references. Fox as well as de Sa (1984) were not impressed with the opinion that mechanical factors such as traction play an important role in fetal compromise when short cords are present. Perhaps vascular spasm (Camilleri, 1964) is the important event. This hypothesis is supported by our finding a nuchal cord with fetal death in an otherwise well developed extrauterine (tubal) fetus. The umbilical cord of this fetus was occluded, yet it was clearly stationary.

Prolapse of the cord is associated more often with multiparity, premature labor, multiple gestation, and with cords that are longer than those of normal length. At times, this situation has grave prognostic significance for the fetus and Uchida et al. (1997), who diagnosed it sonographically, suggested that its recognition by Doppler sonography is mandatory for a good outcome. Widholm and Nieminen (1963) recorded cord prolapse in 0.41% of 7500 deliveries with a 13.4% perinatal mortality. This figure is similar to the results published by Brant and Lewis (1966), who urged that a prolapsed cord be kept

warm so as to avoid spasm of vessels. Another review of the topic was provided by Levy et al. (1984), who also found this complication more often in multiparous women. One half of their study group had fetal malpresentations, one third had premature onset of labor, and a variety of other abnormal factors was present. Good obstetrical management usually gave a good fetal outcome so long as the fetus was alive on admission. Dildy and Clark (1993) found that cord prolapse occurred in 1 of 275 deliveries and that the risk was greatest with artificial rupture of membranes with high presenting fetal parts. It has been cautioned that many cases of fatal cord prolapse result from amniotomy, and that some occur after external fetal version (Lehman, 1983). It is now possible to make the diagnosis antenatally with ultrasonography, particularly when malposition and hydramnios suggest this possibility (Lange et al., 1985). A large study on causes of, or associations with cord prolapse was undertaken by Critchlow et al. (1994). Their findings indicated a high cesarean section rate, a 10% mortality, and high prematurity and breech rates, but data on length of cord were not available. The hemodynamic response with fetal heart rate monitoring has been detailed by Lee and Hon (1963) and is of particular importance for the cases with occult prolapse. These authors found prompt, marked bradycardia when the umbilical arteries were occluded and believed that this probably resulted from increased fetal blood pressure. This finding has come to be looked at as being pathognomonic for the detection of cord compression during monitored labor. The compressed umbilical cord may show profound pathologic changes, such as

hemorrhage, and even rupture at the site of compression. It leads occasionally to thrombosis, found when multiple sections are taken, but thrombi ensue more commonly in the surface chorionic vessels. That cord compression may have serious fetal neurologic consequences is one of the reasons for taking the cord compression pattern of fetal heart monitoring so seriously. Its effects on CNS damage have been amply studied in fetal sheep (Mallard et al., 1992; Kaneko et al., 2003). They detected that even short arterial occlusion may cause damage, predominantly in the hippocampal area. We have seen a stillbirth at 19 weeks' gestation from an excessively long prolapsed cord with an extremely pale placenta. The villous tissue had the appearance of being exsanguinated and was similar to the hydropic placenta of erythroblastosis. Instead, the umbilical arteries had constricted from presumed cold exposure, with labor leading to the return of placental blood to the polycythemic fetus.

A few other findings may be mentioned briefly. Thus, when all factors contributing possibly to intrauterine fetal death, Karin et al. (2002) found that cord problems accounted for 9% (infection 24%, growth restriction 22%, abruption 19%, maternal conditions 12%, anomalies 10%). Williams and O'Brien (2000a) found that cord entanglement was associated more frequently with a larger placental mass and decreased fetal/placental ratio in a cohort of 37,014 infants they reviewed. In a second contribution (Williams & O'Brien, 2000b) they concluded that nuchal cords and tight loops did not cause significant peripartum morbidity but appeared to be related to chronic rather than acute stress. Clapp et al. (2003) determined the occurrence of nuchal cords prospectively from 24 weeks on and found it to increase from 12% to 37%. They thought of it as a chance phenomenon that bears little relation to perinatal morbidity. An interesting sonographic study by Habek et al. (2003) recorded the grasping of the umbilical cord by the fetus. They observed seven cases and all had normal outcome ultimately but had flow-related abnormalities during the event. Camann and Marquardt (2003) produced a fine picture of a compound knot of the umbilical cord with normal outcome but variable decelerations before birth. Hershkovitz et al. (2001) emphasized the need for careful study of the cord in pregnancies with fetal distress; they described a 1.2% incidence of knots (in 69,139 gestations) and higher perinatal morbidity. Hydramnios and male fetuses had a greater propensity. Finally, a statistical study of 926 cases with excessively long cords (70+ cm) was performed by Baergen et al. (2001). They found a "significantly increased risk of brain imaging abnormalities and/or abnormal neurological follow-up." In addition, mothers with a history of an excessively long umbilical cord are at increased risk of a second long cord. Our experience with excessively long and short cords and their presumed causes are provided in Figures 12.28 and 12.29.

## Site of Cord Insertion

The umbilical cord normally inserts on the placental tissue itself, more often near or at the center than elsewhere, as shown in Figure 12.25. In nearly 7% of term placentas, it has a marginal insertion, which, in the English-language literature, is often referred to as a "Battledore" placenta. In about 1% of placentas the umbilical cord inserts on the membranes, referred to as velamentous or membranous insertion. Here, the umbilical vessels course over the free membranes and, having lost their protection by Wharton's jelly, are more vulnerable to trauma and disruption.

Not only are the sites of insertion variable, the insertion itself may take an abnormal shape. Thus, the branching of vessels can occur before the cord comes to the surface of the placenta in the "furcate cord" insertion (Ottow, 1923; see Fig. 12.27). At times, the cord runs parallel to the placental surface or in the membranes before its vessels branch, the "interposition" (Ottow, 1922). The fetal end of the umbilical cord may also be anomalous, as is found primarily in infants with gastroschisis (short cords) (see Fig. 12.20) or with omphaloceles. These conditions can now be diagnosed prenatally and assume a greater importance in management than they did in the past (Didolkar et al., 1981). Some of these anomalies are associated with significant disturbances in fetal growth or during delivery and are thus of importance. Moreover, the formal genesis has interested students of the placenta so that they may obtain a better insight into the factors that regulate placental growth. We have seen typical interposition in a case of trisomy 13, associated with a severely malformed fetus and extensive thrombosis of fetal vessels. The umbilical vein of the interposed segment had mural thrombosis and old calcifications in the wall; the fetus had intestinal arterial thrombi.

FIGURE 12.25. Normal term placenta with near-central insertion of the umbilical cord. Note the disperse distribution of vessels, marginal membranes, and calcified yolk sac remnant (arrow).

FIGURE 12.26. Furcate cord insertion with thrombosis. (Courtesy of Dr. S. Lewis, Miami, Florida.)

### Furcate Cord Insertion

Furcate cord insertion is a rare abnormality in which the umbilical vessels separate from the cord substance prior to reaching the surface of the placenta. They lose the protection afforded by Wharton's jelly and are prone to thrombosis and injury. The condition was first described in three patients by Hyrtl (1870) and has received more attention from Herberz (1938) (six cases) and Swanberg and Wiquist (1951) (stillborn, hemorrhage). Four of

Herberz's cases were associated with normal infants, and much discussion was devoted to its differentiation from velamentous insertion. Kessler (1960) also described fatal hemorrhage associated with this condition and supplied an extensive literature of intrapartum hemorrhage on request. The manner of insertion and the dissociation of vessels from the cord substance and membranes are well seen in Figures 12.25 and 12.26. This placenta was associated with normal outcome. The infant whose placenta is shown in Figure 12.30, however, was growth-restricted and had low Apgar scores. The furcate and velamentous cord had varices and numerous mural thrombi; many of the placental vessels had degenerations and calcifications in their walls. This case illustrates why the conditions furcate and velamentous have often posed semantic problems of classification.

FIGURE 12.27. Furcate insertion and interposition of umbilical cord. The vessels divide and spread prior to their insertion on the placental surface and course in amnion.

### Fatal cord strictures

FIGURE 12.28. Diagram to show the relation of knots, twin cords, and excessively long cords in prenatal deaths. Knots and fatal strictures are nearly always found with cords of excessive length. (Line depicts expected normal length.)

FIGURE 12.29. The length of umbilical cord in our cases of osteogenesis imperfecta, thanatophoric dwarfism and camptomelia. All have shorter umbilical cords, presumably because of “fear to move” in utero because of pain or inability to move.

### Velamentous Cord Insertion

Because of its relative frequency and importance to the course of pregnancy and delivery, velamentous or membranous insertion of the umbilical cord has been studied by many investigators. Complications include rupture of membranous vessels and vasa previa. Moreover, vasa previa may be compressed during labor and cause fetal distress (Cordero et al., 1993). Velamentously inserted

cords are associated with twinning and single umbilical artery (SUA). The incidence of various types of cord insertion varies throughout numerous reported series because the interpretation of what is truly a marginal or already a velamentous insertion, or merely an excessively eccentric one, differs in the eyes of the beholder. Nevertheless, Table 12.2 shows that most observers agree that

FIGURE 12.30. Velamentous and furcate insertion of the cord in a growth-restricted infant with low Apgar scores. There are numerous aneurysms, extensive mural thrombosis, and vessel wall calcifications. (Courtesy of Dr. M. Rockwell.)

FIGURE 12.31. Velamentous insertion of umbilical cord on the dividing membranes (M) of dichorionic twin placentas.

its frequency is around 1% of singleton term deliveries. The cord may insert reasonably close to the edge of the placenta or far away from it. The close insertion is much more common than the extreme situation, where the cord inserts at the apex of the membranous sac. In the latter configuration, the long membranous course of the vessels makes them even more vulnerable to injury. It should be pointed out though that a membranous course of fetal blood vessels is not reserved to a velamentous insertion of the cord. Quite often there are such membranous vessels issuing from marginally inserted cords, and they have the same serious prognosis. Also, membranous fetal vessels are not synonymous with vasa previa. The latter condition exists only when the membranous vessels course over the internal os uteri, previous to (ahead of)

the fetal head during delivery. In multiple gestations, the velamentous cord insertion often arises on the dividing membranes (Fig. 12.31) and the membranous vessels are then similarly prone to disruption. Fries et al. (1993) found that velamentous cord insertion is more common in placentas of the twin-to-twin transfusion syndrome and suggested that this may impact the severity of the growth restriction to the donor twin.

Thrombosis of arteries (Fig. 12.32) and veins (Fig. 12.33) has both been seen in this insertional anomaly, and thrombi may be associated with neonatal purpura and fetal death. Hemorrhages arise most commonly from the veins, and they are the most frequent complications of membranous vessels. Hemorrhages may even commence in utero, before labor has begun (Bilek et al., 1962). In

FIGURE 12.32. Velamentous (membranous) insertion of the umbilical cord (large arrow) with several calcified arterial thrombi (small arrows). Apgar scores were 1/9.

FIGURE 12.33. Velamentous insertion of the umbilical cord with sudden fetal death at 37 weeks. Note the large venous thrombi (arrows). The different ages of thrombi are seen in darker and lighter colors, indicating different degrees of hemolysis.

several cases that we have seen there were numerous hemosiderin-laden macrophages around the necrotic, thrombosed artery, presumably derived from the hemolysis of extravasated blood. In addition, it has been our observation that there is older medial necrosis of the muscular wall than of its periphery. We have sought to explain this by better oxygen supply from the periphery (through the cord substance). Thrombosis and arterial necrosis occasionally follow arterial spasm after cordocentesis, perhaps in response to the release of vasoactive substances measured by Rizzo et al. (1996). Depending on whether a Hyrtl anastomosis is present, large areas of placental tissue may also infarct. We have seen such isolated thrombosis also in two cases with excessively spiraled umbilical cords. Cook et al. (1995) discovered thrombosis by sonography at 31 weeks' gestation when the fetus had decreased movements. The thrombus originated from the aorta and embolization to umbilical vessels was suggested. It resolved spontaneously after birth, without an etiology having been ascertained. The more distal consequences of fetal artery thromboses were studied by McDermott and Gillan (1995a). They found that, macroscopically, isolated areas of the placenta assumed pallor and, microscopically, granular iron-containing incrustations located at the trophoblastic basement membrane. Similar incrustations are frequent in spontaneous abortion. In subsequent studies of infarcts (McDermott and Gillan, 1995b), these authors affirmed such deposits in placental infarcts and inferred disturbed maternofetal transfer as their cause.

Thromboses and disruptions are more often found when the membranous vessels course over the internal os and are, as vasa previa, broken by the exiting fetal head or by the obstetrical attendant who ruptures the membranes (Quek & Tan, 1972). Obolensky (1967) provided a description of the differential diagnosis of fetal (versus maternal) blood, in such unsuspected vaginal bleeding.

The manner by which fetal blood can be distinguished from maternal blood is discussed in greater detail in the discussion on hemorrhage due to placenta previa and in Chapter 17. Exsanguination from ruptured vasa previa can proceed within minutes. We have seen fatalities occur within 3 minutes of disruption through unrecognized velamentous vessels. Experience of successful immediate blood transfusion has also been reported (Mitchell et al., 1957). The frequency of hemorrhages is difficult to assess but has been estimated by Quek and Tan (1972) to be 1 in 50 cases of velamentous insertions. The mortality rate from intrapartum rupture and hemorrhage was given as 58% by Rucker and Tureman (1945) in their report of three cases and in their comprehensive literature review. Remarkably, the mortality has been 73% when the hemorrhage occurred before delivery (Torrey, 1952). Pent (1979) went so far as to state that "an active obstetric service can expect to have one perinatal death each year due to vasa previa."

Hemorrhages have on occasion been recognized by palpation of vasa previa, by amnioscopy, and even by sonography (Gianopoulos et al., 1987). Vasa previa were diagnosed by ultrasonography (color Doppler) prior to hemorrhage and thus leading to elective section (Meyer et al., 1993). The aberrant vessels coursed toward a succenturiate lobe. When the velamentous vessels are compressed during labor, this may be recognized by a sinusoidal fetal heart rate pattern much as in cord prolapse. An example is the twin pregnancy described by Antoine et al. (1982). These authors reviewed the dismal experience with vasa previa in twin pregnancies. Obstetricians have also occasionally made the diagnosis of bleeding from vasa previa by examining vaginal blood during labor or color Doppler sonographic study (Harding et al., 1990). Diagnostic methods have included Kleihauer stains and other techniques to detect fetal blood (Bergström, 1963; Carp et al., 1979; Vandriede & Kammeraad, 1981;

Silva et al., 1985; Jones et al., 1987). Because of the ability to ascertain fetal blood in vaginal bleeding from vasa previa, it has become a topic for litigation, but Messer et al. (1987) surveyed 100 community hospitals and concluded that such testing is currently not a standard of care in the United States.

As already stated, vasa previa are not confined to velamentous insertions. At times, a marginally inserted cord may have aberrant branches that course over the membranes; even cords with a more central position can have such vessels. Vasa previa may also occur with succenturiate lobes (Radcliffe et al., 1961) and in bilobed placentas (Waidl, 1960; Kouyoumdjian, 1980). Scheuner (1965) studied the histologic characteristics of nine term velamentous cord insertions and discussed the rich literature of this condition in detail. He found that membranous vessels are firmly anchored to the chorion by collagenous fibers, which explains why it is that the vessels rupture so readily when the chorion breaks.

It has been of great interest to understand the pathogenesis of velamentous and marginal insertions of the umbilical cord. There are two mutually contradictory theories: abnormal primary implantation (polarity theory), and trophotropism. Arguments have been brought to bear for both of these points of view. We favor the second and believe that it derives stronger support from the various placental constellations one finds associated with this condition.

The primarily abnormal implantation theory postulates that, at the nidation of the blastocyst, the embryo does not face the endometrium; rather, that it is located at the opposite side, or that it is obliquely oriented. Thus, when the vascular stalk develops, this trunk has to seek its connection with the future area of placentation by extending its vessels from the embryo to the base of implantation. Eventually, the vessels must thereby become membranous in location. This view was championed, among others, by Hertig (1968), despite the fact that in virtually all of the normal early embryos that he discovered and described in meticulous detail, the embryo had a normal (endometrial) position. Carnegie specimen 8671 (his Figure 65), however, had a somewhat oblique orientation, which might have caused a marginal insertion of the cord. Beer (1954) suggested that the cord arises "from the most vascular portion of the decidua," an opinion that is difficult to comprehend. If that were the case, one would perhaps expect to find as high a frequency (or a higher one) of velamentous and marginal cords during the first trimester as that which occurs later in gestation—which is not the case.

Monie (1965) found 15.3% of velamentous and 14.7% of marginal cords among 183 specimens of 9- to 13-week abortuses. He confirmed that velamentous insertion was highly correlated with congenital anomalies (marginal

cords were in between) and provided a particularly good discussion and diagrams of the various notions published by earlier investigators. Monie acknowledged the frequency of velamentous cords in South American monkeys that have a superficial implantation. This finding negated earlier suggestions by Torpin (1953) that too deep an implantation may be the cause of velamentous cord insertion. Monie also reviewed the two types of velamentous insertion: normal and interpositional. Parenthetically, it may be mentioned that the umbilical cords of gorillas have nearly always been found to be marginal and also to be relatively long, about 100cm (Ludwig, 1961). Hathout (1964) searched for cord insertion sites in 131 abortions, to 28 weeks' gestation. He found velamentous cords in 8.1% (three twins); 21.5% had marginal cords (one twin). It was central/eccentric in 70%. Because the abnormal cords were from midtrimester abortions, one might consider that the factors involved in trophotropism were also the cause of abortion. This contention is not supported by the extensive mathematical analysis of McLennan (1968), who sided with the theory of primarily disturbed placentation.

The case for trophotropism was first presented in detail by Strassmann (1902) in his large study of placenta previa and associated placental anomalies. The etiologic role of trophotropism is supported by cogent considerations: Velamentous and marginal cords are much more common in twins and are almost invariably present in higher multiple births. They are common when intrauterine devices (IUDs) are found in the placental membranes. Some of these pregnancies have led to prenatal hemorrhages and abortion (Golden, 1973). Moreover, one can sonographically observe eccentric expansion of the placenta during the course of advancing pregnancy, which would leave the cord insertion site behind. The distribution of cord insertions of some consecutive twin placentas are recorded in Table 12.3. It can be seen that, with the exception of diamniotic/dichorionic separate twin placentas, all others have an excessively high rate of abnormal cord insertions.

Finally, a series of successively undertaken ultrasonographs has shown that the placenta may "wander," called dynamic placentation (King, 1973). That is, when during early pregnancy a placenta previa was unmistakably diagnosed (in 5.3% of patients), it often converted to a marginal or higher-lying placenta with progressing pregnancy; a placenta previa was found at term in only 0.58% (Rizos et al., 1979). In the series published by Meyenburg (1976), which supports these observations, the point is made that an opposite migration never takes place. Regrettably, in none of these studies is the location of the umbilical cord mentioned—neither at the time when the placenta was first localized nor after delivery. It would be desirable to collect this information in the future. The placental movement is not accomplished by the placenta unseating and

TABLE 12.3. Distribution of cord insertion in twin placentas past 20 weeks

MoMo, monoamniotic/monochorionic; DiMo, diamniotic/monochorionic; DiDi, diamniotic/dichorionic.

relocating itself, but rather through marginal atrophy on one side and expansion on the other, as well as through the development and thinning of the lower uterine segment. This mechanism is also the best one to explain the sickle-shaped, marginal placental atrophy that has been observed (Winter, 1978). Young (1978), who studied a large number of such early placentas previa, referred to the process as an “amoeba-like growth.”

The most extensive writings on this topic come from Krone. In 1962 this author began studies showing that marginal and velamentous cords tend to correlate with fetal anomalies. In his early contributions, Krone (1960) presented data to show that 9% of normal infants had a markedly eccentric cord, as did 28% of malformed babies. Marginal and velamentous cord insertion was present in 6% and 26%, respectively. In a later study of 2868 placental examinations, Krone et al. (1965) found that such cord insertional anomalies correlated with advanced maternal age and multiparity, and that they often followed abortions and curettage. He believed that the abnormal placentas could not be the cause of fetal anomalies because final placental shape occurs only *after* the “teratogenetic termination period” of Schwalbe (1906).

These placentas, however, direct our attention to the existence of an abnormal nidation/placentation process (Krone, 1967). Our own studies of fetal anomalies and cord insertion clearly showed such a relation and it has been noted by others as well (Robinson et al., 1983). The suggestion by Shanklin (1970) that abnormal cord insertion correlates with low birth weight was not supported by the study of Woods and Malan (1978), who evaluated 940 placentas with marginal or central cords. Shen-Schwarz et al. (1997b), however, found a significant reduction of birth weights with velamentous cord insertion in diamniotic/monochorionic (DiMo) twins, but not in diamniotic/dichorionic (DiDi) twins. Although we have not done a statistical study of the topic, our findings also suggest reduced birth weight to be associated with velamentous cord insertion. Similar findings come from a large retrospective study by Heinonen et al. (1996). They detected significantly more low birth weight fetuses, growth retardation, low Apgar scores, and abnormal fetal

heart rate patterns with velamentous insertions. Rarely were they able to identify the cause sonographically, and they called for new diagnostic modalities, such as Doppler study, in order to detect the correct cord insertion site. Nöldeke (1934) found that abnormally inserted cords occur more often in prematurely delivered infants. He noted increased difficulty of placental separation, as did Earn (1951). Their findings were not confirmed, however, by the study of Uyanwah-Akpom and Fox (1977). In all these considerations one must remember that twins have to be excluded from any study so as to make the data truly comparable. This is often not done; thus, from many of the original papers it is impossible to discern the extent to which twins were present within the data sets and thereby increased the numbers of velamentous cords. Therefore, the numbers in Table 12.2 and in the reports must be interpreted with some caution.

Eddleman and colleagues (1992) reviewed the sonograms of the 82 cases of velamentous cord insertions seen in their 4-year experience (77 singletons). In none of them had the diagnosis been made before birth, including the three cases of vasa previa later identified. The infants born to these women had lower birth weights than controls and more intrapartum complications, but the mothers did not have higher parity or more frequently prior cesarean sections as is often assumed. Importantly, the study showed that, sonographically, this diagnosis cannot be expected to be made routinely.

## Placental Surface Vessels

It is convenient to consider the placental vascular tree at this point, as future discussion of the thrombotic events of the cord often interrelate to those of the vasculature on the surface of the placenta. The distribution of the blood vessels across the placenta is not random, although we do not understand the mechanisms that govern their growth. Two principal patterns of vessel distribution have been described in the literature, and admixtures exist occasionally. The disperse pattern has a fine network of vessels that course from the cord insertion to the various

FIGURE 12.34. Disperse and magistral distributions of placental arterial vessels.

placental cotyledons. The magistral pattern has arteries that course across the placental surface nearly to the edge without diminishing their diameters. The arteries have a fairly uniform diameter, and they have many branches. These two types are shown in Figure 12.34. They have been delineated by injection and corrosion techniques that employ a variety of materials, including lead salts and plastics (Hyrtl, 1870; Schordania, 1929b; Bacsich & Smout, 1938; Smart, 1962; Kishore & Sarkar, 1967; and others cited by these authors). Schordania (1929b), who is responsible for the aforementioned terminology, advanced the theory that the magistral type of vascularity leads to better-developed fetuses. This theory was not affirmed by the studies of Crawford (1959), however; and Bacsich and Smout (1938) failed to identify the arterial anastomoses in the periphery of the placenta that were delineated by Hyrtl (1870) and others. The same observation was made by Priman (1959). The superficial arteries are end-arteries to which feature Bacsich and Smout (1938), incorrectly we believe, attributed the occurrence of white infarcts near term. The disperse type of vessel distribution is more commonly present (61.8%), with the magistral type occurring in 38.2% (Kishore & Sarkar, 1967). The latter authors found no association with placental size or anomalies but noted that the disperse type was more frequent in placentas with centrally inserted cords. There is no racial influence on these features (Andrade, 1968).

At the periphery, the arteries individually supply a single cotyledon ("placentone"), turning abruptly toward the maternal surface, then branching repeatedly and finally becoming capillaries; the blood is then returned from the capillary loops of the cotyledon to the umbilical cord by veins that merge. It is crucial to recognize that, in the overwhelming majority of cotyledons, there is a 1:1 relation between artery and vein at the periphery. Otherwise, the transfusion syndrome of monochorial twins could not be understood. It is further remarkable that at least the larger arteries always cross over the veins, par-

ticularly nearer the cord insertion (Smart, 1962). Wentworth (1965) reported that only about 3% show the opposite condition. Also, Bhargava and colleagues, in a series of studies (Bhargava & Raja, 1969), suggested that veins may occasionally cross over arteries. They undertook a quantitative analysis of these features. In their material, this reversal of the normal pattern correlated significantly with abnormal fetal development and with hydramnios. However, according to Boyd and Hamilton (1970) the superficial position of one or few veins at points of arteriovenous crossing is not unusual even in normal placentas. They can thus be readily identified by macroscopic examination. Histologically, it is nearly impossible to make this distinction (Fig. 12.35). What makes these vessels assume this pattern so uniformly? Because we understand genetic influences on the placenta very poorly at this point, it is our belief that when the earliest embryonic vessels grow into the placental surface, the subsequent perfusion, at first sluggish, determines the vascular pattern that ultimately results. It may well be subject to trophic or mechanical (pressure) forces. For a better comprehension of the complexities of the vascularity in twin placentation, it would be helpful to have a better understanding of these vascular phenomena.

FIGURE 12.35. Microscopic appearance of the surface of the placenta with the artery (A) above the vein (V). Note that the fetal side of both vessels has a much thinner muscular wall and that the artery lies on top of the vein. H&E  $\times 60$ .

It is further remarkable that the circumferential architecture of the placental surface vessels is asymmetrical (Fig. 12.36). This area has been studied by Fujikura and Carleton (1968), who found that the thinning of the muscular wall of arteries (80%) commences after 12 weeks of gestation. Of the two theories they advanced (trophic growth of muscle and hemodynamic thinning), we favor the latter and believe that the pressure buckles and thins the superficial portions of the vessels, whereas the fixed portions resist this pressure. This phenomenon of thinning of the superficial aspect of chorionic vessels (also shared with cord vessels) may actually be a sequel of amniotic rupture and a change in intraamniotic pressure relation **after** that event of membrane rupture. Contrary to the observations of Fujikura and Carleton (1968), we believe this property to be shared by veins (Fig. 12.35), a feature Fujikura and Hosoda (1990) have now acknowledged. Unilateral thickening of the muscular walls of large chorionic veins (>1.0mm diameter) on the chorionic side is a usual finding in all normal placentas after 17 weeks of gestation. The ratio of amniotic to chorionic wall thickness may be 1:3 to 1:4. It is caused by muscular hyperplasia rather than by arteriosclerotic changes. Fujikura and Hosoda (1990) concluded that differences in wall movement were the etiologic factors.

Surface arteries and veins are subject to spontaneous rhythmic contractions and to the influences of various

mediators, such as serotonin, prostaglandins, atrial natriuretic peptide, nitric oxide and endothelin-1 (Panigel, 1962; Panizza et al., 1981; Robaut et al., 1991; Salas et al., 1991; Omar et al., 1992; Myatt et al., 1993; Rath et al., 1993). Methyldopa, for instance, was found to decrease the placental vascular resistance in maternal hypertensive disease when Doppler velocimetry was done (Rey, 1992). Isolated fetal placental arteries dilated experimentally when exposed to nitric oxide (Learmont & Poston, 1996). In general, the larger chorionic and stem vessels seem to behave like the umbilical vessels (see above) (Macara et al., 1993). Endothelin, on the other hand, is said to increase resistance in the arterial bed (Bodelsson et al., 1992).

Studies have also endeavored to correlate umbilical artery flow waveforms with abnormalities in the vascular beds of tertiary villi (McCowan et al., 1987). When the cord arterial pulsatility index is high, indicating peripheral vascular resistance, the peripheral arterial vessel count is low, a finding that is strongly correlated with growth-restricted fetuses (Hitschold et al., 1993). Similar studies by Doppler waveform analysis of umbilical cord flow showed that, during preterm labor, ritodrine (but not magnesium sulfate) affected umbilical vascular resistance (Brar et al., 1988). When, with serial determinations, different patterns of flow were thus determined, the placenta was subsequently found to have one large infarcted lobe, supplied by one artery; and the authors believed that the infarction may have been the reason for the difference (Trudinger & Cook, 1988). The pattern of umbilical blood velocity waveforms changes abruptly at about 12 weeks' gestation. Prior to that time, there are no end-diastolic frequencies (EDFs), which, in later life, would be held to be an abnormal feature of fetal circulation. Fisk et al. (1988) and Loquet et al. (1988) simultaneously reported that no EDFs were observed before 12 weeks (as is normal in peripheral arteries), and that their appearance at the second trimester perhaps signals the development of vessels in the tertiary villi and the disappearance of the membranous circulation. It signals the sudden decrease of placental villous flow resistance. Interesting observations of fetuses grasping and constricting the umbilical cords in utero are referred to in letters by Petrikovsky and Kaplan (1993), Collins (1995a), and Habek et al. (2003).

A variety of disease processes affect placental surface vessels. The easiest to understand is hemorrhage after traumatic laceration. Disruption of chorionic vessels is commonest after amniocentesis and may lead to rapid fetal exsanguination (Goodlin & Clewell, 1974) and intraamniotic bleeding. It has been recognized by sonography during amniocentesis as a spurt. We have seen three such lacerations of surface vessels due to amniocentesis in a patient with diabetes, done to assess fetal maturity (Fig. 12.37). The infant survived. In another case,

FIGURE 12.36. Differences in wall thickness of the umbilical vein branch at term. H&E  $\times 240$ .

FIGURE 12.37. Three lacerations (arrows) from amniocentesis at 38 weeks' gestation in a patient with diabetes, performed to assess fetal maturity. Cesarean section, live birth.

where amniocentesis was performed at 12 weeks to obtain genetic information, the anterior placenta had one surface vessel ruptured, and blood dissected underneath the amnion. When a stillborn fetus was eventually delivered, hemosiderin and nucleated red blood cells were found along the well-defined needle track. Intraamniotic bleeding has been studied with sonographic surveillance and correlation with Kleihauer tests, so as to adjudicate the amount of RhoGAM needed for Rh-negative patients (Lenke et al., 1985). It was found that bleeding occurred most commonly when, in anterior placentas, the placenta needed to be traversed by the needle. No correlation with fetal-to-maternal hemorrhage has been found. A case was referred to us with a posterior placenta that exsanguinated through a transverse laceration of a surface artery. The amniocentesis needle had caused this lesion after much amniotic fluid had been withdrawn, perhaps because the posterior placenta had then come closer. Considerable search may be required to identify such defects, but the pallor of the placental tissue is the first sign of blood loss, the suspicion of which then leads to a detailed inspection for an explanation. Needle puncture of the fetus at amniocentesis has also been reported. When it occurs during early diagnostic procedures fetal scars may result (Broome et al., 1975, 1976); in later gestations, hemorrhage may ensue (Galle & Meis, 1982). The practice of cordocentesis may also cause hematoma and other injury to the umbilical cord. Jauniaux et al. (1989b) found, among 50 cases studied, one giant hematoma of the cord and four small hematomas that encircled the walls of the arteries. The needle puncture sites were readily visible in 37 cases. Thrombosis was not found, and these authors suspected that the injured vessel was repaired within 1 week. In a fortuitous section, de Sa (1984) depicted (his Figures 5 to 8) the disruption of an umbilical vein within a cord hematoma. We have seen several such hematomas after cordocentesis, occasionally

so massive that they required delivery. In others, repeated ( $\times 6$ ) cordocentesis left only small defects in the amnion.

In recent years, the practice of prenatal transfusion of blood at the site of cord insertion has become more commonly practiced. It has also led to some disastrous results. Weiner et al. (1991) analyzed the results of 594 cordocenteses and 156 transfusions and found that the results differed with the type of procedure. Ney et al. (1989) deduced from *in vitro* studies that amniotic fluid had coagulative properties that prevent massive hemorrhage, whereas Chénard et al. (1990) depicted the circumstances of a rapidly developing fatal hematoma in a 29-week fetus. It must be cautioned, however, that subamniotic fresh blood is commonly found in placentas. It may then be the result of traction (with disruption) of the cord for delivery of the placenta or, more commonly perhaps, because neonatologists have drawn blood from placental surface vessels for pH determination, and the site continued to ooze blood thereafter. It is of historic interest to review the practice of traction on the cord for placental delivery (Rehstein, 1969), as it was a feared practice in the past because of the possibility of uterine inversion. Now, with oxytocics that better contract the uterus, this is rarely observed. Khoury et al. (1991) compared cord pH and gases from blood obtained before delivery (in cesarean sections) and after delivery and found significant differences.

More frequent perhaps are hemorrhages that occur after laceration of velamentous vessels and vasa previa. This subject is discussed later in this chapter. A remarkable case was described by Tuggle and Cook (1978): An infant had experienced massive bleeding from a surface vein that led to cesarean section; no therapeutic intervention could be blamed for this spontaneous rupture. Because of the unusually long fingernails of the newborn, it was conjectured that the nails of the fetus may have caused the tear.

## Nucleated Red Blood Cells (NRBCs)

A really important observation needs to be made when examining the fetal blood within chorionic vessels, easiest done in the blood of the larger vessels on the fetal surface, or in the umbilical cord. That observation is to gain an appreciation of the presence of nucleated red blood cells (NRBCs) in the fetal circulation. In normal term pregnancies, very few red blood cells with nuclei are visible in the fetal blood during placental examination. There is, however, considerable controversy about how many NRBCs may be found in truly normal neonates. When many NRBCs are seen in the absence of anemia or erythroblastosis, it is a distinctly abnormal finding and the pathologist should endeavor to ascertain the reason for

their presence. There exists an extensive literature on this topic and its findings are not always in agreement. One reason for discrepant results may be that, especially in older citations, the authors have not always excluded infants who suffered hypoxia or other causes for the presence of NRBCs. This aspect is fully discussed in Chapter 8, and by Korst et al., 1996.

## Cysts and Edema

Aside from the aforementioned cysts, we have seen a small amnionic epithelial inclusion cyst in a fetus with 47, XXX chromosome constitution. It was filled with clear fluid. And then, on rare occasion cysts arise within Wharton's jelly. They are most obvious in the edematous umbilical cords that have been associated with some cases of the respiratory distress syndrome of newborns (Coulter et al., 1975). Coulter and colleagues found 10% of babies to have edematous cords; the occurrence is more common in premature infants. These authors related the edema to reduced oncotic pressure. Edema is apparent in the markedly swollen, glistening umbilical cord shown in Figure 12.38. It resembles the condition of "mucoid degeneration," described by Bergman et al. (1961). These investigators believed that one of their patients died as a result of this degeneration. Whether this is truly a degenerative event, however, remains to be ascertained. Rolschau (1978), on the other hand, found that edema of the cord had no influence on fetal development and well-being. This pathologic change may be diffusely distributed, as happens for instance in some cases of severe funisitis, or it occur focally as cysts. Usually, the cysts in Wharton's jelly are not accompanied by fetal disease, and there is a normal fetal outcome. Severe distention, up to 5 cm diameter, occurs for unknown reason

occasionally and may then be accompanied by hydramnios and an excessive number of mast cells (Howorka & Kapczynski, 1971). Walz (1947) has studied this phenomenon in more detail when he observed a growth-retarded infant with a normal placenta but "arm-thick" umbilical cord that was difficult to ligate. It also had calcifications that will be discussed shortly. The cord was 46 cm long and 7 cm thick. Histologically, it was edematous and had acute inflammatory cell infiltration, mural thrombi, and many areas of degeneration. Walz reviewed the older literature on this finding. Occasionally, the cord has a complete lack of Wharton's jelly, which is usually a sign of fetal growth retardation (Scott & Jordan, 1972). The association is not a strict one, however, and many infants with IUGR (e.g., renal agenesis) have normal cords. Nevertheless, experienced obstetricians regard lean cords as a sign of dysmaturity (Goodlin, 1987). A large cyst of the umbilical cord is depicted in Figure 12.6. Degeneration of cord substance, with an absence of Wharton's jelly, has also been reported by Labarrere et al. (1985). They found three cases of meconium-stained term neonates who died shortly after birth in whom the umbilical arteries were detached from the cord substance. Much of the amnionic epithelium of the cord was defective, as was Wharton's jelly. They speculated that there may have been incomplete fusion of amnion with cord and likened the condition's etiology to that of furcate insertion. The pathologic change may be diffusely distributed or occur focally as cysts (Figures 12.5 and 12.39). The relationship to meconium was disputed by Thomson and Hoo (1996), who described such a case of "linear disruption of the umbilical cord" in a severely retarded child, but in whose delivery notes meconium was not described as having been present. We have seen such degenerated cords, most often associated with prolonged meconium staining, but not always associated with bad fetal outcome, and a relevant

FIGURE 12.38. Marked edema in the umbilical cord of a normal newborn infant. Note the dissociation of fibrous tissue underneath the surface of the cord. H&E  $\times 160$ .

FIGURE 12.39. Umbilical artery after meconium damage. Note the apparent acellularity of the cord, due to toxicity, and the thinned portion of umbilical cord. This is the result of meconium damage penetrating from the outside.

case with normal outcome is depicted in Chapter 11. A typical example of meconium-induced necrosis of portions of the umbilical arterial wall is shown in Figure 12.39. It will be noted that the necrosis is confined toward the cord's surface whence the toxic meconium originated. The dissociated vessels in many of such damaged arteries, however, have often been severely inflamed; our opinion is that this is most often the result of meconium toxicity and does not represent a congenital anomaly. More discussion of meconium-induced arterial toxicity follows later in this chapter and is also to be found in Chapter 11.

The water content of the umbilical cord has been studied in great detail by Scott and Wilkinson (1978). Edematous cords had a water content of 93.5%, and wrinkled cords had 89.2% water. The correlation with cystic spaces such as those of Figure 12.38 is then excel-

lent. There is a tendency for the amount of Wharton's jelly or its water content to decrease with advancing gestation. Bender et al. (1978) provided a particularly useful review of the older literature on this topic and studied the relation of the amount of jelly to outcome. They found that infants with much jelly and more spiraling of vessels have better outcomes than those who do not. In the still-born with a markedly spiraled, jelly-poor cord, it can be argued that the jelly has disappeared because of vascular compression. It is not proved that Wharton's jelly was primarily absent; in general, we are ignorant of the mechanisms that provide cord jelly and its water content. Realizing that the amniotic fluid decreases with advancing gestational age and that there may be a correlation with cord thickness, R.K. Silver et al. (1987) sonographically studied the cord thickness and circumference after birth. The cord diameter varied from 1.25 to 2.00 cm and its circumference from 2.4 to 4.4 cm. Fetal monitoring inferred to be compression patterns increased in frequency with decreasing fluid content of the cord. It may also be mentioned that experimental evidence has indicated that, in fetal lambs, intermittent partial cord occlusion leads to cerebral necrosis (Clapp et al., 1988; Mallard et al., 1992). Gill and Jarjoura (1993) measured the quantity of jelly in umbilical cords; they found a positive relation to male fetuses, increased prepartum maternal weight and heavier birth weight.

Excessively thin umbilical cords are abnormal and potential causes of fetal problems. This has been referred to as the "thin cord syndrome" by Hall (1961). It may involve the entire cord and also only portions of the umbilical cord. The latter examples are most often those cases in which the cord has become extremely thinned near the abdominal surface of the fetus due to torsion, the so-called coarctation. It frequently leads to fetal death and abortion (see Fig. 12.47). In the prototype of an abnormally thin cord, there is a deficiency of Wharton's jelly and compression of vessels is a greater possibility than when they are protected. Thin cords occur more often with growth-restricted fetuses and in preeclampsia, but unknown causes exist as well. Labarrere et al. (1985) presented three cases in which Wharton's jelly was deficient with arteries free next to the umbilical cords and causing fetal demise. As mentioned earlier, meconium is often present and it may be able to cause the degenerative changes. It is of parenthetical interest again to recall that similar fetal deaths due to excessively long umbilical cords with marked coiling occur in race horses (Whitwell, 1975; Giles et al., 1993; Hong et al., 1993). Microscopic calcification was often present in the vessels of these abnormal cords. Because the longitudinal orientation of equine fetuses prevents turning in later stages of pregnancy, here too, early motion of the fetus must be held responsible for the excessive lengths and twisting.

# Single Umbilical Artery

Single umbilical artery (SUA) is the commonest true congenital anomaly of humans. An enormous literature has been created in efforts to explain its nature and significance. Our file contains more than 80 articles dealing with SUA, and many more are reviewed and critically analyzed in the review articles by Heifetz (1984) and Leung and Robson (1989). These reports can be consulted for all of the relevant literature.

Single umbilical artery was apparently first described by Vesalius. It did not attract further notice until the 40 cases listed by Otto (1830) and the later attention by Hyrtl (1870), who summarized 70 cases in his interesting monograph. Considering its incidence of about 1% in newborns (Heifetz compiled all data and reported there being a 0.63% frequency), it is surprising that its relation to anomalous fetal development was overlooked for so long, until we drew attention to it again (Benirschke & Brown, 1953; Benirschke & Bourne, 1960). Since then, there has been a veritable flood of information on SUA (Table 12.4). Single umbilical artery can now be detected prenatally by ultrasonography (Tortora et al., 1984; Herrmann & Sidiropoulos, 1988), and Jones et al. (1993) make the point that it is unforgivable if it is not ascertained at birth. Raio et al. (1999) found that SUA is more commonly associated with reduced amounts of Wharton's jelly, irrespective of its association with chromosomal disorders. Among the seven patients of Tortora et al. (1984), four had hydramnios, two were growth-retarded, two died, two survived with anomalies, and three were normal infants. Herrmann and Sidiropoulos (1988) found SUA in four cases and drew attention to the growth restriction of the neonates. The relation of SUA to growth restriction has also been studied by Rolschau (1978). He found that SUA correlated with circumvallation of the placenta, and that marginal cord insertion was moderately well correlated with small placentas and fetuses. Velamentous insertion of the cord, however, had a strong negative effect on fetal and placental weights. Leung and Robson (1989) found SUA in 159 of 56,919 infants. Twins had an incidence of 8.8%, and it was usually the smaller twin who had the anomaly. Single umbilical artery was associated with diabetes, epilepsy, preeclampsia, antepartum hemorrhage, hydramnios, and oligohydramnios. Anomalies were detected in 44.7% of the associated infants, and other placental abnormalities were found in 16.4%. Because of the frequency of renal anomalies (18.5%), these authors recommended that neonatal renal sonography be performed when SUA is found. Abuhamad et al. (1995) found sonographically that in 73% of 77 cases of SUA the defect locates to the left artery and that cytogenetic and complex anomalies were associated nearly exclusively with the left-sided absence. Theirs is the largest

TABLE 12.4. Frequency of single umbilical artery (SUA) in various populations

Twin Infants	2,399	56	2.3

Source: Data from Heifetz (1984).

prospective series, and they found a 30% associated anomaly incidence. Growth retardation was found in 8% of cases. Parilla et al. (1995) deduced from their 50 cases that an isolated SUA (without other sonographic anomalies) did not affect outcome and should not alter obstetric management. Conversely, when Pavlopoulos et al. (1998) studied infants with SUA they found a significantly higher frequency of hollow organ pathology, especially intestinal atresia, and cautioned sonographers to pay special attention to the intestines before birth when SUA is identified. A meta-analysis of cases with SUA was conducted by Thummala et al. (1998) that showed that in otherwise apparently normal neonates, SUA is associated with only a slight increase in renal anomalies and does "not justify extensive urologic radiographic investigation." Benoit et al. (2002) came to similar conclusions more recently.

Absence of one umbilical artery may occur as aplasia or as the consequence of atrophy of one artery. The latter mechanism is probably more frequent and can be seen to have occurred in many specimens when histologic examination is undertaken (Fig. 12.40). Degeneration of one artery occasionally occurs late in pregnancy but when it

FIGURE 12.40. Umbilical cord from a placenta with marginal cord insertion. A degenerating second artery is seen (arrow). Elastic tissue stain (right) shows the internal elastica of the umbilical vein and absence in both arteries. H&E (left), von Gieson (right).  $\times 10$ .

FIGURE 12.41. Muscular remnant of a vanished second umbilical artery (arrow); the other is a remnant of an allantoic duct. H&E  $\times 60$ .

took place some longer time before birth, the arterial lumen gradually vanishes, and only a tiny muscular remnant then remains (Fig. 12.41). We have seen a relevant case that bears on this question: A patient had decreased fetal movements and was studied repeatedly sonographically; eventually she delivered at 35 weeks an infant who did well after having had initial problems. One umbilical artery was completely thrombosed and the wall was autolyzing with hemoglobin staining of the jelly. Remarkably, there was an inflammatory response from artery and vein toward the degenerating vessel and not, as is usual, toward the cord's surface; also there was no chorioamnionitis. Hyrtl's anastomosis was absent. The Gravida 5 Para 1 patient had anticardiolipin titers, but it is not certain that these relate to the thrombosis. The newer Doppler techniques have now allowed prenatal diagnosis of discordant umbilical arterial size (Raio et al., 1998). The smaller vessel was found to have an increased resistance index and, remarkably, five of the 14 cases analyzed lacked Hyrtl's anastomosis.

The question of whether SUA from aplasia has a prognosis different from that from atrophy was examined in a large study by Altshuler et al. (1975). These authors found 19 placentas with SUA among 4138 consecutive deliveries (0.46%). Altogether, they analyzed 48 children with this anomaly and found no significant difference "in congenital malformations or neonatal mortality." The more frequent detection of SUA in term placentas than in placentas of early gestation further supports the view that the etiology involves arterial atrophy. On the other hand, early embryos with SUA have also been seen, and SUA has been observed associated with many chromosomal anomalies and exposure to such teratogens as thalidomide. It has even occurred in baboons so treated experimentally. Single umbilical artery is also found almost regularly in association with sirenomelia and is present in the cords of most acardiac fetuses (malformed monozygotic twins; see Chapter 25), which also supports

the notion of occasional aplasia as its origin. Perez-Aytes et al. (1997) described a relevant case in which the single artery of a sirenomelic fetus was directly continuous with the aorta.

It must be cautioned that SUA may be found at one end of the cord and not the other. We have therefore suggested that, to verify its existence, one must sample three areas of the umbilical cord. At times, the arteries fuse far above the cord insertion on the placenta (Kelber, 1976) in a manner that is similar to their normal communication near the placenta. An interesting question is what happens when there is no communicating artery during early development, as is the case in some 4% of term umbilical cords (Priman, 1959). Because each artery supplies a portion of placental tissue, the area supplied by an atrophying artery would then presumably undergo atrophy. Such atrophic changes may explain the much higher frequency of SUA in multiple births. Trophotropic expansion and pressures from one twin placenta may then affect the placental expansion of the other placenta (Thomas, 1961). Such considerations may also relate to the finding that SUA is associated with lower birth weight, as the amount of some placental area would be reduced by the placental atrophy. This concept has been supported by the experimental ligation of one artery in sheep fetuses (Hobel et al., 1970). Bhargava et al. (1971) found a higher frequency of the magistral pattern of chorial blood vessels with SUA, and the vascular pattern of SUA differs from that of cords with fused arteries.

Much has been made of the significance of SUA with respect to other congenital anomalies in the fetus and how seriously one should look for such anomalies. It can now be said that there is no predilection for any specific type of fetal anomaly. Moreover, SUA is often found in perfectly healthy infants who eventually attain normal size and development. Therefore, an extraordinary or invasive study of infants born with SUA is not warranted. To be sure, the pediatrician should be notified of its existence and then should make certain by doing a more detailed physical examination that the infant has no hidden anomalies. We do not perform radiographic or invasive studies.

The SUA is commoner in European whites than in Orientals, in multiple births, in autopsy series (because of associated anomalies), in spontaneous abortions, with other placental anomalies [velamentous cord and chorangioma: 2.70% and 0.65%, respectively (Froehlich & Fujikura, 1966); perhaps circumvallates], and chromosomal errors; it has no familial or genetic tendency. The suggested relation to the development of inguinal hernias has been disputed. Infants with SUA have lower birth weights and are more often prematurely born. When one considers all the details of the enormous study produced by Heifetz (1984), it is apparent that the diagnosis of SUA is usually made at birth and, when found, one proceeds

with cautious further studies in an attempt to find its possible cause and relevance. There is no reason, however, to change our view from that expressed earlier (Benirschke & Driscoll, 1967) that the "indiscriminate association of the absence of one umbilical artery with various and quite diverse chromosomal disorders indicates how limited the placenta is in expressing a variety of constitutional defects." Most likely, SUA is either part of a constellation of multiple anomalies, not its cause, or it develops during pregnancy by atrophy and then it may be the reason for restricted fetal growth (small for gestational age, SGA). The importance of abnormal cord insertion in SUA is borne out, for instance, in the study of Matheus and Sala (1980), who reported an incidence of 0.95%. Of their 42 cases, 11.9% had velamentous insertion, and 33.3% were associated with abnormal fetuses. Kaplan et al. (1990) have suggested that SUA may be associated with cord accidents during labor. They reported on four infants with SUA who died suddenly in utero, presumably because of cord accidents, but these were not growth-restricted because of SUA.

Sireniform fetuses (sympodia) form perhaps a special case of SUA; it is nearly invariably found in this condition. The question posed by this finding is whether the single umbilical artery, arising usually directly from the aorta and immediately distal to the celiac artery, is of enteric (omphalomesenteric, vitelline) nature or whether it is an allantoic vessel, as would be normal for the cord. This anomaly (sympus) has occasionally been referred to as caudal regression syndrome, but this term is inappropriately used; frequently there is no evidence for regression, particularly in the cases that are so descriptive of diabetic embryopathy (Benirschke, 1987). In any event, we have suggested that this vessel "steals" blood from the lower aortic blood flow and is thus responsible for the caudal maldevelopment (Stevenson et al., 1986). The older literature on this topic has been considered in this study of 11 sireniform fetuses. This review and the papers cited by Heifetz (1984) can be consulted when further insight into this phenomenon is desired. The dispute is not totally resolved, however, as studies in mice with this anomaly suggest the vessel to be allantoic in nature; it is thought only to take an abnormal course, with fusion of the two arteries (Schreiner & Hoornbeek, 1973). How complex these embryologic considerations are can be seen in the study by Monie and Khemmani (1973). They induced SUA in rat fetuses with retinoic acid and described the vitello-umbilical anastomosis in the embryos. After due consideration, they could not rule out the occasional existence of such anastomoses in human embryos; it is their opinion, however, that the SUA of symmelia represents a remaining allantoic vessel. These considerations are of interest only in that the view of persisting vitelline vessels would support the notion that, when these vessels become dominant, they can acquire

muscular coats. This is not the case in the usual persistence of omphalomesenteric vessels; they are composed essentially of only endothelium.

More than three umbilical vessels are normal for many species (Benirschke et al., 1964), but this is rare in human umbilical cords. Painter and Russell (1977) described a stillborn with ectopia cordis and other anomalies; there were two umbilical veins, the right umbilical vein having persisted. Hathout (1964) mentioned that one of his cases had five vessels due to "division of both arteries" and one had four and a nodular embryo. One must take care, when assessing an increased number of vessels, not to be misled by the frequent looping that occurs in many cord vessels.

## Placental Transfusion

When the fetus is delivered, the umbilical cord may break by the mechanisms discussed above, and bleeding ceases shortly thereafter. More commonly now, the attending obstetrician clamps the cord. With vaginal deliveries the amount of fetal blood remaining in the placenta is 2.5% of fetal body weight, even with prompt cord ligation. With cesarean section, that figure is 4.5% (Gruenwald, 1969). It has become customary to clamp both sides of the cord, even though the loss of placental fetal blood might be thought irrelevant. One reason for clamping has been the realization that, on occasion, an unrecognized twin may be present; that twin may exsanguinate quickly through inter-twin arterial anastomoses of monochorial placentas. Moreover, the continuous blood issuing from the cut end of the cord is messy. On the other hand, a less turgid, deflated placenta may separate more readily when the uterus contracts.

Walsh (1968) found that postpartum hemorrhage and retained secundines are significantly more common when early clamping is practiced. The amount of fetal blood contained within the placenta varies. It is generally between 50 and 100 mL but is significantly greater in pregnancies of diabetic mothers (Kjeldsen & Pedersen, 1967; Klebe & Ingomar, 1974a,b). Newton and Moody (1961) estimated that 9.4 mL of fetal blood per 100 g of placenta remained after delivery when the cord was ligated immediately, and there were 9.6 mL maternal blood. The latter quantity did not change with delivery and clamping practices. When the cord was ligated after pulsations ceased, only 5 mL fetal blood remained. They estimated that the term neonate may receive as much as 10% of his blood volume (26.6 mL) when cord ligation is delayed and the placental vessels allowed to empty. The presence of fetal blood is what imparts the red color to the villous tissue, not the maternal intervillous blood content. That has largely been squeezed out by uterine contractions.

Numerous studies have been conducted to ascertain whether it is best to allow as much blood to drain from the placenta into the fetus as possible (under the influence of maternal uterine contractions) before the cord is ligated and severed. Vardi (1965) reviewed the older literature and advocated that the delivered placenta be held above the infant but advised against stripping the cord. His studies showed that it is beneficial for the hematologic and iron requirements of the infant to let as much blood drain into the fetus as possible. Yao et al. (1968) found marked hematologic changes with different clamping times, studied up to 3 minutes. They thought that the maximum transfer had taken place by that time. Later, these investigators studied the fetal/placental blood volume changes (Yao et al., 1969). When the cord was clamped within 5 seconds of birth, the infant/placental volume distribution was 67%/33%; by 3 minutes it was 87%/13%. In later studies, which included a complete summary of their findings, Yao and Lind (1974, 1982) evaluated the consequences of cord clamping at various times after birth with respect to the development and behavior of the newborn infant. Special attention was paid to the occasional hypervolemia resulting from late clamping. Their recommendation was that, for vaginal deliveries clamping be done within 30 seconds, provided that the baby is not elevated. With cesarean section, elevation of the infant is to be avoided; and when there is no distress, the cord be handled as for vaginal births.

Fetal-to-maternal red blood cell transfer during labor is not influenced by the timing of cord ligation (Dunn et al., 1966; Moncrieff et al., 1986). An interesting study of residual placental fetal blood content and neonatal outcome was done by Philip et al. (1969). They found that, compared with normal newborns, asphyxiated neonates had already received more blood prenatally, irrespective of postnatal transfusions. There are other complex questions of cord clamping time, for example, the increased frequency of neonatal hyperbilirubinemia with draining of the placental blood into the fetus; but they are beyond the scope of this chapter (see Philip, 1973).

The spontaneous detachment of the umbilicus from the infant is variable, with a mean of 7.4 days according to Oudesluys-Murphy et al. (1987), and 13.9 days as per Novack et al. (1988). Numerous studies have endeavored to ascertain its causes, which remain unresolved, but drying and bacterial colonization have been held responsible. Cesarean section delays it by several days, immature cords separate later than mature ones, and infection may delay separation but does not always do so. Cesarean sectioned infants separated their cord stumps slightly later (Anhalt et al., 1992). It was found by Ronchera-Oms et al. (1994) that bacterial colonization enhances separation, antiseptic therapy prolongs the interval.

## Knots

Excessively long umbilical cords are apt to become knotted. We have seen three true knots in a 76-cm-long cord with which the fetus suffered severe cerebral palsy. He was born without fibrinogen and had widespread petechiae. Much venous distention was evident behind the first knot. Collins (1993; Collins et al., 1993) also described triple knots associated with fetal demise and other cord abnormalities, such as torsion. Knots in the umbilical cord may not only cause fetal death (see Fig. 12.43), but they may lead to significant prepartum hypoxia with lasting damage. A study by Maher and Conti (1996), however, suggested that true knots were not significantly associated with fetal acidemia. These authors also reviewed the controversial aspect of the time when knots are first formed in the umbilical cord.

There are thus some important questions: Does every knot cause some damage (Fig. 12.42)? If not, when are umbilical cord knots clinically significant? Although knots are important clinical findings, with an associated fetal mortality of around 10% (Scheffel & Langanke, 1970), it is surprising how little has been written about them. Perhaps the topic is too obvious to demand the attention of many investigators. Browne (1925) reported that true knots occur with a frequency of 0.4% to 0.5%. He performed perfusion experiments to ascertain the resultant perfusion pressure that presumably follows the presence of knots. The normal pressure in the umbilical vein (10 mm Hg) was raised to 20 mm by one slack knot; two knots raised it to 60 mm. If a weight of 100 g was used to cause increased tension on the one knot, the perfusion pressure was raised to 100 mm. These findings were partially contradicted by the investigations of Chasnoff and Fletcher (1977), who did not find that elevated pressure for perfusion was required when a loose knot was laid; only when more than a 20 g weight was applied did the pressure requirements for perfusion rise markedly. They saw a 0.35% incidence of true knots among 2000 consecutive deliveries: one was stillborn, one had low Apgar scores, five were normal.

The venous stasis that occurs with true knots of the umbilical cord often results in thrombosis of placental surface veins. Mural thrombosis or complete occlusion may be found, some even being calcified. In addition, the veins are frequently thickened and may exhibit "cushions." These frequent lesions have long been recognized and were beautifully depicted by Becker (1962). He inferred that their frequency was related to the unusual construction of the placental vessels, especially their deficiency of an elastic membrane. Therefore, he writes, such lesions develop; but their precise etiology was not demonstrated. De Sa (1973) clearly identified these lesions in surface veins of abnormal placentas in which an "elevation of umbilical venous pressure" must be inferred. These

FIGURE 12.42. Knot in the umbilical cord (actually two loops) that had no untoward sequelae.

are myxoid-appearing, irregular areas of thickening of blood vessels (Fig. 12.44), similar to those that pathologists find in the pulmonary vessels of patients with pulmonary hypertension. Because they are associated with (inferred) venous hypertension and often have mural thrombi overlying them, we believe them to result from blood stasis. They are commonest in placental surface veins, but cushions may also be found in major villous stem vessels. Some of these cushions are undoubtedly organized thrombi; others may merely reflect the reaction of blood vessels to hypertension. We think it likely that cushions form first and then, after much distention and further exposure to elevated pressure, their endothelial surface degenerates and mural thrombosis forms locally (Fig. 12.44). We have also encountered these cushions in vessels of the twin-to-twin transfusion syndrome and

found no fibrin within them; antibodies to actin, myosin heavy chain antigens and collagen IV, as well as vimentin stained them readily, while they lacked endothelial markers (S.C. Emery, personal observations).

Knots cause compression of Wharton's jelly at the site of knotting. When examined microscopically, one often finds mural thrombosis in the vein. Venous distention distal to the knot is a characteristic finding in knots with clinical significance, as is the tendency of the unknotted cord to curl if the knot had been present for some time. Parenthetically, it may be mentioned that stillbirth due to a cord knot has also been recorded in an African green monkey (Brady, 1983). Its cord was unusually long, and there was congestion behind the knot. Chimpanzees and orangutans have also been reported to have true knots in some cords (Naaktgeboren & Wagtendonk, 1966).

FIGURE 12.43. Macerated stillborn fetus. Death was due to a true knot with obstruction of venous return from the placenta 10cm from the abdomen. Total length was 65 cm. Note the marked congestion of the cord distal to the knot.

FIGURE 12.44. Mural thrombi in surface veins of case shown in Figure 12.43. Mural thrombi are shown at sites of marked wall thickening, the cushions. Note pallor of thickened vein wall on right. H&E  $\times 16$ , left; Masson trichrome  $\times 64$ , right.

## False Knots

False knots should not be listed as knots at all. This term has become so customary, however, that it merits brief discussion. One such structure is shown in Figure 12.45. These anomalies are local redundancies of umbilical vessels (mostly the vein), rather than knots, and they are often large. Their vasculature has been depicted by Hyrtl (1870), Arvy and Pilleri (1976a), and others. A rarely used term for these changes is **nodus spuriosus vasculosus**. When an excessive amount of Wharton's jelly is present, the term **nodus spuriosus gelatinosus** has been used. So far as can be determined, these structures have absolutely no clinical importance. Of course, there may be the occa-

sional clot formed in this area, and it is conceivable that they might bleed. Despite their clinical irrelevancy, questions persist just why these redundancies appear at all. What are the forces that regulate the growth of fetal vessels in the first place and do the false knots merely signify a temporal discrepancy of vascular growth with inadequate cord lengthening? Answers to these questions elude us at present.

A completely forgotten notion, the angle of insertion (*Insertionswinkel*) to which Hyrtl (1870) tried to draw attention, suggests that one may infer the position held in utero, and reflecting trophotropic departure of the placenta from its original site of implantation. This angle was between 0 and 90 degrees in the original observations

FIGURE 12.45. False knots, representing vascular redundancies.

and is clearly variable when one examines placentas. Strassmann (1902) regretted that in his studies on placenta previa he failed to take note of this feature, which might have enhanced his conviction of trophotropism.

## Strictures

Significant reductions in the size of the umbilical cord are referred to as stricture, torsion, and coarctation (Figs. 12.46 and 12.47). These abnormalities are not uncommon and are especially frequently found on the abdominal surfaces of macerated fetuses with long, heavily spiraled cords (Benirschke, 1994). Javert and Barton (1952) have also depicted this problem in several of their illustrations. One must assume that the fetus has been so active as to have sheared off the blood supply at the site of torsion. In the first edition of this book we were skeptical about the significance of this lesion and some of the case reports. Since then we have seen many additional cases that have convinced us it is a real phenomenon. One may even see much congestion on one side of the torsion and find thrombi in placental surface veins. Because they are often macerated fetuses, the demonstration of thrombi is hampered. Moreover, coagulation is inadequately developed in embryos. Nevertheless, the constriction near the fetal abdominal surface often shows the vein to be severely compressed. Heifetz (1996) had a different opinion. He argued that strictures at the fetal abdomen were secondary to gradually diminishing Wharton's jelly at that end of the cord, and that they were not the cause of fetal (embryonic) demise. The fact that this lesion is associated with excessively long cords, with heavy spiraling, with frequent placental surface venous thrombi and cushions, makes us believe in the primacy of the constriction as cause of fetal demise. Heifetz points out that the association with many small vessels at the abdominal portion of the cord is a normal feature. These vessels ultimately aid in the healing ("organization") of the cord stump after birth.

A typical case of cord constriction is shown in Figure 12.46, and several authors have provided single and multiple case reports (King, 1926; Weber, 1963; Quinlan, 1965; Virgilio & Spangler, 1978; Robertson et al., 1981; Glanfield & Watson, 1986; Herman et al., 1991; Sun et al., 1995; Masliah & Wahl, 2004). These authors have shown that the phenomenon is not confined to abortions or to the fetal end of the cord. Glanfield and Watson (1986) reported a case with a fresh thrombus at the site of torsion at the twisted placental end of the cord that led to fetal death at 35 weeks of gestation. They also reviewed the sparse literature of this anomaly whose etiology is not known. Nevertheless, Weber (1963) stated that the constriction is rarely reported although it is not uncommon, and described five cases. Dargent et al. (2002) described an interesting arrangement of markedly twisted blood vessels ("cork-

FIGURE 12.46. 12 weeks' gestation fetus with velamentous cord insertion, excessive length and excessive spiraling of the umbilical cord. The fetus died because of the constriction near the fetal end (arrow). This is not due to a deficiency of Wharton's jelly but it is the result of spiraling and consequent dissipation of jelly; it is often inappropriately referred to as "coarctation". This cause of death in abortion specimens is usually overlooked by pathologists.

screw-like twist") in a set of monoamniotic twins. Of course, cord entanglement and often knotting are commonly observed in monoamniotic/monochorionic (MoMo) twins and a cause for their excessive mortality.

Robertson et al. (1981) surmised that the cause of constriction is a primary deficiency of Wharton's jelly, a true coarctation. These investigators lost two fetuses with this lesion soon after amniocentesis. Hersh and Buchino (1988), who observed two successive deaths in one family from torsion of the cord, also believed that primary absence of Wharton's jelly is the cause of this lesion. They had previously seen two similar cases in one family and hinted at the possibility that the recurrence risk is greater than what had been thought. There is normally a gradually

FIGURE 12.47. Both of these two spontaneous abortuses, at 12 and 14 weeks gestation respectively, had markedly spiraled umbilical cords and severe constrictions of the cords (“coarctation”, torsion) near the fetal surfaces that led to their deaths. This is not a deficiency of Wharton’s jelly and it is commonly overlooked by pathologists.

diminishing amount of Wharton’s jelly near the abdominal surface. It may be for this reason that the stricture is most commonly seen at that site. We have had such a case, with a 64-cm umbilical cord in a stillborn; the two umbilical arteries exhibited significant, long-standing degenerative changes at this site. It was the cause of the fetal death. Collins (1995b) proposed severe torsion as a cause of nonimmune hydrops (see also Poeschmann et al., 1991). Colgan and Luk (1982), who reported the death of one MoMo twin from such a torsion, found thrombi in all three vessels at that site. Very frequently, the stricture is associated with an excessively long umbilical cord that is markedly spiraled throughout as well. Again, it is our opinion that the absence of Wharton’s jelly is secondary to being squeezed out by the twisting. Although future studies will have to confirm this assumption, we believe that undue movements of the early fetus lead to the lengthening of the cord and its twisting. Remarkably, the excessive twisting with fetal demise can occur repetitively. Thus, Bakotic et al. (2000) found it in three successive gestations and depict it well. Wiedersberg et al. (2001) found strictures (“thin cord syndrome” they called it) often as cause of fetal demise and abortion. Singh et al. (2003) confirmed this for early abortion specimens. The entire topic has been thoroughly reviewed by Benirschke (1994).

## Rupture

It is not surprising that short cords may avulse from the placenta during descensus, particularly during a precipitous delivery. The cord may rupture completely or partially, and it may bleed or form hematomas. Bahary et al.

(1965) reported a severely anemic newborn whose marginally inserted short cord (24cm) had ruptured during descensus. They believed that velamentous cord insertion was the most frequent antecedent of this complication. Rhen and Kinnunen (1962) lost a fetus with a 50-cm cord before labor due to a ruptured umbilical vein. It occurred spontaneously after tumultuous movements by the fetus. Foldes (1957) reported a stillbirth after rupture in which the normally long cord was wound tightly around the neck. These authors reviewed older literature of this rare event. Bleeding from the injured cord after amniocentesis has been recorded by ultrasonography (Romero et al., 1982); and the development of a cord hematoma following in utero transfusion, with bradycardia secondary to arterial spasm, was observed by Moise et al. (1987).

Such experiences and the question as to how much traction may be applied to the cord during delivery have stimulated systematic studies on the tensile strength of the umbilical cord (e.g., Crichton, 1973). Crichton tested 200 normal term umbilical cords without having their blood drained. He thus obtained a nearly normal distribution of breaking weights. Most cords ruptured when 12 pounds were applied, the extremes being 4 and 24 pounds. There was no correlation with fetal weight, length of cord, or placental weight. Although the cord ruptured most often (22.5%) at the site of its placental attachment, rupture could occur anywhere (Siddall, 1925). It must be said, however, that spontaneous complete rupture is an uncommon event; most ruptures are partial and cause local hematomas or hemorrhage. Leinzinger (1972) reported such a case in association with hydramnios and reviewed the relevant literature, but the case reported by Golden (1973) must not be cited as one of umbilical cord

rupture. In his patient the cord separated when traction was applied to it after the child was delivered; the hematoma was at the site of detachment, and there was an adjacent IUD (Lippe's loop). The photograph he supplied suggests that the cord was either marginal or in a velamentous insertion, a finding that is frequently made when IUDs remain during pregnancy. The IUD was certainly not within the amniotic sac and had nothing directly to do with the traumatic postnatal cord separation. More likely, the cord ruptured through velamentous vessels.

## Hematoma

Hemorrhages into the cord substance are more common than complete rupture, and they may be similarly life-threatening. Figure 12.48 shows such an example, associated with a slightly shorter than average cord (42 cm). It has been conjectured in the past that such hemorrhages occur because of fatty degeneration of the cord (Browne, 1925), but we have not seen such changes. In our experience, spontaneous cord hematomas are associated with short cords, trauma, and with entangling. At times there are associated thrombi. Whichever event is the primary one is then unknown. Vu et al. (1984) reported on five cases; they stated that inflammation eventually occurs when the hemorrhage is not lethal. This finding is also contrary to our experience. Hemorrhage may be recognized sonographically (Sutro et al., 1984) and fetal heart rate problems have been reported with hematomas (Ballas et al., 1985).

It is a common practice for the obstetrician to use a clamp to apply gentle traction to the cord after delivery. This may induce local hematoma formation, and such a history must be ascertained before the diagnosis of spontaneous hematoma is entertained. Hematomas due to cord clamping is often obvious because the serrations of

FIGURE 12.48. Stillbirth because of rupture (hematoma) of a 46-cm-long umbilical cord.

a clamp remain visible. Traumatic injury to cord vessels during amniocentesis has often been reported (James & Nickerson, 1976; Gassner & Paul, 1976; Bobitt, 1979). This potential hazard, when it occurs, demands emergency attention.

Ruvinsky et al. (1981), reviewing the entire literature (57 cases), found that hematomas of the cord are associated with a 50% fetal mortality. They described a case that was diagnosed by at 32 weeks by ultrasonography. The hematoma measured  $6 \times 9 \times 3$  cm and was estimated to contain 100 mL of blood. The cord was 52 cm long and had a ruptured vein from which the sac-like extension of the hematoma took place. The fetus exsanguinated; it did not die from compression of vessels. In the cord shown in Figure 12.49, the aneurysmally distended vein was so huge that the arteries were compressed and the fetus stillborn. Remarkably, the external appearance was not one of

FIGURE 12.49. Aneurysmal dilatation of the umbilical vein with fatal compression of arteries. Stillborn at term after a normal pregnancy and delivery. No cause was identified for this lesion. There were also no thrombi.

hemorrhage. A similar case, but involving the umbilical artery, has been described by Fortune and Östör (1978). It was a 36-week spontaneous intrauterine death. The two umbilical arteries were looped and one had an  $8 \times 3$  cm aneurysmal dilatation that had obstructed the blood flow through the other vessels. There was no thrombosis and no underlying pathology existed. Gerlach (1968) had previously described a cherry-sized aneurysm of the umbilical artery, in its abdominal portion of a child with anomalies. He concluded that it was part of a dysmorphic condition. The wall of that vessel was partially calcified. Two similar cases were described by Rissmann (1931); one was a stillborn, and the other lived. The classical report of cord hematoma is that of Dippel (1940), who found 36 cases. He believed that congenital thinning, fatty and mucoid degeneration of the vein wall, varices, and looping of a long cord are instrumental in the cause. Schreier and Brown (1962) depicted such a defect in the vein of a child who survived a large hematoma. When elastic stains are done on such cords it has been repeatedly found that the elastic fibers of the vein are focally deficient. Remarkably, the infant of the cord shown in Figure 12.50 survived, even though much clotted blood was found in the distorted Wharton's jelly. Although the disruptive lesion is usually located in the vein (Dippel cited a 9:1 ratio), one of the cases described by Gardner and Trussell (1964) involved an artery in a patient who had a prolapsed cord. Other case reports have stressed that the overall mortality rate is around 50%, that hematomas may occur with long and short cords, with and without inflammation, and that their primary cause remains generally unknown (Irani, 1964; Ratten, 1969; Clare et al., 1979; Dillon & O'Leary, 1981; Feldberg et al., 1986). Although funisitis renders the cords generally

slightly more friable (Summerville et al., 1987), it was an infrequent finding. Syphilis, once thought to be a major cause, was specifically ruled out by Dippel (1940), and Fox (1978) also agreed with the unimportant contribution of infection to hematomas. He lamented that the main etiology is usually obscure but considered deficient Wharton's jelly as possibly important, particularly as hematomas are relatively more frequent in prolonged pregnancy. We have seen one case of cord hematoma with fatal prenatal myocardial infarct of the fetus. Aneurysms of cord and placental surface vessels are considered below. Cordocentesis may lead to hemorrhage into the umbilical cord as well (see above). In a case we saw, the umbilical artery had been aspirated at cordocentesis for presumed thrombocytopenia with thrombosis ensuing. The artery had become completely obliterated and its wall was necrotic. Hemosiderin-laden macrophages were adjacent to the hemolyzing blood in this artery. The neonate suffered cerebral palsy. In another case, spontaneous thrombosis of one umbilical artery, with necrosis of its wall, was accompanied by a longitudinal hematoma-like streak of hemolysis in Wharton's jelly. The fetus had exhibited decreased reactivity and reduced movements, but survived. The villous tissue showed chorangiosis, and many nucleated red blood cells were present in fetal vessels.

Several investigators have attempted ultrastructural delineation of the vessels' unusual structure. We once saw an apparently normal umbilical artery that had two well-defined lumens. Spiteri et al. (1966) were anxious to state that there was no sign of senescence in term arteries when they were compared with those of 7-week-old fetuses. This finding is in contrast to the expected degenerative changes seen in the aging intraabdominal portions of the umbilical arteries (Takagi et al., 1984).

FIGURE 12.50. Large, 90-cm-long umbilical cord with hematoma and surviving 5300-g infant. Despite the large hematoma, the vascular lumens were patent and had no thrombus, as also described by Bret and Bardiaux (1956).

Vascular structure and changes induced in the umbilical vein by maternal smoking were investigated by Asmussen (1978). These studies showed damage to the intima, elastic subintimal membrane, and media. There are also edema, deficiency of collagen, and myocyte proliferation. A peculiar feature of these large and thick umbilical vessels is that they allow penetration of many polymorphonuclear leukocytes in the usual inflammatory reaction of the amnionic sac infection syndrome. This trait is so striking and so different from other vessels that it is discussed in more detail in the consideration of chorioamnionitis. It may be related to the absence of a true adventitia, as it is seen in systemic blood vessels. Moreover, in the umbilical cord, the extensions of Wharton's jelly penetrate in the muscular walls of the arteries and vein, which may enhance transport of signals, such as leukotaxins.

## Varices and Aneurysms

As happens with umbilical cords, surface vessels may have aneurysms that can bleed, thrombose, and rupture (Fig. 12.51). Six such placentas with subamniotic hemorrhages from partially thrombosed chorionic vessels were described by de Sa (1971). He made the point that such thrombi are often associated with fetal growth retardation, diabetes, diffuse thromboses, and organized clots. These lesions must be differentiated from tears induced during delivery. It must also be cautioned that the obstetrician and neonatologist often draw blood from the chorionic vessels after birth, and the vessels may subsequently leak blood. Thus, when a pathologist observes these surface hematomas, he or she must make sure that they are not artifacts of handling. Varices must not be confused with hemorrhagic subchorial cysts originating from degenerating trophoblastic cell islands. Note,

however, that a number of cases have been described that are difficult to trace. They are instances where blood was found in the amniotic space and in which subamniotic hemorrhages had occurred before birth. They originated from small lesions in vessels that could be demonstrated only by an injection study (Gad, 1968). Their etiology was often obscure. Such a case was reported by Leff (1931). The most detailed study of placental aneurysms derived from the examination of 1000 consecutive placentas reported by Lemtis (1968), whose article was accompanied by exemplary photographs. Lemtis found these lesions in 24 cases, one of which was a partial hydatidiform mole that had numerous aneurysms. Lemtis classified the anomalies into several types. The aneurysms were usually associated with atypical insertion of the cord, SUA, fetal growth retardation, or other placental anomalies; therefore, Lemtis considered them to be true developmental errors. In a set of dizygotic twins we saw, one twin's placenta had two chorionic venous aneurysms. This twin expired from completely spontaneous rupture during labor. Because rupture and exsanguination have been reported only during labor, it is our conviction that the aforementioned distention of the surface half of chorionic vessels after membrane rupture leads to this thinning and the vulnerability of potential aneurysms. Other large aneurysms we have seen have been described as "cirroid." They were huge dilatations of surface vessels, often partially thrombosed and associated with thrombocytopenia of the neonate. A relevant case of cirroid or serpentine aneurysm has been described by us (Zhang & Benirschke, 2000). Characteristically, there were many thrombi and some infarction with this anomaly. In one such case, the subjacent main stem vessels had a mole-like myxoid distention. Similarly, Lee et al. (1991) described a huge placenta (1490g) with a typical cirroid angiomatous configuration that arose from the umbilical vein of an otherwise normal cord. The umbilical cord of

FIGURE 12.52. Multiple aneurysms of the umbilical cord associated with a single umbilical artery. The child was well at 3 years. (Courtesy of R.E. Wybel, Bakersfield, California.)

this growth-restricted neonate had a membranous insertion. The infant was anemic and did well after transfusion. Some of the veins had massive aneurysmal dilatation but lacked thrombotic deposits. The so-called mesenchymal dysplasia that is frequently associated with cirroid aneurysms and chorangiomas is discussed in greater detail in Chapter 24. Siddiqi and colleagues (1992) described a classic umbilical arterial aneurysm in a two-vessel cord. It was noted to grow in repeated sonographic studies and had a partially calcified wall. It measured  $13 \times 5$  cm and was 15 cm from the fetus; although it had no thrombus, the cardiac hypertrophy found in the stillborn infant suggested that it had circulatory consequences. Reinhardt et al. (1999) described sonographic findings with mural thrombosis of subchorionic aneurysms that could be confused with chorangiomas. Vandevijver et al. (2000) lost an infant during labor at 41 weeks due to a large aneurysm of the umbilical vein and deduced that excessive thinning (absence of muscle) was the cause of the aneurysm.

Varicosities in the umbilical cord are much more common than aneurysms. An example is illustrated in Figure 12.45. Real varix formations, such as are seen in Figures 12.52 and 12.53 are rare. A case was described by Leinzinger (1969), who also reviewed the sparse literature. Leinzinger observed during a normal delivery a 70-cm-long umbilical cord that had a peach-sized varix of the umbilical vein that was largely thrombosed. He drew attention to the focally marked thinning of the wall of the umbilical vein. This has also been reported to be associated with necrosis of muscle wall and has attracted greater interest recently (Qureshi & Jacques, 1994). Altshuler and Hyde (1989) first depicted necrosis of umbilical vessel walls and suggested that it is the occasional result of chronic and severe meconium exposure. These authors also demonstrated, *in vitro*, that meconium may induce a significant contraction when strips of umbilical vein are exposed to solutions of meconium. The vasoconstrictive effect of cholic acids was later confirmed when Sepúlveda et al. (1991) experimentally exposed chorionic surface vein samples to these agents. Their interest derived from the poor fetal outcomes in the condition known as cholestasis of pregnancy (Laatikainen et al., 1978). Bile aci-

demia for other reasons than cholestasis of pregnancy is thought to have similar consequences (Nolan et al., 1994). Figure 12.54 shows a somewhat similar thinning of the vein wall as described by Altshuler and Hyde in a child with cerebral palsy. Note that this thinning did not take place in a varix; there is no thrombus, nor is the thinned wall toward the cord surface, which might be expected if mechanical pressure had been the cause of this marked diminution in vessel wall thickness. Such areas of degeneration not only occur in the vein but also may affect arteries for still unknown reasons. To be sure, on occasion they are the sequelae of thrombosis, but they may occur without it. It may also be that constriction is mediated by interleukin-1, as demonstrated to occur in meconium staining (Baergen et al., 1994). Within the stillborn whose umbilical artery is shown in Figure 12.55, a thin segment of artery had numerous rounded, degenerating myocytes. This process was confined to only one artery, it lay under the cord surface, and there was mild phlebitis. The short cord was loosely wound around the neck, but no reason-

FIGURE 12.53. Partially thrombosed varix near the fetal end of the cord. Normal infant, 65-cm-long cord.

FIGURE 12.54. Segmental thinning toward the middle of the cord in an umbilical vein (arrows). The child suffered cerebral palsy. A cause for this anomaly was not detected. H&E  $\times 60$ , left;  $\times 160$ , right.

able cause of the lesion was identified. Similar hypoplasia of segments of umbilical vessels, usually veins, has been reported a few times in the literature. It is usually associated with rupture of the cord or hematomas (Bender et al., 1978). Severe venous distention of the umbilical vein, detected sonographically, has been used as an indicator of severe hemolytic disease in the fetus (DeVore et al., 1981). In recent years, there have been many reports of umbilical arterial necrosis associated with meconium staining in which the meconium toxicity is held responsible, even though the exact toxic moiety of this material

is unknown (see Chapter 11). Bendon et al. (1991) described such necrosis with ulceration in association with intestinal atresia and suggested this to be a new syndrome. Similarly, Khurana (1995) found duodenal atresia in a fetus with ulcerated umbilical arteries. The amniotic fluid was bloody at the time of delivery, at 35 weeks' gestation. The neonate died with numerous infarctive lesions. Because the duodenum had two areas of obliteration, the only explanation for meconium-induced arterial wall degeneration would be prenatal bilious vomiting had occurred.

FIGURE 12.55. Segmental thinning of one umbilical arterial wall with degenerating rounded myocytes (arrows) under the surface. Stillborn infant, short nuchal cord. H&E  $\times 60$ , left;  $\times 160$ , right.

## Thrombosis of the Umbilical Vessels

Thrombi of vessels in the umbilical cord are common, and they occur most often in surface veins. They may take place already during early pregnancy and then lead to SUA; but this is not very likely because of the difficulty in fetal clotting during early pregnancy. More frequently, thrombi occur near term. The formation of thrombi with velamentous insertion of the cord is readily understandable. Here the membranous vessels course in the chorion, unprotected by Wharton's jelly; they are thus prone to injury from compression and are also subject to tears. Neonatal thrombocytopenia and bruising has been witnessed on several such occasions.

Severe inflammatory reactions of the cord often cause mural thrombi as well. Such a case with a surviving, bruised infant has been described by Wolfman et al. (1983). The umbilical vein of this premature infant of an otherwise uncomplicated pregnancy was inflamed and nearly completely thrombosed. In addition, there was one peculiar lesion of the cord with old inflammatory exudate surrounding the vessels. These lesions are often calcified, and macroscopically resemble the precipitation ring in Ouchterlony plates. This unusual entity is further discussed in Chapter 20. Thrombi are frequent in this condition.

It is also easy to understand that thrombosis of cord vessels may occur in varices (Figs. 12.53 and 12.56), and from looping and knotting of the umbilical cord. Likewise, the entangling of cords in monoamniotic twins, with vascular obstruction ensuing, and that from amniotic bands are mechanical reasons for thrombosis. Thrombosis has also followed intravascular exchange transfusion and was there associated with an intrafunicular hematoma (Seeds et al., 1989). These situations can all compromise the circulation and lead to fetal death, and experimentally, cord occlusion in fetal lambs has been shown to cause neuropathologic changes (Ikeda et al.,

1998). The thrombi may break off and potentially embolize to the fetus or to the placenta, where they may cause infarction. Thrombosis can become so extensive that they so compromise the circulation and lead to fetal death. Myocardial infarction with prenatal tamponade has been reported from embolism (Wolf et al., 1985).

Thrombi have been held responsible for amputations (Hoyme et al., 1982) and for a generalized bleeding tendency due to disseminated intravascular coagulation (DIC) or consumption coagulopathy (Williams & Benirschke, 1978). More remarkable are the thrombi that occur in the absence of all of these more readily understood complications, and they are perhaps the most common. We have seen many such cases that resulted in fetal death, and others in children who developed cerebral palsy. In retrospect, there is often no good explanation for their genesis (Fig. 12.57). There are numerous case reports on the subject; often the pathologist is unable to explain the origin of thrombi. Very frequently thromboses of vessels in the cord are associated with similar events in the villous ramifications. From finding occasionally deposits of calcium salts in such vessel walls, and because of the apparent organization of these thrombosed vessels, it must be inferred that the clots have been present for days, if not weeks. Doshi and Klionsky (1979) also found it to be a frequent problem in severely ill newborns. They described 40 cases of DIC with thromboses in placental vessels, at least six of which had a prenatal onset. Coagulation problems caused by activated protein C resistance (factor V Leiden mutation) or S deficiency are sometimes suspected (Kraus, 1996), but they have only recently been proved to exist. The cases of Seligsohn et al. (1984) and Marcianiak et al. (1985) of familial protein C deficiency supported this notion. The neonatal purpura fulminans of protein C deficiency was reviewed by Dreyfus et al. (1991) and depicted by Hartman et al. (1990). In these pedigrees, prenatal thrombosis was not reported, although the condition at birth is summarized

FIGURE 12.56. Partially calcified vessel walls (arrows) in the cord of a stillborn. Cord also had varices but no inflammation. H&E  $\times 60$ .

FIGURE 12.57. Nearly occlusive venous thrombus with fetal death. Long cord. H&E  $\times 40$ .

by the latter authors. In three cases of neonatal CNS disorders, Thorarensen et al. (1997) found thrombosis because of inherited Leiden heterozygosity. One of these infants had placental multiple thromboses, was born with seizures and had extensive CNS lesions. DNA analysis on the infant showed it to possess the mutation. Because factor V Leiden mutation is now recognized as perhaps the most important cause of familial thrombophilia, future placental vascular disease needs to be studied with this in mind (see Chapter 21). The possibility of making the genetic diagnosis of a factor V Leiden mutation was demonstrated by Newman et al. (1998). They purified DNA from paraffin blocks of a neonate dying with aortic thrombosis and unequivocally diagnosed the mutation. Maternal thrombotic events have also often been ascribed to activated protein-C resistance, as by Rotmensch et al. (1997), who found extremely poor obstetric outcomes. It must be appreciated, however, that normally pregnancy is associated with an increase in activated protein-C resistance (Walker et al., 1997). One case of protein-S deficiency in pregnancy has been reported (Tharakan et al., 1993). The pregnancy of this patient ended in a stillbirth with placental vascular thrombosis and the patient had a pulmonary embolus. After anticoagulation, she had a successful pregnancy. Unfortunately, the state of the placenta in each of these four newborns with massive venous thrombosis and fulminant purpura developing shortly after birth was not reported. Heifetz (1988) has reviewed three patient populations, in addition to 68 cases gathered from the literature. The incidence of thrombosis was 1 in 1300 deliveries, 1 in 1000 perinatal autopsies, and 1 in 250 high-risk gestations. Venous thromboses were more common than thromboses in one or both arteries, but the latter was more often lethal.

Protein C deficiency was found to be associated with the 11 neonatal cases reported by Marco-Johnson et al. (1988). They established that the protein C levels are very low in newborns, and that an inherited deficiency to explain neonatal thrombosis must be carefully docu-

mented. The relatives of their patients were not heterozygotes and, after successful therapy with heparin in four patients, their protein C levels gradually rose to normal. Five of their patients were one of twins; one of these twins was the recipient of the transfusion syndrome and the co-twin had died at birth; one patient had a diabetic mother. Four infants had aortic thromboses (one also had renal thrombosis), and one had CNS thrombosis. The mechanism of this presumably acquired absence of protein C in these neonates remained unknown, and the placentas were not described.

In two other cases of arterial thrombosis we have witnessed, one umbilical artery had a completely necrotic wall, and many thrombi were found in the fetal chorionic vascular ramifications. One child died during the neonatal period with prenatal thrombosis of one pulmonary artery and an infarcted lung; the other survived but developed severe cerebral palsy. Maternal diabetes, which is occasionally associated with thromboses, was not present, and no other morphologic or clinical features helped to explain the cause of this fetal vascular coagulation.

It is often desirable to estimate the age of the thrombi. When calcification accompanies them, they are clearly old; for younger clots, the table derived from the detailed investigations on aging of thrombi by Leu and Leu (1989) is helpful.

There was such massive calcification in the walls of some umbilical cord blood vessels in a few cases (Rust, 1937; Walz, 1947; Perrin & Bel, 1965; Pekarske, 1995) that it occasionally became difficult to ligate the cord (Fig. 12.56). Two of these infants survived. In others, the calcification affected fetal arteries with lethal consequences (Ivemark et al., 1962). Schiff et al. (1976) were the first to recognize a calcified cord antenatally. The three vessels were calcified virtually over the entire length of the cord and attended by much inflammation; the neonate died with pulmonary hypoplasia. There are some reports of venous thrombosis associated with severe fetal distress (Eggens & Bruins, 1984), cerebral palsy, massive fetoma-

ternal hemorrhage (Hoag, 1986), and other complications. Occasionally, maternal smoking and diabetes have been implicated. Abrams et al. (1985) were able to make the diagnosis by sonography, and there are many other case reports, too numerous to list, that attest to thromboses as being an important problem in perinatology. It stands to reason that such occlusions, particularly when associated with villous vascular disease, raise fetal blood pressure and, like the experimental obliteration of placental vessels by microembolization (Trudinger et al., 1987), they may have abnormal sonographic consequences. Thrombi may also lead to fetal growth restriction. In an occasional case, one may observe strange phenomena that clearly betray long-standing prenatal problems, as shown later in Figure 12.63. Here, the cord of an infant with renal agenesis can be seen to be unusually long (77 cm) for an oligohydramneic pregnancy (Fig. 12.58). The placenta had many thrombi in its surface vessels, and the partially calcified umbilical vein had ruptured. Squamous debris (vernix caseosa) had dissected underneath the cord surface, all of which suggested that the process had been ongoing for weeks prior to delivery. Parenthetically, it may be mentioned that fatal air embolization has been reported when, during cesarean section, the placenta had to be incised (Allen et al., 1969). In addition, the frequent amnion nodosum of the placental surface seen in renal agenesis or in other causes of severe oligohydramnios is rarely present on the cord's surface.

Khong and Dilly (1989) reviewed the topic of the rare calcifications in umbilical arteries and presented five new cases. These authors were of the opinion that the calcifications fall into two classes: those with calcific thrombi, and those with evidence of funisitis, inflammation of the

amniotic sac, or both. They described two complete thromboses of one artery with calcification. In one, the mother had a lupus-like disease and there was 20% infarction of the placenta, with a liveborn at 35 weeks. In the other, a mother with a skin rash at 28 weeks' gestation gave birth to a severely growth-retarded (940 g) macerated fetus at 34 weeks with apparent amniotic bands, with amputations and cord constriction. The other three cases (one living) had associated inflammation without recognized microorganisms.

## Thrombosis of the Placental Vascular Tree

Mural and occlusive thrombi occur frequently in the superficial placental vessels and their villous ramifications. They are variably located across the fetal surface and within the placenta, and only occasionally are they accompanied by thrombi in the umbilical cord. Often these vascular occlusions have grave consequences. Surface thrombi are usually recognized during careful gross examination. When the vessel is hugely distended, as that shown in Figure 12.59A, the identification of thrombosis is easy. Much more frequently overlooked are such thrombi as seen in Figures 12.60 and 12.61. When thrombi are fresh, their gross appearance is that of a slightly enlarged vessel that may have an unusual color. It is not so shiny and blue as normal vessels. One is also unable to move the blood mechanically in thrombosed vessels and of course histologically they are easily diagnosed (Fig. 12.62). Older thrombi become white or yellow.

Mural thrombosis is much more frequent than complete obliteration of the vessel. Such thromboses often

FIGURE 12.58. Umbilical cord (77 cm) in renal agenesis with partial calcification of the vein wall (left, arrows) and vernix dissection (right, arrows). H&E  $\times 160$ .

FIGURE 12.59. A: Varix in a surface chorionic vein branch (arrow) and hugely distended, thrombosed umbilical vein tributary (at right). Neonatal death with umbilical vein thrombosis,

renal necrosis, and possible maternal diabetes. B: The layered thrombi are apparent in the cross sections.

calcify (Fig. 12.63) but variations are frequent; and when thrombosis has occurred a long time before examination, the vessel may obliterate completely. It then appears as a fibrous strand that may be difficult to recognize as once having been a vessel. We have seen such thrombi in placentas of trisomy 18 and associated with cytomegalovirus infection, excessively long cords with and without excessive spiraling, cord knots, velamentous cord insertion, amputation necrosis in the fetus, severe chorioamnionitis, neonatal purpura, generalized fetal thrombosis, and many other conditions. They are not rare events and clearly bespeak a pathologic prenatal environment. They may occur in arteries as well as (more commonly) in veins, and the vascular wall may show various stages of degeneration or calcification. Thrombi are generally not

FIGURE 12.63. Unexplained thrombus with partial calcification (right margin) of surface vein in a stillborn infant. H&E  $\times 26$ .

a cause of local inflammation. The topic has been discussed extensively in a study of umbilical cord lesions (Benirschke, 1994).

Similar thrombosis of the further ramifications of the vascular tree exist (Fig. 12.64). If the thrombi have been occlusive for a prolonged time, the entire villous tree may

FIGURE 12.64. Muscular hypertrophy and old occlusions in several of many stem vessels of a child with unexplained mid-forearm amputation. H&E  $\times 260$ .

become avascular and atrophy, undergo fibrosis (Fig. 12.65). It does not infarct; true infarction of villous tissue occurs only when the maternal blood supply is interrupted. The villous tissue merely atrophies over time. Localized thrombosis with early blanching of the affected villous district has been well illustrated by Fox (1966).

In the blood of neonates whose placental vessels had thrombi, one may detect schistocytes and find hematologic derangements such as fibrinogen and platelet deficiencies. Kristiansen and Nielsen (1985) described three cases with fatal thromboses; they concluded that, most often, mechanical factors are the cause. The relation of thrombi to fetal deaths was evaluated by Cook et al. (1987). They found thrombi in 98% of fetal deaths, which is much in excess of our observations; moreover, we disagree with their interpretation of organization of the thrombotic material. In fact, true organization of dead tissues, as the pathologist knows it from renal or splenic infarcts, is rare in all placental degenerative lesions. That is, removal of debris by phagocytes and the ingrowth of granulation tissue with fibrous tissue substitution are phenomena not seen in true placental infarcts, nor do they occur in thrombosed placental vessels. Rather, these lesions shrink, and some phagocytes may appear; but eventually they either become calcified (Pekarske, 1995), or the vessel atrophies. It may eventually disappear completely, becoming unrecognizable as having been a vessel.

As indicated, thromboses extend occasionally into the major ramifications of villous vessels. They may be occlusive; their walls and the extensions of Wharton's jelly may calcify also. When many placentas are examined histologically, one finds these lesions more often than they are suspected macroscopically. They are not always associated with recognizable surface thrombi (Fig. 12.66), and often the etiology of the lesions remains unknown. They are frequently associated with fetal growth restriction,

intrauterine demise, and occasionally with neonatal coagulation disorders. When associated with excessively long cords, Boué et al. (1995) found occasional cerebral degenerative changes, and Kraus (1997) has drawn attention to its frequent relevance in medicolegal cases. We have speculated that they may be the result of prenatal insults, such as virus infections or perhaps even trauma due to fetal motions, but the etiology remains often obscure. Cytomegalovirus infection is definitely an occasional cause of these vascular calcifications. It is common to find occlusions of placental vessels with stillborns but to differentiate thrombi from autolytic degeneration may be difficult. Caution must be exercised when these large stem villi are evaluated. Collagenous trabeculae therein have much the same appearance as old occlusive thrombi.

Obliterative vascular changes were probably first described by Merttens (1894). They have since been discussed at length by Becker and Dolling (1965), who believed them to be the sequelae of infections in earlier fetal life. These authors found neovascularization and other phenomena that they thought to be indications of organization. The former notion of a syphilitic endovasculitis as the etiology was negated. Other authors cited by these investigators and by Fox (1966) found such vascular obliterations unduly commonly in diabetic pregnancies, 3.6% single arterial stem thrombi in liveborn infants. Fox (1966) also observed them much more commonly in the placentas of stillborns.

Apparently dissatisfied with the varied literature of this topic, Fox (1967) studied fetal stem arteries from 682 placentas, 36 of which were from stillbirths. He observed three lesions: obliterative endarteritis, fibromuscular sclerosis, and thrombosis. These lesions were common in patients with diabetes (23%) and hypertension (about 30%). From a comparison of material from live and dead infants he asserted that the "sclerosis" of vessel walls was a postmortem change. Similar vascular changes were held

FIGURE 12.65. Diffuse atrophy (degeneration and disappearance) of villous vessels in a placenta with extensive surface thromboses. Fetal growth retardation was evident, and the infant had low Apgar scores. H&E  $\times 60$ .

FIGURE 12.66. Composite of cases with villous stem vascular lesions. A: Growth retardation, wavy ribs, 29 weeks' gestation. B: Neonate with phocomelia. C: Growth retardation, purpura,

pulmonary hypoplasia, degenerations in several organs, neonatal death. All have calcified deposits in stem vessel walls, and some have thrombi or muscular lesions. H&E  $\times 60$ .

to be of postmortem nature by Theuring (1968) in his study of placentas from stillborns. He considered that the placenta continues to live after fetal death and that the vessels live in a tissue-culture-like environment to attain such occlusions. The longer the fetal death, the more extensive the occlusions. A similar position was taken by Altemani (1987) who concluded that, because the placental perfusion after fetal death keeps the tissue alive, many of the vascular occlusions seen in stillborns were of post-mortem origin. He believed that true organization occurs in these vessels and alluded to the relation of vascular occlusions to hemorrhagic endovascularitis (HEV). The vascular changes found in diabetics were discussed by Fox (1967) and thought to be true *in vivo* lesions, as had been suggested by Fujikura and Benson (1964) earlier, an observation that was supported by others. Dolff (1978) studied the phenomenon in serial sections, mostly in placentas of stillborn infants. Having duly considered the two principal theories (postnatal change versus prenatal endarteritis obliterans), Dolff came to the conclusion that (1) this lesion is an *in vivo* phenomenon of importance, and (2) the dynamics that lead to recanalization of the affected vessels is the function of the paracapillary network of the placental stem vessels. Altemani and Lopes de Faria (1987) made a thorough study of the muscular and endothelial changes of main stem blood vessels in 50 stillborns and 50 controls. In their opinion,

the occlusive changes seen were mostly a postmortem phenomenon that was not the cause of fetal demise. Becker and Röckelein (1989) saw in the endarteritis obliterans a common end stage of infections (syphilis, rubella) but also believed that diabetes and preeclampsia have pathogenic importance. In our view this vascular lesion of main stem villous vessels is not a true inflammation, but results most often from thrombosis of more proximal vessels or occasionally represents a postmortem phenomenon. Fok et al. (1990) and other authors (reviewed by Divon, 1996) correlated abnormal Doppler velocimetry studies with occlusive or constrictive placental stem villous arterial lesions. Growth restriction was commonly found. Hitschold (1998) now found that Doppler flow velocity of umbilical arteries accurately correlates with intravillous blood volume in term gestations. In his study of postmortem changes of the placenta, Genest (1992) was able to time the vascular events and confirmed that most endothelial abnormalities occurred after fetal death. Karyorrhexis of villous capillaries occurred in 6 hours, stem villus vascular septation and complete obliteration took 2 days or longer, and fibrosis of terminal villi took weeks to occur.

Such studies have recently become more interesting as prenatal Doppler studies identify frequently abnormal fetal blood flow and correlations are sought to endothelial damage of placental vessels. Thus, Wang et al. (2002,

2003) have obtained plasma from such abnormal fetuses and exposed a culture of fetal endothelial cells to this medium. They found that there was a significant increase in endothelial cell apoptosis due to fetal cytokines apparently released with the abnormal Doppler findings. Importantly, this was independent of maternal preeclampsia that did not have this effect. This is relevant because Trollmann et al. (2003) have demonstrated upregulation of the fetal vascular endothelial growth factor in preeclampsia, speculating that it may be a “potential early indicator of severe birth asphyxia.” It is further relevant because fetal villous obliteration and capillary thromboses are by some considered to be indicators of sequelae of “poor maternal intervillous perfusion.”

These considerations are important because the entity “hemorrhagic endovasculitis” (Sander, 1980) has aroused so much controversy. Briefly stated, this concept evolved from the study of many formalin-fixed placentas seen in a registry of placentas collected from perinatal deaths and infants with perinatal problems. It was hypothesized that HEV may play an important role in the etiology of these tragedies and that it may be caused by a specific viral or other infectious agent. Hemosiderin was found in some cases to indicate the presumed antiquity of the lesion. HEV is not one lesion; it is a microangiopathy that etiologically and pathologically resembles the glomerulopathy of the hemolytic uremic syndrome. A proliferative, inflammatory vasculitis is not present. The pathologic changes consist in endothelial degeneration, thrombosis, and diapedesis of red blood cells (Fig. 12.67). Stevens and Sander (1984) found HEV to be present in 52% of stillborns and in 22% of liveborn infants. They found associations with preeclampsia, prolonged pregnancy, meconium staining, and with growth retardation. In a later study,

Sander et al. (1997) described recurrence in 28% of subsequent pregnancies. Other investigators (Shen-Schwarz et al., 1986, 1988) found a much lower incidence of this lesion (0.67% after 20 weeks), and associated it with nuchal cords, meconium staining, and postmaturity. Many of these associations did not involve infection, and many infants survived. Also, ultrastructural investigations have not shown organisms. Therefore, the etiology must be considered to include hypoxia, acidosis, and perhaps the DIC associated with the Schwartzman phenomenon.

M.M. Silver et al. (1987, 1988) have done a complete analysis of HEV and confirmed the findings of Ornoy et al. (1976) that the fetal vascular occlusions are most frequently seen in the placentas of macerated stillborns. They presumed it to be a postmortem development. For that reason, they cultured villous tissue in vitro and sampled it at regular intervals for light and electron-microscopic study. They saw a similar lesion develop, in time, when organ explants were allowed to degenerate, thus confirming their original assumption. They believed that it is the sequela of focal or uniform postmortem autolysis of vessel walls. Our own assessment is that HEV is not a specific entity. Clearly, thrombotic lesions of villous stem vessels occur, and often they are associated with cord lesions and surface thrombi. They can be seen in a variety of clinical circumstances, as we have indicated. The occlusion of vessels after death, however, so much mimic degenerative lesions that they may be over-interpreted. Moreover, we now believe the vascular anomaly (proliferation of vessels in an abortus) shown in their Figure 276 (Benirschke & Driscoll, 1967), to be a typical, albeit unusual postmortem phenomenon. In short, although HEV does exist, it does not represent a specific disease entity.

## Tumors of the Umbilical Cord

Aside from the tumor-like swellings of aneurysms discussed above, only two true tumors occur in the umbilical cord: angiomas of great variety and significance and, much more rarely, teratomas.

As early as 1939 Marchetti was able to summarize 209 cases of placental angioma (chorangioma) and added eight cases of his own, and Fortune and Östör (1980) summarized 58 cases. A cord angioma was not among this large group. Frequently, the fetus dies when large tumors exist in the cord; hemangiomas or other anomalies may coexist in the fetus (Barry et al., 1951; Corkill, 1961). Some authors have found myxoma-like Wharton's jelly in such tumors (Benirschke & Dodds, 1967; Fortune & Östör, 1980), or have interpreted them to be hamartomas. These neoplasms are never malignant and have a uniform appearance (Figs. 12.68 and 12.69). Death often occurs because of obstruction of blood flow. Occasionally, an associated atrophic artery signifies their long existence before birth. Heifetz and Rueda-Pedreza (1983b) have summarized much of the literature; they noted that angiomas tend to occur at the placental end of the cord and arise from one or more umbilical vessels. Unlike chorangiomas, angiomas of the cord are also usually not associated with hydramnios. Thus, the large angioma described by Barents (1953) was not associated with hydramnios and resulted in a normal infant. Mishriki et al. (1987) described an exception.

Resta et al. (1988) have described an angioma of the cord in association with extremely high (887 to 1030 IU/mL)  $\alpha$ -fetoprotein (AFP) levels in the maternal serum at 16 weeks' gestation. The lesion was unsuccessfully biopsied, and the fetus died 1 week later. A  $3.2 \times 1.8 \times 2.0$  cm angioma was found, in addition to severe narrowing of the cord at the fetal end. Resta et al. found 22 cases of

funicular angioma in the literature. Transplacental bleeding was excluded as possibly accounting for this 30-fold elevation. The neoplasms may attain rather large size, such as the  $9 \times 7 \times 6$  cm lesion found by Nieder and Link (1970) or that reported by Yavner and Redline (1989). The angiomyxoma of theirs was associated with a slightly elevated AFP level and was diagnosed sonographically at 19 weeks' gestation. The infant was delivered at 38 weeks and was normal. The large tumor ( $5.0 \times 9.5$  cm, 900 g) included a large cystic mass. Its location was typically near the fetal end of the cord. Other large tumors have been diagnosed prenatally. A cord angioma measuring 18 cm in length and associated with a cord that measured 9 cm in width was responsible for nonimmune hydrops of one of dichorionic twins successfully treated during the neonatal period and reported by Seifert et al. (1985). These authors postulated that the cause of the nonimmune hydrops was high-output cardiac failure. Dombrowski et al. (1987) reported a case of severe fetal hemorrhage from the angiomatous cord. Interestingly, this specimen also had intestinal epithelium on the cord's surface. Another case of cystic angiomyxoma reported by Wilson et al. (1994) was followed sonographically during pregnancy and decompressed prior to delivery. At 36 weeks, 350 mL fluid were aspirated from the cyst, decreasing its volume by one half. When the mass increased in size again, delivery was accomplished with good outcome. The angioma was 14 cm in greatest diameter with a 5-cm solid component and was located near the fetal end of the 39-cm-long umbilical cord. An unusual arteriovenous malformation of the umbilical cord was diagnosed sonographically in the distal end (5 cm) of a fetus by Richards et al. (1995). Funipuncture allowed the diagnosis of fetal DIC with low hematocrit due to hemolytic anemia. The neonate was appropriately treated and did well; there was, however, an echogenic hepatic focus associated with

FIGURE 12.68. Angioma at the insertion of the cord in one of twins.

FIGURE 12.69. Histologic appearance of a hemangioma of the umbilical cord. H&E  $\times 20$ . (Source: Benirschke & Dodds, 1967, with permission.)

umbilical vein thrombosis. The angiomatous mass had areas of thrombosis and calcification.

Teratomas are much less common than angiomas. Browne (1925) discussed the semantics of teratoma and dermoid. He reported one teratoma and one dermoid, with an anencephalic fetus. Smith and Majmudar (1985) presented a case of a term fetus with bladder exstrophy who also had a pendulous  $1.8 \times 0.6$  cm tumor that was 30 cm from the placental surface. It was focally calcified and contained skin with appendages, colonic epithelium, smooth muscle, and connective tissue. The authors found four previously reported cases in the literature, and six cases in which the lesions were located on the placental surface, the largest measuring 7.5 cm. All were benign. Kreczy and colleagues (1994) reported another case and reviewed the sparse literature of cord teratomas. Their 210-g skin-covered tumor was attached to the cord 2 cm from the neonate's abdominal surface, which also had an omphalocele. The authors discussed the difficult differential diagnosis, especially the distinction from acardiac twins. They came to the conclusion that, lacking a skeletal axis, their lesion represented a true tumor.

One still wonders if these teratomas represent variations of acardiac twins. The latter, however, usually have some longitudinal differentiation and should have their own, separate umbilical cords. Nevertheless, the possibility that teratomas of the cord may represent a form of acardiac fetus has been considered by several authors. Thus, Kreyberg (1958) observed a stillborn premature infant with a 36-cm cord that had, 16 cm from its insertion, a bulky tumor with cystic cavities and a variety of tissues (platysma?, sebaceous glands, hair, myelinated nerves, glia). He cited other similar tumors, one the size of a child's head. Heckmann et al. (1972) illustrated their finding of a  $9 \times 7$  cm tumor that was situated 25 cm from

the fetal end of the cord and 45 cm from the placenta. It had an epidermoid surface and several chambers lined by skin and intestinal epithelium, as well as cartilage and lymphatic remnants. The child did well. The authors considered displaced germ cells as its origin.
