## Placental Shape Aberrations

In recent years, it has become practical to record and follow the location of the placenta during the course of gestation by sonography. This methodology has shown that a “dynamic placentation” occurs. That is to say, the original location of the implanting blastocyst may be modified during the course of its development to becoming a term placenta. This chapter discusses these concepts, the various types of abnormal placental development, and the morphology of placenta accreta, percreta, and ectopic implantation.

The factors that determine the site of nidation of the human blastocyst are not fully understood. The human blastocyst implants normally in the upper portion of the uterus; nevertheless, abnormal implantation is frequent and may lead to pregnancy complications, such as placenta previa. It has been suggested, for instance, that the site of placental implantation influences the frequency of fetal malpresentation. Wingate and Pauls (1968) studied this using chromium 51 as tracer in placental localization in 85 patients. They found no correlation between either fundal or lower uterine implantation and fetal malpresentations. Previous authors, on the other hand, had suggested that an abnormal location of the blastocyst in the endometrium may lead to abnormal forms of the mature placenta. An early proponent of such thoughts was Schatz (1886), who envisaged normal, broad, and superficial implantations. Later, these ideas were particularly strongly championed by Torpin (1969a), who related the depth of implantation and its location in the uterus to the development of circumvallate placentation. The location of the implantation may be important and can be better correlated now with sonography. Thus, we have seen two circumvallate placentas in cornual implantations. Others have suggested that the placental location is instrumental in triggering the normal impulse for the initiation of labor and that it is correlated with the length of gestation.

### SITE OF PLACENTAL ATTACHMENT

There are several means by which investigators have approached localization of the implantation and the ultimate placental site. Hertig and Rock (1973) summarized their findings from the successful search of 34 early human ova; they obtained the following results:

Tubal location	1
Free in uterus	7
Implanted, normal	17
Implanted, abnormal	9

The normal embryos were more often on the posterior wall than were the implantations of abnormal blastocysts.

When the placental site is determined by postpartum palpation, as was done by Booth et al. (1962) in 200 patients, the following distribution emerged:

Anterior	53%
Posterior	39%
Lateral	8%

When these data are expressed with respect to the height of placental location, the following distributions were found:

Fundal position	2%
Fundal and upper segment	42%
Upper segment	47%
Upper and lower segments	9%

A fundal attachment was found in 44% of primigravidae and 20% of multigravidae; preeclampsia was twice as common in fundal placentas, which may merely reflect the fact that this condition is commoner in a first pregnancy. There was no relation to the length of pregnancy and labor. Scipiadès and Burg (1930), in an extensive study on placentation, cited Orsini (1928), who found an anterior placenta in 26.6%, a posterior implantation in 41.6%, a fundal site in 2.2%, a lower uterus site in 23%, and at other sites in 3.5%. Later methods have used the distance of the membrane rupture site to the edge of the placenta as an indicator of placental localization (Little, 1962; Little & Friedman, 1964). This method needs to take into consideration that the placenta must be carefully extracted and not disturbed after delivery. Among the 10,101 placentas correlated during the evaluation by Little and Friedman (1964), the mean rupture site was between 5 and 9 cm in 39.3%. In 11% it was 0 cm (possible marginal placenta previa), and in only 0.3% was it more than 19 cm. These authors were unable to confirm the relation of high uterine position and preeclampsia but did

not make a distinction with the parity of their patients. They found a twofold higher frequency of vaginal bleeding with low-lying placentas, but otherwise no influence on the length of labor, type of delivery, or neonatal outcome was identified. Torpin (1958) used his method of distending the membranous sac in a bucket of water after birth and determined, in 147 cases, that when the placenta had implanted in the "crease made by the reflection of the anterior and posterior uterine walls, the resulting placenta is almost invariably bilobate."

Indium isotope scanning and sonography were employed by Harris (1975) in 401 patients for placental localization in an effort to ascertain whether localization over the putative uterine "pacemaker" (Larks et al., 1959) influences the length of pregnancy. It was found in the right upper quadrant in about the same frequency as in the left (85%/79%), although the former had statistically slightly significantly shorter pregnancies. This finding disagrees with the theory that the location in the right upper quadrant lengthens pregnancy.

More incisive results come from studies using sonographic localization of the placenta (Gottesfeld et al., 1966), which is now almost routinely ascertained during the course of pregnancy. Taipale et al. (1997) found that when transvaginal sonographic screening was done at between 12 and 16 weeks of gestation, and the placenta then extended 15 mm over the internal os, the probability of a placenta previa at delivery was 5.1%. Studies such as these have stimulated interest in the past on the mechanism of the outcome of low placentation. King (1973) was the first to show that a placenta previa of early pregnancy changes to one that does not require surgery for placenta previa at term, and that this change takes place in most cases. He termed this phenomenon "dynamic placentation." In none of his 14 cases of marginal placenta previa, observed near mid-gestation, was there a true placenta previa at term, although several had a near cervical implantation. He reasoned that this change in position comes about largely by uterine growth and its changing shape as gestation advances. Nearly the same conclusions were arrived at independently by Meyenburg (1976) and have since been confirmed by many other investigators (e.g., Winters, 1978). Young (1978), who studied the same features with arteriography, located the placenta twice as often in the upper uterine segment than as a placenta previa. He also noted the disappearance of most placentas previa with term approaching. He suggested that those placentas that do not move may represent accretas, but there was no histologic support for this concept. In a large study of ultrasonographic findings prior to amniocentesis between 16 and 18 weeks, Rizos et al. (1979) found the following locations:

Site	Previas (%)	All placentas (%)
Anterior	69	37
Posterior	10	24
Anterior and posterior	21	5
Fundal	0	34

Their incidence of placenta previa at midterm was 5.3%, and it converted to a nonprevia in 90.4% by term. Their overall term previa incidence was 0.58%, similar to that of other studies.

A similar, large study of placental localization by sonography was reported by Fried (1978). When he followed the location over the three trimesters, he observed the following:

Site	10–20 weeks (%)	21–31 weeks (%)	32–40 weeks (%)
Anterior	25	41	44
Posterior	37	28	26
Anterior-fundal	9	6	8
Posterior-fundal	17	18	15
Fundal	12	7	7

In other words, little change occurred in the overall location of placentas. Parenthetically, he found many more cephalic presentations with anterior than posterior placentas. Castro et al. (1995) found that 77% of initially low-lying placentas moved upward, whereas 68% of fundal implantations extended downward as pregnancy progressed; laterally located placentas tended to move the least.

Gallagher et al. (1987) performed sonography during the second trimester of pregnancy in 1239 women and found a central placenta previa in three patients and marginal or partial previa in 48 (5%). At term, only four (0.3%) of the following patients had a placenta previa: the three patients with the central previa previously identified and one with marginal previa found during the second trimester. The authors chose, therefore, to name this condition "potential previa" when it is so identified during mid-gestation in order to clearly distinguish this sonographic condition from the true placenta previa at term. Studies have shown that transvaginal ultrasonography is informative with respect to the presence of placenta previa when third trimester hemorrhage necessitates diagnosis (Lim et al., 1989). Of considerable interest is the study by Guy et al. (1990) on patients with antepartum bleeding. They showed by transvaginal sonography of many patients with persistent previas that the intervillous blood flow is predominantly "lacunar." These patients also had a greater requirement for blood replacement subsequent to delivery. Oppenheimer et al. (1994) documented the "migration" by transvaginal sonography during the third trimester. When more migration occurred, then cesarean section was much less often needed. Magann et al. (1998) studied the "migration" of singleton placentas ( $n = 2526$ ) at 18 weeks. They found that posterior implantation is more common than anterior (45.1% vs. 42.1%) and that these are more likely to migrate fundally than anterior-located implantations; they related it to a putative greater growth of the posterior uterus with advancing gestation. In contrast, Ghourab and Al-Jabari (2000) found that when a posterior placenta previa lay within 1 cm of the internal os or when it was a complete previa, it did not migrate in the third trimester. We have studied the rates of placental "migration" in low-lying placentas and placental previa (unpublished). Those patients who had placenta previa at delivery had slower rates of placental migration and more often had a deceleration pattern of placental migration. This suggests that abnormalities in the rates of placental migration may have more effect on the presence of placental previa than the original site of implantation. Higher rates of placenta accreta and manual removal of the placenta were also seen.

An incisive study of localization by indium scintigraphy and cobalt cervical marker comes from Nordlander et al. (1977; see also Nelp & Larson, 1967; Gustafson et al., 1974). Their rather clear-cut data are redrawn in Figure 13.1; they showed an anterior placenta in 98 instances and a posterior placenta in 80. An anterior placenta had a significantly greater chance of being low-lying, and the distance of the placental edge from the uterine internal cervical os increased with the age of the gestation. Attempts at making the exact diagnosis of placenta

FIGURE 13.1. Distribution of placental location in quadrants when viewed from side (frontal) and with respect to anterior and posterior portions of the uterus. (Source: After Nordlander et al., 1977.)

previa during early gestation have ramifications for therapy. Thus, Arias (1988) reported that the use of cervical cerclage in the treatment of vaginal bleeding from placenta previa has merits as a temporary measure.

## Volumetric Growth

Sonography has also remedied the absence of data about growth of the human placenta. In 1967 Boyd and Hamilton lamented that few studies on the *in situ* placenta were published. They presented their findings of 151 such specimens beyond the third month of gestation and found striking variations in the thickness of the placentas; they also reviewed the published data from many countries on placental growth. Their findings refuted the then prevalent thought of Grosser (1927) that placental expansion ceases after the 4th month of gestation. In their study, it was evident that continuous growth of the placental diameter could be measured up to 17.2 cm, with a surface area of 23,245 mm<sup>2</sup> at term. Conversely, Bleker et al. (1977), who measured the placental volume from 23 weeks on and expressed it from sonographic determinations of cross sections, found that growth in volume ceased well before term, peaking at 250 days and then even decreasing. Hoogland et al. (1980) suggested from their sonographic study of placental size at 150 days' menstrual age that this methodology is reliable only when the placenta occupies an anterior position. It is interesting to note that small size of the placenta foreshadowed low birth weight even at that early age. Reliable data on placental volume were also obtained sonographically by Wolf et al. (1979), who compared their measured volume with that of the delivered placenta in a water bath. Habib (2002) estimated volumetric growth sonographically and deduced that a placental diameter of less than 18 cm and

thickness of 2 cm at 36 weeks are prognostic indicators of growth restriction.

## Abnormal Shapes (“Errors in Outline”)

The term **error in outline** (Shanklin, 1958) is a rather descriptive and appropriate designation for a variety of placental forms. The placenta is rarely truly circular. More often it is oval, and not infrequently it has an irregular, often triangular shape that is presumably determined by its site of location, areas of atrophy, and perhaps the manner of its original implantation. The most striking abnormality is the placenta bilobata, two lobes being separated by a segment of membranes (Fig. 13.2). It stands to reason that these membranous vessels occasionally thrombose, or that they present clinically as vasa previa with bleeding. The second lobe is not always as large as the main lobe; it varies, becoming occasionally a much smaller lobe, which is then called a succenturiate (accessory) lobe. When the placental halves are connected by a broad or even a narrow band, one may classify the misshapen organ differently, according to the whim of the observer. Firm rules do not exist. It must also be acknowledged that vasa previa may bleed and still cause fetal problems because of compression of the vessels (Cordero et al., 1993).

Succenturiate lobes may occur singly or multiply, have a tendency to infarct, may present as placenta previa (Roth, 1957; Fig. 13.3), and they may be retained in utero after delivery. A wide spectrum of abnormalities exists here, and the incidence differs with the series published. Thus, Fujikura et al. (1970) found a “bipartite” (duplex) placenta in 4.2% of 8505 specimens collected in the Collaborative Perinatal Study. They found both multiparity

FIGURE 13.2. Bilobed placenta (duplex; bipartite). One disk was attached anteriorly, and the other was on the posterior wall of the uterus. Membranous vessels course from the characteristically velamentous insertion of the umbilical cord.

FIGURE 13.3. Succenturiate lobes in an immature placenta. Some of these lobes are infarcted (pallor) and would atrophy in time.

and relative sterility overrepresented in these women, as well as prenatal bleeding, placenta previa (Fig. 13.4), and retained placentas. They also commented on the fact that the cord usually inserts between the two lobes, as in Figure 13.4. Torpin and Barfield (1968), who clearly had the greatest interest in this condition, found that in one third of bilobed placentas the cord inserts on the larger lobe, and in two thirds it has a velamentous insertion. Occasionally, though, it takes its position on the smaller lobe (Fig. 13.5). Torpin and Hart (1941) had twice the incidence (8.6%) in their extensive historical review and reported on 355 cases. Usually, the placental lobes of bilobed organs had an anterior and a posterior location, and the larger lobe was usually marginate. The collar-shaped placenta reported by Keeler and Cope (1963) is but a variation of the theme. Likewise, the "pendulous

placental polyp" described by Thomas (1962), although unusual, probably merely represents an exceptional succenturiate lobe.

In our experience, succenturiate lobes occur in 5% to 6% of routinely examined placentas. One third of them are associated with some type of infarction of placental tissue, and occasional atrophy occurs between the extra lobe and the main placenta. This situation contrasts with the 13% overall incidence of infarcts without succenturiate lobes. Succenturiate lobes have been recognized by ultrasonography (Hata et al., 1988).

Other unusual shapes occur. Thus, Bergman (1961) reported on a placenta whose surface looked as though it was a loosely tied sac (a circumvallate placenta) and found that it was caused by a bicornuate uterus. Figure 13.6 shows a placenta fenestrata, one in which a central

FIGURE 13.4. Succenturiate lobe (attached to the main placenta by a broad bridge) having necessitated cesarean section because it was positioned as a placenta previa. It is one of a number of such specimens. The accessory lobe is remarkably hemorrhagic.

FIGURE 13.5. Large succenturiate (accessory) lobe from which the cord arises. No complications are evident. (Courtesy of Drs. Farsad and Gore, Birmingham, Alabama.)

portion is atrophied sufficiently to appear like the membranes. There was no cotyledon missing, and the cause (myoma?, possible site of cornual tubal orifice?) could not be ascertained. A similar condition must have prevailed in Greig's (1950) case of a central placenta previa with bulging membranes and hemorrhage. Another case of "placenta fenestrata" has since come to my attention. In this 29 weeks' gestation the fenestrated area was underlain by clot and located over the internal os, obviously having been a placenta previa at one time (courtesy of Dr. L. Matsumoto, 2004).

The mechanism by which succenturiate lobes and duplex placentas develop is unclear. It is relevant, however, that this placentation occurs nearly regularly in many catarrhine monkeys and has best been studied in the rhesus monkey. Torpin (1969b) found 75% of rhesus monkey placentas to be bidiscoid, whereas the other 25% had a single lobe, and he observed that the connecting vessels always course laterally, never otherwise. He made the important notation that atrophic villi are found in the membranes, implying that the blastocyst must have originally implanted interstitially and not, as had been

FIGURE 13.6. Placenta fenestrata. The central area of the placenta has a distinct defect, only chorionic membranes being present. No explanation was evident. (Courtesy of Dr. L.F. Moreno, Caracas, Venezuela.)

assumed, only superficially so as to reach both uterine surfaces. Because baboons are close relatives—indeed may mate and hybridize with rhesus monkeys—but have a single-disked placenta, their placental evolution was of interest to Chez et al. (1972). These authors found single disks in 22% of the 121 rhesus monkey placentas studied. They suggested that implantation is partially under genetic influence because some males were much more prone to father the single placentas. A clear-cut mode of genetic transmission was absent, but they searched for membranous villi, as did we (Benirschke & Miller, 1982), and found none. They concluded that these monkeys (but also baboons) have a more superficial implantation, supporting Heuser and Streeter's (1941) finding that the primary disk implants on day 9, and the secondary disk on day 14, but on the opposite side of the uterus. This differs clearly from human placentation and to date, then, a decisive answer of the origin of placentas with accessory lobes is outstanding. It is interesting, however, that at least half of the placentas with succenturiate lobes have areas of atrophy or frank infarction. This finding much supports the notion of a secondary conversion from more normal placentation. As with other anomalies, we await studies of the births of offspring from such abnormal placentas in order to ascertain possible genetic causes.

The condition "capped placenta" has been described by Defoort and Thiery (1988). This abnormal shape is characterized by having a cup or bell shape, and curvatures in two axes. These investigators studied the uncommon (0.8%) feature of bleeding during the second trimester. Previously, bleeding at that time had been considered to be most frequently a feature of a placenta previa-like implantation. Defoort and Thiery did not find it to be so. Circumvallate placentation, succenturiate lobes, low-lying placentas, and retroamniotic bleeding were found instead. In addition, 17 of their 63 cases (27%) were due to "capped placentas"—placentas with implantation on lateral, anterior, and posterior walls of the uterus. The lower portion of the placenta did not reach the uterine isthmus. Round or oval placentas are clearly the predominant forms of human placentas, abnormalities are rare. This is particularly the case for zonary (annular) placentas, which are the regular shapes of many carnivores. Steemers et al. (1995) described an annular placenta, sonographically diagnosed and with a velamentous cord insertion. It is likely that it derived from focal atrophy of low-lying villous tissue.

## Placenta Previa

The term **placenta previa** refers to the location of the placenta over the internal os. The placenta is thus being "previous" to the delivering part of the baby. Low implantation is the cause, and the condition is of great medical

concern. Placenta previa is the principal cause of third trimester bleeding, and it often necessitates an emergency cesarean section. Both mother and fetus may bleed in a life-threatening manner. The incidence is variably given as between 0.3% and 1.0% (even 3.0%) since the first publication of a large database by Strassmann (1902). Abnormal cord insertion and circumvallation are frequently present as well. Nielsen and colleagues (1989) found an incidence of 0.33% among 26,644 patients of placenta previa that necessitated abdominal delivery. The risk was 0.25% in "unscarred" uteri, compared to 1.22% in patients with previous cesarean section(s). These authors concluded that previous cesarean section predisposes to placenta previa and antenatal hemorrhage, a notion that was confirmed in the large review by Hemminki and Meriläinen (1996). Nevertheless, when Taylor et al. (1994) reexamined this relation and eliminated confounding factors, they found only a small influence of prior section as a cause. A large National statistical review by Iyasu et al. (1993) describes the overall incidence of placenta previa to be 4.8 per 1000 deliveries with a fatality of 0.03% of the cases; it was higher in black women than in white women. In addition, these authors ascertained a higher risk for abruptio, fetal malpresentation, postpartum hemorrhage, and cesarean section. For some as yet to be explained reason, placenta previa is reported as being more frequent in Asian women living in the United States (Taylor et al., 1995). When Miller et al. (1997a) examined the risk for placenta previa and accreta in 155,670 deliveries, they found that placenta accreta occurred in 29% when the placenta implanted over a previous section scar (6.5% when it was not there located). Their overall incidence of placenta accreta was 1:2500 deliveries, as compared with 10% in placenta previa.

Placenta previa has been the topic of a large body of literature. Many authors are concerned with optimal clinical management (Kellogg, 1943; Schmitz et al., 1954; Scott, 1964; Brenner et al., 1978; Khashoggi, 1995, and many others). Some investigators concern themselves mostly with the origin of the blood in the vaginal hemorrhage (Bartholomew et al., 1953; Hartemann et al., 1962; McShane et al., 1985). Yet others address fetal prematurity, early diagnosis, and its causes and relation to cervical pregnancy and placenta accreta. Ananth et al. (2003) found a 2.8% frequency in live births with a 10.7 rate of neonatal mortality compared to 2.5 in normal implantation when the pregnancy was >37 weeks, but not so in younger gestations. Salihu et al. (2003) studied the outcome of 3,773,369 live births in the U.S. and found a tripling of neonatal mortality with placenta previa.

It has become customary to subdivide placenta previa into several categories, such as "central" (total) and "partial" (lateral or marginal) placenta previa. Strassmann (1902) criticized rigid subdivisions and questioned their terminology. Despite this criticism, everyone under-

stands the terms **central previa** and **marginal previa**. The former generally poses the greater threat and requires early diagnosis. Schmitz et al. (1954) separated their 112 cases (0.6%) into 31% total, 27% partial, and 42% low-lying previas. (The latter are somewhat dubiously included in this group.)

Tatum and Mulé (1965) evolved a complex “overlay” method of grading the previas (depending on cervical canal coverage if the cervix were allowed to completely efface). They found that their classification did not correlate well with effective clinical management. The term **low-lying previa** therefore is not a well-defined entity.

Brenner et al. (1978) surveyed 31,070 pregnancies (185 previas) and found an 0.6% overall frequency, with 0.12% of total previas. They confirmed the long-suspected correlation with multiparity (also older women), previous abortion, multiple births, and male infant. Surprisingly, prolapsed cord was also three times more common. Fetal and placental weights were not affected when corrected for fetal age. There was a significant association with fetal mortality, fetal anomalies, and low Apgar scores. Francois et al. (2003) found no increase of placenta previa with multiple gestations. Gabert (1971) also found normal fetal weights. Jopp and Krone (1966), on the other hand, reported significant fetal weight depression and increases in placental weight, which they attributed to compensatory placental hyperplasia. Higginbottom et al. (1975) also found lower than expected fetal weights and associated dysmaturity.

It is easy to understand that the maternal hemorrhage may originate from the placental margin or the disrupted intervillous space. There is, however, also significant neonatal anemia associated with the birth from a placenta previa, and it is the case more so when the maternal bleeding has been excessive (Wickster, 1952; McShane et al., 1985). This anemia is clearly due to the well recognized, but rarely recorded, fetal bleeding that occurs from disrupted placental villous vessels during labor (Bromberg et al., 1957; Hartemann et al., 1962; Bar-David et al., 1984). However, it may be difficult to detect the defects by placental examination (Wiener, 1948). Some authors found that fetomaternal bleeding also occurs (Zilliacus, 1964; Huntington, 1968). The neonatal anemia can result from the disruption that occurs when the placenta is cut during cesarean section, aspects that are well discussed by Schellong (1969).

The early diagnosis of placenta previa was once accomplished by arteriography (Borell et al., 1963) but is now readily made sonographically. Evidence for the frequent finding of previa placentation during early pregnancy and the subsequent “conversion” of such placentas previa to low-lying, nonprevias is reviewed in the section above. Wexler and Gottesfeld (1977, 1979) went so far as to consider this previa position as a “normal” variant of placentation, and Ballas et al. (1979) stated that it fre-

quently causes midtrimester vaginal bleeding. From their evaluation of the location of the placenta, these authors prognosticated the ultimate outcome by the extent of previa placental tissue. Many other investigators (e.g., Comeau et al., 1983) subsequently addressed this topic with an aim to improve fetal outcome in this common condition. Bartholomew et al. (1953) suggested a novel mechanism of bleeding in central placenta previa. They observed that in the central villous portion of the tissue that overlies the internal os there were numerous old clots, apparently from former bleeding episodes. They held these clots to be evidence of placental villous disruption and assumed that it is not the detachment of placenta from the decidua that causes the bleeding. Moreover, at the edge of the placenta, disruption of the “marginal sinus” may take place in marginal placenta previa, and thus lead to bleeding when the endocervix dilates during late gestation. These findings are currently supported by sonographic appearances (*vide infra*).

Marginal bleeding occurs frequently in ascending infection and chorioamnionitis (see Chapter 20); it then also often separates the edges of the placenta in the low-lying portion and is occasionally referred to as “abruptio.” Harris (1988) reviewed this topic and considered it to be a distinct entity that is associated with minimal bleeding and prematurity. He distinguished it from placenta previa; in our opinion this is principally decidual bleeding that is secondary to deciduitis.

The pathology of placenta previa is easy to understand. The membranes have no free margin in the vaginally delivered placenta, and the edge of the placenta is frequently disrupted and hemorrhagic. Because there are often old clots at this site, these may vary from being laminated and brown, friable loose blood to partly decomposed material that is sometimes green from hemosiderin (Figs. 13.7 and 13.8; also see Fig. 13.16). The fetal vessels of the chorionic surface, when at the edge, may be disrupted.

According to Strassmann (1902), one often encounters some degree of circumvallation or margination. It is rarely reported in other series and is also not our experience. Strassmann also correlated the insertion of the umbilical cord with previas and found that the cord may insert anywhere but is more often near the site of the cervical os. That problem is certainly not the case in the placenta shown in Figure 13.7, and examples of the eccentric placental growth that made Strassmann such an ardent champion of the trophotropic expansion theory of placental tissue (expanding toward the better endometrial grounds above) are not often clearly seen.

Low-lying portions of placenta are occasionally either atrophied or infarcted. It is most often the case when the initially marginal previa has failed to develop, has undergone atrophy, and has thus become a “marginal” previa or better, a low-lying placenta. An intact uterus with an immature fetus from a placenta previa complication is

FIGURE 13.7. Placenta previa from cesarean section. Note the disruption and discoloration of the right, previa-pole of the placenta. The cord is centrally inserted in a “disperse vasculature” arrangement.

seen in Figure 13.9. The cervical canal and the forelying placental tissue betray the bleeding that had occurred. That the bleeding can be due to a succenturiate placental lobe has been described several times (Radcliffe et al., 1961; Van Huysen, 1961), and the condition has been observed in a variety of animals as well. These reports even included cases where placenta previa caused fetal exsanguination (Kingsley & Martin, 1979).

The cause of placenta previa is perhaps the most widely debated aspect of this anomaly. Obstetricians of the last century suggested much the same pathophysiology that we know today. It is aptly summarized in the long article by Strassmann (1902). Multiparity, advanced maternal age, previous abortions, and rapid succession of pregnancies are the principal factors. Studies have been contradictory as to whether induced abortions were (Barrett et al., 1981) or were not (Grimes & Techman, 1984) precursors of placenta previa. Grimes and Techman reviewed

the early literature that reported no such correlation; they also found no risk from preceding curettage. Thus, there is still dispute as to the main reasons for this condition. Strassmann believed that the placenta implanted low because of unsuitability of the fundal endometrium. He reasoned that in rapidly successive pregnancies the endometrium had not reconstituted sufficiently to become a site of implantation. His discussion included the putative *Haftfleck* (point of attachment) of Schatz that was disturbed by a previous pregnancy or abortion. Similar notions were reiterated by Nieminen and Klinge (1963), who discussed Iffy's (1962) theory of abnormal endocrine support. Although occasionally disputed, the dependence of placenta previa on maternal age and parity has been solidly supported by the findings of Penrose (1939) and Kalmus (1947). It has often been stated that placenta previa is significantly more common after a prior cesarean section, and the more sections, the greater the prob-

FIGURE 13.8. Maternal surface of the placenta in Figure 13.7. The old marginal clot is brown and friable, and the edge of the placenta is disrupted; the membranes are torn.

FIGURE 13.9. Placenta previa accreta. Hysterectomy was done at approximately 14 weeks (fetus is 10 cm crown-rump length). Note the endocervical blood and congested sickle-shaped previa (arrows).

ability of a previa (To & Leung, 1995; Ananth et al., 1997). Strangely, placenta previa is also said to be more common in users of cocaine (Macones et al., 1997). Rarely is a placenta previa found in association with incompetent cervix, but such may be difficult to diagnose as an independent condition when the previa has already led to hemorrhage (Ringrose, 1976). An extensive analysis of correlative factors has emerged from the oft-mentioned Collaborative Perinatal Study and was published by Naeye (1978). This author found no increase in fetal anomalies, and there was no association with maternal age in placenta previa. There was a relatively high perinatal mortality (11%) and increased fetal hematopoiesis (anemia?, stress?) as well as growth restriction were found. Moreover, contrary to many earlier reports, the placentas and fetal organs were lighter. The placental villi were interpreted to show hyperplasia. Nielsen et al. (1989) found a greater incidence after cesarean section in a large cohort.

There can be no doubt, however, that placenta previa is often associated with placenta accreta. In placenta accreta, the placenta fails to dislodge from the uterus after delivery of the newborn. When such a uterus is studied histologically, it is found that the villous tissue had not been attached to decidua, but that it had grown

onto the myometrium without intervening decidua. There is good evidence that placenta accreta is due to the failure of normal decidua to form, usually because the endometrium is deficient and cannot transform. Kistner et al. (1952) stated that the absence of the “spongy layer” of the decidua is the important feature. Thus, the trophoblast does not stop invading when it should, and it penetrates more broadly into muscle than is normal. Placenta accreta is also a regular finding in abdominal and tubal pregnancies, where there is also no normal endometrium to transform into decidua. A similar situation arises in the lower uterine segment and endocervix. Despite the thick nature of the endocervical mucosa, it does not follow the normal hormonal signals for decidualization, and when implantation occurs here, a placenta accreta forms. Although placenta previa accreta and cervical pregnancy are relatively rare, many reports (reviews by Kistner et al., 1952; Friesen, 1961) attest to the importance of this condition, which may endanger the mother’s life because of afibrinogenemia, aside from the hemorrhage that takes place (Rosa et al., 1956; Koren et al., 1961; Khashoggi, 1995). Some authors note the frequency of prior cesarean section and curettage as being important (Rubenstone & Lash, 1963; Clark et al., 1985). Clark et al. believed that placenta previa and its variants are not rare, and cited a

steady rise in case reports, whereas Comstock et al. (2004) stated that the condition of placenta accreta can be detected as early as at 15 to 20 weeks' gestation because of the sonographic "visualization of irregular vascular spaces within the placenta (placental lacunae)." More discussion is to be found in Chapter 9.

It is then surprising to find the study from Khong and Robertson (1987), which purported to negate the previous theories on the pathogenesis of placenta accreta and placenta previa accreta. Their novel view, which requires more discussion, is based on study of the placental bed in placenta accreta (inappropriately referred to as "creta"). Here they found a deficiency of the usual placental bed giant cells, a preponderance of uninuclear trophoblast, and a difference in the maternal vasculature in the areas of adherence. Moreover, they (as did other investigators) found that accretas may be focal and that, next to areas of adherence, there may be normal decidua, and that the decidua parietalis of such cases is also normal. From these findings they deduced that "there is a defective interaction between maternal tissues, particularly decidua, and migratory trophoblast in early stages of placentation, resulting in undue adherence of the placenta or penetration into the uterus coupled with the development of an abnormal uteroplacental circulation." In other words, they believed that absent decidua is not the primary event, as is our opinion and that held by most previous students of the matter. This concept is contrary to all other findings made in studies of this disease. Similar findings of accreta placentation are regularly made with ectopic pregnancy, in both the tubal and abdominal varieties. Although occasional decidualization of tubal mucosa does occur, it is uncommon, and true decidua in ectopic pregnancy is rare. One must be able to differentiate decidual cells from X

cells (extravillous trophoblast), which is not always easy for pathologists. A recent study by Kim et al. (2004) suggests that an excess of intermediate trophoblast is found in accretas, and the authors suggested a relationship of this excess to the development of accretas. They examined 56 hysterectomy specimens, 34 with and 22 without accreta, using immunohistochemistry with the cell adhesion molecule marker CD146 that is expressed by these X cells. They found a significant increase in confluent masses of extravillous trophoblast with the myometrium in accretas, as in ectopic tubal gestations and related this to the development of accretas. There was no significant increase in multinuclear trophoblastic cells. In addition, they reviewed older theories of deficient or increased enzymes as being the principal cause of the formation of placenta accreta. Our belief is that the really primary aspect is the deficient decidua basalis, and that in that deficiency, the infiltrating trophoblast assumes different behaviors. It is not unusual, however, to find a few myometrial fibers in the basal plate of delivered placenta near spiral arteries and especially in prematurely delivered organs (9.5% by Sherer et al., 1996), without this representing true accretas. Minimal accretas, not necessitating hysterectomy, were found occasionally by Jacques et al. (1996) in careful placental studies, especially following previous cesarean sections (see also Sarantopoulos & Natarajan, 2002) (Fig. 13.10). Placenta accreta is also an occasional finding during evacuation in the second trimester (Rashbaum et al., 1995), and Ophir et al. (1999) found an increase in creatine kinase with these conditions. Mussalli et al. (2000) suggested conservative therapy for accretes with methotrexate.

Placenta accreta is also typical for endocervical implantation and in uteri that were altered focally by curettage or by the scars of cesarean section. Khong and Robertson

FIGURE 13.10. Microscopic region of focal placenta accreta showing absence of decidua basalis and extravillous trophoblast infiltrating myometrium. Otherwise this is a normal term placenta and there was no history of former curettage or cesarean section.

(1987) dismissed the analogy of deficient decidua in tubal pregnancy by saying that these pregnancies rarely go to term. [Augensen (1983) described an exception and reviewed the literature; *vide infra*. Similarly, Steyn and Gebhardt (1999) had a stillbirth at 35 weeks—2250 g—from a ruptured tubal gestation and stated that this is not so infrequent in South Africa because of the frequency of salpingitis.] True enough, but the reason for the usual failure of ectopic pregnancies to reach term is that the accretas of tubal pregnancy usually become placentas percretas with bleeding. This point has also been emphasized by Pauerstein et al. (1986), who recommended local resection on that basis. Moreover, many term tubal pregnancies have indeed been observed (e.g., Frachtman, 1953; Miller, 1987).

In our opinion, the adherent placental bed morphology betrays the ill-understood interactions between trophoblast and normal decidua. After all, why is it that not every pregnancy results in placenta accreta? The trophoblast stops destroying the endometrium or decidua at a given point in placentation and leaves (in humans) a portion of decidua basalis untouched. It is not so in all species, as in the *Dasypodidae*, where the superficial myometrium is also differently constructed. This failure to destroy all of the decidua basalis in human gestations may be related to temporal changes in the trophoblast's behavior, carefully timed genetically; or it may be that the decidua plays a specific role in this delimitation of the advancing invasion by trophoblastic cells (see Chapter 5). This is not to say that some of the advancing trophoblast does not reach deeper into the mouths of vessels and into the myometrium; it certainly does. A primary deficiency of decidual transformation or of the depth of endometrium/decidua, however, still best explains the placenta accreta. The findings described by Khong and Robertson (1987) may be explained as sequelae of absent decidua rather than as its cause. Parenthetically, we agree with their statement that the presence of adenomyosis as a basis of placenta accreta has been vastly overrated in the past.

Cramer (1987) described a placenta increta that had invaded and partially destroyed the leiomyoma on which it rested. From this finding he deduced that accretas/incretas are due to overly aggressive trophoblast, rather than decidual deficiency. He believed it to be the cause, not only in this case but also of other accretas. He reasoned that the ability of decidua to produce laminin, fibronectin, collagen type IV, and proteoglycans (Wewer et al., 1986) may be defective, and suggested that the normal balance of the placental invasiveness and the decidua to resist invasion may be disturbed in accretas. Rice et al. (1989), who studied pregnancies complicated by leiomyomas, found that retroplacental tumors were significantly frequently complicated by abruptio placentae. It might be mentioned here parenthetically that Arcangeli and Pasquarette (1997) observed the rupture of a uterus at 26

weeks' gestation after laparoscopic myolysis of a leiomyoma had been done months before pregnancy. Spontaneous rupture of an unscarred uterus seldom occurs (review by Miller et al., 1997b). In this connection, **placenta percreta** needs to be discussed separately and in more detail because of the apparent increase reported in the recent literature and because of our increasing concern with this formerly rare condition. It is frequently associated with uterine rupture, major maternal problems, stillbirths, and placenta accreta/increta. There is little doubt that structural abnormalities of the uterus can lead to uterine rupture during pregnancy without it having been "scarred" earlier; but that is uncommon. Much the most frequent antecedent condition is prior cesarean section with dehiscence of the scar and thus mimicking a "percreta." Because this relates to the overall conditions subsumed under trophoblastic invasion, the topic is covered extensively in Chapter 9; it is of great current relevance.

## Placenta Membranacea

Placenta membranacea is an unusual abnormality of placental form. Although some authors have estimated its occurrence to be 1 in 3300 pregnancies, this approximation is a gross overestimate. Although the entity was described as early as 1807, only a handful of references can be found on placenta membranacea. Many cases are hidden in the literature on placenta accreta. Thus, of the 622 cases of placenta accreta gathered by Fox (1972) for his report, seven were placentas membranacea. Although it is true that some membranaceae are also accretas, it is not the case for all. The placenta membranacea (*diffusa*) is an organ in which all, or nearly all, of the circumference of the fetal sac is covered by villous tissue. The placental mass is generally thin (1 to 2 cm), and it is often disrupted (Figs. 13.11 and 13.12). Although one may suggest that placenta membranacea is a variant of extensive succenturiate lobe formation, we do not believe it to be the case. There is never a separation or even a hint of segregation of tissue from a main placental disk; the tissue is uniformly thin. This type of placental anomaly has been likened to the placenta found in Suidae, Equidae, and Cetacea. It is not an appropriate comparison, however, because these orders of mammals do not have an invasive placenta. Only a superficial macroscopic similarity to the animals' placentas exists, and it is thus not appropriate to speak of "atavism."

Placenta membranacea manifests frequently clinically as early bleeding and placenta previa. Affected pregnancies often also terminate in premature delivery, but not invariably. They also may incur difficulties with placental separation after delivery. The literature on placenta membranacea has been reviewed by Finn (1954) and Janovski and Granowitz (1961); later cases were reported by

FIGURE 13.11. Placenta membranacea at 35 weeks' gestation. Virtually no free membranes are seen: the placenta is very thin. Patient had recurrent bleeding necessitating hysterotomy.

Mathews (1974), Las Heras et al. (1982), and Hurley and Beischer (1987). A complete review of this unusual anomaly comes from Ekoukou et al. (1995), who found only 36 cases to be reported. More recently, Ahmed and Gilbert-Barnes (2003) described three cases without finding an etiologic factor. In fact, the etiology of placenta membranacea is not understood. It is easy to state that those villi that are destined to become the chorion laeve do not atrophy normally and that there is endometrial hypoplasia on "constitutional" or other grounds; but, in general, no author has presented support for these hypotheses. The fact that the anomaly often presents with middle trimester bleeding and is thus often diagnosed with placenta accreta may merely reflect that placenta

membranacea also overlies the internal os and thereby has a chance of becoming a placenta previa accreta. Occasional cases, such as the one depicted in the previous edition of this book, may have other areas of accretion. Most reported patients delivered their placentas without evidence of accreta. There has not been any associated fetal growth restriction.

One of the cases, described by Finn (1954), is of particular interest. He was the obstetrician for this "infant" 27 years after her birth. She delivered a macerated, stillborn fetus at 5 months, after several weeks of bleeding. This placenta, just like that associated with her own birth, was a typical placenta membranacea (Finn, personal communication, 1976). Thus, either genetic influences determined

FIGURE 13.12. Maternal surface of Figure 13.11, showing old clot but the absence of accreta in this placenta membranacea.

this abnormal placenta, or it was the result of an abnormal uterine environment that was under genetic control. It seems highly improbable that such a rare anomaly would occur twice within this one pedigree by accident.

Circumvallate Placenta (Extrachorial, Circummarginate Placentas)

Some writers have regarded the circumvallate placenta to be clinically important; others have stated that it is a clinically meaningless deviation from normal. In circumvallate placentas, the membranes of the chorion laeve insert not at the edge of the placenta but at some inward distance from the margin, toward the umbilical cord. At the margin, one usually finds variable amounts of fibrin, with recent and old blood. At times, a striking number of such deposits are present. In typical circumvallates, there is a truly complete circumferential ring that severely restricts the total surface of the chorion frondosum. At the periphery, “naked” placental tissue protrudes, which is the reason for the designation **placenta extrachoralis**. This condition should not be confused with the placenta accompanying an extramembranous fetus, a placental anomaly that occurs after early rupture of the membranes with the fetus lying in the endometrial cavity and outside the membranous sac. This situation is not the case with ordinary circumvallate placentas, although, as is seen in the considerations of the extramembranous pregnancy, in that condition there is also a striking circumvallation present (see Chapter 11). When no typical plication of the membranes occurs at the margin, and when the edge of the protruding placenta is covered only by some fibrin, we speak of a circummarginate placenta.

These two forms blend into each other, and partial circumvallation is common. The incidence of these

TABLE 13.1. Reported frequency of circumvallate and circummarginate placentas

Authors	No. of studies	Circumvallate (%)	Circummarginate (%)
Scott (1960)	3,161	18.3% extrachorial	
Ziel (1963)	40,143	0.62	
Wilson and Paalman (1967)	10,927	1.0	
Wentworth (1968)	895	6.5	25.5
Benson and Fujikura (1969)	39,514	3.6 (whites) 2.0 (blacks)	3.3 (whites) 3.4 (blacks)
Fox and Sen (1972)	3,000	2.4	22
Benirschke (this series)	13,537	5.25	

common conditions is listed in Table 13.1, which was compiled from several large prospectively and retrospectively collected series. Circumvallates are rarely found during the first trimester, although Meyer (1909) and Torpin (1966) depicted uteri at 3.5 months with intact circumvallate placentas. Most authors agree that circumvallation is often complicated by prenatal bleeding and premature delivery.

Two characteristic circumvallate placentas with different amounts of extrachorial tissue are illustrated in Figures 13.13 and 13.14, and Figure 13.15 shows a typical circummarginate placenta. Variations between these degrees are frequent. Gross examination of such placentas often shows yellow-brown discolored marginal fibrin, testifying to its origin from hematomas. In cases where this anomaly is the cause of midtrimester hemorrhage and premature delivery, one may find a substantial amount of blood at the margin. It may undermine the margin of the placenta and may thus initiate a clinical picture of abruptio placentae. Although much of this

FIGURE 13.13. Typical circumvallate placenta at approximately 35 weeks' gestation. Note the small surface area of the remaining chorion frondosum and large white fibrin ring at the periphery.

FIGURE 13.14. There is a lesser degree of circumvallation than in Figure 13.13.

blood comes from the maternal vessels, the bleeding may be so significant that it elevates the chorion laeve from the site of its insertion and then disrupts the fetal vessels (Fig. 13.16). Thus, the hematoma and vaginal bleeding are frequently of mixed maternal and fetal origin. In some cases, it is the mechanism of neonatal anemia (Mitchell et al., 1957). Scott (1960) superbly investigated the structure of the margins of extrachorial pregnancies and found evidence that the chorion, once upon a time, must have been more marginally inserted. When he injected placental vessels with radiopaque dye and placed a wire around the insertion sites of the membranes, he found pictures such as that shown in Figure 13.17. Here one can see that the fetal surface vessels pursue a horizontal course way past the wire circumference before they dip vertically

into the placental tissue. It indicates that the vessels must have been running in chorion initially, before this membrane was dislodged by the hematoma; this is dramatically shown in Figure 13.16. The bleeding was so acute in this case that many fetal vessels were severed. This old blood accumulated at the margin, hemolyzed, and changed into fibrin-like deposits that cover up the old horizontal vessels. It is also the cause of the discoloration. Hemosiderin is often found in the more extensive cases. This fibrin causes the plica to form that is so characteristic of circumvallates (Figs. 13.18 and 13.19). The amnion may follow the chorion into this plica, or most commonly, it flatly covers the plica without infolding.

Because circumvallation is so frequent, this anomaly has been investigated many times to explain its formal

FIGURE 13.15. Sickie-shaped circummarginate placenta with free villous tissue protruding beyond the membrane insertion. This point, combined with the near-marginal insertion of the cord at the opposite end, is considered to reflect trophotropism.

FIGURE 13.16. Immature placenta from an exsanguinated premature infant. Massive old and recent blood clot was circumferentially present; it has been partially removed to show the stretched and occasionally interrupted fetal vessels (arrows) through which the fetus bled. The membranes were brown from deposits of hematoidin and hemosiderin, and from hemolyzed blood.

genesis. As a result, numerous theories have been proposed. Several opposing ideas have been presented without, it is fair to say, firm resolution that would be acceptable to all. Schatz (1886) reviewed older writings with which he strongly disagreed. He contended that circumvallates arise because the embryonic mass implants too superficially. That concept was supported by Hertig

and Gore (1969). The opposite view has been defended by Torpin (1953, 1955, 1965, 1966). He confessed a life-long preoccupation with understanding the etiology of these abnormal placental forms. Torpin believed that the evidence points to excessively deep implantation of the blastocyst into a “fungating,” hyperplastic decidua. He concurred with Gottschalk’s (1891) opinion. That view-

FIGURE 13.17. Radiograph of placenta “extrachorialis” (circumvallate) whose fetal vessels were injected with barium sulfate. The circular wire marks the edge of the chorionic plate. Note the many chorionic vessels pursuing a straight course past the edge of the membranes’ insertion. (Source: Scott, 1960, with permission.)

FIGURE 13.18. Margin of circumvallate placenta. The gray, homogeneous material under the plica represents fibrin and degenerating clot. Note that the amnion is not infolding with the chorion in this example, as is otherwise so often the case. H&E.  $\times 4$ .

point, expressed many years earlier, was a dissenting voice against Schatz's superficial ("polypoid") placenta theory. Nevertheless, this superficial implantation theory has become the predominant thought in our texts, perhaps because of the eminence of Schatz (1886) and Meyer (1909). Likewise, the pronouncements of Williams (1927) carried much weight in the United States. Williams

had done a study of circumvallate placentas and opined that "all had been said" about the theories of its genesis. He further suggested that we discard the term **marginata** (circummarginate). His opinions included claims that true circumvallation occurs in less than 2% of deliveries, and he supported the notion of superficial implantation.

A challenging consideration of pathogenesis is that which was originally enunciated by Liepmann (1906). He saw several early circumvallates, one of which clearly related to premature loss of amniotic fluid. Exactly the same mechanism takes place in all extramembranous pregnancies, which are some of the most classical examples of circumvallate placentation (see Chapter 12). Liepmann proposed that the marginal infolding derives from *Stauchung* (impaction, collision, jamming), the failure of the sac to be held open. Later students have either confirmed Torpin's view (Wentworth, 1968) or were noncommittal (Scott, 1960).

All theories seem to suggest that there is only one way for circumvallates to originate, whereas in fact there may be different types and origins. Reduced amniotic fluid pressure distending the sac in extramembranous pregnancy clearly speaks as an etiologic moment in those cases. When significant hemorrhage occurs circumferentially, as can happen with middle trimester abortion, it may be the primary cause of circumvallation. When a middle trimester placenta previa changes to a marginal insertion at the lower segment and the fundal portion expands, it may be the origin of the sickle-shaped, so-called marginatas. The terms **placenta marginata** and **circummarginate placenta** are poor ones, and most authors consider these placentas to be part of the spectrum of circumvallation. These terms should be abandoned. When the apposing membranous sacs of twins exert differential pressures on one another, the meeting point is often discordant with the placental bed. That is, the membranes often do not meet exactly over the place where the respective placental areas terminate. They are frequently

FIGURE 13.19. Plica of the circumvallate margin with a wire holding up the overhanging margin of the membrane insertion, showing the simultaneous infolding of the amnion.

pushed away from this “equator,” and “bare” placental tissue exists; at least it is covered by the membranes of the other twin. It, too, is a form of extrachorial placenta. If, as has been suggested, a polypoid, superficial implantation were the cause of circumvallation, one might find fewer atrophied villi in the chorion laeve. This possibility had already been entertained by Torpin (1969a), and we have looked for such a possible deficiency in rolled membranes of normal and circumvallate placentas as well. We found that there was a high degree of variation in the number of villi so discovered, but circumvallates often did have such atrophic villi. Harbert et al. (1970) described three circumvallates in rhesus monkeys that had only a single disk (instead of their normal two-disked placenta). Harbert et al. evaluated the respective interrelations of these anomalies and concluded that if they were indeed related it would mean that the cause must have been aberrant trophoblastic behavior before the 17th day of pregnancy. Johnson et al. (1978) had two similar cases in stump-tailed macaques. Suzuki (1971), however, found two circumvallates in two-disked rhesus placentas. This finding negates the hypothesis of Harbert and colleagues (1970). Because of the relative frequency of single-disked placentas in macaques (25%), the concurrences of the two conditions may be merely happenstance.

As stated earlier, “true” circumvallates are correlated with prenatal bleeding, premature termination of pregnancy, multiparity, abruptio, and early fluid loss (Ziel, 1963; Naftolin et al., 1973), and occasionally it is familial (Deacon et al., 1974). For a consideration of clinical significance, it must be cautioned that the term **circumvallate** is not used uniformly by all pathologists and obstetricians, which is perhaps one reason for the marked differences in the reported incidence (1% to 7%) and for the confusion with the so-called marginatas. Moreover, many circumvallates masquerade clinically as abruptios. Elliott et al. (1998) have written about chronic abruptio with oligohydramnios, representing perhaps one end of the spectrum of this entity. Our data include only cases such as are shown in Figures 13.13, 13.14, and 13.16, but not Figure 13.15. Lademacher et al. (1981), who favored a genetic etiology of this anomaly, identified significantly higher frequencies of perinatal death (11% versus 3%), premature deliveries (37% versus 13%), congenital anomalies (15% versus 4%), and single umbilical artery (SUA) with circumvallate placentation. It was true also for circummarginates, where the figures were 3%, 25%, and 4%, respectively. In a study of 3000 consecutive deliveries, Fox and Sen (1972) again suggested that circummarginates have no clinical importance but that circumvallates associate significantly frequently with threatened abortion, premature labor, and fetal growth restriction. To this list some authors (Morgan, 1955) have added that circumvallation is associated with a higher maternal morbidity rate due to postpartum hemorrhage

and the more frequent need for manual removal of the placenta. Repeated occurrence of circumvallate placentas in successive pregnancies has been reported occasionally (Wilson & Paalman, 1967).

Benson and Fujikura (1969) concluded, after an exhaustive analysis of the 39,514 pregnancies in the Collaborative Perinatal Study, that “despite some well-documented obstetric-pediatric complications, extrachorial placenta is an uncommon, rarely serious clinical problem.” They further believed that “our finding of minimal correlation between these morphologic variations and clinical abnormalities is due to the prospective nature of the study.” We doubt that everyone would agree with this statement. Rolschau (1978), for instance, found this placentation to be correlated with single umbilical artery, growth restriction, and an increased incidence of prematurity. Other authors found similar results from large studies of prospectively collected placentas.

# Histopathologic Approach to Villous Alterations

## How to Assess Villous Histopathology

Evaluation of the placental villous tissue during the routine evaluation of the placenta is important to gain an overall understanding of the normalcy of the placenta and to ascertain possible disorders. If the villous structure is abnormal, this helps to direct one's attention to certain pregnancy disturbances that may require further study.

In addition, one needs to consider the influences on the villous structure between delivery and preparation of tissue sections, such as the time and mode of cord clamping (Bouw et al., 1976) and the method of fixation (see Chapter 28, Tables 28.8 to 28.10). Different fixatives produce different histologic appearances with which one needs to be familiar. Moreover, the rapidity of fixation is important if such features as edema are to be evaluated properly (Voigt et al., 1978; Kaufmann, 1985). All these findings are crucial for a proper microscopic evaluation of villous tissue, which is peculiarly subject to artifacts.

The placental examination can then lead to significant insight as to the pathogenesis of many disorders. Salafia et al. (1992), Macara et al. (1996), and Todros et al. (1998) found, for instance, an excellent correlation of various features with intrauterine growth restriction (IUGR). Importantly, the associated or causative villous pathology was chronic villitis, infarcts, so-called hemorrhagic endovascularitis, thromboses, and fetoplacental vascular maldevelopment. In their quantitative study of placentas from undefined growth-retarded newborns and appropriate controls, Wong and Latour (1966) found only minor changes that would not allow characterization by ordinary microscopy. It was, however, possible only to show that the placentas of growth-retarded neonates had a reduced villous surface area when quantitative measurement of villi and trophoblast were made. Since then, however, a much better understanding of IUGR has been gained and one cannot help but believe that the cases studied by these authors had a very mixed etiology. Like-

wise, one must then presume that the placental changes might differ markedly.

Such scrutiny presupposes a considerable familiarity with the normal structure of the placenta and also that sufficient tissue samples have been collected for this study. For instance, it must be appreciated that the center of placental lobules differs in its villous appearance from that of the lobular periphery. In the central areas and under the chorion the villi are more widely separated, and they may have quite a different appearance from the villi at the periphery of a lobule (see Chapter 7, Fig. 7.18). This organization of the "placentone," as the German histologists have named this area (Schuhmann, 1981), is particularly well shown in Figure 24 of Becker and Röckelein (1989). Misinterpretation of that feature alone may lead to an assessment of the so-called dysmaturity of villi. Altshuler and Herman (1989) characterized villous dysmaturity thus: "Third trimester placentas that have large villi with numerous stromal cells, a lack of syncytiotrophoblast, and syncytiotrophoblastic knots . . . examples are chorangiosis, diabetes, and immunohemolytic anemia." It must be said, however, that there is no unifying hypothesis to define, let alone explain, "dysmaturity." We prefer not to use this term at all because it is not sufficiently specific. Rather, we employ the term **villous maldevelopment** to mean similar abnormalities in structure when no specific cause is apparent. What is meant is that the villous architecture is admixed; there are perhaps mature villi mixed with edematous or hypercellular immature villi, scarred avascular villi with chorangiosis (Figs. 14.1 to 14.3), and so on. Dysmaturity is not a precise diagnosis and it would be better to describe the abnormality specifically rather than to use the poorly defined term **dysmaturity**.

## Assessment of Villous Maturation

Other considerations concerning errors in villous development have been summarized by Vogel (1996). He suggested that these maturational disturbances occur as

FIGURE 14.1. Chorangiosis (grade 2 according to Altshuler, 1984), associated with villitis of unknown origin. H&E  $\times 90$ . (Courtesy of Dr. G. Altshuler, Oklahoma City, Oklahoma.)

FIGURE 14.2. Tenney-Parker changes at 25 weeks' gestation. This placenta is from a preeclamptic pregnancy and shows features of accelerated maturation. Large numbers of syncytial knots (Tenney-Parker) are everywhere present. H&E  $\times 64$ .

FIGURE 14.3. Marked congestion of villous capillaries and veins in a 30-week placenta of preeclampsia. Note association with increased knotting. Similar congestion of capillaries and veins is usually found after preterm rupture of membranes; it is probably caused by cord compression due to loss of amniotic fluid. H&E  $\times 100$ .

often as in 25% of otherwise normal placentas, albeit only in confined, small areas of the placentone. Most did not have a known fetal impact, although their frequency was

much increased in problem pregnancies. As there exists no uniform, agreed-upon terminology, Vogel (1996) produced the following table:

Becker (1981a)	Schweikhart (1985)	Kloos and Vogel (1974)	Vogel (1984)
Normal maturation	Synchronous maturation	Mature, age-corresponding	Mature gestation, age-appropriate
Delayed maturation		Discontinuous vascularization	Dissociated villous maturation, mostly mature
Retarded maturation	Terminal villi deficiency	Concordant retarded villi	Dissociated villous maturation, mostly immature
Arrested maturation	Persisting immaturity	Persisting embryonal structure	Arrest of villous maturation
Premature maturation	Asynchronous postterm maturity	Premature maturation	Villous premature maturation
Chorangiosis		Chorangiomas	Chorangiosis, type I
Pseudochorangiosis		Angiomas	Chorangiosis, type II
Chorangiomas		Chorangiosis	

The term placental dysfunction was perhaps first used by Clifford (1954), when he described the features of **postmature** gestations. He suggested that postmature delivery occurred then as often as in 5% of gestations, and he indicated that perinatal mortality increased significantly after term. He was emphatic that much of this mortality reflected intrauterine fetal demise and suggested that it resulted from the supposed decrease of placental function. Clifford addressed fetal function but had little to say about placental findings. Meconium discharge, deficient water transfer, and meconium aspiration seem to have been the principal aspects of postmaturity he considered, although oxygen deficiency was inferred. From the pathologist’s point of view there are no truly characteristic histologic findings that allow one to make the diagnosis of postmaturity in placental examination. Rather, two different features can be found:

1. In the first group of cases, one finds persisting immaturity with scarcity of terminal villi and prevalence of immature intermediate villi, resembling placentas from the early third trimester (Fox, 1968d; Kemnitz & Theuring, 1974; Mikolajczak et al., 1987) (cf. Chapter 8). Other pathologic findings are generally absent. The delay of villous maturation in these cases suggests that postterm delivery was due to absence of placental signals inducing labor. According to Becker (1981a) there was no indication that, from a placental point of view, there was no urgency of delivery.
2. Another quite different entity of postterm placentas shows full villous maturity or even “hypermaturation” with prevalence of mature intermediate and terminal villi and complete absence of immature villous types. The picture may also include increased syncytial knotting (Tenney-Parker changes). Statistically speaking, this type of post-

mature placenta is more calcified, but because not all postmature placentas have an excess of calcification, this is a difficult parameter to judge. These placentas are also more frequently meconium stained, and they have more often chorioamnionitis (Naeye, 1992), but not all are so altered (see Chapter 1).

The same heterogeneity of findings is typical for **pre-mature** deliveries:

1. The inexperienced pathologist, when studying the histology of a prematurely delivered placenta, expects prevalence of large-caliber, lightly stained immature villous types and scarcity of terminal villi. Surprisingly, this is the case in only 33% of the respective placentas; the immature villous maturational state corresponds to the premature stage of pregnancy (synchronous villous immaturity) (Schweikhart et al., 1986).

2. The majority of spontaneous preterm deliveries show more advanced villous maturation. Fully mature villous trees or even abnormal-appearing villi showing increased degrees of capillarization occur frequently in prematurely delivered placentas of preeclamptic women. They are primarily manifest as an increase of syncytial knots (Tenney-Parker changes), smaller villi, and perhaps an increase in the cross sections of capillary lumens (Fig. 14.2). Schweikhart et al. (1986) were impressed with the proliferation of terminal villi in premature placentas, likening their architecture to “bonsai” trees; they found “hypermaturation” placentas as often as in 42% of placentas delivered between 29 and 32 weeks. In the case of preeclampsia, the incidence was raised to 60%. This frequent combination of premature delivery with villous maturity has been called accelerated maturation or *maturitas praecox placentae* (Becker, 1960), to indicate that some villous features indicated greater development than expected for the gestational age. Naeye (1992), however, made the point that this concept of accelerated maturation has often led to confusion and that it is difficult to define precisely. Becker (1981a) proposed that full maturity of the placenta is needed to be responsible for a spontaneous induction of labor (“placental need for delivery”).

In summary, these data suggest that spontaneous induction of labor requires the coincidence of placental maturation with extraplacental signals. Various mixtures of these two factors allow for five different combinations, all of which have been described:

1. Normal villous maturation and extraplacental signals at term: **term** delivery with normal **maturity** of villi.
2. Normal villous maturation, but delayed or missing extraplacental signals for delivery: **postterm** delivery with **hypermaturity** of the placenta.

3. Normal villous maturation, but premature induction of labor: **preterm** delivery with **immaturity** of villi (synchronous immaturity).
4. Delayed maturation of villi, delayed or missing spontaneous induction of labor: **postterm** delivery with **immaturity** of villi (persisting immaturity).
5. Premature maturation of villi, with preterm induction of labor: **preterm** delivery with full maturity or even **hypermaturity** of villi.

## Placental Insufficiency

The term **placental insufficiency** is a most difficult one to define precisely. One might expect that placental weight bears on this question, and placental weight has often been used to suggest that the placental function is “adequate” or “insufficient.” Ratios to fetal weight have then been used to correlate placental function. Sinclair (1948) found the placental weight to increase linearly as gestation progresses; he was unable to account for the great microscopic variability among placentas. He indicated also that birth weights were lower when a marginal insertion of the umbilical cord was present, a feature that is often neglected in published studies because the cord insertion is usually not recorded. This feature is easiest to observe in dizygotic twin pregnancies, where marked discrepancies in size and development can occur.

Garrow and Hawes (1971) examined the proposition of placental weight increases in some detail. They showed that after 42 weeks there was no accumulation of structural proteins in the placenta but that the increasing weight resulted from pooling of fetal blood, a variable that also needs to be carefully controlled for meaningful analysis. After much effort at quantitative analysis they concluded that studies such as the ones reported are “a laborious task, and the yield of additional information is relatively small.” Mayhew and colleagues (1994) assessed placental growth from 12 weeks to term and showed linear growth by “hyperplasia” rather than by ultimate hypertrophy. Generally, the weight ratio given for such comparisons is that of fetus/placenta. Normally, this ratio is between 7 and 7.5, but alterations of the ratio are so frequent that one cannot deduce placental dysfunction from an altered ratio. It is now possible to ascertain sonographically the placental volume (thickness and circumference) and to relate it to fetal growth. Perhaps more appropriate correlations will be made in the future with this modality. That these parameters are more useful was impressively shown by early results of studies by Jauniaux et al. (1994).

A consideration of the entity placental insufficiency fits well into the context of this discussion. As can be imagined, we prefer not to use this term. It implies a specific placental disease when in fact the malady is usually caused by one of a variety of factors. These include an

abnormal fetal genome, chronic infection, and a large number of maternal diseases; they may also relate to the localization of the placenta in the uterus. A good case in point to illuminate the semantic complexity is the discussion by Fejgin et al. (1993). These authors suggested that the low gonadotropin secretion of triploid placentas was caused by placental insufficiency. A much more cogent and persuasive argument was supplied by Goshen and Hochberg (1994). They explained the secretory levels as being caused by the genetic contribution in the two different types of partial hydatidiform moles (PHMs), and in complete hydatidiform moles (CHMs). Thus, two **maternal** genomes (in triploidy) leads to low human chorionic gonadotropin (hCG) values, and two **paternal** genomes (in some cases of PHM, and usually in CHM) leads to excessive secretion of this hormone because of the genetic expression of specific genes.

For somewhat different reasons, others have also spoken against the use of this all-inclusive term (Gille, 1985; Kuss, 1987), as was quoted in some detail by Vogel (1996). Conversely, Becker and Röckelein (1989) made cogent pleas to retain the term **placental insufficiency**. They then produced a complex tabular account of the possible causes of placental insufficiency and stated that an insufficient placenta is one of critical reduction of placental exchange membrane. This entity then encompasses all those features discussed under their special headings, such as preeclamptic changes, chorangiomas, tumors, avascular villi, and excessive fibrin deposits. We prefer to specify and name the lesions rather than to embrace them all in the imprecise terminology of placental insufficiency.

For routine examination of the histologic picture it is important to study various areas in the placenta as they do not all have the same appearance. For example, the peripheral edge of the placenta often has some increased fibrinoid deposition as a normal feature, and some degree of infarction may be present that is not representative of the remainder of the organ. The villi beneath the chorionic plate are also more widely spaced than those of the floor, and this anatomic difference often leads to focal coagulation that is not necessarily pathologic. At the margin of the placenta, infarction and excessive fibrin deposits are common and should be considered to be normal events, if that is the only location of these changes.

## Examination of Fetal Stem Vessels

In assessing the adequacy of villous tissue for fetal growth, it is our practice to proceed in an orderly fashion with the examination so that all aspects are inspected and evaluated. We begin with the assessment of the **umbilical cord and its vessels**. It is of interest to know whether the vasculature is congested, whether there is a sufficient amount

of blood within the vessels, and, importantly, whether there are nucleated red blood cells (NRBCs) within the fetal blood. The presence of NRBCs is abnormal and connotes anemia, previous hypoxia of some duration, or fetal growth disturbances (Bernstein et al., 1997). When NRBCs are found, we make it a practice to check the newborn blood smear to enumerate these cells (see Chapter 8). At this time we also examine the vessels of the umbilical cord for thrombi, inflammation, and possible meconium damage.

The vascular system is next studied in the **surface of the placenta**. Here, the presence or absence of thrombi is carefully assessed. These frequent, important aspects of prenatal pathology are most commonly found in the veins. These surface veins are difficult to differentiate from arteries by histologic study alone. Veins lie usually below the arteries, but it is best to identify them macroscopically. When thrombi are very old, they transform ultimately into “cushions” (see Chapter 12) (de Sa, 1973), organized thickenings of the venous vascular wall. It must be emphasized that some of these cushions are readily misinterpreted as they may represent bifurcations of vessels. The thrombi may be occlusive, and they may also calcify; this change is prominently found in cytomegalovirus (CMV) infections and also when the thrombi are very old. Calcification also occurs in the walls of vessels when thrombi have been long-standing.

Similar cushions have been described in walls of umbilical arteries, chorionic arteries, and occasionally also in those of larger villous arteries (Emmrich, 1991). Altshuler (1993) stated that he found cushions “associated with clinically diagnosed neonatal asphyxia.” Becker (1981a) introduced the term asphyxial infiltrates. This view has been contradicted by Emmrich et al. (1998a,b), who did not find any correlation between incidence of arterial cushions and signs of hypoxia or acidosis in the neonate.

More often than obliterative thrombosis, one finds only mural fibrin deposits. These usually betray long-standing diseases and correlate primarily with stasis from cord problems such as knots, entangling, or prolapse. Occasionally, mural thrombosis of surface veins results solely from marked twisting of the umbilical cord.

The **main stem villous vessels** are next inspected. It is in these vessels that hemorrhagic endovasculitis (HEV) is most commonly seen (Sander, 1980), which is primarily a feature associated with stillbirths. It represents in our opinion a postmortem or postthrombotic phenomenon; the lesion is discussed in greater detail in Chapter 12 (see Thrombosis of the Placental Vascular Tree).

## Examination of the Fetal Capillary Bed

The number of capillaries in the terminal villi is next evaluated. They may be markedly congested when the cord has been clamped soon after delivery of the neonate and also

when maternal diabetes has complicated the pregnancy. **Congestion** as shown in Figure 14.3, however, must not be confused with the more ominous condition known as **chorangiosis** (Altshuler, 1984). The designation *chorangiosis* makes reference to a numerical increase of capillaries within the peripheral placental villi. Although *chorangiosis* can be a very impressive feature, it does not relate to neoplastic changes such as angiomas, as has been suggested. This condition is presently underrated as an indicator of chronic prenatal hypoxia. In studying the placentas of infants that were admitted to the neonatal intensive care unit of his hospital, Altshuler found that 5.5% had *chorangiosis* in their placentas. He provided criteria for the evaluation that have not yet been challenged.

What is important about *chorangiosis* is its relative rarity and that it is strongly correlated with perinatal mortality and a wide variety of pregnancy and placental disorders. It is definitely a pathologic feature. The appearance is characteristic, and it is obvious that weeks must be required for the degree of capillary proliferation to take place that produces *chorangiosis*. It is perhaps for these reasons that the lesion had been termed *chorangiomatosis* in the past (see Chapter 24).

*Chorangiosis* occurs also in women who have pregnancies at very high altitude (Reshetnikova et al., 1994) and in severely anemic mothers (Kadyrov et al., 1998). That the proliferation of villous capillaries is an adaptation to chronic oxygen deficiency is further supported by the experimental results in guinea pigs described by Scheffen et al. (1990). They demonstrated such increase of capillaries when guinea pigs were chronically (45 days) deprived of normal oxygen tension in their environment. This point is relevant also to the long history of placental studies at high altitude, where the smaller size of infants and placentas found has much interested investigators. Jackson and her coworkers (1987) have studied the placenta of women at high altitude in Bolivia and compared them with those at sea level. The total villous length was smaller at high altitude, and capillary cross sections were increased. Thus, an altered capillary/villus ratio emerged as being characteristic.

The terminal villi may lack all capillaries, markedly reducing the available exchange area, and its quantity needs to be estimated. Such **avascular villi** are most common following chronic villitis, as in CMV infection. Next most commonly, avascular villi result from main stem and surface vessel thrombosis (Fig. 14.4) (Altshuler & Herman, 1989). In similar degenerative events, McDermott and Gillan (1995) have shown that a chronic reduction of fetal blood flow precedes villous infarction. They suggested that siderosis of villous basement membranes, seen so prominently in cases with arterial thrombosis, was a good marker for this reduced flow. Calcifications of villous basement membranes, having a similar appearance, are discussed next.

FIGURE 14.4. Marked fibrosis and “avascularity” of villous district caused by obliteration of a large surface vessel. Note the extremely thin trophoblastic cover of villi and pyknotic nuclei. H&E  $\times 160$ .

### Villous Architecture and Fibrinoid

Having studied the vasculature, we prefer next to evaluate the low-power appearance of the villous architecture. It is at this time that structural abnormalities are identified that have an only focal distribution. Focal edema (Naeye et al., 1983; Shen-Schwarz et al., 1989; Naeye, 1992; Altshuler, 1993) is easiest to identify at this time and its abundance can then be estimated. Naeye et al. (1983) had described **villous edema** to occur especially in placentas affected by chorioamnionitis but believed it to correlate best with fetal hypoxia. The extent of edema also correlated with low Apgar scores and other features leading to perinatal mortality. Naeye (1992) specifically suggested that severe villous edema may interfere with oxygen delivery to the fetus by compression of capillaries within villi. Edema would also allow one to recognize possibly increased numbers of Hofbauer cells, especially in Rh incompatibility, chronic infections, and maternal diabetes. It is important to note that not all lightly stained villi represent truly edematous villi. Rather normal immature intermediate villi may be misinterpreted as such, as

their reticular stromal core has only a low affinity for conventional histologic stains (see following, and Immature Intermediate Villi in Chapter 7).

During this survey with low-power inspection of the villous tissue, the **maturity of villi** is adjudicated, perhaps representing the most difficult task in placental examination for the novice. It must be admitted that it is often impossible to accomplish this task accurately, mostly because of preparative problems. Thus, the diagnosis of postmature villi cannot easily be made correctly from villous examination alone. Maternal factors, fixation, and storage all strongly affect the histologic villous appearance and must be weighed. The influence of maternal conditions is perhaps best seen in preeclampsia when the reduced intervillous blood flow leads to the “Tenney-Parker changes” (Tenney & Parker, 1940). These changes are exemplified by a diffuse increase in syncytial knotting and a decreased size of terminal villi caused by lack of interstitial fluid.

An examination of the villous tissue under low power also allows one to identify irregular maturation of villi, foci of fibrosis, and the quantity of **fibrin** or **fibrinoid** deposited. A diffuse increase of perivillous fibrin is sometimes interpreted as reflecting chronic intervillous perfusional problems (Altshuler, 1993). Alternatively, excessive fibrinoid deposition is a striking feature of the so-called maternal floor infarction syndrome (see Chapter 9). In this condition, not only is the decidual floor heavily infiltrated by “fibrinoid,” but also this material often disseminates throughout the villous tissue and is associated with proliferation of extravillous trophoblast. The villous tissue in such cases is stiff during macroscopic study, is diffusely penetrated with gray fibrin masses (*Gitterinfarkt*), and may show many microcysts in the increased extravillous trophoblast deposits. Microscopically, the fibrin encases villi that are being strangled, consequently lack vessels, and ultimately die. It strongly correlates with fetal growth retardation and intrauterine fetal demise. Naturally, true infarcts are also noted during this survey and their age is estimated as well (see Infarcts in Chapter 19).

## Intervillous Space, Infarcts

Finally, the intervillous space is evaluated. Does it contain **thrombi**, especially beneath the chorionic plate? Are they fresh or old, and are they the possible sites of fetal bleeding? Are there tumor metastases or other abnormal features that need study with higher magnification? And are the maternal red blood cells perhaps sickled? Subchorionic thrombi are common, as was discussed extensively in Chapter 12. Sonographers have often referred to the subchorionic space as being “lucent” and have speculated that sonographic lucencies are meaningful abnormalities of placentation. There is some indication also that lucencies are a possible warning sign of placenta accreta or

placenta percreta. In most, the sonographically identified subchorionic lucencies disappear with delivery. Nevertheless, large laminated thromboses may occur in this location that can interfere with fetal development. Growth retardation, vascular compromise, and lateral expansion of these thrombi with abruptio have all been described and were discussed in some detail earlier (see Chapter 9). What is not clear from the current literature is the etiology of large “thrombohematomas,” as the larger of these abnormalities have been referred to. Some authors consider them to be related to abruptio placentae, whereas others have likened them to Breus’ mole. We consider it possible that they are accidental expansions of the normal subchorionic thrombi that make up the fibrinous plaques of term placental surface and which arise most likely by eddying and rheologic aberrations in the intervillous circulation. None of these lesions are related to angiomas, even though sonographically they may have similar appearances.

Also evaluation of the **width of the intervillous space** may give important hints: An unusually wide intervillous space combined with abnormally small villous calibers (see Figs. 14.8 and 15.7) is a usual finding in postplacental hypoxia (Kingdom & Kaufmann, 1997) (see Types of Hypoxia and Its Effects on Villous Development in Chapter 7). Clinically, this condition is characterized by intrauterine growth restriction combined with absent or reverse end-diastolic umbilical flow (Macara et al., 1996; Kingdom et al., 1997). In contrast, an extremely narrow, cleft-like intervillous space combined with irregularly shaped, highly branched terminal villi and impressive Tenney-Parker changes (see Fig. 15.5) is characteristic for villi with increased numbers of highly branched capillaries (excessive branching angiogenesis, chorangiosis). It is often found in severe preplacental hypoxia (maternal anemia; Kadyrov et al., 1998) and in uteroplacental hypoxia (IUGR with preserved end-diastolic flow in the umbilical arteries, with or without preeclampsia, Todros et al., 1999).

**True placental infarcts** result from occlusion of maternal vascular supply. They have different qualities sonographically and are also clearly different from thromboses. They involve actual placental tissue, whereas the thromboses push the villous structures aside. There may be some infarction of villi adjacent to the thromboses, but that is not a major feature. Infarcts are generally the result of disturbances of intervillous circulation, usually secondary to obstruction of maternal arteries in the placental floor. They also accompany most abruptios. In a true infarct, the trophoblast dies first and subsequently the stroma, vessels, and all other components of the villi undergo necrosis. Initially, there is still some nuclear dusting from karyorrhexis, but eventually that disappears too. Early infarcts still possess some fetal red blood cells with hemoglobin and they are therefore red; later the

hemoglobin lyses and the infarcts turn white or yellowish. Eventually, infarcts atrophy remarkably and may focally calcify. In the adjacent villous tissue there is frequently some degree of Tenney-Parker change because of the circulatory disturbance and the ensuing local hypoxia. Virtually all infarcts have the same appearance, and it is uncommon that their microscopic evaluation makes a useful contribution to the understanding of the placental pathology. Although we have recommended that few of them be examined microscopically and, rather, that more noninfarcted tissue be sampled in placentas affected by infarcts, this is not always prudent. Numerous cases of unsuspected choriocarcinoma in situ have now been described in term placentas that have the macroscopic appearance of ordinary infarcts (see Chapter 23). One usually can reliably identify infarcts macroscopically, and then make a judgment as to their volumetric contribution to the whole organ.

### Abruptio Placentae

More problematic is the evaluation of abruptio placentae. When it is very fresh, no histopathology may be visible. The retroplacental hematoma may have the same appearance as that blood which normally follows placental detachment. Older abruptios tend to compress the villous tissue and are then more easily identified microscopically. The blood cells are degenerating, there is laminated fibrin, pigmented macrophages may be present after a few days, and the decidua basalis is degenerated and often replaced by the hematoma. Indeed, this destruction of the decidua basalis usually makes it impossible to identify the maternal blood vessels and the atherosclerosis or thrombosis within them that were responsible for the abruptio.

It is noteworthy that small areas of abruptio placentae are much more common than is usually stated (Benirschke & Gille, 1977). The reason for this is that most retroplacental hemorrhages do not produce the usually cited clinical symptomatology of sudden abdominal pain and bleeding. Their contribution to fetal well-being may also be much less significant than is that of the large retroplacental hemorrhage with detachment of a major portion of placental tissue. Because most abruptios are considered to be the result of trauma or maternal vascular disease, an assessment of the decidual spiral arterioles is desirable. In the locale of the abruptio, however, this is usually impossible. The vessels here are often destroyed by the process or have remained behind during the delivery of the placenta. Therefore, one must look in adjacent portions of decidua, and especially in the decidua capsularis. Atherosclerosis and thrombosis are often well displayed in these vessels, but it must be cautioned that their absence is not meaningful. These lesions are often very irregularly distributed, and to ascertain their status with certainty requires blunt curettage after delivery of the placenta.

That procedure is not a favorite part of obstetrical care and thus it is not often undertaken. It is therefore frequently impossible to rule out vascular changes as a cause of abruptions, and therefore their etiology remains obscure.

## Major Histopathologic Findings

This brief survey lists the major histopathologic observations that should be made in placental microscopy.

### Syncytiotrophoblast

The syncytiotrophoblastic cover of the villous trees usually shows considerable variations in thickness, distribution of nuclei, and structure of nuclei. Extremely thin anuclear areas (epithelial plates) and accumulations of nuclei (syncytial knots) are arranged in a mosaic-like pattern. **Homogeneous trophoblastic thickness**, combined with numerous Langhans' cells (villous cytotrophoblast), are found in immature placentas (see Fig. 6.13), in persisting villous immaturity, erythroblastosis (see Fig. 15.10), and in most placentas from diabetic mothers (see Fig. 19.6).

Homogeneous trophoblastic thickness, combined with loss of villous cytotrophoblast, is a typical feature of post-placental hypoxia that is discussed in detail in Chapter 15 (see Fig. 15.17) (Fig. 14.5). Extremely thin syncytiotrophoblast with evenly distributed pyknotic nuclei locally forming large knots (Figs. 14.4 and 14.6; also see Fig. 12.60) are additional important features. Most of the latter are indications of accumulation and shedding of apoptotic nuclei (cf. Chapter 6). When they are combined with the absence of villous cytotrophoblast, this usually points to deficient fetal perfusion of the villi (e.g., fetal death, thrombosis of stem vessels). This malperfusion leads to an increased intravillous oxygen partial pressure and failure of villous cytotrophoblast to proliferate and to regenerate the syncytium (see Oxygen and Oxygen-Controlled Growth Factors as Regulators of Villous Development in Chapter 7).

### Knotting of the Syncytiotrophoblast

Increased numbers of syncytial knots, sprouts, and bridges are called syncytial knotting, or Tenney-Parker changes. As discussed in Chapter 15 (see Syncytial Knotting), these features have to be interpreted with care because they are influenced by the thickness of the section. Küstermann (1981), Burton (1986a,b), and Cantle et al. (1987) have shown that most of these nuclear accumulations are flat sections of irregularly shaped villous surfaces. An **increased incidence of syncytial knotting** thus points to abnormal villous shapes (increased branching and bulging

FIGURE 14.5. Persisting immaturity near term. Note the slender, straight sections of mature intermediate villi are arranged in parallel and the absence of terminal villi with sinusoidally dilated capillaries. In normal pregnancy, this feature would correspond to the 32nd to 34th week of gestation. It is also a common feature of postmature placentas, combined with IUGR. H&E  $\times 30$ .

FIGURE 14.6. Immature placenta at 30 weeks from a patient with preeclampsia. Note the accelerated maturity (at left) with numerous syncytial knots (Tenney-Parker change) associated with small terminal villi and large immature intermediate villi at right. The latter are not edematous in nature but, rather, display a reticular stroma. H&E  $\times 64$ .

of villi) (see Chapter 15), and they can usually be found under hypoxic conditions. Typical clinical examples include hypertensive disorders (Alvarez et al., 1969) (Fig. 14.6), maternal anemia (Piotrowicz et al., 1969), and pregnancy at high altitude (Jackson et al., 1987). Also, some cases of prolonged pregnancy (see Fig. 15.14) (Essbach & Röse, 1966; Emmrich & Mälzer, 1968) and many cases of preterm delivery (*maturitas precox placentae*) (Becker, 1981a; Schweikhart et al., 1986) show similar features. When groups of small terminal villi with increased knotting alternate with groups of severely immature villi (Fig. 14.6), preeclampsia is a prominent possibility (see Chapter 19).

The syncytial knots caused by trophoblastic flat sectioning just discussed are usually concentrated in groups of terminal villi. Similar trophoblastic features around the surfaces of immature villous types represent, in most cases, **villous sprouting**. Abnormal degrees of this phenomenon can be seen in moles and in several of the chromosomal aberrations (see Chapter 21, Fig. 21.27, and Chapter 22).

### Langhans' Cells

The villous cytotrophoblast is difficult to identify in routine paraffin sections. Despite the fact that Langhans' cells are present at about 20% of the villous surfaces at term, one usually finds only one clearly identifiable Langhans' cell per cross section of any peripheral villus. **Lower frequencies of Langhans' cells** (in routine paraffin histology: fewer than a mean of one visible in two peripheral villous cross sections) are found in postplacental hypoxia (e.g., IUGR with absent end-diastolic flow in the umbilical arteries) (Macara et al., 1996) (see Chapter 15), and in fetally malperfused villi (fetal death, thrombosis of stem vessels) (see Placental Surface Vessels in Chapter 12).

In contrast, **increased numbers of Langhans' cells** (in routine paraffin histology: more than two visible per peripheral villous cross section) are usual findings in immature placentas; they also exist in "persisting immaturity" (Becker & Röckelein, 1989) (see Chapter 15), erythroblastosis (Wentworth, 1967; Pilz et al., 1980) (see Chapter 16), maternal anemia (Kosanke et al., 1998) (see Chapter 19), and maternal diabetes mellitus (Werner & Schneiderhan, 1972) (see Chapter 19). It is said that their number increases with the severity and duration of preeclampsia (Fox, 1997).

### Vasculosyncytial Membranes

Vasculosyncytial membranes are the result of sinusoidal dilatation of the terminal villous capillaries, which bulge against the trophoblastic surfaces and attenuate them to thin lamellae (see Figs. 6.4A and 6.7A). The incidence is closely related to fetal villous vascularization. Imma-

ture placentas and cases of "persisting immaturity" (Fig. 14.5; also see Chapter 15) show reduced villous capillarization and, consequently, a **paucity of vasculosyncytial membranes**.

On the other hand, an increased capillarization of terminal villi is found at high altitude (Jackson et al., 1987; Reshetnikova et al., 1994) and in some other hypoxic disorders (preeclampsia, maternal heart failure, maternal anemia) (Beischer et al., 1970; Alvarez et al., 1970, 1972; Kadyrov et al., 1998) (see Control of Villous Development in Chapter 7). It results in an **increase of the vasculosyncytial membranes**; it can come about only when these conditions have existed for some time. In IUGR with absent end-diastolic umbilical blood flow, similar features are observed. Here, abnormally long, unbranched capillaries are combined with reduced diameters of terminal villi (Krebs et al., 1996; Macara et al., 1996). Finally, fetal villous congestion (see Fig. 14.1) can increase vasculosyncytial membranes.

### Trophoblastic Basement Membrane

In routine paraffin sections of normal villi, the trophoblastic basement membrane is usually only seen when special stains are applied, such as aldehyde-fuchsin, periodic acid-Schiff (PAS), and immunohistochemistry for collagen IV or laminin. **Marked thickening** of the basement membrane that becomes clearly visible has been described under various pathologic conditions, such as preeclampsia and essential hypertension (Fox, 1968c), maternal diabetes (Liebhart, 1971, 1974), and IUGR with absent end-diastolic umbilical blood flow (Macara et al., 1996). The reason for these basement membrane changes presumably is that constituents of the basal lamina are secretory products of the villous trophoblast; the increased thickness indicates an altered trophoblastic activity, for example, increased secretion or decreased turnover of basal lamina molecules.

### Perivillous Fibrinoid

Most perivillous fibrinoid is a blood clotting product. It is found in defects of the villous trophoblastic cover (see Perivillous Fibrinoid in Chapter 6) and here may act as a substitute for damaged trophoblast. The deposition of perivillous fibrinoid is a regular phenomenon, occurring in every placenta, and the amount increases with advancing pregnancy. This increase is particularly true for the stem villi, whose trophoblastic surface is largely replaced by fibrinoid at term (see Figs. 8.11 and 8.12). One normally finds some increase of fibrin encasing larger groups of villi below the chorionic plate (subchorionic laminated fibrin, bosselation), and also in the marginal zone.

Macroscopically visible deposits that embed larger parts of villous trees are abnormal. These are referred to

as *Gitterinfarkts* (Becker & Röckelein, 1989), whereas increased amounts of fibrinoid at the base of the placenta belong to the entity known as **maternal floor infarction**, an important placental disease (see Maternal Floor Infarction in Chapter 9). In obstructing large parts of the maternofetal exchange surface, these deposits may endanger fetal growth and survival. Otherwise, **disseminated perivillous fibrinoid deposition** has no pathologic significance (Fox, 1967, 1997).

### Intravillous Fibrinoid

This different type of fibrinoid has also been referred to as villous fibrinoid necrosis. It must not be confused with the perivillous fibrinoid just discussed. It is a fibrinoid patch that replaces villous stroma and vasculature underneath a more or less intact trophoblastic cover (see Fig. 3.2F). It occurs occasionally in normal mature placentas, but its incidence is increased in placentas from diabetic mothers and in cases of erythroblastosis fetalis (Fox, 1968a). Its genesis has been discussed in context with immune attacks (Burstein et al., 1973).

### Villous Calcification

Villous calcifications are relatively uncommon and quite different from the minute calcium deposits in fibrinoid that occur with advancing gestation. The latter is found mostly in the floor and septa and was discussed in Chapter 9. **Villous calcification** may occur when villi have been destroyed by processes of the past such as thrombosis, CMV infection, and infarction (Fig. 14.7). Calcifications of villous tissues are also observed in some retained placental fragments or when the placenta of a fetus papyraceus is retained to term. Quantitatively they play no important role in placental pathology.

An entirely different type of calcification is the finely granular deposition of purple-staining **calcium precipitate in basement membranes** of abortuses. It is currently not certain that this represents calcium salts, as other salts have similar staining characteristics. This fine stippling is perhaps the result of deficient transport of materials through the trophoblast but not consumed after fetal death with its cessation of capillary flow. It has no known etiologic role.

### Stem Vessels

It was suggested that the number of arteries in peripheral stem villi is decreased in association with umbilical Doppler high resistance (Giles et al., 1985). Since then, the topic of fetal villous arteries has attracted much attention. Studies by other investigators have not corroborated this finding (Jackson et al., 1995; Macara et al., 1995).

FIGURE 14.7. Immature placenta with degenerated villi that contain conspicuous areas of calcification (black, irregular, and fragmented intravillous foci). H&E  $\times 160$ .

The most conspicuous pathologic changes of fetal stem vessels comprise **thromboses**. These are common features and affect mostly superficial veins. Laminated mural thrombi are our most common finding. They result primarily from obstruction of venous return to the fetus (cord knots, spirals, and prolapse) and velamentous insertion, and accompany long-standing chorioamnionitis and CMV infection. The main stem vessels and further distal vascular structures may atrophy or disappear completely. Thrombosis may thus lead to complete atrophy of portions of the villous tissue (see Fig. 12.60). Thrombosis of large arteries is less common, and usually it remains unclear what the etiology might have been. Protein C and S deficiencies have been entertained as possible causes but have never been proved. They are extremely serious for fetal development and survival.

**Obliterative endarteritis** (see Fig. 13.14) and especially **hemorrhagic endovascularitis (HEV)** (see Fig. 12.62) are prominent aspects of this area. HEV is found nearly exclusively in stillborn infants and most often results from post-mortem dissolution of the large blood vessels and those of

stem villi. Identical changes accompany local obliterations (velamentous vessels); there is no convincing evidence that they represent an infection (see Chapter 12).

Other vascular phenomena, such as **fibromuscular sclerosis**, also occur in stem vessels, primarily arteries. They are extensively discussed by Fox (1997) and other placentologists. We see them as secondary features of vascular phenomena and usually find them in the “localized” form. It is very uncommon to identify such lesions in widespread distribution. They are then related to Doppler flow anomalies and growth restriction (Fok et al., 1990), but a precise etiology has not been identified. Occlusions of this type are found after infarcts and primarily in long-standing thrombosis. Indeed, when they occur in infarcts we find it unlikely that they are “proliferative” in nature; rather, it is more probable that they come about by the condensation of dying tissues. These obliterations are usual findings in placentas associated with fetal demise. We believe them to be secondary features because other diseases nearly always explain the fetal death. In the presence of absent or reversed end-diastolic velocity in Doppler flow studies, and fetal growth retardation, NRBCs are elevated, and Bernstein et al. (1997) presumed the stem vessel lesions to have derived from thromboses. These were held to be responsible for increased impedance and, thus, growth restriction. By contrast, Krebs et al. (1996) and Macara et al. (1996) studied the vascularization of peripheral villi of growth-restricted neonates and absent end-diastolic flow velocity by scanning and transmission electron microscopy. They found significant villous abnormalities caused by abnormal capillarization, which they declared to be the reason for growth restriction of the fetus. Concentric thickening of media and intima of the tertiary villous vessels were found by Harvey-Wilkes and her colleagues (1996). Associated with this, they observed elevated endothelin levels and used these findings to explain an increased placental resistance and the fetal growth restriction. But what the original etiology for most of these changes is remains speculative, although thrombosis remains the most attractive hypothesis. For that reason, microembolism studies were undertaken in sheep (Gagnon et al., 1996); the results are similar to the spontaneous occurrence in human placentas.

The extensive discussion of endarteritis obliterans by Fox (1997) includes a photograph (see Fig. 6.23) of a vessel depicting “endothelial swelling.” Others have called similar features **endothelial edema**. It very likely represents an artifact and has no relationship to endarteritis. Similar discussions occurred in considerations of HIV-related vascular alterations (see Contractility of Umbilical Vessels in Chapter 12). Indeed, the entity has been widely discussed as occurring in diabetes, preeclampsia, erythroblastosis, and other conditions. Rapid fixation and the use of Bouin’s solution usually prevents

“endarteritis” from being recognizable. It must also be said that the peripheral districts of so-called endarteritis are usually not disturbed, negating its importance as a primary disease of the placenta.

### Nucleated Red Blood Cells

The fetal blood vessels may contain NRBCs. This is a normal finding in gestations of less than 3 months’ duration (see Fig. 3.1C). These elements are abnormal in the last trimester, however, especially when they are identified in routine histology. They then betray the fetal response to erythropoietin (EPO), a hormone that is now frequently measured in neonates. When NRBCs are present one must enumerate them in neonatal blood smears as they rapidly decline after birth. They signify fetal anemia, infection, erythroblastosis, transplacental hemorrhage, or, importantly, prenatal hypoxia. Because it takes time for the secretion of these cells from precursor stores (liver, marrow) through the intervention of EPO and perhaps other signals, the presence of NRBCs suggests that fetal tissue hypoxia of whatever type has occurred many hours, perhaps days, before birth. The topic is covered more extensively in Chapter 8 (see Nucleated Red Blood Cells).

### Villous Capillarization

The vasculature of villi is difficult to adjudicate because the capillaries tend to collapse after delivery. The degree of collapse depends on the mode of delivery, the mode of cord clamping, the time elapsed between cessation of umbilical circulation and fixation, and the composition of the fixative (see Tables 28.8 to 28.10). Moreover, when the tissue is fixed in inadequate volumes of fixative the tissue becomes compressed. Thus, asymmetrical compression or distortion of the placenta during fixation may cause considerable shifts of intravascular volume with complete collapse in one part of the fetal vascular bed and apparent overdistention in another. Conclusions concerning villous capillarization, therefore, must always take these potential errors into consideration.

**Reduced capillarization** of the terminal villous tree is found in slightly immature placentas (see Figs. 14.5 and 15.9). This feature is combined with a uniform trophoblastic cover of the mature intermediate villi that show unusually straight and parallel sections because terminal side branches are largely missing (Fig. 14.5; see Chapter 15).

**Complete atrophy of capillaries** can be found peripheral to obstructive lesions in the stem vessels (see Placental Surface Vessels in Chapter 12). Small groups of avascular villi are seen in every placenta (Fig. 14.4), but a higher incidence is often combined with IUGR or intrauterine fetal death.

Hypercapillarization may show different features, some of these have already been considered. Cases of **hypoxic hypercapillarization** are usually characterized by numerous but small capillary cross sections in clusters of aggregated terminal villi. The latter are often connected to each other by trophoblastic flat sections. This feature is often referred to as chorangiosis (see Figs. 14.1, 15.6, and 15.16, and Chapter 24) (Bacon et al., 1984; Jackson et al., 1985, 1988). Three-dimensional reconstruction revealed richly branched capillary nets (Scheffen et al., 1990) resulting from branching angiogenesis. Branching angiogenesis is driven by vascular endothelial growth factor (VEGF), the expression of which is upregulated by low oxygen partial pressures (see Chapter 7). Typical examples of hypoxic hypercapillarization are found in maternal anemia (Kadyrov et al., 1998), and in IUGR with preserved end-diastolic umbilical flow with or without preeclampsia (Todros et al., 1999).

One sometimes finds cases in which very few (usually only two) but locally dilated capillary cross sections occupy extremely small terminal villi (see Fig. 15.13). These villi have long, unbranched capillary loops (see Figs. 7.17 and 15.6) resulting from **excessive nonbranching angiogenesis**. The respective terminal villi rarely aggregate, forming clusters of villi connected by syncytial knotting. Rather, they represent a mixture of single villous cross sections measuring only 40 to 60  $\mu\text{m}$  in diameter, together with few filiform longitudinal sections (Fig. 14.8). These features often exist among premature deliveries (Schweikhardt et al., 1986). We observed the most impressive cases of this kind associated with severe IUGR with absent umbilical end-diastolic blood flow (Krebs et al., 1996; Macara et al., 1996; Kingdom et al., 1997) (Fig. 14.8). This condition is thought to be caused by abnormally high intervillous oxygen partial pressures (postplacental hypoxia) (Kingdom & Kaufmann, 1997).

These features are not always easy to differentiate from **villous congestion** (see Fig. 14.3), also resulting in overdilated peripheral vessels. The presence of overdilated veins in stem villi, the normalcy of villous caliber distribution, the loss of plasma between the erythrocytes, extravasations, and signs of hemolysis may be helpful for the diagnosis. Congestion may be the result of cord complications (see the sections Knots and Thrombosis of the Placental Vascular Tree in Chapter 12) and also of thrombosis of major villous stem veins. Finally, we have often observed congestion in cases of premature rupture of the membranes, perhaps because of loss of amniotic fluid thus altering venous umbilical blood flow.

### Stromal Architecture and Stromal Fibrosis

Fibrosis of stem villi is a good indicator of placental maturity (see Chapter 8, Figs. 8.2 to 8.12). Fibrosis starts on about the 15th week postmenstruation (p.m.), begins

FIGURE 14.8. Placenta at 29 weeks' gestation associated with severe fetal growth retardation (neonatal death), showing marked accelerated maturation of the terminal villous branches. The small diameter of terminal villi and the absence of syncytial knotting suggest this is a case of nonbranching angiogenesis in terminal villi caused by postplacental hypoxia (cf. Chapter 15). As is typical for many cases of accelerated maturation, stem villi remain in their normal immature condition. Their appearance must not be confused with edema. H&E  $\times 64$ .

around the stem vessels, and should be complete a few weeks before term. When reticular, unfibrosed connective tissue persists under the trophoblastic membrane, as in Figures 8.5 and 8.6, it signifies immaturity.

**Extensive stromal fibrosis** is abnormal, especially when it is not restricted to the stem villi (i.e., those with media-endowed vessels). It can be found in "intrauterine growth retardation combined with absent umbilical end-diastolic blood flow" (Macara et al., 1996), in avascular villi following stem vessel obstruction or fetal death (see Fig. 14.4) (Becker, 1981b; Veen et al., 1982), in CMV infection, and in a few other conditions. It has been speculated that increased intravillous oxygen partial pressure stimulates collagen synthesis when it occurs in the maternally well oxygenated but fetally malperfused placenta (for review, see Kaufmann et al., 1993; Kingdom & Kaufmann, 1997). In contrast, intraplacental hypoxia has been inferred to be responsible for reduced villous fibrosis (Fox, 1968b,

1997), for example, unfibrosed, immature villi in pre-eclampsia (see Fig. 14.6).

### Hofbauer Cells (Macrophages)

These cells can easily be seen within the stromal channels of the immature intermediate villi (see Figs. 7.4 and 7.9). When one uses immunohistochemical markers for macrophages (CD68 antibodies), it becomes evident that they are present in all villous types throughout all stages of pregnancy, although they may be difficult to see. Therefore, the impression of increased numbers of Hofbauer cells is usually the result of increased numbers of immature intermediate villi. It thus points to an immature placenta or persisting immaturity in a term organ. Other associations are unknown.

An apparent deficiency of macrophages is observed in moles and some chromosomal aberrations, especially in their large, pale villi that otherwise have the appearance of immature intermediate villi. In these cases, the pale stroma is very loose and hydropic and does not belong to the reticular type, that which has stromal channels and contains macrophages (see Chapters 21 and 22, Figs. 21.5, 22.9, and 22.21).

### Inflammatory Changes

Villi may participate in infectious diseases by infiltration of mononuclear and polymorphonuclear leukocytes (polys). Polys are rarely within villi; they are most common in the amnionic sac infection syndrome, chorioamnionitis. When polys are present within villi, this signifies an acute infectious bacterial disease. **Acute villitis** is a prominent feature of listeriosis, a disease that is disseminated by maternal septicemia. Other maternal bacterial infections, such as staphylococcal sepsis and other bacterial septicemias, are extremely uncommon. They all produce abscesses in the placenta with dissolution of villous tissue.

Much the commonest placental infection recognized is that with **cytomegalovirus** (CMV). The picture this virus produces is extremely variable. When one finds plasma cells concentrated in a few villi, especially when they are accompanied by hemosiderin-laden macrophages and villous sclerosis, then CMV infection is likely. One may then have to search for the typical inclusion bodies, a sometimes difficult task, or stain with immunoprobes or identify the virus with the polymerase chain reaction (PCR) technique. Typical "owl-eye" cells may be found in endothelium, trophoblast, and unidentified stromal cells (see Fig. 20.48). Other chronic villitides are caused by toxoplasma and syphilis; they are rarely due to rubella and other recognized viruses (see Chapter 20).

Much the most problematic is the entity known as **villitis of unknown etiology** (VUE), which is also discussed at length in Chapter 20. In this villitis chronic inflamma-

FIGURE 14.9. Placenta from a patient with villitis of unknown etiology (VUE) at 36 weeks' gestation. The infant was stillborn. Note marked infiltration of chronic inflammatory cells and simultaneous destruction of villous integrity (right). H&E  $\times 250$ .

tory cells predominate but plasma cells and polys are generally absent. The villi, however, may disintegrate as Figure 14.9 shows. Villitis of unknown etiology is frequent and has no known etiology. It may recur in subsequent gestations and, when extensive, it may cause fetal death. No microorganisms have been discovered as its cause and recent suggestions of the possible infiltration with maternal immunocytes are too inconclusive still. They may signal immune recognition of the fetal antigen, but that is far from certain.

### Villous Edema or Immaturity

Many authors call every large, pale-staining villus an edematous villus following the description by Naeye et al. (1983). It is our experience that most of these villi are in fact normal immature intermediate villi (Fig. 14.10) (Pilz et al., 1980; Kaufmann et al., 1987). They may cause diagnostic problems, as their reticular stromal core has only a weak affinity for conventional stains because it lacks collagen. The resulting histologic picture is that of a seemingly edematous villus that had accumulated much interstitial fluid.

True **edematous villi** indeed exist, however, as well. They are particularly impressive in hydatidiform moles and hydatid degeneration of abortion specimens (Fig. 14.11), but some are found occasionally in infections such as syphilis, toxoplasmosis, CMV infection, and a variety of cases of hydrops (Fig. 14.12). Placentas from erythroblastosis and other causes of hydrops may show a combination of the two features, as most villi display a retarded maturation and many are additionally edematous (Fig. 14.13).

FIGURE 14.10. Placenta at 26 weeks' gestation of a case of congenital epidermolysis bullosa. The villous architecture, appropriate for this gestational age, is composed of immature intermediate villi with reticular stroma. They are surrounded by small mesenchymal villi. H&E  $\times 160$ .

FIGURE 14.11. Villi of a partial hydatidiform mole caused by triploidy. There is marked villous distention with edema fluid. On first glance, this appearance is similar to that of immature intermediate villi (Figs. 14.10 and 14.13), but the macrophages of normal intermediate villi are lacking. H&E  $\times 64$ .

FIGURE 14.12. Villi of hydropic fetus with Finnish nephrosis. Most villi are severely hydropic, but they are not different from villi in placentas of other hydrops cases. Compare with Figure 14.11. H&E  $\times 160$ .

FIGURE 14.13. Immature placenta of a pregnancy with hydrops fetalis caused by fetal endocardial fibroelastosis. The placenta shows a combination of normal immaturity with edema. The villi exhibit partly normal immature reticular stroma with an abundance of macrophages (Hofbauer cells, dark cells in reticular spaces), which is normal for immature intermediate villi. In other villi the reticular pattern is partially destroyed by various degrees of edema. H&E  $\times 256$ .

Small numbers of **immature intermediate villi** are found in the centers of the villous trees in nearly every mature placenta (see Fig. 7.18). These are the still proliferating villi and may represent a kind of growth reserve. When they occur in disseminated fashion, or even when there is only a prevalence of this villous type, this indicates immaturity, synchronous or asynchronous. It may be found in many cases of preterm delivery (Schweikhart et al., 1986) and of prolonged pregnancy (Fox, 1968d; Kemnitz & Theuring, 1974; Mikolajczak et al., 1987).

# Classification of Villous Maldevelopment

## Three-Dimensional Interpretation of Two-Dimensional Sections

The histopathology of villous maldevelopment is based on the light microscopy of paraffin sections. Thus, the normal and pathologic features of the placenta are usually described in terms of the two dimensions apparent by light microscopy. These two-dimensional findings very often do not reflect the underlying three-dimensional malformation of villi, as becomes particularly obvious when considering the pathologically meaningful finding of “syncytial knotting” (Tenney-Parker changes).

### Syncytial Knotting: Artifact or Meaningful Pathologic Finding

In past decades several studies have revealed that the two-dimensional impression does not always reflect the three-dimensional structure. Küstermann (1981) used reconstructions of serial paraffin sections to show that most sprouts and bridges are in fact flat sections of irregularly shaped villous surfaces. Burton (1986a,b, 1987), who worked with plastic serial sections, and Cantle et al. (1987) and Kaufmann et al. (1987), who compared light microscopic findings of villous sections with scanning electron microscopy of the identical material (Fig. 15.1), arrived at similar conclusions. All three groups concluded that most of the syncytial knots, syncytial sprouts, and syncytial bridges, summarized as syncytial knotting or Tenney-Parker changes (for definition, see Chapter 6) proved to be only tangential sections of the villous surface. The true interpretation is of considerable importance for aspects of placental pathology, as the histologic appearance of syncytial knotting is widely accepted as a diagnostic indicator of placental ischemia, for example, in preeclampsia (Tenney & Parker, 1940; Alvarez et al., 1964, 1969, 1970; Schuhmann & Geier, 1972).

Küstermann’s (1981) statement that all sprouts, knots, and bridges of the mature placenta must be interpreted as sectional artifacts brought about the question whether the histopathologic experience should be abandoned. Küstermann’s results were largely corroborated by the studies of Burton (1986a) and Cantle et al. (1987). At the same time, it became apparent (Kaufmann et al., 1987) that despite this new interpretation, the diagnostic value of syncytial knotting, even in most cases representing artifacts, was still useful. As is described next, they are significant artifacts that point to a characteristic deformation of the terminal villi. This deformation is usually caused by abnormal villous angiogenesis resulting from abnormal placental oxygenation (see Fig. 15.6). Therefore, the final conclusions drawn by Alvarez et al. (1969, 1970) are generally correct: the diagnostic value of the two-dimensional findings of syncytial knotting remains.

### Interpretation of Syncytial Knotting

Küstermann (1981) and Burton (1986a) used three-dimensional reconstructions of serial sections to verify that most knots, sprouts, and bridges are only flat sections (see Fig. 15.4), a point that can be demonstrated even more impressively in two other ways. Cantle et al. (1987) prepared 10- $\mu$ m epoxy resin sections stained with toluidine blue. This dye does not infiltrate the resin and stains it only superficially. The resulting light microscopic picture corresponds to that of a semithin section of 0.5 to 1.0  $\mu$ m (Fig. 15.2A). When studying the same section with phase contrast microscopy, one obtains a view of the complete 10- $\mu$ m section of the identical material. When comparing the two pictures of the same section shown in Figure 15.2B, one easily realizes that the thin section does not show any sprouts, whereas the thick section reveals three apparent sprouts that were obviously tangential sections of the trophoblastic surface.

This finding is in agreement with the experience of all electron microscopists who have studied the placenta:

FIGURE 15.1. Term placenta. After preparing a semithin section (A), the epoxy resin has been removed from the remaining tissue block. The latter was prepared for scanning electron microscopy. Identical villi are shown in a semithin section (A) and scanning electron micrographs in vertical (B) and nearly horizontal orientations (C). The arrowhead points to a true syncytial bridge, histologically characterized by its smooth

surface, whereas the other “bridge” (double arrow), characterized by its irregular histologic appearance, proves to be a tangential section of a curved villous portion. The large arrow marks an artificial “sprout” that can easily be identified as a tangential section.  $\times 265$ . (Source: Cantle et al., 1987, with permission.)

knots, sprouts, and bridges are common in paraffin sections ( $5\text{--}10\mu\text{m}$ ), rare in semithin sections ( $0.5\text{--}1.0\mu\text{m}$ ), and mostly absent in the ultrathin sections ( $0.05\text{--}0.1\mu\text{m}$ ) prepared for electron microscopy. The situation is schematically depicted in Figure 15.3.

Similar conclusions were deduced when we prepared semithin sections for light microscopy and subsequently removed the epoxy resin from the remaining tissue block. The remaining villi were studied with the scanning electron microscope and compared to the semithin section (Fig. 15.1) (Cantle et al., 1987). Using this method, real sprouts and bridges as well as flat-sectioned villous surfaces can easily be identified and compared to the sectional picture of this tissue. It became evident from such material that branching, twisting, and coiling of villi (e.g., as a result of hypoxia) enhances the chance of tangential sectioning of trophoblastic surfaces and thus increases

the number of artificial knots, sprouts, and ridges (see Fig. 15.6).

On the other hand, scanning electron microscopic proof was presented by Schiebler and Kaufmann (1981), Burton (1986b, 1987), and Cantle et al. (1987) that not all sprouts, knots, and bridges are sectional artifacts; rather, few real such trophoblastic specializations do exist. They may serve (1) as first steps of villous sprouting, that is, formation of new villi (trophoblastic or syncytial sprouts) (Boyd & Hamilton, 1970; Cantle et al., 1987; Castellucci et al., 1990); (2) as a mechanism of extrusion of old syncytial nuclei (Martin & Spicer, 1973; Jones & Fox, 1977), most of the latter meanwhile identified as being apoptotic in nature (Huppertz et al., 1998); or (3) as simple mechanical aids to establish junctions between neighboring villi (syncytial bridges) (Cantle et al., 1987). Based on the findings by Cantle et al. (1987) and Huppertz et al.

FIGURE 15.2. Term placenta from a patient with preeclampsia. A: A 10- $\mu$ m epoxy resin section is stained only superficially with toluidine blue, comparable to a semithin section of about 1- $\mu$ m thickness. B: The same section as in A is observed with phase contrast microscopy and now represents the full section thickness of 10 $\mu$ m. It shows three sprout-like structures, obviously

tangential sections of the trophoblastic surface and not visible in the “thinner” section. It demonstrates the influence of the thickness of the section on the appearance of so-called sprouts and knots, caused by trophoblastic tangential sectioning.  $\times 380$ . (Source: Cantle et al., 1987, with permission.)

(1998) we suggest the following criteria for discriminating between true trophoblastic specializations and tangential sections (Fig. 15.5):

- **True syncytial sprouting** resulting from trophoblastic proliferation is usually characterized by smooth surfaces with well-developed microvilli and loosely scattered, ovoid nuclei (see Fig. 6.11A,B). Only incidentally do they fuse with neighboring villi to form syncytial bridges (see Figs. 6.12A,B and 15.1A).

- Degenerative, **apoptotic knotting** results in knot- or sprout-like structures showing smooth surfaces, mostly devoid of microvilli; the densely packed nuclei show highly condensed chromatin, the most peripheral nuclei usually displaying annular chromatin condensation (see Figs. 6.10A, 6.18, and 6.22).
- Flat sections (**syncytial knotting, Tenney-Parker changes**) result in knots, sprouts, and bridges that are irregularly shaped and notched (see Figs. 6.10C and 15.1A); they are characterized by heterogeneous nuclear shapes as these are typical for syncytiotropho-

FIGURE 15.3. Influence of section thickness on the structural appearance of villi in the microscope. 1, electron microscopic ultrathin section that normally shows only few sprout- and knot-like structures; 2, light microscopic semithin section; 3, light microscopic paraffin section in which, because of its thickness, “syncytial knotting” is a frequent feature.

FIGURE 15.4. Ways by which the appearance of apparent syncytial fusion between villi may arise. Only in the first case (top left) is there true syncytial fusion, whereas in the other three

cases the histologic appearance of sprouting and bridging is of artifactual nature. (Source: Adapted from Burton, 1986a, with permission.)

blast. The apparent numerical density of nuclei increases with section thickness.

Not only the structural features but also the stage of pregnancy and the type of villi involved, may be helpful for discrimination between the true sprouting, apoptotic shedding, and trophoblastic flat sectioning (Fig. 15.5).

Generally, in paraffin sections of the **young placenta** most sprouts attached to immature intermediate and mesenchymal villi are signs of villous sprouting; less often are they sites of extrusion of apoptotic nuclei. Only a minority is artificially produced by trophoblastic flat sectioning. In contrast, in paraffin sections of the **mature placenta**, most knots, sprouts, and bridges are caused by flat sectioning; this is particularly true for those found in conglomerates of terminal villi. Far fewer are sites of accumulation of apoptotic nuclei. Only a very small minority, mostly arising from immature intermediate villi located in the centers of the villous trees, represents real villous sprouting.

### Artificial Knotting as Related to Villous Shapes in Paraffin Sections

The question of how to interpret knots, sprouts, and bridges relates to the more relevant question of how to interpret villous shapes and branching patterns three-

dimensionally. Figure 15.4 based on a drawing by Burton (1986a) and the diagrammatic reconstruction in Figure 15.6, show that three factors increase the chance of tangential sectioning of villi: branching, curving, and superficial notching:

1. Long, slender, stretched villi, such as those derived from a slightly immature placenta of about 32 to 36 weeks menstrual age (see Figs. 8.9, 8.10, and 15.9) or from intra-uterine growth restriction (IUGR) with absent or reversed end-diastolic umbilical flow (postplacental hypoxia) (see Figs. 15.6C to 15.17) have a low incidence of tangential sectioning.
2. Thicker, bulbous, and partly notched villi, as during the early stages of pregnancy (see Fig. 15.8), gestational diabetes mellitus (see Fig. 15.18), persisting immaturity at term, and rhesus incompatibility (see Fig. 15.10), show a few more tangential sections.
3. The normal mature placenta, which has numerous short terminal villi branching from the curved surfaces of the mature intermediate villi (see Figs. 15.6B and 15.11), has a higher incidence of tangential sectioning.
4. The hypoxic, hypercapillarized placenta (preplacental or uteroplacental hypoxia; e.g., maternal anemia as well as most cases of preeclampsia) is characterized by multiply branched, short, fist-like terminal villi (see Figs. 15.6A, 15.15, and 15.16). It shows such a degree of flat sectioning (syncytial knotting, Tenney-Parker changes)

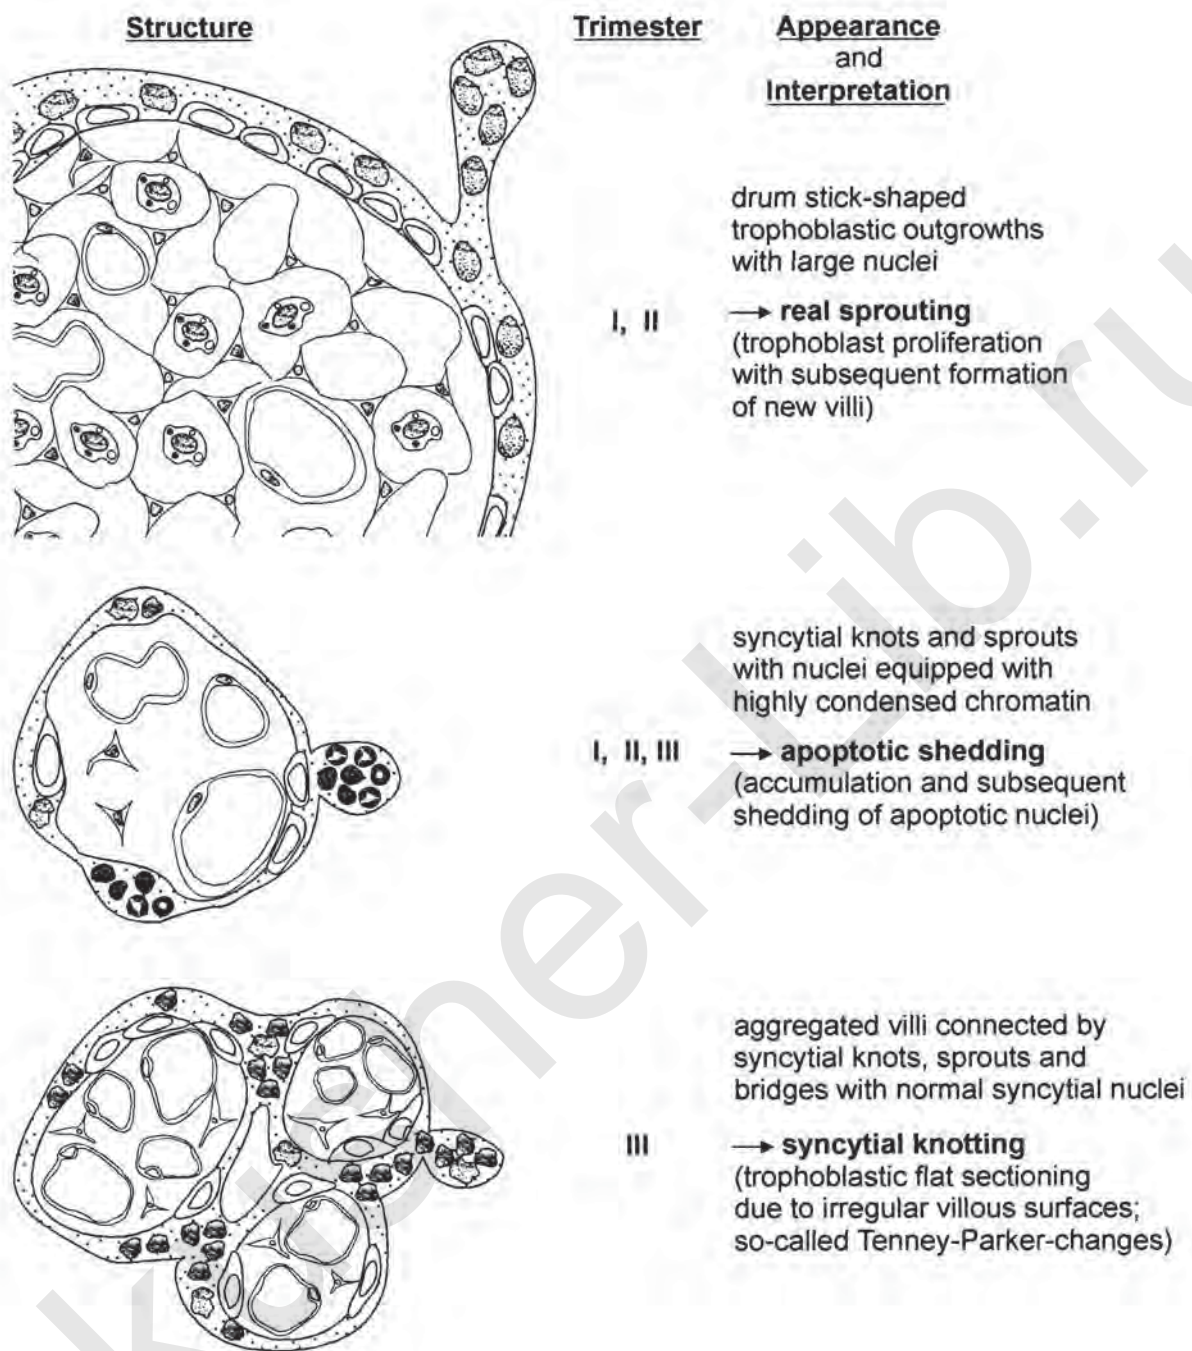

FIGURE 15.5. Diagrammatic aid for the interpretation of trophoblastic knotting, sprouting, and bridging. Upper panel: Sprouts characterized by loosely arranged, large nuclei with homogeneously distributed chromatin are attached to the surfaces of immature intermediate and mesenchymal villi and are results of real trophoblastic sprouting. These true syncytial sprouts prevail throughout the first two trimesters of pregnancy. Middle panel: Knot- and sprout-like structures equipped with densely packed small nuclei with highly condensed, partly

annular chromatin represent stages of extrusion of apoptotic nuclei; they can be found along the surfaces of all villous types in all stages of pregnancy. Lower panel: Aggregates of nuclei forming knots, sprouts, and bridges between densely packed third trimester terminal villi are likely to be the result of trophoblastic flat sectioning. Their nuclei display the same variability of chromatin condensation as is found along all villous surfaces of third trimester placentas.

that the two-dimensional picture may achieve a net-like appearance in which most terminal villi are seemingly connected to each other by syncytial “bridges” (see Fig. 15.15B).

### Conclusions Concerning Knotting

Three different phenotypes of syncytial knotting have been described: syncytial knots are local accumulations of syncytial nuclei in a moderately thickened syncytial layer, syncytial sprouts are multinucleated, fungiform protrusions of the syncytiotrophoblast into the intervillous space, and syncytial bridges are multinucleated syncytiotrophoblast connections between neighboring villous cross sections.

Unfortunately, all three definitions are sometimes used for mere structural description. In other cases, their use implies a functional meaning, such as trophoblastic sprouting, nuclear extrusion, or flat sectioning. In our experience, there is no histopathologic need to identify every multinucleated structure. Rather, it is important to decide for every placenta how to interpret the majority of its respective structures. For this purpose we suggest the following practical nomenclature (see Fig. 15.5):

- Use of the term **syncytial sprouting** is recommended only when describing true syncytial sprouts protruding from immature villous types, the former representing early stages of villous growth and branching.
- The term **apoptotic knotting** is justified when referring to local knot- or sprout-like intrasyncytial accumulations of aged or apoptotic nuclei characterized by high degrees of chromatin condensation.
- Local accumulations of syncytial knots, sprouts, and bridges in groups of irregularly shaped terminal villi are very likely to represent **trophoblastic flat sectioning** and should be referred to as **syncytial knotting** or **Tenney-Parker changes**. They are usually restricted to third trimester placentas.

## Classification of Villous Maldevelopment

Based on these considerations, the following sections briefly consider typical cases of villous maldevelopment and their three-dimensional branching patterns and the diagnostic problems they cause in histologic sections. This chapter is not the place for a detailed discussion of their pathogenetic and clinical background.

The primary finding in placentas with villous maldevelopment is an abnormal numerical composition of otherwise largely normal villous types (Kaufmann et al., 1987):

- This is true for **immature intermediate villi** and the **mesenchymal villi** branching off, and for the **mature intermediate villi** and the **terminal villi** branching off. The villous trees in the case of villous maldevelopment differ from the mature villous trees at term by predominance of only one of these villous types at the expense of others. Furthermore, they differ concerning the type of capillarization of terminal villi.
- In contrast, the structure and the number of **stem villi** seem to be largely independent of the pathologic conditions. Rather, they are influenced by the stage of maturation (Macara et al., 1995; Todros et al., 1999). Therefore, even in cases of severe villous maldevelopment, they can be easily used for determination of gestational age (Kaufmann & Castellucci, 1995) (Table 15.1).

### Summarizing Diagram of Villous Maldevelopment

Systematic analysis of the various cases of villous maldevelopment has shown that the balance among the various villous types is affected mainly by two different factors: the degree of placental maturation (Castellucci et al.,

FIGURE 15.6. Capillary branching patterns and their effects on terminal villous shapes in histologic cross sections. A: Predominance of branching angiogenesis results in highly branching capillary nets and in short, knob-like, multiply indented terminal villi. In paraffin sections these irregularly shaped terminal villi cause increased trophoblastic flat sectioning. The resulting villous profiles are connected to each other by syncytial “bridges” and show increased numbers of syncytial knots and sprouts (so-called syncytial knotting or Tenney-Parker changes). B: Groups of grape-like terminal villi with smooth surfaces are the result of a balanced mixture of branching and nonbranching

angiogenesis. The resulting histologic sections reveal less trophoblastic flat sectioning than shown in A. The terminal villi are rather large and equipped with sinusoidally dilated capillaries. C: Prevalence of nonbranching angiogenesis causes long poorly branched, slightly coiled capillaries in long, filiform terminal villi. Because of the absence of parallel capillary loops within one villus, the villi have unusually small diameters, ranging between 30 and 40  $\mu\text{m}$ . Histologically, these features result in isolated villous cross sections intermingled with a few longitudinal villous profiles, both showing unusually small calibers.

TABLE 15.1. Villous maturation scores in normoxic villous development

Score	Distribution of villous types	Maturation of stem villi	Usually found in pregnancy at weeks
<b>Normal maturation</b>			
<b>00</b>	Predominance of immature intermediate villi	Stem villi are only partly fibrosed	Weeks 8 to 23 <sup>a</sup>
<b>01</b>	Predominance of immature intermediate villi, but few newly formed mature intermediate villi; terminal villi still absent	Only stem villi measuring <300 mm in caliber are completely fibrosed	Weeks 24 to 28 <sup>a</sup>
<b>10</b>	Predominance of mature intermediate villi, immature intermediate villi less common, few terminal villi	Only small stem villi (caliber <200 mm) are completely fibrosed	Weeks 29 to 32 <sup>a</sup>
<b>11</b>	Predominance of mature intermediate villi, few terminal villi, immature intermediate villi restricted to isolated foci	Only small stem villi (caliber <200 mm) are completely fibrosed; larger stems superficially still have reticular stroma	Weeks 32 to 34 <sup>a</sup>
<b>12</b>	Predominance of mature intermediate villi, increasing numbers of normally capillarized terminal villi; very few immature intermediate villi, locally restricted	Most stem villi are fully fibrosed; those partly fibrosed lack reticular stroma	Weeks 34 to 36 <sup>a</sup>
<b>21</b>	Balance between mature intermediate villi and terminal villi; very few immature intermediate villi, locally restricted	Large-caliber stem villi show an unfibrosed, highly cellular subtrophoblastic rim; little perivillous fibrinoid replacing the trophoblast	Weeks 36 to 37 <sup>a</sup>
<b>22</b>	Fully mature, normally capillarized villous trees with predominance of terminal villi; many mature intermediate villi; only accidental foci with immature intermediate villi	All stem villi fully fibrosed; trophoblast focally replaced by perivillous fibrinoid	Weeks 38 to 41 <sup>a</sup>
<b>34</b>	Hypermaturation villous trees in postmature pregnancies, showing a mixture of enhanced branching (33) and nonbranching angiogenesis (44) (see Table 15.2)	Stem villi are usually fully fibrosed	>42 weeks <sup>b</sup>
<b>Delayed maturation</b>			
<b>02</b>	Mixture of immature intermediate villi with largely mature villous types (specific feature of placentas following asynchronous maturation)	Mostly poorly fibrosed, largely immature stem villi	Usually term placentas <sup>c</sup>
<b>20</b>	Largely mature villous trees with locally increased numbers of immature intermediate villi	Locally poorly fibrosed, partly immature stem villi	Usually term placentas <sup>d</sup>
<b>00, 01, 10, 11, 12</b>	Structurally similar to earlier stages of normal maturation, but now persisting in later stages	As described for the respective scores	Term or preterm pregnancies
<b>Accelerated maturation</b>			
<b>22, rarely 12, 02</b>	Fully or nearly mature features	Larger stem villi usually show <sup>a</sup> subtrophoblastic layer with reticular stroma	<36 weeks
<b>34</b>	Hypermaturation villous trees showing a mixture of enhanced branching (33) and nonbranching angiogenesis (44)	Stem villi are usually fully fibrosed	Term or near-term pregnancies

Normal maturation (scores 00 through 22) is compared to delayed maturation (persisting immaturity) and accelerated maturation.

<sup>a</sup> Data are valid only for normal pregnancies.

<sup>b</sup> "Hypermaturation" in prolonged pregnancy.

<sup>c</sup> Unusual mixture of villi in normal pregnancies; more common in cases of persisting villous immaturity.

<sup>d</sup> Usual feature in persisting villous immaturity and sometimes even in normal term pregnancies.

FIGURE 15.7. Classification of normal and abnormal villous ramification patterns at term. Because villous maldevelopment affects mainly immature and mature intermediate as well as terminal villi, the stem villi are neglected in this diagram. The left arrow represents villous development from the first trimester (00, upper corner) until term (44, lower-left corner) with prevailing nonbranching angiogenesis, as is found in cases of postplacental hypoxia. This type of maldevelopment results in scarce, poorly branched, filiform terminal villi. The right arrow illustrates villous development in placental hypoxia, resulting in branching angiogenesis with multiply branched, fist-like terminal villi (33, lower-right corner). The central arrow represents normal villous development from prevalence of immature

intermediate villi (00) via prevalence of mature intermediate villi (11) to the normal term situation with prevalence of terminal villi with some admixture of mature intermediate villi (22). The two-digit scores define the composition of the villous trees: 0, prevalence of immature intermediate villi; 1, prevalence of mature intermediate villi; 2, prevalence of terminal villi with balanced angiogenesis; 3, prevalence of terminal villi with branching angiogenesis; 4, prevalence of terminal villi with non-branching angiogenesis. The point-shaded area indicates those features that usually are found in combination with normal pregnancy outcome at term. (Source: Modified from Kaufmann et al., 1987, with permission.)

1990), and the degree of oxygenation (Macara et al., 1996; Kingdom & Kaufmann, 1997; Todros et al., 1999). Figure 15.7 summarizes the resulting types of maldevelopment as a diagnostic aid:

1. The vertical axis of the diagram represents the **degree of maturation**, resulting in changes in numerical composition of the villous trees. From the first trimester (top) until term (bottom), a developmental shift occurs

from immature intermediate villi toward mature intermediate and finally terminal villi.

2. The horizontal axis of the diagram represents the **degree and type of fetoplacental angiogenesis**, controlled by intraplacental oxygen levels. The fetoplacental angiogenesis influences the numbers and shapes of terminal villi.

3. The left route of maturation represents villous features resulting from **placental oxygenation that is better than normal** ("postplacental hypoxia"; cf. Fig. 7.19). It is characterized by the predominance of nonbranching angiogenesis resulting in poorly developed, long, filiform terminal villi with long, largely unbranched capillary loops (see Fig. 15.6C).

4. The right route of maturation is the result of **intra-placental hypoxia** ("preplacental hypoxia" and "uteroplacental hypoxia"; cf. Fig. 7.19). The low oxygen levels induce branching angiogenesis (cf. Chapter 7), resulting in clusters of richly developed, short, highly branched and notched terminal villi, showing intense Tenney-Parker changes (see Fig. 15.6A).

5. The intermediate route of villous maturation is the result of **normal oxygenation of the placenta**. It is characterized by a balance between branching and nonbranching angiogenesis in terminal villi. The latter are grape-like in shape and poorly branched. Large numbers of such fungus-shaped terminal villi branch off from long, multiply bending mature intermediate villi (see Fig. 15.6B).

#### VILLOUS MATURATION SCORE

In our experience, villous cross-sectional patterns are difficult to define. Moreover, descriptions provided by different histopathologists are rarely comparable. In our hands, a simple two-digit code (villous maturation score) proved to be useful. It summarizes the developmental status of the villous trees including its numerical composition of the various villous types as well as the kind of terminal villous capillarization. As discussed earlier, number and differentiation of stem villi remain unconsidered.

- 00** signifies uniform predominance of immature intermediate villi
- 11** codes for general predominance of mature intermediate villi
- 22** characterizes normally matured villous trees composed of normally capillarized mature intermediate and terminal villi
- 33** denotes predominance of clustered terminal villi connected to each other by intense syncytial knotting, pointing to branching angiogenesis caused by preplacental or uteroplacental hypoxia
- 44** codes for predominance of loosely arranged, extremely small, filiform terminal villi, resulting from nonbranching angiogenesis

Scores with mixed digits such as **23**, **32**, **01**, or **40** describe features intermediate between the above extremes, the dominating feature represented by the first digit and the secondary feature by the second digit. For example, the score **23** codes for a more or less normally matured villous tree with a slight touch of Tenney-Parker changes, pointing to the existence of very mild hypoxia; in contrast, the score **32** denotes a similar situation with more pronounced Tenney-Parker changes.

Using this score, the different pathways of villous development and maldevelopment can be described as follows (see Table 15.1):

- The **normal maturation** of villous trees described by this score starts with **00** [pregnancy weeks 8–23 postmenstruation (p.m.)] and proceeds via **01** (weeks 24–28), **10** (weeks 29–32), **11** (weeks 32–34), **12** (weeks 34–36), **21** (weeks 36–37) to **22** (weeks 38–41). The scores **21** and **22** represent the normal range of villous maturational patterns at term. If delivery is delayed (prolonged pregnancies), the villi may even reach excessive degrees of branching and nonbranching angiogenesis with respective terminal villus formation, summarized by the score **34** or **43**, depending on the prevailing type of angiogenesis.
- **Persisting villous immaturity** can be described by the actual villous maturational stage as compared to the age-appropriate maturational score, given in parentheses: the score **00 (21)** codes for a slightly preterm delivered placenta (weeks 36–37; expected age-appropriate score, **21**) composed of immature intermediate villi, resembling a placenta from week 23 or earlier; the score **11 (22)** codes for a placenta delivered at term, composed of stem and mature intermediate villi, but largely lacking terminal villi, thus resembling a placenta about weeks 32 to 34.
- **Accelerated villous maturation** can be coded accordingly by characterizing the actual developmental status as compared to the score expected for that particular stage of pregnancy (in parentheses): the score **22 (12)** describes a structurally fully mature placenta delivered between weeks 34 and 36 (preterm maturation, maturitas praecox placentae); the score **34 (22)** codes for a placenta delivered at term, but displaying "hypermaturation" features composed of a mixture of enhanced branching and nonbranching angiogenesis.

The developmental pathways resulting from abnormal degrees of placental oxygenation can also be characterized by the villous maturation score (Table 15.2):

- Villous trees in **severely hypoxic placentas** (preplacental and uteroplacental hypoxia), such as maternal anemia, high altitude, or preeclampsia, are characterized by scores proceeding from **00** via **03** and **30** to **33**: The respective histologic features show syncytial knotting (Tenney-Parker changes) clearly exceeding normal degrees. Typically, in this developmental pathway mature intermediate villi (coded by the digit **1**) do not dominate the sections in any stage.
- **Less severe cases of placental hypoxia** result in villous features with less expressive knotting and are coded by **32** or **23**, the latter entity still belonging to the normal range of full-term placentas.
- Cases of **severe postplacental hypoxia** (e.g., IUGR with absent end-diastolic flow in the umbilical arteries) are coded by scores proceeding from **00** via **04** and **40** to **44**. The typical histologic features comprise increased numbers of filiform terminal villi of minimum diameters with absence of capillary branching. Also in these cases, the paucity of mature intermediate villi is highly characteristic; at the transition from the second to the third trimester, immature intermediate villi mix with terminal villi (stages **04** or **40**).
- **Less severe cases of postplacental hypoxia** lead to a mixture of normally matured terminal villi with filiform terminal villi resulting from nonbranching angiogenesis, coded by **42** to **24**, the latter feature still belonging to the normal full-term range of villous development.

Clearly, not all cases of villous maldevelopment can be coded accordingly. This condition is particularly valid for those abnormalities in which the quality of villous differentiation is affected rather than the numerical composition of the villous trees, including the types of angiogenesis. Typical examples comprise placentas from diabetic mothers, from heavy smokers, and cases with chromosomal aberrations.

TABLE 15.2. Villous maturation scores in cases of abnormal oxygenation

Score	Distribution of villous types	Maturation of stem villi	Usually found in pregnancy at weeks
<b>Prevailing branching angiogenesis</b>			
<b>03</b>	Predominance of immature intermediate villi; small groups of clustered terminal villi with Tenney-Parker changes	Only stem villi with calibers <300mm are completely fibrosed	Weeks 24 to 28 <sup>a</sup>
<b>30</b>	Prevalence of clustered, knotted terminal villi (moderate Tenney-Parker changes); numerous small capillary cross sections; many immature intermediate villi	Only small stem villi (caliber <200mm) are completely fibrosed; larger stems superficially still have reticular stroma	Weeks 28 to 34 <sup>a</sup>
<b>33</b>	Predominance of clustered, highly knotted terminal villi (severe Tenney-Parker changes); numerous small capillary cross sections; immature intermediate villi absent	All stem villi fully fibrosed; trophoblast focally replaced by perivillous fibrinoid	Weeks 34 to 40 <sup>a</sup>
<b>32</b>	Less severe form: mixture of <b>33</b> with <b>22</b> , predominance of <b>33</b>	Most stem villi fully fibrosed; trophoblast focally replaced by fibrinoid	Weeks 34 to 40 <sup>b</sup> Weeks 34 to 40 <sup>c</sup>
<b>23</b>	Mild form: mixture of <b>33</b> with <b>22</b> , predominance of <b>22</b>	Only stem villi with calibers <300mm are completely fibrosed	Weeks 20 to 40 <sup>d</sup>
<b>Prevailing nonbranching angiogenesis</b>			
<b>04</b>	Predominance of immature intermediate villi; small groups of extremely small, filiform terminal villi with long, wide capillary loops; locally intense superficial capillarization of immature intermediate villi	Only small stem villi (caliber <200mm) are completely fibrosed; the larger ones still have subtrophoblastic reticular stroma	Weeks 24 to 28 <sup>d</sup>
<b>40</b>	Large groups of extremely small, filiform terminal villi with long, wide capillary loops; still some evenly distributed, highly capillarized immature intermediate villi	Most stem villi are fully fibrosed; trophoblast is focally replaced by perivillous fibrinoid	Weeks 28 to 34 <sup>d</sup>
<b>44</b>	Predominance of extremely small, filiform terminal villi with long, wide capillary loops; obvious gap in calibers between the unusually small terminal villi and the larger stem villi	Most stem villi are fully fibrosed; the trophoblast is focally replaced by perivillous fibrinoid	Weeks 32 to 38 <sup>e</sup> Weeks 36 to 40 <sup>f</sup>
<b>42</b>	Less severe form: mixture of <b>44</b> with <b>22</b> , predominance of <b>44</b>		
<b>24</b>	Mild form: mixture of <b>44</b> with <b>22</b> , predominance of <b>22</b>		

Maturation during preplacental and uteroplacental hypoxia with prevailing branching angiogenesis (scores **03** through **33**) is compared with the maturation during postplacental hypoxia with prevailing nonbranching angiogenesis (scores **04** through **44**).

<sup>a</sup> Characteristic feature for cases of severe maternal anemia, pregnancies in high altitude or IUGR/preeclampsia with preserved end-diastolic flow in the umbilical arteries.

<sup>b</sup> Milder cases of maternal anemia, high altitude, or IUGR/preeclampsia with preserved end-diastolic flow in the umbilical arteries.

<sup>c</sup> Usual feature also in normal term pregnancies.

<sup>d</sup> Characteristic feature for IUGR with absent or reverse end-diastolic flow in the umbilical arteries.

<sup>e</sup> Less severe cases of IUGR with absent or reverse end-diastolic flow in the umbilical arteries.

<sup>f</sup> Usual feature also in normal term pregnancies.

TABLE 15.3. Comparison of different terminologies concerning villous maldevelopment

Villous maturation score (as compared to age- appropriate score)	Author's nomenclature	Becker and Röckelein, 1989	Becker, 1981; Vogel, 1984, 1996	Schweikhart, 1985
<b>Normal maturation</b>				
Ideally 22, but also 20, 21, 23, 24	Synchronous villous maturity	Maturitas iusta (normal maturation)	Mature gestation, age-appropriate	Synchronous maturity
00, 01, 10, 11, 12	Synchronous villous immaturity	—	—	Synchronous immaturity
<b>Delayed maturation</b>				
12 (22)	Persisting immaturity, very mild form	Maturitas tarda (delayed maturation)	Dissociated villous maturation, mostly mature	Mild form of terminal villus deficiency
11 (22)	Persisting villous immaturity, Moderate form	Maturitas retardata (retarded maturation)	Dissociated villous maturation, mostly immature	Terminal villus deficiency
10 (22)				
00 (22)	Persisting villous immaturity, Severe form	Arrested maturation	Arrest of villous maturation	Persisting immaturity
01 (22)				
<b>Accelerated maturation</b>				
22 (12)	Preterm villous maturation	Maturitas praecox (premature maturation)	Premature maturation	Asynchronous maturation
22 (11)				
34 (22)	Hypermaturation	—	—	Hypermaturation
<b>Abnormal angiogenesis</b>				
33 (22)	Terminal villi with prevalence of branching angiogenesis	—	—	Hypercapillarization
44 (22)	Terminal villi with prevalence of nonbranching angiogenesis	—	Intermediate villus deficiency	Terminal villus deficiency?
40 (10 or 01)				

Note that for the pathologic villous maturation scores listed in the left column the age-appropriate normal scores are given in parentheses.

Our villous maturation score is not the first attempt to classify villous maldevelopment. In Table 15.3 we have tried to compare our classification with the terminologies introduced by other authors (Becker, 1981; Vogel, 1984, 1996; Schweikhart, 1985; Becker & Röckelein, 1989).

## Cases of Villous Maldevelopment

### Synchronous Villous Immaturity

The term **synchronous** is used for histologic features of immature villous trees that correspond to what we expect to be normal for the respective stage of pregnancy (Schweikhart et al., 1986). For a normal baseline, we refer to the pictures and data provided by Boyd and Hamilton (1970), Kaufmann (1981), Vogel (1986), Stoz et al. (1988), and Vogel (1996), and to the data presented in Chapter 8.

From the 8th to 24th week p.m., the immature villous trees are composed of uniformly thick, bulbous, immature intermediate villi (villous maturation score **00**). Until week 28 these are completed by some newly formed mature intermediate villi (score **01**). The trophoblastic surface of the immature intermediate villi is unevenly curved and distended (Fig. 15.8A). Terminal villi are virtually absent. The numerous side branches of small caliber are composed of real sprouts and newly produced mesenchymal villi. For geometrical reasons, the chance of obtaining flat sections depends on the villous diameter and decreases with increasing villous caliber. Therefore,

the rare event of tangential sectioning of such immature cases with prevailing large villi does not give an incorrect impression of sprouting (Fig. 15.8B).

In later stages of villous development (weeks 29–36; villous maturation scores **10–12**), increasing amounts of mature intermediate villi are formed. In particular, in weeks 32 to 34, when these villi clearly dominate the histologic section, they are characterized by rather large, homogeneous calibers (150–250 µm) and a highly cellular stroma (Fig. 15.9; also see Fig. 8.9). The number of terminal villi slowly increases throughout this period. By definition, placentas showing synchronous villous immaturity can be found only in cases of premature deliveries. On the other hand, as discussed in Chapter 14, in only 33% of premature deliveries are the placentas in fact structurally immature (Schweikhart et al., 1986); rather, most prematurely delivered cases are characterized by fully mature or even “hypermature” features. Becker and Röckelein (1989) suggested this to be responsible for preterm onset of labor. This, however, still remains speculative.

### Persisting Villous Immaturity and Rhesus Incompatibility

Persisting immaturity of unknown etiology is a usual feature in postterm pregnancies (Fox, 1968; Kemnitz &

FIGURE 15.8. Immature placenta, 20th week of gestation. The immature intermediate villi are devoid of terminal villi. Large-caliber villi prevail. The numerous true sprouts, clearly visible

in the scanning electron micrograph (A), are rarely seen (arrows) in the corresponding cross-sectional picture (B).  $\times 66$ . (Source: Part A from Kaufmann et al., 1987, with permission.)

FIGURE 15.9. Immature placenta, 34th week of pregnancy. Long, straight, mature intermediate villi with calibers ranging from 150 to 250  $\mu\text{m}$  prevail. Due to the paucity of terminal villi branching off, the mature intermediate villi are arranged in parallel and do not show the zigzag course of mature intermedi-

ate villi at term. The uniformity of calibers is typical for this stage of pregnancy. Similar features can be found in postterm pregnancies combined with slight persisting immaturity; in this condition this feature has been called "terminal villus deficiency." A:  $\times 60$ ; B:  $\times 125$ .

FIGURE 15.10. Placenta from a case of severe rhesus incompatibility, near term. Immature intermediate villi with a large caliber prevail. Only a few smaller side branches (terminal or mesenchymal villi) arise from the surfaces (A). True syncytial sprouting comparable to that seen in normal immature intermediate villi is rare. The occasional “sprouts” and “bridges” visible in semithin sections (B) are mostly artifacts caused by

tangential sectioning of the irregular, notched outer surface of the immature intermediate villi. These villi are much better vascularized in rhesus incompatibility than are those of normal early pregnancy. In well-stained, thin histologic sections, one can easily identify that the large caliber of the villi is the result of villous immaturity rather than of villous edema.  $\times 195$ . (Source: From Kaufmann et al., 1987, with permission.)

Theuring, 1974) (for details, see Chapter 14). Villous maturation features in most cases resemble synchronous developmental stages from the 26th to 32nd week of pregnancy (villous maturation scores **01** or **10**); the villous trees are composed mainly of immature intermediate villi with various degrees of admixture of mature intermediate villi.

Severe cases of persisting immaturity are regular features following rhesus immunization (scores **00**, **01**, or **10**). It is generally considered that villous maturation is retarded in this condition (Wentworth, 1967; Werner et al., 1973; Fox, 1997; Pilz et al., 1980), but it is still disputed whether the villous features are further complicated by edema. In our experience, the villous features are influenced by a delay in villous maturation at an unduly early stage of development; thus, immature intermediate villi of large caliber persist (Fig. 15.10A). As is characteristic for this villous type, terminal branches are uncommon and depend on the degree of isoimmunization. There are, however, some differences when compared to cases of synchronous villous immaturity. True syncytial sprouts are less common (compare Figs. 15.8 and 15.10). This finding is in agreement with the pathogenetic concept

that villous maturation, and thus the formation of new villi, is decelerated in this condition. Moreover, cases of persisting immaturity at term or of severe maturational arrest in patients with erythroblastosis exhibit better fetal vascularization (Fig. 15.10B) than cases of synchronous immaturity. In accordance with the straight course of the large villi and their intensively notched surfaces seen in scanning electron micrographs (Fig. 15.10A), the histologic sections (Fig. 15.10B) usually reveal large-caliber villi of varying sizes, with occasional signs of syncytial knotting. Most of the latter structures are caused by tangential sectioning.

### Normal Mature Placenta

In the normal, term placenta, the dominant structures are long, slender, mature intermediate villi from which short, grape-like terminal villi branch (Fig. 15.11A; also see Fig. 7.7). As long as the terminal villi are short and only poorly branched, as in the cases depicted, the incidence of tangential sectioning is low. Most of the peripheral villous cross sections have calibers ranging from 60 to 150  $\mu\text{m}$  (Figs. 15.11B,C), except for some occasional stem and

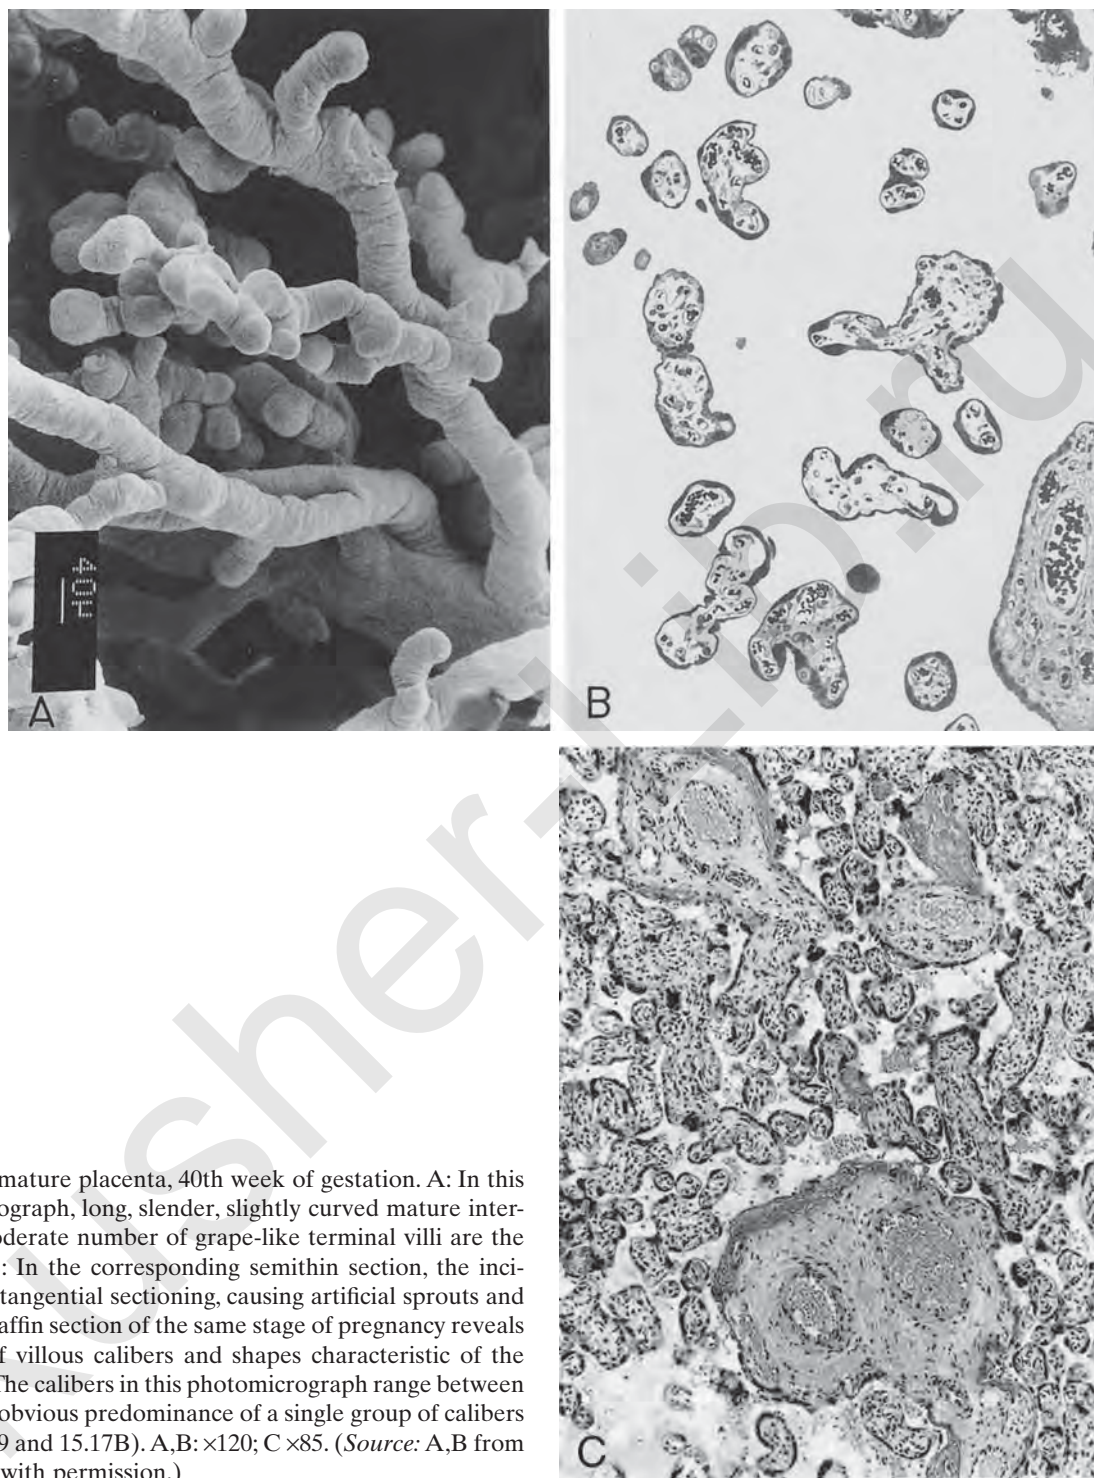

FIGURE 15.11. Normal mature placenta, 40th week of gestation. A: In this scanning electron micrograph, long, slender, slightly curved mature intermediate villi with a moderate number of grape-like terminal villi are the dominating features. B: In the corresponding semithin section, the incidence of trophoblastic tangential sectioning, causing artificial sprouts and bridges, is low. C: A paraffin section of the same stage of pregnancy reveals the colorful mixture of villous calibers and shapes characteristic of the normal term placenta. The calibers in this photomicrograph range between 40 and 250  $\mu\text{m}$  without obvious predominance of a single group of calibers (compare with Figs. 15.9 and 15.17B). A,B:  $\times 120$ ; C  $\times 85$ . (Source: A,B from Kaufmann et al., 1987, with permission.)

immature intermediate villi. Usually, the latter villi accumulate in the centers of the villous trees and should not be misunderstood as signs of persisting immaturity (Fig. 15.12; compare parts A and B).

Trophoblastic tangential sectioning resulting in the incorrect impression of sprouting is a rare event in thin plastic sections (Fig. 15.11B); this picture is seen some-

what more frequently in the thicker paraffin sections (see Figs. 8.11 and 8.12) (Becker, 1981; Fox, 1997). Only some of these “typical signs of villous maturation” (*Reifezeichen* of Becker, 1981) have a real structural basis. We estimate that less than 5% of sprout-like structures seen in paraffin sections are true trophoblastic outgrowths, that is, signs of trophoblastic sprouting or extrusion of apoptotic

FIGURE 15.12. Comparison of immature intermediate villi in two different types of term placentas. A: In the center of the villous tree of a normal, term placenta, the immature intermediate villi together with sprouts and mesenchymal side branches form an isolated group surrounded by ample intervillous space

belonging to the central cavity. This normal feature should not be confused with the more homogeneously distributed immature intermediate villi as shown in part B, which represents a case of persisting immaturity at term.  $\times 15$ .

nuclei; the remaining 95% are artifacts from sectioning. Despite this fact, they can be regarded as reliable signs of full maturation in paraffin sections (see Fig. 8.12). Their artificial genesis points to the existence of mature villous shapes. When studying the thinner semithin sections (1 mm) (see Fig. 15.11B), one must exercise care because to the inexperienced observer the reduced incidence of artificial “sprouting” may wrongly suggest an organ that is not yet fully mature.

In the ideal case of full, normal villous maturation, the villous trees are composed as outlined here, corresponding to a villous maturation score of **22**. It is, however, the general histopathologic experience that uncomplicated term pregnancies with normal fetal outcome very often are combined with less ideally structured placentas. These may include (1) slightly increased numbers of immature intermediate villi (score **20**), (2) a certain prevalence of large-caliber mature intermediate villi (score **21**), (3) locally restricted admixtures of clusters of villi with intense knotting (score **23**), and (4) a certain number of long, filiform, unbranched terminal villi with minimum diameters as typical results of nonbranching angiogenesis (score **24**).

### Preterm Villous Maturation and Villous Hypermaturity

In 50% of placentas of preterm deliveries from the 29th to 32nd week of pregnancy and in 33% of those of preterm deliveries from the 33rd to 37th week, Schweikhart et al. (1986) found a villous maturational state that corresponded to the normal mature placenta. Becker (1981) used the term **maturitas praecox placentae** when the villous maturation is accelerated and reaches structurally normal term features (score **22**) considerably before the 40th week. In other cases, the villi even displayed degrees of formation of terminal villi exceeding those in normal maturity, resulting in “hypermaturity” (score **34**) (Salvatore, 1968). According to the results of Schweikhart et al. (1986), hypermaturity is an even more common finding in cases of preterm delivery than is *maturitas praecox*. Becker (1981) concluded that the prematurely matured placenta may induce labor (cf. Chapter 14).

Preterm villous maturation is characterized by normal villous features that under normal conditions would have been reached only in later stages of pregnancy. In contrast, the more severe form of this entity, hypermaturity, is struc-

FIGURE 15.13. Prematurely delivered placenta (37th week of pregnancy) from a pregnancy complicated by preeclampsia and IUGR. A: Scanning electron micrograph shows the typical feature of preterm maturation (or hypermaturity), with long, twisted, partly branched terminal villi that are aggregated around the hidden mature intermediate villus. The underlying pathogenesis is likely to be a severe alteration of terminal

villous capillarization, showing local variations from nonbranching to prevailing branching angiogenesis (villous maturation score, **34**). B: In a plastic section, this feature results in the appearance of numerous small cross sections of highly capillarized terminal villi, locally intermingled with increased trophoblastic flat sectioning. A:  $\times 125$ ; B:  $\times 200$ . (Source: Part A from Kaufmann et al., 1987, with permission.)

turally characterized by a mixture of two different types of abnormal terminal villi: (1) long, unbranched, and twisted small-diameter terminal villi, corresponding to those found in cases of postplacental hypoxia (scores **42** and rarely even **44**); these terminal villi largely hide the central mature intermediate villus from which they branch (Fig. 15.13A); and (2) short, highly branched, fist-like terminal villi with increased branching angiogenesis showing increased incidence of knotting (Tenney-Parker changes) in paraffin sections. These villi resemble those displayed in preplacental hypoxia and uteroplacental hypoxia (villous maturation scores **32** or even **33**). Accordingly, the features typical for hypermaturity may overlap with those found following preplacental hypoxia (e.g., maternal anemia), or they are displayed by postplacental hypoxia (IUGR with absent end-diastolic umbilical flow). Usually a mixture of both types of terminal villi, caused by mixtures of branching and nonbranching angiogenesis, is found (score **34**). In histologic sections, complicated networks of narrow capillaries are accompanied in parallel by long, winding dilated capillaries. The corresponding branching patterns of the terminal villi, as seen by scanning electron microscopy (Fig.

15.13A), showed partly long winding, partly short, and multiply indented villi. Histologically, this situation results in complex pictures with partly isolated villous sections having dilated capillaries and partly net-like villous conglomerates (Fig. 15.13B).

The coexistence of these features suggests that overstimulated angiogenesis (branching or nonbranching type) is one of the underlying pathogenetic mechanisms for hypermature villous maturation. This concept agrees with the experience that these pregnancies often are complicated by hypertensive disorders as well as intra-uterine growth retardation. At present it is still difficult to differentiate between cause and effect. The molecular basis of the obvious alteration of villous angiogenesis is not yet understood.

### Prolonged Pregnancy

For decades, most “prolonged pregnancies” have actually been miscalculated term pregnancies (Fox, 1997); however, careful ultrasound examination throughout pregnancy now has allowed more precise dating. Placen-

FIGURE 15.14. Placenta in prolonged pregnancy, 43rd week of gestation. This case shows a mixture of hypermature and hypoxic changes of the terminal villi, both resulting in hypercapillarization and overproduction of terminal branches. A: Scanning electron micrograph shows complicated convolutions of long, branched, and multiply notched and indented terminal villi,

completely hiding the central mature intermediate axis. B: The semithin section is a mixture of small terminal villus cross sections (as in the case of postplacental hypoxia; see Fig. 15.17) with tangentially sectioned, web-like arrangement of terminal villi (as in pre- and uteroplacental hypoxia; see Figs. 15.15 and 15.16).  $\times 115$ . (Source: Kaufmann et al., 1987, with permission.)

tas from true 42 and 43 weeks' gestations (postmaturity) usually are characterized by one of two contrasting histological features:

1. The usual finding is slight immaturity: dominance of mature intermediate villi with deficiency of terminal villi (Kaufmann et al., 1987) (scores **11** and **12**) (see Fig. 14.5) or even more severe cases of persisting immaturity (Fox, 1968; Kemnitz & Theuring, 1974; Mikolajczak et al., 1987) (scores **10**, **01**, and **00**). In the latter cases, the villous maturation features resemble synchronous developmental stages from the 26th to 32nd week of pregnancy, the villous trees being composed mainly of immature intermediate villi with various degrees of admixture of mature intermediate villi. Many placenta pathologists had already pointed to this correlation with abnormal villous maturation before ultrasound confirmation of pregnancy length (Becker, 1963; Emmrich & Mälzer, 1968; Kemnitz & Theuring, 1974; Kloos & Vogel, 1974).

2. By contrast, a certain percentage of prolonged pregnancies is characterized by normal mature villous patterns (score **22**) or even "hypermature" features characterized by increased branching angiogenesis (scores **32**, **33**, **34**) (Fig. 15.14). According to Schweikhart (1985),

hypermaturity amounts to about 12% of postterm pregnancies (see Preterm Villous Maturation and Villous Hypermaturity, above); these data are generally in agreement with those of Essbach and Röse (1966), Emmrich and Mälzer (1968), and Mikolajczak et al. (1987).

### Placentas at High Altitude and Maternal Anemia (Preplacental Hypoxia)

There is general agreement that hypoxia is responsible for the placental changes in women with anemia (Piotrowicz et al., 1969; Beischer et al., 1970; Kadyrov et al., 1998; Kusanke et al., 1998) and those women living at high altitude (Jackson et al., 1987, 1988a,b; Reshetnikova et al., 1993). Corresponding features have also been observed in placentas from mothers with cyanotic heart disease. All three conditions have been characterized as preplacental hypoxia (Kingdom & Kaufmann, 1997). Experimental studies have supported the view that deficiency of oxygen is the decisive pathogenetic mechanism in this group of disorders. Studies of the *in vitro* influence of hypoxia on villous explants (Tominaga & Page, 1966; Fox, 1970; Amaladoss & Burton, 1985; Burton et al., 1989;

FIGURE 15.15. Placenta from maternal anemia at term. The chronic preplacental hypoxia causes prevalence of branching angiogenesis, resulting in multiply branched and indented terminal villi, as shown in Fig. 15.16A. The corresponding paraffin section (A) reveals intense trophoblastic knotting (Tenney-

Parker changes) as a result of increased flat sectioning across irregular villous surfaces. A higher magnified plastic section (B) demonstrates even better artifactually caused syncytial knotting and bridging. A:  $\times 120$ ; B:  $\times 300$ .

Ong & Burton, 1991) and experimental studies on long-term effects of hypoxia on pregnant guinea pigs (Bacon et al., 1984; Geisen et al., 1990; Scheffen et al., 1990) and pregnant ewes (Krebs et al., 1997) have reported comparable structural features.

All these studies indicate that increased trophoblastic proliferation and increased villous capillary branching are the typical placental responses to long-term hypoxia (see Fig. 7.17). Branching angiogenesis is probably caused by stimulated expression of vascular endothelial growth factor (VEGF) and its two receptors, flt-1 and KDR (see Chapter 7). Hypoxia results in richly branched, net-like capillary beds that are easy to perfuse, as their structure provides less flow resistance than comparably large capillary beds composed of longer, less branched capillaries. This situation is compatible with the decrease in capillary diameter that was found in related animal experiments (Bacon et al., 1984; Scheffen et al., 1990) and which seemed to be highly characteristic for hypoxic villi in the studies on human placentas from high altitude performed by Jackson et al. (1987, 1988a,b). It must be pointed out, however, that Reshetnikova et al. (1993) in this particular respect arrived at opposite conclusions; in their group of placentas from women who lived and delivered in high

altitude, they observed a general increase in capillary diameters as compared to lowland pregnancies.

The richly branched capillaries from hypoxic placentas (see Figs. 7.17 and 15.6A) are responsible for a characteristic deformation of the outer shape of the terminal villi (Fig. 15.15; also see Fig. 15.6A). These are usually short, knob-like, and have multiply indented surfaces that resemble fists (compare Fig. 15.16A). Histologic sections of such villi show increased areas of flat sectioning of trophoblast, histologically appearing as increased syncytial knotting (Tenney-Parker changes). Groups of villi are connected to each other by syncytial bridges (Figs. 15.6 and 15.15). Often a net-like appearance is achieved, the extent of which depends on the thickness of the section. The respective villous maturation scores are **03**, **30**, or **33**, depending on the stage of pregnancy.

#### Intrauterine Growth Restriction with Preserved End-Diastolic Umbilical Flow in the Third Trimester, with or Without Late-Onset Preeclampsia (Uteroplacental Hypoxia)

A great variety of pathologic correlates has been found in cases of IUGR, such as small placenta, persisting

FIGURE 15.16. Placenta from a patient with severe preeclampsia, near term. Because of long-lasting uteroplacental hypoxia, the branching pattern of the villi in this case is similar to that in maternal anemia (see Fig. 15.15). A: The multiply branched, short capillary loops (cf. Fig. 15.6A) cause short, knob-like,

indented villous surfaces. B: The corresponding semithin section shows a conglomeration of terminal villi with apparent syncytial “bridging” and “sprouting” artifactually, caused by tangential sectioning. Sometimes it results in a net-like appearance.  $\times 125$ . (Source: Part B from Kaufmann et al., 1987, with permission.)

placental immaturity, high degree of placental infarction, fetoplacental vasculopathy, villous hypermaturity, deficiency of terminal villus, etc. (for reviews, see Chapter 19; also Vogel, 1996; Fox, 1997; Kingdom et al., 1997). The pathogenesis is thought to be a consequence of failing trophoblast invasion and consequently falling dilatation of the uteroplacental arteries (Brosens et al., 1967; Brosens, 1988). This loss results in maternal malperfusion of the placenta. Different from the preplacental hypoxia that is found in maternal anemia, for example, in IUGR, the mother is generally normoxic and due to the underlying maladaptation of the uteroplacental arteries only the intrauterine compartment, that is, placenta and fetus, may become hypoxic (“uteroplacental hypoxia”).

In a certain percentage of cases, IUGR becomes complicated by preeclampsia. Originally, this disease was thought to be a direct consequence of failing trophoblast invasion of uteroplacental arteries (Brosens et al., 1970). Meanwhile there is general agreement that the direct consequence of the latter is malperfusion of the placenta resulting in IUGR; whether the latter becomes addition-

ally complicated by preeclampsia or not seems to be a question of whether villous trophoblast turnover is impaired by placental malperfusion or not (Black et al., 2002; Huppertz et al., 2002; 2003; Sibley et al., 2002; Kaufmann et al., 2003).

Histologic evaluation of placentas in IUGR resulted in extremely heterogeneous features. These features become more homogeneous, classifying the cases according to the presence or absence of end-diastolic flow in the umbilical arteries (Macara et al., 1995, 1996; Todros et al., 1998). The placentas derived from pregnancies with IUGR with abnormal but still preserved end-diastolic (PED) flow in the umbilical arteries, irrespective of whether complicated by preeclampsia or not, show the same, very homogeneous histologic structure as has been described for preplacental hypoxia (maternal anemia, high altitude) (Todros et al., 1998): Richly branched, net-like capillary beds with mostly narrow capillaries are responsible for the characteristic fist-like deformation of the terminal villi (Fig. 15.16). They are short, knob-like, and multiply indented. Histology displays increased knotting, and Tenney-Parker changes

(flat sectioning) (Alvarez et al., 1964, 1970). The respective villous maturation scores are **03, 30, 32, or 33**, depending on severity and stage of pregnancy. As a consequence of increased terminal villus branching, the intervillous space is abnormally narrow and sometimes difficult to identify.

An alternative view for the Tenney-Parker change is that the increased knotting relates to deficient water transfer from mother to baby. Neonates of such pregnancies are generally dehydrated and have elevated hemato-crits; the placentas are thin, appear dark on sectioning, and the villi are small and composed primarily of capillaries. It is also possible that the syncytium “buckles” because of this deficient water transfer, thus causing increased knotting in histologic preparations.

### Intrauterine Growth Restriction Combined with Absent or Reverse End-Diastolic Umbilical Blood Flow in the Second Trimester, with or without Early-Onset Preeclampsia (Postplacental Hypoxia)

When fetal IUGR in the second trimester of pregnancy is combined with absent or reverse end-diastolic (ARED) umbilical blood flow, as judged by Doppler examination, the histopathologic findings are very homogeneous, but surprisingly quite different from those obtained in IUGR with PED (Macara et al., 1995, 1996; Krebs et al., 1996; Kingdom & Kaufmann, 1997; Kingdom et al., 1997; Todros et al., 1999). Also in this entity, as in IUGR with PED, whether or not the case is complicated by preeclampsia does neither influence villous maturation patterns or fetoplacental vascularization, or other gross pathohistologic features.

In general, the histopathologic features resemble those described earlier as “terminal villi deficiency,” a type of villous maldevelopment that is clinically characterized by imminent fetal asphyxia (Schweikhart & Kaufmann, 1983, 1987; Schweikhart et al., 1986; Kaufmann et al., 1987). It is likely that the two entities are basically identical, even though we have to admit that the cases of “terminal villus deficiency” were not defined by Doppler ultrasound and probably were mixed up with cases of mild persisting immaturity (cf. Prolonged Pregnancy, above).

Scanning electron microscopy (Kaufmann et al., 1987; Krebs et al., 1996) revealed that the mature intermediate villi together with their terminal villous continuations are extremely long, largely unbranched, filiform structures (Fig. 15.17A; also see Fig. 15.6C). Terminal villous side branches of the mature intermediate villi are largely missing. The terminal capillary loops, resulting from non-branching angiogenesis (see Figs. 7.17 and 15.6C), are

long, slender, and usually unbranched, thus explaining the high Doppler resistance index (Kingdom et al., 1997).

Further findings, according to Macara et al. (1996), include (1) thinning of villous trophoblast; (2) numerical reduction of cytotrophoblast and reduction of cytotrophoblastic proliferation; (3) increased incidence of apoptotic trophoblastic nuclei and syncytial knotting with extrusion of nuclei; (4) increased amounts of stromal collagen I, collagen IV, and laminin; and (5) wide intervillous space as a consequence of reduced peripheral villous branching.

The straight course of the largely unbranched, filiform terminal villi results in predominance of villous cross sections of minimum diameters (30–60 µm) with admixture of some longitudinal sections (Figs. 15.6C and 15.17B). The prevalence of smallest villous diameters, in combination with occasional unbranched, filiform, small-caliber villous sections, absence of syncytial knotting (Tenney-Parker changes), an obvious caliber gap between small-caliber terminal villi and stem villi, and an unusually wide intervillous space, make this condition easily identifiable. The villous maturation scores are **04, 40, and 44**, and in less severe cases **42**, depending on the stage of pregnancy. In agreement with the experimental findings of Panigel and Myers (1972), these features were interpreted as signs of intraplacental oxygen levels higher than normal, possibly caused by decreased oxygen extraction by the fetally malperfused villi (Kingdom & Kaufmann, 1997; Kingdom et al., 1997).

Casts of the fetoplacental villous vessels, prepared from such specimens and studied in the scanning electron microscope, revealed long, poorly branched capillaries (Krebs et al., 1996) (compare Figs. 7.17 and 15.6C). Focal sinusoidal dilatation is only sometimes present; it can be interpreted as an attempt at compensation for the increase in blood flow impedance in these long capillary loops. The Doppler measurement cited provided evidence that the resulting blood flow impedance was considerably increased, despite sinusoidal dilatation. In some parts of the fetoplacental vascular bed the flow of blood obviously came to a standstill; histologically, one may find aggregation of fetal erythrocytes caused by stasis (Macara et al., 1996). Ultrastructurally, the erythrocytes showed damage to their membranes and partial lysis, which can be interpreted as signs of fetal circulatory decompensation. Clinically the Doppler findings were considered in all these cases as evidence of fetal compromise with need for immediate termination of pregnancy (Macara et al., 1996; Kingdom et al., 1997).

The relative or absolute scarcity of mature intermediate villi in this condition has led Vogel (1996) to call this entity “deficiency of intermediate villi”; in fact, seen histologically, well-fibrosed stem villi and perfectly capillarized terminal villi are the prevailing structures.

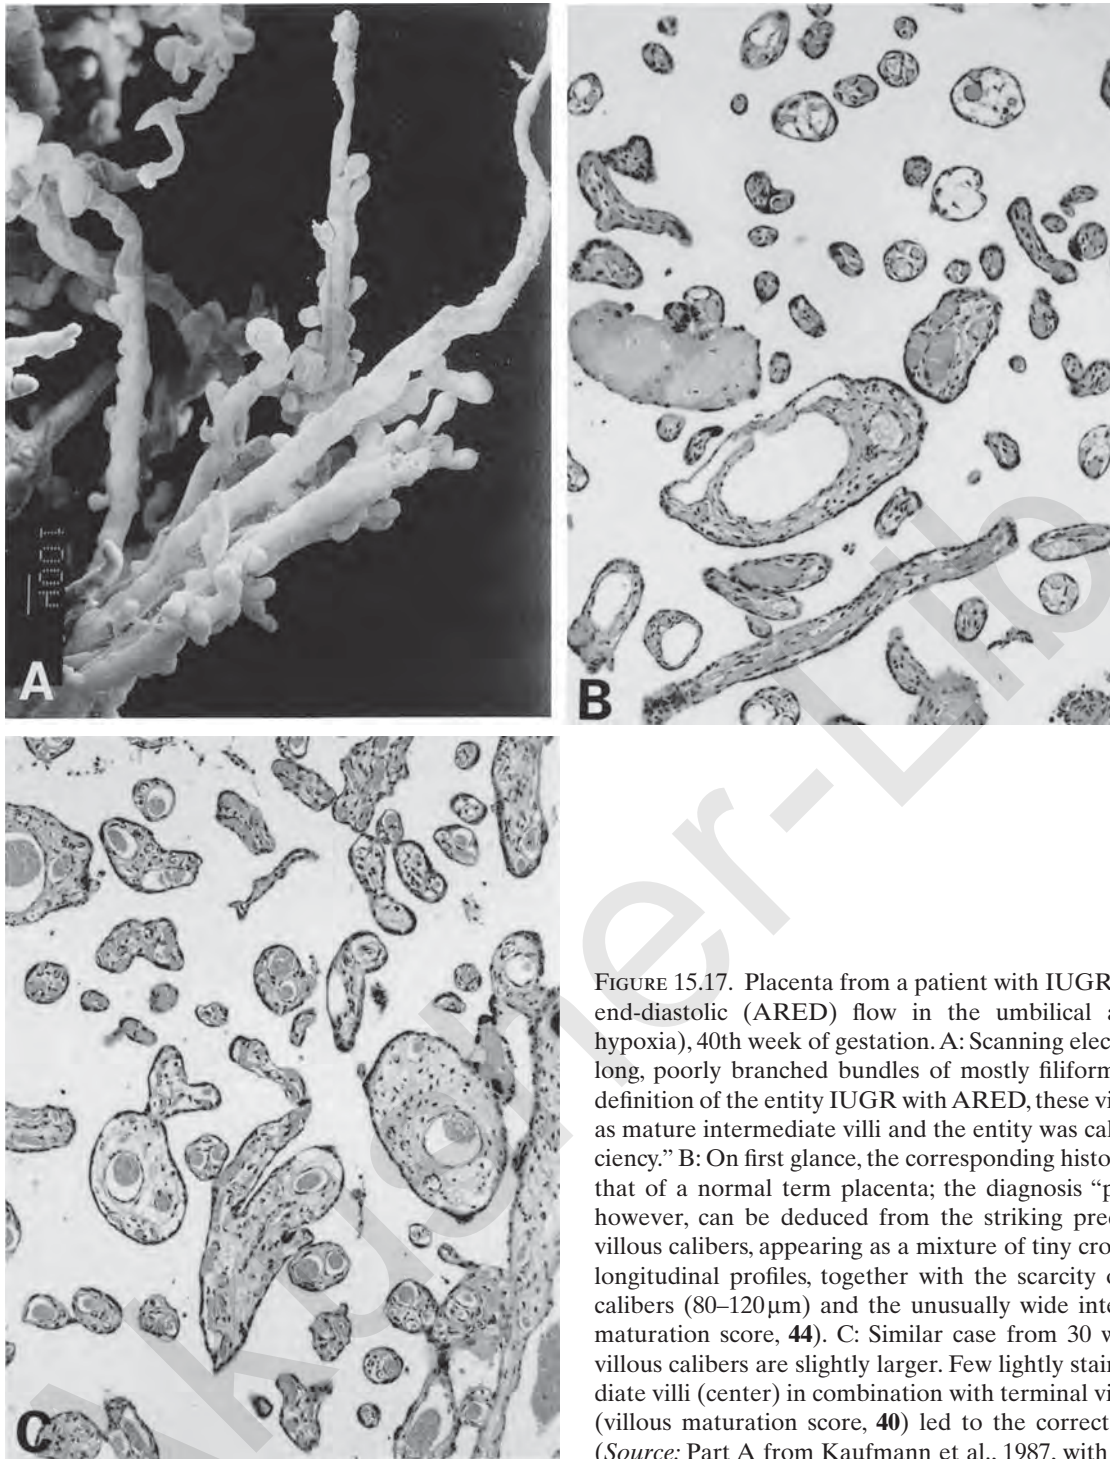

FIGURE 15.17. Placenta from a patient with IUGR with absent or reverse end-diastolic (ARED) flow in the umbilical arteries (postplacental hypoxia), 40th week of gestation. A: Scanning electron micrograph shows long, poorly branched bundles of mostly filiform terminal villi. Before definition of the entity IUGR with ARED, these villi were misunderstood as mature intermediate villi and the entity was called “terminal villi deficiency.” B: On first glance, the corresponding histologic section resembles that of a normal term placenta; the diagnosis “postplacental hypoxia,” however, can be deduced from the striking predominance of smallest villous calibers, appearing as a mixture of tiny cross sections and filiform longitudinal profiles, together with the scarcity of intermediate villous calibers (80–120 $\mu$ m) and the unusually wide intervillous space (villous maturation score, **44**). C: Similar case from 30 weeks of gestation: the villous calibers are slightly larger. Few lightly stained immature intermediate villi (center) in combination with terminal villi of smallest diameter (villous maturation score, **40**) led to the correct diagnosis. A,B,C:  $\times 55$ . (Source: Part A from Kaufmann et al., 1987, with permission.)

## Preeclampsia

As already described above, the presence or absence of preeclampsia does not influence either villous maturational patterns or fetoplacental capillarization. Rather, these features are defined by the type of IUGR, which is normally combined with preeclampsia:

- IUGR with PED accompanying late-onset preeclampsia in the third trimester is characterized by the features of uteroplacental hypoxia: richly branched, net-like villous capillary beds with mostly narrow capillaries resulting in short, knob-like, and multiply indented villi, which in scanning electron microscopy have a fist-like appearance (see Fig. 15.16). Histology

displays increased knotting and Tenney-Parker changes (flat sectioning) (Alvarez et al., 1964, 1970). The respective villous maturation scores are **03, 30, 32, or 33**, depending on severity and stage of pregnancy. Due to increased villous branching, the intervillous space is abnormally narrow. The amount of villous cytotrophoblast is increased as the thickness of syncytiotrophoblast is.

- IUGR with ARED accompanying early-onset preeclampsia at the transition of the second to the third trimester shows extremely long, largely unbranched, filiform villi (Figs. 15.6C and 15.17A). Terminal villous side branches are largely missing. The terminal capillary loops, resulting from nonbranching angiogenesis (see Figs. 7.17 and 15.6C), are long, slender, and usually unbranched, thus explaining the high Doppler resistance index (Kingdom et al., 1997). Villous cytotrophoblast is scarce; the thickness of villous syncytiotrophoblast is dramatically decreased. As a consequence of reduced peripheral villous branching, the intervillous space is abnormally wide.
- Preeclampsia without obvious IUGR and with normal umbilical Doppler patterns usually also shows normal villous branching patterns.

Despite the fact that gross villous maturational patterns are only influenced by the type of IUGR accompanying preeclampsia, there seems to be one parameter that is directly correlated with the presence or absence of this hypertensive disorder: the amount and extent of necrotic foci in villous syncytiotrophoblast (Black et al., 2002; Huppertz et al., 2002, 2003). Due to the absence of immunohistochemical markers for trophoblast necrosis, it is still impossible to quantify trophoblast necrosis. The visual impression of increased necrosis, however, is underlined by the facts (a) that cell-free fetal DNA is increased in the blood of mothers with preeclampsia (Hahn & Holzgreve, 2002) and (b) that experimental data suggest that this cell-free DNA is derived from increased trophoblast necrosis (Black et al., 2002; Huppertz et al., 2002). Under normal pregnancy conditions daily up to 3g of aged, apoptotic syncytiotrophoblast are shed into the maternal circulation. These trophoblast fragments are sealed by membranes, are trapped by maternal macrophages in the maternal lung, and do not induce any adverse maternal reactions. If, by contrast, apoptotic discharge of trophoblast due to adverse local energy supply becomes impossible, the aging trophoblast is discharged into the maternal circulation by necrosis: in this case trophoblastic compounds such as fetal DNA, free globular actin, and other fetal proteins are directly set free into the maternal circulation and cause an inflammatory response including maternal macrophage activation and maternal endothelial damage (Stepan et al., 2004; Zhong et al., 2004) (for details see Chapter 6).

## HELLP Syndrome (Postplacental Hypoxia)

To our best knowledge, data on the placental histology in the case of HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome have never been published. We, too, have analyzed only very few cases of acute HELLP syndrome, resulting in C-section between 28 and 32 weeks of pregnancy. These cases showed a surprising structural homogeneity. All of them were characterized by features of postplacental hypoxia, similar to those described above for IUGR with ARED, combined with early-onset preeclampsia: Mature intermediate villi and terminal villi were extremely long, thin, filiform, and largely unbranched. Terminal villous side branches are largely missing. Consequently, intervillous space is abnormally wide (Fig. 15.18A,B). The terminal capillary loops, resulting from nonbranching angiogenesis are long, slender, and usually unbranched (Fig. 15.18D). Their geometry explains the abnormally high umbilical Doppler resistance indices. As in postplacental hypoxia, villous cytotrophoblast is barely undetectable. Accordingly, in spite of ample immunoreactivities for proliferation marker MIB-1 in the villous stroma, proliferating cytotrophoblast is missing. The thickness of villous syncytiotrophoblast is dramatically decreased. Signs of apoptotic knotting and respective TUNEL reactivity are largely missing, whereas disintegration of the apical plasmalemma, accumulation of trophoblastic debris in the intervillous space, as well as fresh intervillous blood clot and perivillous fibrinoid are universally visible.

Because most placentas in HELLP syndrome are delivered at the beginning of the third trimester, local areas with obvious synchronous villous immaturity are found (Fig. 15.18C). These are in striking contrast to the otherwise prematurely differentiated villi.

These preliminary findings support the view that HELLP syndrome is a hypertensive disorder of the late second trimester and therefore shows features similar to those of early-onset preeclampsia combined with IUGR with ARED (see above). As already indicated above, our findings are based on only a few cases. Two findings from the literature suggest, however, that the general structural features described above may be representative:

- Our findings of numerical reduction of villous cytotrophoblast and increased syncytiotrophoblast necrosis suggest a decreased rate of syncytial fusion. This is in agreement with the data by Knerr et al. (2002), who showed that syncytin expression in these placentas is reduced (cf. Chapter 6).
- Prevalence of nonbranching angiogenesis in the placental villi, as described above, is supported by the findings by Zhou et al. (2002), who found reduced VEGF but normal placental growth factor (PlGF) expression, by cytotrophoblast from HELLP placentas, both in situ and in vivo. This is a combination of angiogenic

FIGURE 15.18. Placenta from a patient with severe HELLP syndrome showing typical features of postplacental hypoxia, 30th week of gestation. A: Paraffin survey picture. Note the long, poorly branched bundles of mostly filiform terminal villi with an extremely wide intervillous space.  $\times 25$ . B: In higher magnification the unusually small diameter of the majority of terminal

villi becomes evident.  $\times 50$  C: The center of a villous tree of the same case still shows synchronous immaturity, which reflects the stage of pregnancy.  $\times 50$ . D: QBend10 staining of the same case reveals few, mostly undilated, poorly branched capillaries (brown). This feature is highly characteristic for postplacental hypoxia.  $\times 140$ .

growth factors that are thought to be responsible for the development of excessive nonbranching angiogenesis in placental villi (for review see Charnock-Jones et al., 2004 and Kaufmann et al., 2004).

### Maternal Diabetes Mellitus

The villi associated with maternal diabetes mellitus have usually been described as being immature (Greco et al., 1989; Vogel, 1996; Fox, 1997). A more detailed evaluation reveals several differences when compared to synchronous immature villi or to those of persisting immaturity and rhesus incompatibility. Werner and Schneiderhan (1972), Emmrich et al. (1975), Gödel and Emmrich (1976), and Fox (1997) have all described characteristic features in diabetes, including increased villous diameters, stromal fibroblastic proliferation (Fig. 15.19A,B), increased basal lamina thickness, an excess of Langhans' cells, and

FIGURE 15.19. Maternal type 1 diabetes mellitus, 40th week of gestation, untreated. Among a majority of seemingly normal villi (A), few highly characteristic large caliber villi with multiply indented surfaces (A–C) can be found. They are characterized by a highly cellular stroma (B), numerous syncytiotro-

phoblastic nuclei (B), and large numbers of small capillaries, which are evenly distributed throughout the stroma. A:  $\times 25$ ; B:  $\times 50$ ; C: QBend10 staining,  $\times 50$ . (Courtesy of Dr. Berthold Hupertz, Aachen, Germany.)

decreased fetal vascularization with increased maternal-fetal diffusion distances. On the other hand, we also observed large, hypercellular villi from diabetic pregnancies that showed unusually dense capillarization (Fig. 15.19C). We agree with Vogel (1996), who pointed to the local and interindividual variability of the villous patterns, which can be only partly explained by various degrees of illness or success of treatment.

The scanning electron microscopic appearance is similar to that of cases of synchronous immaturity but different from that of persisting immaturity and rhesus incompatibility. The number of drumstick-shaped true trophoblastic sprouts increases with increasing diameter of the immature villi, suggesting considerable proliferative activity. Because of their small size, the incidence of true sprouts is moderate in histologic sections. The diagnosis can be based on the large caliber of the villi, which often show fist-like indented surface (Fig. 15.19). Moreover, unusual amounts of villous cytotrophoblast and voluminous stromal cells are significant findings. The villous maturation score is not applicable to these villous features because qualitative alterations of villous structure prevail, rather than alterations of the numerical composition of villous trees.

# Erythroblastosis Fetalis and Hydrops Fetalis

## ERYTHROBLASTOSIS FETALIS

Erythroblastosis fetalis, or hemolytic disease of the newborn, is a condition caused by specific antibodies of the mother, directed against red cell antigens of the fetus. These are largely Rh-(D) antigens, but rare cases of sensitization against other antigens (e.g., Kell), and of ABO incompatibility with fetal hemolytic disease have been described. Leventhal and Wolf (1956) have presented Kell-isoimmunization as a cause of fatal erythroblastosis fetalis (EF). This was also found in the well-illustrated case of Ivemark et al. (1959). Anti-K antibodies usually arise as a result of transfusion and the fetal disease is usually mild. Of 194 pregnancies complicated by this antibody constellation, only 16 affected babies were identified, of which three were severely affected by hemolytic disease (Leggat et al., 1991). The difficulty in this situation is the identification of the pregnancies at risk, an aspect discussed in some detail in an editorial in *Lancet* (1991). Anti-K hemolytic disease does not differ histopathologically from anti-D-caused erythroblastosis. However, there may be a difference in the response to this antibody. Vaughan et al. (1998) showed that they specifically inhibit growth of K-positive erythroid precursors and may thus lead to severe fetal anemia. Relatively few cases of typical, severe EF have been described as being due to ABO incompatibility. These were summarized by Freda and Carter (1962), and a fatal case is delineated by Miller and Petrie (1963), but usually, the hemolytic disease of ABO-incompatibility is mild. The pathologic findings of infant and placenta are the same as those in EF due to Rh incompatibility; in their case, the placenta weighed 900g and had typical features of erythroblastosis. Other types of hemolysis occur which also produce similar pathologic features of infant and placenta. Thus, hemolysis in fetal blood may rarely result because of glucose-6-phosphate dehydrogenase (G-6-PD) deficiency, virus infection, and for other uncommon reasons. These causes of fetal hemolysis must be differentiated from the classic erythroblastosis.

As RhoGAM prophylaxis (Mittendorf & Williams, 1991) has become more widespread, the typical disease has become relatively uncommon in this country. Pathologists and clinicians are now more challenged to unravel the causes and therapy of "nonimmunologic hydrops fetalis" (vide infra) and of other causes of prenatal anemia, such as transplacental bleeding (vide infra and Chapter 17). From a pathologist's point of view, these conditions are often indistinguishable, and additional tests need to be employed to identify the many specific disease entities that comprise this complex fetal condition. It is worth mentioning that the fetal genotype (RhD+) is now commonly made in Europe from free DNA in maternal serum (Gautier et al. 2005).

The cause of typical erythroblastosis is the transplacental transfer of maternal antibodies that cause hemolysis in the fetus. As a consequence, the fetus attempts to repair this loss of red blood cells by over-

production and premature dissemination of immature red cell precursors (nucleated red blood cells, NRBCs). The hematopoietic tissue becomes increasingly activated in the fetus and the peripheral blood thus contains an increased number of NRBCs and erythroblasts, elegantly demonstrated by Nicolaides et al. (1988a,b). They performed reticulocyte counts in 127 pregnancies with isoimmunization, from 17 to 36 weeks, and also suggested that it may be the extensive hepatic red cell production that may cause the hydrops, by obstruction of sinusoidal blood flow. In our opinion, this is not the most likely mechanism for hydrops to develop. We believe that fetal cardiac failure is the main cause of hydrops and of the placental changes. The high-output congestive heart failure results from anemia and is the presumed cause of cardiomegaly and heart failure in EF (Naeye, 1967). The issue is not completely resolved, however, as there is no strict correlation between the severity of anemia and cardiac hypertrophy (Carter et al., 1990). From the frequently extensive hemolysis, large iron stores may occur in the liver and spleen, whereas the fetus becomes progressively anemic. When the hematocrit falls much below 15%, edema, ascites, and eventually anasarca develop—the condition known as hydrops fetalis (Saltzman et al., 1989). Normative values for hemoglobin and NRBC and reticulocyte counts, ascertained by cordocentesis, are to be found in the contribution by Nicolaides et al. (1989). They discovered that hemoglobin and red blood cell counts increased linearly from 17 to 40 weeks' gestation. Importantly, the "erythroblast count decreased exponentially from a mean of 83/100 leukocytes at 17 weeks to 4/100 leukocytes at 40 weeks." Similar values obtained by other investigators were reviewed by Weiner et al. (1992), who also measured protein levels, enzymes, pH, and gases, as well as venous pressure. Thilaganathan and collaborators (1992) found that erythropoietin (EPO) levels were significantly increased only in severe fetal anemia. Moya and his colleagues (1993) found that EPO levels were elevated in erythroblastosis also, but before 24 weeks' gestation this response was much smaller.

Fetal hydrops is now readily diagnosed sonographically (Saltzman et al., 1989); if it is due to hemolysis, the hydrops may be quickly and completely reversed when the anemic fetus is transfused intravascularly before birth (abdominally or by cordocentesis), thus restoring oxygenation (Socol et al., 1987; Grannum et al., 1988). The latter authors documented the impressive changes in protein and hemoglobin levels that occur. Nicolaides et al. (1988) who provided the normative values for fetal hemoglobin levels from 17 to 40 weeks' gestation (11–15g/dL), found that hydropic fetuses had hemoglobin values of 7 to 10g/dL. A study investigating the possible mechanism of fetal death occurring in such pregnancies during transfusion showed that acute increases in hematocrit were associated with substantial mortality (Radunovic et al., 1992), whereas Nicolini et al. (1989) implicated

increases in venous pressure during transfusion. The bilirubin, liberated by hemolysis, is effectively exchanged transplacentally and the neonate rarely has much jaundice. This is a later, usually neonatal development in erythroblastosis.

Other fetal changes are worth mentioning. Hepatosplenomegaly is prominent; usually the infants have some hypoproteinemia. They also often suffer severe thrombocytopenia (Harman et al., 1988) and display increased beta-cell activity of their islets of Langerhans. The islet cell hyperplasia, which is combined with a greater islet insulin content (Driscoll & Steinke, 1967), was explained to result from insulin binding by the circulating hemoglobin (Steinke et al., 1967). The occasional presence of large maternal ovarian lutein cysts with hydrops fetalis is more difficult to explain. These cysts are clearly associated with an usually enlarged placenta, as was shown by Burger (1947), Christie (1961), Rabinowitz et al. (1961), and Hatjis (1985). Ovarian lutein cysts are also found in nonimmune hydrops, and they occasionally accompany fetal triploidy as well. These varied observations have led to the suggestion that, similar to the ovaries of women with hydatidiform moles, the fetal ovarian cysts result from elevated titers of human chorionic gonadotropin (hCG), produced because of the enlargement of the placentas with increased trophoblastic mass. Christie (1961) and Hatjis (1985) have determined that the maternal serum levels of hCG are significantly above normal with fetal hydrops. Initially, this elevation of hCG titers was thought to result from the persistent presence of the Langhans layer of trophoblast, or from its exaggerated appearance. Now that the origin of hCG has clearly been determined to be the syncytium, the abundance of hCG with fetal hydrops must be assumed to result from placental enlargement alone. In this connection, it is relevant to point out that human placental lactogen (hPL) and placental protein 5 (PP5) are also elevated in fetal hydrops (Lee et al., 1984). Although the elevation of hPL and hCG levels may relate to a larger placental mass, as suggested by Lee et al. (1984), the increase of PP5 levels is not so readily understood.

## Placental Pathology in Erythroblastosis

The striking features of the placenta in erythroblastosis fetalis are its pallor, uniform enlargement, presence of bone marrow elements in the fetal circulation, and the villous "immaturity" (Fig. 16.1). Because of the edema and enlargement, placentas of erythroblastosis are also

very friable. The changes were delineated early by Hellman and Hertig (1937), prior to a knowledge of the nature of the disease. They enumerated syncytial degeneration, persistence of Langhans' layer, prominence of Hofbauer cells, presence of erythropoietic cells in the vascular spaces, and stromal edema of villi. Since then, many studies have been conducted, all with essentially the same findings. Of comparative interest is that the hematopoiesis proceeds within the villous blood vessels (Alenghat & Esterly, 1983), in contrast to the villous arrangement in marmoset monkeys where it also proceeds in the villous stroma. It is now apparent that the placental alterations are largely secondary to the fetal anemia and to cardiac failure. Wentworth (1967) studied the placentas with the Gough large-section technique and affirmed that "the more severely the baby was affected, the larger the placenta was in relation to the baby." In the severe cases, the placentas were extremely pale and more friable than normal. Additional diagnostic histologic features in the placenta were a marked decrease in the number of fetal vessels and an increase in the number of NRBC in these vessels. Langhans' layer persisted in all cases but in itself it was not considered to be a specific change. Wentworth believed that the pathologic changes resulted from a direct effect of antibodies on the placenta. Montemagno et al. (1966) suggested from immunofluorescent antibody studies, that the syncytium possesses the Rh antigen and that antibodies localize to these antigens. Thus, the antibodies were believed to damage the syncytium and thereby produce the pathologic changes seen in the placenta of EF. More detailed examination of this question by Benachi et al. (1998), however, revealed decisively that the RhD antigen is not expressed by syncytiotrophoblast.

On occasion, one may find small amounts of hemosiderin deposited in chorionic macrophages betraying the long-standing hemolysis. It is not a prominent finding,

FIGURE 16.1. Villus in stillborn with typical erythroblastosis fetalis showing edema, abundance of Hofbauer cells, and persistent cytotrophoblast. Because of fetal demise, the fetal vessels are obliterated. H&E  $\times 250$ .

however. We presume that the affinity for iron of fetuses is too great for substantial hemosiderin accumulation to take place in the placenta. Rarely, one observes some icteric staining of placental surface vessels and umbilical cord. We now know that these are nonspecific changes that are essentially similar in placentas of unrelated types of hydrops fetalis (e.g.,  $\alpha$ -thalassemia). We believe that it is impossible, without history or specific immunologic tests, to make the specific diagnosis of EF from a placental examination alone, an opinion similar to that expressed by Bouissou et al. (1969), who suggested, however, that the crowding of hematopoietic elements in the hepatic parenchyma may cause the fetal edema, which is contrary to our views. It is noteworthy that with the polymerase chain reaction (PCR) to ascertain fetal Rh genotype, the diagnosis is now readily achieved from blood and by the usage of amniotic fluid (Veyer & Moise, 1996; Veyer et al., 1996). The possible importance of vascular endothelial growth factor (VEGF) distribution in the placenta was investigated by Shiraishi et al. (1997). Because Rh disease is uncommon in Japan, they studied primarily the placentas of nonimmune hydrops by immunohistochemistry of this placentally active cytokine (Jackson et al., 1994). VEGF was found in syncytiotrophoblast of all placentas and in stromal cells (fibroblasts) during the first trimester of normal placentas, but not later. In the hydropic organs, however, stromal cells remained positive in 12 of 18 cases, those whose outcome was poor. They confirmed also that hydropic placentas are composed of hypovascular villi and made reference to the persistence of  $\beta$ -hCG, lactogen, and phosphatase expression throughout pregnancy in hydrops fetalis (Kamat et al., 1989). Their suggestion is that, functionally as well as structurally, hydropic placentas remain immature and that VEGF may have a regulatory function in the vasculogenesis of these abnormal placentas.

Wentworth (1967) provided an excellent photograph of the anemic and normal placental portions of a set of dizygotic (DZ) twins in which only one twin was affected. Becker and Bleyl (1961) performed fluorescence microscopy on such placentas and believed that these demonstrated the increased permeability of the erythroblastotic placentas. The authors showed a "condensation of . . . the interfibrillary substance of the connective tissue" of villi and believed it to be due to an increase in interfibrillary substance. This, we believe is largely the result of edema and of the accumulation of Hofbauer cells. It has occasionally been suggested that extramedullary hematopoiesis also takes place within the villous stroma. We believe that this is not the case. To be sure, the abundance of erythroblasts in some cases so much crowds the fetal capillaries that a villous production site is simulated. There is normally a large number of bone marrow-like elements in the fetal capillaries in EF; Alenghat and Esterly (1983) even found some of these cells to contain

mitoses in abortions specimens. Burstein and Blumenthal (1962) found that the abundance of syncytial knots was about the same as that found in normal controls but that the villi were much expanded; by their method, this resulted in a decreased villus count. They also emphasized the occurrence of fetal capillary proliferative lesions. There was no mention as to whether any of the placentas came from stillborn infants. Apparently similar pathologic findings were presented in a Russian article that was not accessible to us (Iakovtsova, 1964). Busch and Vogel (1972) provided a complete review of the historical aspects "of the placental changes theretofore described" and added their own observations of 58 cases. They found that these related to the severity of the hemolytic disease, that is, the degree of anemia, and emphasized the occurrence of "maturational changes of villi." Finally, they found that about one third of their cases had intervillous thrombi. This is indeed a common lesion in the placentas of erythroblastosis fetalis, and it is not easily or satisfactorily explained. One may postulate that intervillous thrombi are the sequel of an increased hydrostatic pressure within the fetal capillaries, and resultant bleeding. This would be supported by finding many nucleated red blood cells within the thrombi (Fig. 16.2). Intervillous thrombi, however, are also extremely frequent in hydatidiform moles that have no fetal vasculature. We believe that the mechanism of the formation of intervillous thromboses in both conditions may be similar. The villous edema so alters the intervillous blood flow as to cause local eddying and stasis, with thrombosis being the end result. Nevertheless, because NRBC are often found in the thrombi, fetal bleeding must occur at times. It may result from local villous hypoxic injury, as it has been repeatedly demonstrated that distention of fetal vessels and necrosis at the surface of the villi take place. This is further discussed in Chapter 17 in considerations of fetal hemorrhage. Busch and Vogel (1972) contended that the placental enlargement was the result of real growth. The investigations by Vidyasagar and Haworth (1973), however, negated this explanation. They found no differences when they compared the weights of non-EF placentas with those from nonhydropic cases of EF. Their decidual surfaces, and DNA, water, and protein contents all were similar.

An electron microscopic study of the placentas from erythroblastotic infants was undertaken by Jones and Fox (1978). These investigators found characteristic syncytial necrosis, cytotrophoblastic hyperplasia, thickening of basement membranes of villi and vessels, and immature endothelial cells. They did not identify a distinct pathogenesis of these alterations, but ruled out immunologically mediated changes. Rather, they felt that the syncytial degeneration was the result of villous enlargement with consequent decrease of the intervillous space. The most detailed study of villous alterations in EF comes from the

FIGURE 16.2. Immature placenta of live infant with edema. Marked villous vascular distention, numerous erythroblasts in the fetal circulation (left). Intervillous thrombi with nucleated red blood cells in same placenta (middle, right). H&E  $\times 60$ ;  $\times 40$ ;  $\times 160$ .

investigations by Pilz et al. (1980). They insisted that, in order to obtain reproducible results, it is necessary for protocols to provide specific fixation and other data. They obtained their material from in situ aspiration biopsies of eight cases of EF, and compared them with 20 normal organs. Their morphometry showed an enlargement of intermediate villi that depended upon the severity of the disease. They also observed an increase in cytotrophoblast; the terminal villi were not altered, and there was an increase in Hofbauer cells. These investigators believed that the increased number and size of Hofbauer cells probably related to the increased antigen-antibody reaction that must take place in the stroma of villi. They were unable to find the alterations in capillary lumens that were suggested to exist by other authors. There was no chorangiosis. They further emphasized that the changes that they observed may represent a true maturational disturbance of the villi. In this regard, it is noteworthy that calcifications of the placenta are very uncommon in EF.

Modern management of the isoimmunized gravida requires supervision of fetal progress. This includes sonography for the detection of edema, evaluation of amniotic bilirubin concentration, and the ascertainment of umbilical vein diameter. When these parameters were correlated, Reece et al. (1988) showed that umbilical venous dimension does not parallel the other time-honored methods of prenatal evaluation. Prenatal intraabdominal transfusion for the therapy of affected fetuses (e.g., Queenan & Douglas, 1965) is gradually being displaced by intravascular transfusion with cordocentesis. This is usually done near the site of cord insertion on the placental surface (Rodeck et al., 1984;

Schumacher & Moise, 1996), a technique that allows sampling of fetal blood and estimation of total blood volume (Macgregor et al., 1988). The survival of transfused blood in the fetus is approximately similar with the two techniques (Pattison & Roberts, 1989; Van Kamp et al., 2005). With the introduction of transfusion by cordocentesis, newly observed pathologic features have been witnessed in the placenta. Berkowitz et al. (1986) presented their results of 18 such transfusions, weighed the advantages and disadvantages of cordocentesis, and drew attention to the problems that ensue from the need for repeated puncture. The complications mainly involved injury to the umbilical cord; they witnessed stillbirth as a result. Pielet et al. (1988) also drew attention to the possible dangers accruing from cordocentesis. They found two stillbirths without recognizable cord injury; in another neonate with postnatal developmental delay, however, one umbilical artery was clotted after transfusion had been performed into the umbilical vein. A similar case is shown in Figure 16.3. This patient had unsuccessful cord blood sampling at 28 weeks' gestation. At 29½ weeks successful transfusion of 45 mL of blood was accomplished into the vein. At 32 weeks, another transfusion was attempted; it ended with infusion of blood into the cord, and emergency cesarean section was necessary. The child survived. The cord had a superficial hematoma that extended onto the placental surface. The entire cord was stained with hemolyzed blood; hemosiderin was found in the chorionic macrophages. One umbilical artery was necrotic and had old obliterative thrombosis. Interestingly, there was a line of polymorphonuclear leukocytic exudation extending between the vein and the occluded artery, in the absence of chorioamnionitis. We concluded that the degenerating

FIGURE 16.3. Umbilical cord with thrombosis of one artery, following cordocentesis 3 weeks earlier. A new attempt caused infusion of blood into the cord substance. A line of leukocytic

exudate (arrows), coming from the umbilical vein, has formed between vein and the occluded artery, whose wall is dead. H&E  $\times 3$ .

vessel caused the (sterile) inflammation. This occlusion had presumably occurred 3 weeks earlier.

Figure 16.4 shows the result of needle puncture of the fetal surface in a relevant case. During amniocentesis, the posterior-located placenta was accidentally injured, and an “upwelling” of blood was seen sonographically. Two weeks later, a stillborn fetus was delivered. The placental surface showed the site of needle injury to a surface vessel. We have also seen a stillborn fetus whose third transfusion was given into the cord. During that procedure, bradycardia developed after the needle was inserted. The procedure was stopped and abdominal blood was given instead, but the fetus succumbed. There was a tense, placental portion of the cord with hematoma, and fresh occlusive thrombi were found within superficial arterial ramifications. Moreover, within this thrombotic material, typical squames were identified (Fig. 16.5), presumably introduced by the needle from the amnionic cavity. Our interpretation was that, after needle insertion, a cord hematoma and vascular spasm ensued, which were followed by arterial thrombosis. Seeds and his colleagues (1989) asserted that the demonstration of “echogenic venous turbulence” was an important feature of successful intravascular transfusion. When they found it absent in a case that developed bradycardia, a hematoma of the cord was found to have developed. In another case one artery thrombosed but the fetus survived. Other hemorrhagic and thrombotic complications of cordocentesis are

FIGURE 16.4. Mid-gestation placental surface, 2 weeks after amniocentesis. The needle injured the chorionic vessel below. Fresh hematoma, with hemosiderin, and attempted repair of vascular wall. H&E  $\times 16$ .

discussed in Chapter 12. James (1970) measured villous size in EF placentas after intrauterine (abdominal) transfusions had been given, and correlated the findings with hemoglobin levels. Normal values were found when the hemoglobin was above 11 g/dL, but the mean villous volume was increased in more severely affected infants. Houston and Brown (1966) reported a case of fetal gas-bacillus infection after fetal transfusion; the edematous placenta was colonized by large numbers of gram-positive bacterial rods and there was chorioamnionitis.

When it is necessary to traverse the placenta to gain access to the fetus, it may be injured and may bleed from the villous tissue. This may then enhance maternal immunization. These aspects were described by Friesen et al. (1967), who identified puncture marks in the placenta in such cases. These investigators found significant bleeding into the mother in 7.5% of cases when transgression of an anterior placenta was necessary to gain access to the amniotic sac.

As Figure 16.8 shows, the placenta of severe erythroblastosis has a remarkable macroscopic appearance but the correct diagnosis cannot be made solely on account of the severe anemia, and the other causes of fetal anemia to be discussed subsequently need to be included in the differential diagnosis.

Twins may also be discordant (Figs. 16.6 to 16.8) or concordant for EF. When discordant, the severity of the disease often differs markedly (Beischer et al., 1969). In one such case with marked discrepancy, a difference in ABO compatibility was held to be responsible. The authors postulated that undetermined factors may be operative in producing discordance. A similarly discordant set of DZ twins with EF was detailed by Wiener et al. (1962). Manning et al. (1985) reported on the prenatal transfusions in a number of such twins. It is further remarkable that maternal Rh isoimmunization may occur after fetal demise. Stedman et al. (1988) described three cases. They assumed that transplacental bleeding had occurred early during this unsuccessful pregnancy, and was thus causally related to the fetal demise by the pro-

FIGURE 16.6. Immature, fraternal twins, one with erythroblastosis, the other normal. The placenta of the erythroblastic twin (Fig. 16.6) is markedly enlarged and is unusually pale.

FIGURE 16.7. Normal term placenta (right) and placenta of erythroblastosis (left). Note the marked pallor and disruption of the erythroblastic placenta.

duction of antibodies. This is most likely to have been true in their first patient who had torsion of the umbilical cord; the others had negative placental findings. This observation brings into question the mechanism of primary immunization against Rh antigens, usually held to occur most frequently at the time of delivery, or imme-

diately thereafter. It is the rationale for postpartum RhoGAM prophylaxis that has been extremely effective in preventing isoimmunization. Injury to the placenta, such as occurs during manual removal of the placenta and during Cesarean section, enhances fetal blood transfer. Queenan and Nakamoto (1964) found that spontaneous placental delivery and previous drainage of cord blood minimize the probability of isoimmunization. Although it is possible that occasional fetal bleeding in early pregnancy may lead to immunization of primigravidae, the commonest time of sensitization is at delivery (Scott et al., 1977).

Maternal bleeding into a female fetus presumably accounts only for very few immunizations in their future gestations, when an Rh-negative infant is delivered to an Rh-positive mother (Taylor, 1967). Such mother-to-fetus transfer of blood, however, is said to occur as often as in 43% of samples analyzed by Luca et al. (1978). This feature of maternal-fetal blood exchange is further discussed in Chapter 17.

The amount of immunogen needed for isoimmunization has been debated. Attempts to elucidate this with experimental findings have been made in Rh-negative volunteers. Zipursky and Israels (1967) suggested that repeated injections of as little as 0.1 mL ABO compatible Rh-positive blood will suffice to immunize Rh-negative individuals. That is an amount that is presumably frequently attained in normal pregnancies. Mollison (1968) opined that the minimum amount needed for immunization is 0.25 mL of fetal blood.

FIGURE 16.8. Placentas of twins as in Figure 17.7. The enlarged, edematous placenta of the diamnionic/dichorionic (DiDi) twins, one with erythroblastosis (left), shows the pallor and bulky cotyledons.

These deliberations are particularly important when one considers whether a hydatidiform mole, spontaneous abortion, or ectopic pregnancy can immunize an Rh-negative woman. Price (1968) reported a case of hydatidiform mole, followed by a normal pregnancy, in which antibodies were detected at about 6 months; the neonate succumbed from EF. The assumption was made that the mole had immunized the primigravida. It seems unlikely to us that a bloodless structure is capable of Rh immunization, unless the original tissue was a partial mole with triploidy and the possibility of fetal blood content. Alternatively, it is now proven that early hydatidiform moles may possess some fetal red blood cells, to disappear later (Baergen et al., 1996; Fisher et al., 1997; Paradinas et al., 1997); perhaps their detection by such a mother led to antibody formation. It has also been debated why, in patients having an abortion, it sometimes becomes necessary to provide RhoGAM to patients. Freda et al. (1970) came to the conclusion that this was indicated only after the second month of pregnancy. Regrettably, their data do not specify whether the abortions they studied were terminations of pregnancy, or whether they were true spontaneous abortions. The vast majority of the latter cases have no circulating fetal blood as they are due to chromosomal errors that led to embryonic death earlier. They would not be expected to deliver sufficient antigen for sensitization; there is no doubt, however, that embryonic erythrocytes are capable of immunization. Examples of this are the cases of therapeutic terminations of early pregnancy studied by Matthews et al. (1969), Jorgensen (1969), Murray and Barron (1971), and Eklund (1981). To be sure, the risk of sensitization is small and it depends also on the type of instrumentation used in the termination of pregnancy, such as suction vs. dilatation and curettage. And it also depends on fetal age. Ectopic pregnancies present a significantly higher risk for isoimmunization than that which occurs with spontaneous abortion (Grimes et al., 1981), presumably because of their less frequent cytogenetic abnormality and fewer embryonic deaths. Whether chorionic villus sampling (CVS) presents a risk, is yet to be determined. When Warren et al. (1985) studied  $\alpha$ -fetoprotein (AFP) levels and Kleihauer-Betke stains following CVS, they found AFP levels to rise. They felt that the Kleihauer technique was not sufficiently sensitive to detect possible fetal bleeding. But to our knowledge, the risk incurred for isoimmunization from CVS has not been sufficiently investigated. It is generally thought that Rh-positive fetal red blood cells represent the only immunogen to Rh-negative women; trophoblastic cells were once thought to contain Rh antigen and also produce sensitization, but the later studies detailed above show this not to be the case. Besides, then every Rh-positive gestation should lead to isoimmunization because of the massive transportation of syncytium to the maternal lung and its subsequent

destruction. Direct immunofluorescent studies with fluorescent anti-Rh D-antibodies have shown that fluorescence may localize to the syncytium (Jarkowski et al., 1964). Goto et al. (1980) extended these studies. They impressively demonstrated, with appropriate controls, that the amount of trophoblastic Rh-antigen decreases with advancing gestation, in contrast to the increasing prevalence on fetal red blood cells. They also showed that it localizes on trophoblastic surfaces, and that it is present in hydatidiform mole. Whether it can be the cause of sensitization remains elusive for reasons alluded to. The newest observations negate such a possibility. The studies by Benachi et al. (1998) have now revealed decisively that the RhD antigen is not expressed by syncytiotrophoblast. There is no answer to the obvious question as to why it is that not all Rh-negative women with Rh-positive conceptuses become immunized. Although the trophoblastic embolization to the maternal lung in all pregnancies was formerly thought to have relevance in this respect, this is no longer held to be so. With the definitive exclusion of the Rh antigen from syncytium, this speculation fails. Complete absence of AB antigens from trophoblast was also demonstrated by the early studies of Szulman (1972), who did, however, readily identify the antigen in fetal epithelium and in placental capillaries, including in a chorangioma.

#### NONIMMUNE HYDROPS

In the majority of cases of hydrops fetalis, the etiology is different from that EF, discussed above. Santolaya et al. (1992) found that of the 76 fetuses with hydrops (among 12,572 ultrasound examinations), only 10 were due to immunologic causes and 66 had nonimmune hydrops fetalis. They were unable to assign a cause in 17 cases. Some of the other hydropic fetuses resulted from fetal anemia and heart failure, trisomies, and other abnormalities. But many other hydropic fetuses are "idiopathic," a euphemism for our lack of knowledge of their precise etiology. It must also be cautioned that ascites alone is insufficient for the diagnosis of hydrops, in which case there is generalized edema, and fluid exists in all cavities. This fluid accumulation in the pleural spaces often leads to pulmonary hypoplasia, a condition that is not the cause of the hydrops, however (Green et al., 1990). The placental pathology is similar to that of EF, but substantial differences are also identified in individual cases. Novak et al. (1991) described cases of what they considered to be "hemorrhagic endovascularitis" of the placental vessels with fetal hydrops, although they did not claim causality. This entity is more fully discussed elsewhere (Chapter 12). They depicted obliterated main stem vessels amidst rather nonhydropic villi; usually this is regarded as a postmortem phenomenon. Eight of their 14 cases were stillborn, and most were complicated by hydramnios. In some unexplained cases of fetal hydrops, pathologists may be able to exclude specific causes. Often, they are confronted with a stillborn, frequently a macerated, hydropic fetus, and are asked to provide an idea as to the mechanism that led to the fetal hydrops. In the following pages we review many of the currently known entities of nonimmunologic hydrops, and then discuss idiopathic hydrops fetalis. Larger series dealing with causes of hydrops fetalis are the following reports: Macafee et al. (1970), Moerman et al. (1982), Hutchison et al. (1982), Nakamura et al. (1987), Machin (1989), Villaespesa et al. (1990), and Lallemand et al. (1999). Watson and Campbell (1986) provided a detailed man-

agement protocol for such pregnancies. A large review of 600 cases is provided by Jauniaux et al. (1990), who ascertained that more than 35% of cases could be ascribed to a genetically transmitted disease, similar to that of Lallemand et al. (1999) who thought that 38% of their 94 cases had a chromosomal origin. Chromosomal disorders also ranked first in Jauniaux's series, with 15.7%,  $\alpha$ -thalassemia was second (10.3%), and a wide variety of anomalies followed. They suggested that chromosomal analysis was needed in such cases. Mallmann and colleagues (1991) suggested that perhaps 49 of their 324 cases of nonimmune hydrops represent an expression of immunologic rejection. Quite uncommonly prenatal trauma (e.g., a motor vehicle accident) has been held responsible for fetal hydrops, and even transitory events have been reported (see Chapter 17).

### *$\alpha$ -Thalassemia*

Normal adult hemoglobin molecules contain two unlike pairs of polypeptide (globin) chains, the  $\alpha$ -chains and the  $\beta$ -chains. In embryonic and fetal life, special forms of hemoglobin are prevalent at different and carefully scheduled times. Abnormal construction of the globin chains that make up fetal hemoglobin results in altered hemoglobins that may be deficient in oxygen-carrying capacity. This, in turn, can lead to abnormal red blood cell shapes, such as occurs in sickle cell disease. In the thalassemias ( $\alpha$ - and  $\beta$ -thalassemias), anemic disorders result from a decreased production of normal hemoglobin. These disorders are classified according to the chain, which is depressed. Examples include  $\alpha$ -,  $\beta$ -,  $\delta$ -, and  $\gamma$ -thalassemia (Nathan, 1973).

$\alpha$ -Thalassemia is an inherited abnormality of hemoglobin structure that often causes hydrops fetalis and that was lethal until the event of intrauterine blood replacement. Carr et al. (1995) have now shown in an afflicted Filipina that repeated transfusions before birth can yield a surviving, transfusion-dependent child.  $\alpha$ -Thalassemia was also the first type of nonimmunologic hydrops for which an innovative explanation was identified. This complication of pregnancy has occupied much greater attention in this country in recent years because of the immigration of Indochinese with this genetic background. It is also a model for which prenatal marrow transplantation and gene therapy are being considered. Thus, diagnosis is important, as the homozygous condition is lethal and recurrence rate is at least 1 in 4. Detailed screening methods (cresyl blue staining, erythrocyte indices, and iron study) have been described for the couples at risk for this disease (Skogerboe et al., 1992). The pathology seen in the newborn is essentially identical to that of Rh disease. Lie-Injo and her colleagues (1959, 1962, 1968) reported the association of hydrops fetalis and Bart's (Bartholomew) hemoglobin, in Indonesian families. Since then, this disease has been recognized in Filipinos (Pearson et al., 1965; Nakayama et al., 1986), Thais (Pootrakul et al., 1967; Thumasathit et al., 1968), Chinese (Kan et al., 1967), Germans (Rönisch & Kleihauer, 1967), and Canadian Orientals (with hemoglobin-H disease: Ing et al., 1968; Gray et al., 1972). It probably occurs in other races. The  $\alpha$ -thal<sub>1</sub> gene has been identified in Kurdish Jews (Horowitz et al., 1966) and in Ashkenazi Jews, but it has there not been associated with hydrops (Goldschmidt et al., 1968). The same is true of American blacks. The frequency of this deletion of  $\alpha$ -chain genes is greatest in Indonesians and Chinese (Zeng & Huang, 1985). Hydrops is caused by the homozygous presence of the gene for Bart's hemoglobin. The four  $\alpha$ -chains are herein replaced by four  $\gamma$ -chains. The  $\gamma$ -chains are often heterogeneous (Vedvick et al., 1979), and different chain composition causes different severities of the disease. In hemoglobin-Bart's disease, the  $\alpha$ -thalassemia, the defective hemoglobin is unable to release its oxygen effectively, which causes tissue hypoxia, fetal cardiac failure, and hydrops (Orkin & Nathan, 1976). It is essentially lethal at birth or very shortly thereafter. The fetal red blood cells in this disorder are frequently misshapen; for example, they may be sickled. Cardiac hypertrophy is often striking, as is the extensive and widespread extramedullary hematopoiesis. The substitution of various types of

hemoglobin chains during development, and the location of their production in the fetus are complex and have been lucidly portrayed by Nalbandian et al. (1971). Orkin and Michelson (1980) showed, by DNA sequence analysis, that the 5'-portion of the  $\alpha$ -globin structural gene was deleted in a case of  $\alpha$ -thalassemia.

The switching of hemoglobins in embryonic development is regulated in a complex manner; it has been studied by Peschle et al. (1985), and by Wood and his colleagues (1985). Different states of DNA-methylation have been identified, but the mechanism that initiates this switch remains unknown. Many other types of neonatal hemoglobinopathies are known, as for instance hemoglobin-H disease, in which four  $\beta$ -chains constitute the molecule. This particular hemoglobinopathy is prevalent in Orientals and has a wide spectrum of severity, including occasional hydrops. It causes neonatal anemia, and hydrops was described later (Milner et al., 1971; Chen et al., 2000). A comprehensive analysis of the various genetic deletions and substitutions of the  $\alpha$ -globin gene in hemoglobin-H disease is found in Chen et al. (2000), who studied Chinese patients from different regions in Asia. Hydrops fetalis is uncommon or unheard of in sickle cell anemia and sickle cell  $\beta$ -thalassemia. Both are associated with poor reproductive outcome, however, but generally do not feature hydrops as a complication (Laros & Kallstone, 1971). A detailed review of many of these considerations was provided by Jonxis (1965). He described details on the switching from embryonic to fetal, and from fetal to adult hemoglobins, and also listed the then known abnormal hemoglobins.

Louderback and Shanbrom (1967) indicated that hemoglobin electrophoresis is perhaps the simplest and most widely available tool for the differential diagnosis of the various types of cord blood hemoglobin. Sexauer et al. (1975) described a simple and rapid electrophoretic method for the analysis of cord bloods. They found that 11% of their 7500 cord blood samples from black newborns contained an abnormal hemoglobin. The methods for genetic diagnosis have now been considerably simplified (Lebo et al., 1990), and they have been successfully applied to prenatal diagnosis as well. Kan et al. (1976) accomplished this by molecular hybridization. Rubin and Kan (1985) presented a rapid and decisive method, based on slot-blot analysis. Williamson et al. (1981) and Chang and Kan (1981) showed that, with CVS biopsy, it is easily possible to make the accurate diagnosis of sickle cell disease in the fetus, and of many cases of thalassemia by direct globin gene analysis. It is important to state that appropriate samples of blood must be saved for such studies at autopsy when the etiology of hydrops is uncertain. The aforementioned methods also much facilitate the diagnosis of heterozygotes that was previously so difficult to accomplish (Terheggen & Kleihauer, 1968). Unusual causes of hemolytic disease of the newborn, such as the  $\gamma$ - $\beta$ -thalassemia reported by Kan et al. (1972), are also thus delineated.

The placenta in thalassemia does not differ very much from that of children with classical erythroblastosis, and histology alone cannot make the correct differential diagnosis. The placenta, however, is usually even more enlarged than in erythroblastosis; it is pale, friable, and edematous. The cytotrophoblast is prominent and, in the much enlarged fetal circulation, large numbers of red-cell precursors are found (Figs. 16.9 and 16.10). Hemosiderin is occasionally seen within chorionic macrophages, but it may also be bilirubin pigment from bilirubinuria and liver damage. Hemosiderosis of the placenta has also been a feature of  $\beta$ -thalassemia (Birkenfeld et al., 1989), although Knisely (1990a) cautions that iron occurs in many placentas. On the whole, Birkenfeld and colleagues were probably correct in their interpretation, because

FIGURE 16.9. Placenta in  $\alpha$ -thalassemia with fetal hydrops. This placenta weighed 1900g and had macroscopic features such as the organ in Figure 16.8. Note the large number of marrow-like elements in the fetal capillaries. H&E  $\times 640$ .

total iron content was compared with the normal and was elevated. The placental enlargement in thalassemia has often been massive. Thus, the placenta shown in Figure 16.9 weighed 1900g. Lie-Injo et al. (1968) described weights up to 3500g (!), most of which is water. They observed a set of fraternal twins, wherein one of the placentas was normal and the other was abnormal. This conclusively established that the pathologic changes in the placenta have a fetal cause. Pregnancy-induced hypertension (preeclampsia) is a frequent corollary of this condition, presumably because of the massive placental enlargement (Suh, 1994). This author also showed hematoipoiesis in the fetal dermis and, by electrophoresis, that 91.2% of the fetal hemoglobin was abnormal.

It is of related interest to be aware of the complex relationships that exist between placental weight (and

edema) to fetal and to maternal anemia. These aspects have been studied by Beischer and his colleagues (1968). These investigators found that the placental weight of mothers with various types of anemia was in an approximately normal range whereas the placental weight in cases of EF was much more increased, even when compared with the enhanced placental weight found usually in the pregnancies of diabetic mothers. Other aspects of clinical management are important. Thus, Guy and colleagues (1985) studied five pregnant Oriental women sonographically and found that sonographic surveillance for hydrops was an invaluable tool in clinical management (see also Saltzman et al., 1989 for criteria). These investigators emphasized that the pregnancies were frequently complicated by preeclampsia, and by retained placentas that necessitated manual removal. Miller et al.

FIGURE 16.10. Villi of macerated, hydropic fetus showing edema and numerous hyperchromatic cells intravascularly. Neuroblastoma was suspected but could not be proved. H&E  $\times 350$ .

(1987) reported theca-lutein cysts in a Vietnamese mother who had hydramnios and an hydropic 1290-g infant who died immediately after birth. The placenta weighed 1600 g. The ovarian cysts are attributed to elevated hCG levels from the enlarged placenta. The mother's  $\beta$ -chain hCG levels were 1,120,000 mIU/mL. The gonadotropin levels fell rapidly to 83.8 mIU/mL within 15 days, and her ovarian masses disappeared. This is not unlike the cases of ovarian cysts that may accompany EF. Mouse models of this disorder have been described. Their potential usefulness for the elucidation of yet unknown aspects of this disease was discussed by Whitney and Popp (1984). With the increasing population of Vietnamese and other Orientals in this country,  $\alpha$ -thalassemia is seen more frequently and must be routinely considered in the differential diagnosis of hydrops (Suh, 1994). As more prenatal sonography is now being practiced, new methods are being sought in early diagnosis of these diseases. Thus, Lam et al. (1999) found that the cardiothoracic ratio may be significantly elevated in  $\alpha$ -thalassemia as early as at 12 to 13 weeks' gestation.

New hematologic disorders have come onto the horizon as the genome is being explored in greater detail. Thus, Gallagher et al. (1995) described the occurrence of fatal anemia in two children (due to red cell membrane instability) with hydrops. The instability was the result of a homozygous mutation of the  $\beta$ -spectrin gene, producing the spectrin "Providence." The Diamond-Blackfan anemia was found to be the cause of hydrops in two children described by Rogers et al. (1997). One child survived after prenatal transfusions and needs lifelong transfusion. The other, born with a hematocrit of 10% and a hydropic placenta, died neonatally. Interestingly, the islets of Langerhans were much enlarged, a condition here assumed to be secondary to anemia. Methemoglobinemia was the cause of hydrops in a case described by Özmen et al. (1995). The pregnancy was terminated and the placenta was not described.

## Fetal Hemorrhage

Hydrops fetalis has repeatedly been the result of massive and usually chronic fetomaternal hemorrhage, and it is for that reason that it has been our practice to examine maternal blood for fetal cells (Kleihauer-Betke technique, see Chapter 17) in all cases of unexplained stillbirths. As in EF, when the hemoglobin levels fall below a certain point (about 7 g/dL, or a hematocrit of approximately 15% or less), cardiac failure may cause hydrops. When the fetal exsanguination is rapid, it does not produce hydrops so quickly and may result more likely in fetal death. It requires ensuing heart failure and transudation for hydrops to occur. This complex aspect of adjustments was discussed in the case presented by

Herman et al. (1987), with a fetal hematocrit of 15% and hemoglobin of 3 g/dL at term. In that case, the mother had a 2.8% Kleihauer test result (which equals approximately 150 mL fetal blood) and no placental abnormalities were found. Bowman et al. (1984) considered transplacental hemorrhage to be an exceptional cause of fetal hydrops. They reviewed the few cases from the literature and described a neonate in whom large and chronic, bidirectional blood exchange must have occurred. The placenta showed major fetal vessels to have ruptured that were believed to explain this phenomenon, and there were also many placental infarcts. The placenta was not markedly enlarged (560 g). No untoward accidents had occurred until 31 weeks, when the mother experienced a rapidly increasing abdominal girth. The authors suggested that the hydrops resulted from fetal hypervolemic heart failure. Cardwell (1988) described an hydropic 2750-g liveborn infant who had been treated by prenatal transfusion at 21 weeks' gestation. The Kleihauer test had been 0.4%, which corresponded to a 50% loss of fetal blood. The finding of NRBCs in the fetal circulation is herein also an important pathologic finding (Fox, 1967). Villaespesa and colleagues (1990), who investigated 59 cases of nonimmune hydrops, felt that right-sided cardiovascular failure should be investigated, as 50% of their cases were due to this mechanism. This is borne out by direct measurements of venous pressures in hydropic fetuses (Johnson et al., 1992).

We have now seen many hydropic neonates with verified fetomaternal hemorrhage. One had the hemorrhage after an amniocentesis, which was done to ascertain fetal maturity (0.3% Kleihauer; hematocrit 19% 3 days later). Another fetus exsanguinated for no known reason (shown in Chapter 17). A third newborn had an 18% hematocrit at birth, and could not be revived. Many NRBCs were found in villous vessels. All three placentas were extremely pale and edematous, but were not so overtly hydropic as in thalassemia. Other cases have since surfaced and I believe that this is not so uncommon a cause of hydrops (certain fetal demise) as had once been believed. It is important, however, to note that ABO incompatibility between mother and fetus may rapidly remove the fetal red blood cells on which (by Kleihauer test) we rely to make the diagnosis of transplacental hemorrhage. This is an important consideration that will be further elaborated upon in Chapter 17. Zwi and Becroft (1986) reported a patient with ulcerative colitis who was on prednisone and sulfasalazine therapy; the fetus developed hydrops fetalis at 24 weeks' gestation, after 4 weeks of vaginal bleeding. No fetal red cells were identified in this blood, but a marginal separation of a 460-g edematous placenta had occurred. The macerated fetus weighed 1070 g. It had a dilated and enlarged heart, and there was complete absence of hematopoiesis in the liver and bone marrow. The latter finding led the authors to suggest

that aplastic anemia was the cause of the fetal hydrops and placentomegaly. The cause of the anemia was not determined, but it is noteworthy that the mother's sulfasalazine therapy had been discontinued in early pregnancy.

#### *Fetal Tumors*

Congenital neuroblastoma has repeatedly been shown to cause fetal death. Birner (1961) described such a fetus and found an unusually enlarged placenta (1240g). The 3925-g fetus was slightly edematous and macerated, but the placenta did not contain neuroblastoma cells. The villi were enlarged, edematous, and had an increased number of Hofbauer cells. Additionally, Langhans' cells had persisted to term. Strauss and Driscoll (1964) were the first authors to draw attention to the involvement of the placenta with neuroblastoma metastases. Their first fetus was edematous and resembled an erythroblastotic infant. The placenta was markedly enlarged and friable, and it also resembled that of EF. Cords of neuroblastoma cells were found in fetal capillaries. Their second infant was born at term, and it was accompanied by a 1030-g placenta. Typical neuroblastoma cells and erythroblasts crowded the fetal capillaries (Figs. 16.10 and 16.11). The fetal heart was enlarged. The first mother had theca lutein cysts, similar to those mentioned earlier in this chapter. Other cases of fetal hydrops with congenital neuroblastoma and placentomegaly have since been described (Anders et al., 1973; Moss & Kaplan, 1978; Slikke & Balk, 1980; Perkins et al., 1980; Smith et al., 1981; Newton et al., 1985). A possible immune hypothesis for the development of the hydrops was entertained by Strauss and Driscoll (1964), but most authors have now discounted this possibility. Hydrops and placentomegaly were present in Birner's case (1961), but there was no placental neoplasm. This finding suggested that it was not the plugging of fetal capillaries with tumor cells that causes the placentomegaly and this could thus not be the etiology of hydrops. The case of Newton et al. (1985) may have relevance to the considerations of pathogenesis. Their case was associated with maternal hypertension, which was presumed to be caused by the production of catecholamines from the fetal neuroblastoma. Perhaps, similar changes of blood pressure occur in the fetus and contribute to fetal heart failure. Perkins et al. (1980) found, in a case of congenital neuroblastoma, that the villous tissue, too, was infiltrated by neuroblastoma cells and that these contained cytoplasmic granules, which, electron microscopically, were typical of neuroblastoma cells.

We have seen placental hydrops with a severely hydropic and macerated fetus in whose placental vessels there were many malignant small cells. A positive diagnosis of the neoplasm was impossible (Fig. 16.12). No tumor mass existed in the fetus. The most recent review of the 11 cases of placental neuroblastoma with fetal hydrops reported comes from Lynn et al. (1997). They concluded that, after careful review of all factors, the pathogenesis of hydrops remains to be identified. They ruled out secretory products from the neuroblasts as mechanism and provided guidelines for a differential diagnosis, as they showed the tumor cells to be positive for neuron-specific enolase, negative for cytokeratin, desmin, synaptophysin, and bcl-2. Determinations of atrial natriuretic factor and aldosterone concentrations showed them to be elevated in hydrops fetalis due to anemia (Ville et al., 1994a,b). Perhaps future studies need to concentrate on such determinations for an explanation of the development of hydrops fetalis in general. It should be pointed out also that not all cases of congenital neuroblastoma are associated with hydrops. This was shown, for instance, in the two patients described by Ohyama et al. (1999) whose tumors were diagnosed by placental examination. These authors also referred to additional congenital cases and described additional differential diagnostic tests.

Very similar in its placental manifestation was the hydropic pregnancy described by Doss et al. (1998) that was the result of a fetal hepatoblastoma. The villous capillaries of this enlarged placenta (1190g at 33 weeks) were filled with immature cells, metastatic from the hepatic lesion. The tumor cells stained positively for  $\alpha$ -fetoprotein. Oetama et al. (2001) described fetal hydrops due to an epithelioid hemangioendothelioma of the fetal bone marrow space. Uniform monocyte-like cells dominated the blood smear, and there was a large number of NRBCs as well. This is a difficult diagnosis to make and it would be even harder in macerated fetuses.

Sacroccygeal teratomas also produce placentomegaly and fetal edema. They are frequently accompanied by hydramnios and elevated hCG levels (Barentsen, 1975). In the first two such cases described, the placental edema and large number of NRBCs in the villous capillaries were identical to that seen in placental erythroblastosis (Kohga et al., 1980). When we wrote this paper, we suggested that high-output cardiac failure produced the hydrops. This was confirmed by the study of Langer et al.

FIGURE 16.11. Villus of case with congenital neuroblastoma. The enlarged villus has numerous neuroblastoma cells in fetal vessels, some of which show some rosetting. H&E  $\times 400$ .

FIGURE 16.12. Placenta from macerated stillborn with presumed leukemia. The villous capillaries are packed with leukemic cells, and some stromal infiltration is also seen. (Courtesy of Dr. E.V. Perrin.) H&E  $\times 60$ ;  $\times 160$ .

(1989). These authors observed such a tumor at 21 weeks' gestation with hydrops and placental edema. After they attempted to remove the tumor they observed a diminution of hydrops and a reduction in placental thickness. Other cases of sacrococcygeal teratoma, hydramnios, hydrops and placentomegaly (occasionally associated with preeclampsia) are reviewed in this publication and those of Perlin et al. (1981), Feige et al. (1982), Holzgreve et al. (1987), Kuhlmann et al. (1987), Pringle et al. (1987), Bock et al. (1990), and in an intrapericardial teratoma by Sklansky et al. (1997). These reports present additional cases that may be consulted for completeness. The usual prenatal recognition of this tumor has now also led to successful therapy. Adzick et al. (1997) found in a fetus with such a tumor that the hydrops and placentomegaly markedly increased between 20 and 25 weeks. The tumor was then resected in utero, whereupon the hydrops disappeared and the 29-week-gestation child was electively delivered by cesarean section and did well.

Fetal placental leukemia is rare. Macroscopically, it resembles erythroblastosis fetalis and causes placentomegaly. Figure 16.12 shows a 1000-g placenta in presumed fetal leukemia that came with a severely macerated fetus that was not autopsied. We have seen only one other similar case, which involved a fetus with trisomy 21.

Various angiomas have repeatedly caused hydrops fetalis and placentomegaly (see Chapter 24). For instance, Imakita et al. (1988) described a patient with severe hydramnios at 31 weeks' gestation; there were sonographic features of hydrops fetalis and a large chorangioma. After an amniocentesis, the patient delivered 2 days later but the infant died at 2 days of age. The neonate's

hemoglobin content was 15 g/dL; there was hypoproteinemia but no evidence of iso-immunization. The fetal heart was markedly hypertrophied and dilated, and the 840 g placenta had a  $5.5 \times 4.5 \times 3$  cm chorangioma. The authors conjectured that the location of the angioma may have been such as to have obstructed the venous return from the placenta. They also reviewed many previously reported cases of the association of chorangioma with hydrops. No doubt, in this case also, high-output cardiac failure of the fetus was responsible for the hydramnios and the placentomegaly. An interesting case of fetal hydrops, resulting from a complex hemangioma of the umbilical cord, was presented by Seifer et al. (1985). This occurred in one of dichorionic female twins who weighed 2100 g at birth but who lost her edema over the course of the first month of life. The birth weight of the co-twin was 1670 g. High-output failure was thought to have been caused by an angioma in the umbilical cord that measured 9 cm in diameter and 18 cm (!) in length. This enlargement was mainly due to edema, however. The placenta was otherwise normal. Hepatic angiomas of the fetus are occasionally so large as to cause fetal heart failure (Gonen et al., 1989; Skopec & Lakatua, 1989) and may be associated with significant neonatal thrombocytopenia. We have seen such a case in which the left lobe of the liver was replaced by a cavernous angioma. The remainder of liver had extensive centrilobular ischemic necrosis, and the kidneys were acutely infarcted. The neonate had cardiomegaly, a markedly hydropic placenta (1050 g), and an increase in NRBCs (Fig. 16.13). The neonate expired in 2 days. In cases of prenatally recognized nonimmune hydrops fetalis, sonographic study may

FIGURE 16.13. Edematous villi with capillaries stuffed with red cells precursors (left) in hydropic patient with cavernous hepatic angioma (right). H&E  $\times 250$ ;  $\times 60$ .

identify such tumors as a cause of hydrops. In the past, Dr. A. James McAdams had shown us a 7-month-old child with a presumed hepatic “hamartoma” in whom the hydropic placenta had weighed 1320 g. Of course, acardiac twins may present so much of a hemodynamic burden to the normal “donor” that hydrops can occur in that donor twin. It is an indication for prenatal ablation of the acardiac. Such a circumstance was recorded by Harkavy and Scanlon (1978) and is further discussed in Chapter 25.

Maternal disease, other than hydramnios, has occasionally occurred with large chorangiomas. Thus, Dorman and Cardwell (1995) observed a patient with a large placental angioma who suffered Ballantyne syndrome, a combination of severe edema, hypertension, and eclamptic fits that resolved promptly after elective delivery. Interestingly, the pregnancy was not accompanied by hydramnios. Three additional patients were described by Selm et al. (1991), who discussed the possible etiology of this complex but rare syndrome.

Cystic-adenomatoid malformation (CAM) of the lung, while not a true neoplasm, is another well-recognized cause of fetal hydrops and placental edema. Figure 16.15 shows the markedly hydropic placenta of the case published by Gottschalk and Abramson (1957). In this case, autopsy findings indicated that the mediastinum had shifted and had thus caused a chronic impediment to venous return from the placenta. The fetal heart was one-half the expected size; the placenta was edematous and weighed 1105 g, at 27 weeks’ gestation. The authors cited

additional similar cases. We saw such a case sonographically in one twin, with shift of the mediastinum, and Bromley et al. (1992) reported a similar set of twins. An infant with anasarca, whose placenta was not described, had a successful removal of such a large “tumor” (Aslam et al., 1970). Clark et al. (1987) even operated successfully on a hydropic child with cystic adenomatoid malformation after having placed an intrathoracic shunt prenatally. Ascites and subcutaneous edema disappeared, and the child delivered normally 17 weeks later. The tumor was removed on the first day of life. These authors and Kohler and Rymer (1973) cited additional cases of hydrops with adenomatoid malformations of the fetal lung. Occasional other tumors may also be associated with hydrops or cause fetal hydrops; some only produce polyhydramnios. Thus, Gray (1989) reported the latter condition with a mesoblastic nephroma. Fung et al. (1995) also found polyhydramnios associated with a fetal mesoblastic nephroma and believed the calciuria to have been responsible for the polyhydramnios. In neither case was the placenta described.

## Congenital Anomalies and Hydrops Fetalis

Aside from the adenomatoid malformation of the lung, numerous other congenital anomalies have been causally or otherwise related to the development of fetal hydrops.

Benacerraf and Frigoletto (1986) diagnosed the presence of a diaphragmatic hernia and then drained a large right hydrothorax; the fetus survived and was born without further complications. The placenta was not described. The Klippel-Trenaunay syndrome (angio-osteohypertrophy) has occurred with hydrops fetalis (Mor et al., 1988). The placenta weighed 760 g and was bulky and friable. The newborn had giant port-wine nevi and high-output cardiac failure. Seward and Zusman (1978) reported the case of a hydropic newborn that had fetal anemia, perhaps due to a small bowel volvulus. Brinson and Goldsmith (1988) reported a child with intrauterine intussusception and intestinal perforation; hypoproteinemia was therein presumed to have caused the hydrops. Pulmonary sequestration has often caused nonimmune hydrops (Weiner et al., 1986), presumably also because of an obstructed venous return to the heart. The placenta in this case was normal. Several cases of hydrops in Noonan's syndrome have been described (Bawle & Black, 1986; Oudesluys-Murphy, 1987); the associated placentas were not mentioned. Koffler et al. (1978) described two cases of chylothorax that were associated with hydramnios, in the absence of hydrops; the placenta was not mentioned. Both infants survived. A similar case comes from Sacks et al. (1983), who stated that the placenta was not enlarged. Chylothorax and lymphangiectasis are occasionally the causes of hydrops. Abnormal development of lymphatics may be responsible for generalized edema (Windebank et al., 1987). These authors identified abnormal connections of lymphatics and vessels in an hydropic infant. They were also associated with cystic hygroma, a feature that may be at the basis of the edema in 45,X fetuses (Turner syndrome). Alternatively, coarctation of the aorta may be causative (Lacro et al., 1988). But the placenta in Turner's syndrome is not truly hydropic. If anything, it is smaller in size, and occasionally has the features of a Breus' mole (subchorionic tuberosus hematoma). We have observed a set of monozygotic twins with abnormal chromosomes; one was 46,XX and normal, the other was 45,X and had massive edema, ascites, and cervical hygroma. A similar set of discordant monozygotic (MZ) twins (46,XY and 45,X) with hydrops in the latter twin was reported by Gonsoulin et al. (1990). Many reports on chromosomal trisomies suggest that these anomalies are an occasional cause of hydrops. Landrum et al. (1986) found that 17 cases of hydrops with trisomy 21, six with trisomy 18, and two with trisomy 13 had been reported. They added three cases with trisomy 21, and one with trisomy 13 of their own. Hendricks et al. (1993) also found two cases of hydrops with trisomy 21 and an associated but transitory myeloproliferative disorder, and anemia. It is of interest to note here that, in a case of chromosome 18p- syndrome, the fetal hydrops was probably due to complete heart block, resulting from calcifications in the atrioventricular node (Bridge et al., 1989). Schwanitz and col-

leagues (1988) have reported hydrops fetalis in a child with duplications of the long arms of chromosomes 15 and 17, offspring of a parent with balanced 15/17 translocation. They suggested that a chromosomal analysis should be undertaken in every case of nonimmune hydrops in which the cause has remained obscure. The cause of hydrops in these infants is unknown (see also Watson & Campbell, 1986), and the placenta is rarely discussed. Greenberg et al. (1983) described hygromas and hydrops in a fetus with trisomy 13 and cautioned that hygromas are not necessarily due to monosomy X; the macerated fetus had many other anomalies, but the placenta was not described. Gropp (1984) found similar conditions of edema in the experimentally induced mouse trisomy. He evaluated the various reported suggestions that seek to explain the fetal hydrops. The Neu-Laxova syndrome is another cause of hydrops; it is accompanied by multiple anomalies, hydramnios, and occasional placental edema (Broderick et al., 1988). It has also been reported that congenital myotonic dystrophy may lead to hydrops and pleural effusions but the status of the placenta was not described (Curry et al., 1988). Tuberous sclerosis has also been implicated in the genesis of hydrops fetalis. Östör and Fortune (1978) described such a case, but did not mention the placenta. The hydrops was presumably secondary to the cardiac rhabdomyoma present.

## Congenital Heart Disease

Numerous cases of congenital heart disease have been described as being accompanied by hydrops fetalis. Best known among these perhaps are Ebstein's anomaly of the tricuspid valve (Moller et al., 1966), endocardial fibroelastosis (Ben Ami et al., 1986), premature closure of the foramen ovale (Rodin & Nichols, 1975; Olson et al., 1987), and some forms of hypoplastic left heart (Leake et al., 1973). Many other types of anomalies have been listed, too numerous for this discussion. Some are listed by Kleinman et al. (1982), who did not have any cases of idiopathic hydrops. They reported 10 cases of cardiovascular anomalies, and three with supraventricular tachycardia. These authors emphasized the importance of fetal echocardiography. McFadden and Taylor (1989), in their review of a large series of congenital heart disease and nonimmune hydrops, expressed the view that the coincidence of the two conditions was not causally related. They were especially emphatic in pointing out that premature closure of the foramen ovale was not a cause of hydrops fetalis. Graves and Baskett (1984) reviewed 26 cases of nonimmune hydrops fetalis. They found 11 cases with anomalies and five with primary heart malformation. There were also four cases of the twin transfusion syndrome. In a set of twins whose placenta did not show

anastomoses, Mogilner et al. (1982) attributed the hydrops to prolonged maternal indomethacin therapy and ductal closure. There is even a report of a massively edematous rhesus monkey fetus with hydrops fetalis due to a complex anomaly of the heart (Cukierski et al., 1986). The placenta was circumvallate, monodiscoid, and had numerous infarcts and features of placenta previa. The fetus was no longer edematous at autopsy, long after fetal death, but its thickened, edematous features had been identified sonographically. Rare cases of hydrops with generalized arterial calcification (Williams syndrome) have occurred (Jones et al., 1972; Carles et al., 1992). Pulmonary hemorrhage (blood clot) was believed to be the cause in the last case. In one such fetus, prenatal blood sampling allowed the diagnosis of fetal hypercalcemia (Westgren et al., 1988). Its placenta was markedly edematous. In other cases, calcifications extended along the cord and placental vessels. In a case with massive calcifications of the placental villous cores that we saw, fetal fructokinase deficiency was diagnosed. It is unknown as to whether this was the cause of hydrops.

## Cardiac Arrhythmias

A variety of arrhythmias have been documented to cause anasarca and placentomegaly, as just mentioned. Some of these, when recognized by sonography or other means, have been treated successfully before birth. Fetal heart block and other rhythm disturbances have occasionally been attributed to specific antibodies, such as occur in lupus, Sjögren's syndrome, and other autoimmune diseases. Vetter and Rashkind (1938) have summarized this. Specific morphologic alterations in the atrioventricular (AV) node, localized deposits of antibodies and other globulins, have occasionally been thus identified. Veille et al. (1985) described such a child in a mother with Sjögren's syndrome, wherein antinuclear antibodies against the Ro (SSA) and La (SSB) antigens were detected during pregnancy. Despite fetal heart block, a normal child was born; the placenta was apparently normal. Taylor et al. (1986) showed that these antibodies cross the placental barrier. In fatal cases, the authors found the antibodies localized in all portions of the fetal hearts. Scheib and Waxman (1989) described recurrent congenital heart block without hydrops. Supraventricular tachycardia has often caused hydrops and placental enlargement. This is particularly important for pathologists to appreciate because, in such stillborns, no specific pathologic findings will explain the placentomegaly and hydrops. Clinical observations are necessary for the diagnosis. One of the first cases described with severe hydrops, hydramnios, and placentomegaly (1025 g) is that by Silber and Durnim (1969). The reduced cardiac output was believed to result in the fetal edema.

Lingman et al. (1986) reviewed 113 cases of fetal cardiac arrhythmia. Ninety-four cases had supraventricular arrhythmias, consisting mostly of extrasystoles. None had heart failure. Five cases had heart block; of these fetuses, three died from congestive heart failure. Fourteen cases had ventricular arrhythmias. In 2%, there were associated congenital anomalies; 13.5% had fetal distress, and there was an 0.7% mortality. Four fetuses required in utero therapy for congestive heart failure. In 72% of cases, the arrhythmias disappeared spontaneously in the perinatal period. Additional cases with successful prenatal therapy were detailed by Copel et al. (1995) and Anandakumar et al. (1996). Vintzileos et al. (1985) found that atrial flutter complicated a case of familial vitamin D-resistant rickets, in which edema and placentomegaly were observed prenatally. The fetus was resistant to therapy. The authors reviewed the previously described cases of prenatally recognized atrial flutter. Fetal hydrops was rare among them, whereas cardiomegaly and hepatomegaly were common.

Since the initial report by Klein et al. (1979) of attempted cardioversion with propranolol, numerous hydropic fetuses with atrioventricular tachycardia have been successfully treated before birth. The treatment was primarily with digitalis (Hallak et al., 1991), but also with quinidine (Guntheroth et al., 1985), verapamil, and other agents (review by Wiggins et al., 1986; DeLia & Emery, 1986). An important consideration is that with severely hydropic fetuses, placental drug transport may be insufficient for effective digitalization (Younis & Granat, 1987). Direct fetal injections have also been given (Weiner & Thompson, 1988). In some of the many reported case, disappearance of hydrops and placental enlargement have been seen sonographically. This indicates that the placental edema results from fetal heart failure. Hydrops and its subsequent resolution have also been induced experimentally in fetal sheep by atrial pacing (Stevens et al., 1982; Nimrod et al., 1987).

Placental edema and enlargement have also been reported following periods of acute fetal tachypnea (Manning et al., 1981). Such rapid respirations are probably the result of the edema rather than its cause.

## Nephrotic Syndrome

Congenital nephrosis is another well-recognized cause of fetal hydrops with placentomegaly. It is an autosomal-recessive condition characterized by anasarca, hypoproteinemia, and albuminuria. Despite the commonly used designation as "Finnish type" of nephrosis, the first case was probably described from Switzerland in 1942 (Giles et al., 1957). The familial nature, a frequent Finnish background of families, and electron-microscopic findings

FIGURE 16.14. Villi with hydropic fetus in "Finnish nephrosis." All villi are severely hydropic, but not different from hydropic placentas in other types of hydrops. The cytotrophoblast (Langhans' layer) is unusually prominent. H&E  $\times 160$ ;  $\times 400$ .

have been summarized by Hoyer et al. (1967, 1973) and Seppälä et al. (1976). The latter authors found that over one half of the more than 200 cases reported came from Finnish ancestry, where the incidence is said to be as high as 1:8000 (Hogge et al., 1992). They also reported that amniotic fluid AFP levels are elevated in this condition, whereas Hogge et al. (1992) found their index cases

through high maternal AFP levels combined with normal acetylcholinesterase levels; fetal death may occur. Although the placenta in their case was described to be grossly and microscopically normal, that of a Chinese patient reported by Hung et al. (1977) was enlarged (700 g) and edematous. Milunsky et al. (1977) also saw a normal placenta with an aborted specimen at 14 weeks' gestation. Kaplan et al. (1985), who reported several cases and did electron microscopy of the glomeruli (see also Hogge et al., 1992), found only mild placental edema. Presumably, the placentomegaly that has been observed occasionally is dependent on the degree of hypoproteinemia in the fetus. There are no characteristic features in the placental pathology (Fig. 16.14). Dr. G. Altshuler kindly provided me with an electron micrograph of the placental barrier in a case with recurrent congenital nephrosis. The patient had a therapeutic abortion at 19 weeks (see Fig. 16.17). No abnormalities were present in the fetus or placenta, grossly or microscopically. The kidneys showed the typical abnormality of the glomeruli.

## Parvovirus Anemia

Pattison et al. (1981) recognized that human parvovirus B19 infection may cause severe anemia and a hypoplastic crisis in patients with sickle cell anemia. Using modern techniques, Essary et al. (1998) reported that 16% of nonimmune hydrops cases are estimated to be due to this infection, whereas maternal infection in pregnancy is estimated to be 1 in 400. A succinct review of the diseases caused by this virus may be found in the editorial by Anderson and Török (1989) and a book edited by Anderson and Young (1997), and Rodis et al. (1998) described the management of the infection during pregnancy. Infec-

FIGURE 16.15. Edematous villi (left) in 27-week-old fetus with hydrops due to cystic adenomatoid malformation of lung (right). H&E  $\times 150$ ;  $\times 100$ .

tion with this highly contagious virus is now known to be one of the more important causes of second trimester abortion and hydrops fetalis. Prospective studies have shown that viral transmission from mother to fetus occurs in approximately 25% to 33% of women with acute infection during pregnancy and that serious fetal disease results in 9% of these cases (Public Health, 1990). The probability of infection is highest from the gravida's own child (Harger et al., 1998) and the risk of fetal hydrops is low. Infections by many different types of parvoviruses have been reviewed by Anderson and Pattison (1984). In children, infection with parvovirus B19 causes the so-called fifth disease, or erythema infectiosum (Pillay et al., 1992). The affliction is commonly referred to as "slapped cheeks (or face)" syndrome because of the facial appearance of infected children, a disease that is usually self-limited, and 40% to 60% of adults have antibodies (immunoglobulin G, IgG) from previous infection. Asymptomatic women (often schoolteachers) may transmit the virus to their fetuses, and anemia and hydrops may thus result (Brown et al., 1984). These authors cited other infectious causes of hydrops as well, including Chagas' disease and cytomegalovirus infection, which will be discussed in Chapter 20. Similarly, listeriosis has been an occasional cause of nonimmune hydrops (Gembruch et al., 1987).

Parvovirus infection does not always cause maternal symptoms, nor does maternal infection always lead to fetal hydrops (Public Health, 1990; Harger et al., 1998). In the fetus, however, the infection can cause hydrops and profound anemia (Figs. 16.16 and 16.18). It can also usually be diagnosed by the typical ground-glass inclusion bodies of NRBCs it produces. These are composed of crystals of the small, 20-nm virus particles. The inclusion bodies may also be seen in stillborn hydropic fetuses, as they are resistant to autolysis and often, but not always, they can be identified in their placentas, as was pointed out in the review by Rogers (1992) (Fig. 16.19). It has been pointed out, however, that care must be exercised when interpreting inclusions. De Krijger et al. (1998) impressively showed many artifactual "inclusions" that were similar to parvovirus crystals, but for which there was no DNA support. They emphasized that PCR studies need to be done to verify the true nature of inclusion bodies. Additionally, one often observes hemosiderin in chorionic macrophages. Among other cases, we have seen a macerated fetus with this condition, with typical placental pathology and whose intestines had ruptured before birth. Bond et al. (1986) reported on a woman with this infection at 15 weeks' gestation. She had a skin rash, and 12 weeks later she delivered an hydropic fetus. DNA hybridization studies and electron microscopy showed many parvovirus particles in the placenta. Some were coated with antibody. Knisely et al. (1988) have also shown that the virions are readily identified in erythroid

precursor cells by electron microscopy, even when only formalin-fixed tissues were available. The virus has a preferential attraction to hemopoietic (erythroid) precursor cells (Srivastara & Lu, 1988), but inclusion bodies have been observed in other tissues (e.g., hepatocytes, myocardium, endothelium; see Knisely, 1990b). But not all infections lead to hydrops, even when they may prove lethal to the fetus (Tolfvenstam et al., 2001). Moreover, in some infections it may be primarily diagnosed by increased nuchal translucency (Markenson et al., 2000).

The characteristic feature of this infection, then, is the presence of lightly staining, eosinophilic intranuclear inclusion bodies in circulating normoblasts (identification from fetal cord samples by Nerlich et al., 1991), and in their precursors in fetal organs (Anand et al., 1987). Cordocentesis has also been employed by Peters and Nicolaidis (1990) for the identification of the virus by DNA hybridization. Immunoglobulins were negative, and the hydrops from fetal parvovirus infection resolved following prenatal transfusions. Other cases of successful intrauterine transfusion have been presented. It may then be impossible to identify the virus in circulating blood, and only by DNA hybridization of marrow cells may it be recovered (Brown et al., 1994). Kovacs et al. (1992), working with fetal blood samples and amniotic fluid, developed a sensitive and rapid PCR test for the detection of the antigen. An even more sensitive method for detection (by nested PCR) was advocated by Yamakawa et al. (1995). The inclusion bodies contain the B19 antigen, whose serologic detection is now widely available (Gray, 1987). Rogers and colleagues (1996) provided a protocol with which to identify viral DNA from archival material. In general, elevated IgG titers in maternal blood denote former infection, whereas an elevated IgM titer diagnoses recent or active disease. Diagnostic criteria on histologic material from marrow are well described and beautifully depicted by Krause et al. (1992). The diagnosis is feasible even in autolyzed specimens because of the resistance of the virus particles. Generally, the fetal tissues show little or no inflammatory reaction. Elsacker-Niele and collaborators reported an exception. They found two aborted fetuses; in one fetus, tissues other than the erythroid cells were involved, and in a terminated pregnancy they discovered extensive ocular malformations and inflammation of all fetal and placental tissues. One wonders if this could have been another infection superimposed on parvovirus disease. Although this virus was believed to lack teratogenicity, Weiland et al. (1987) also found an infected fetus with myocarditis and ocular anomalies. Other case descriptions with the identification of the virus are by Briner et al. (1987), and Franciosi and Tattersall (1987), who used paraffin-embedded tissue for DNA hybridization. Carrington et al. (1987) and Bernstein and Capeless (1989) found elevated maternal serum AFP-levels in this condition. Rogers et al. (1993) and Mark et al. (1993)

FIGURE 16.16. Villi in an immature placenta from a fatal case of parvovirus B19 infection. Numerous nucleated red-blood cells with inclusion bodies are seen at the arrows. H&E  $\times 160$ ,  $200$ ,  $200$ ,  $400$ .

reviewed their 32 past cases of hydrops fetalis and found 16% to have been due to this infection. Sections of liver were most productive, whereas only two of five placentas had diagnostic inclusions. In their analysis, the inclusion

bodies were so characteristic that PCR with DNA hybridization was unnecessary. Jordan (1996) conducted a retrospective study of previously unresolved cases of hydrops fetalis and found that 18% had positive signals of parvo-

FIGURE 16.17. Electronmicrograph of villous surface in a case with fetal hydrops due to the nephrotic syndrome. Villous surface (above), microvilli, basement membranes, fetal capil-

lary, are all normal. (Courtesy of Dr. G. Altshuler, Oklahoma City, Oklahoma.)  $\times 4800$ .

virus B19. Similarly high-incidence figures for prenatal infection were discussed by Swain and Cameron (1997), who suggested that a parvovirus epidemic in 1993 may be partly responsible for these findings.

The reason for the severe anemia of fetuses was explored by Gray et al. (1987) and by Kinney et al. (1988)

in prospective studies of cord bloods during an outbreak of the infection. The investigation of the frequency of stillbirths, occurring during an outbreak, showed that the risk of stillbirth or abortion is not great. Similar prospective studies come from Hall et al. (1990) in England, and Rodis et al. (1990) in the United States.

FIGURE 16.18. Cross section of a normal placenta above; below is the cross section of a placenta of a fetus with parvovirus B19 infection and hydrops.

These studies indicated a rather low risk of fetal hydrops development. Although intrauterine transfusion therapy has been shown to be beneficial (Soothill, 1990; Sahakian et al., 1991), recovery from this infection has also been witnessed without therapy. Humphrey et al. (1991) observed one such case with recovery from hydrops after a 26-week infection, whereas Pryde et al. (1992) observed two cases that resolved spontaneously. A similar case with ascites and spontaneous resolution was described early by Morey and colleagues (1991), and two others

observed by Sheikh et al. (1992) had normal postnatal development. Maeda et al. (1988) depicted the intense hepatic iron deposits in these hydropic infants, perhaps only related to the hemolysis. Schwarz et al. (1988), who observed 42 pregnancies with parvovirus infection, found that the infection was inapparent in one third of the gravidas. In about one quarter, there were fetal complications; the authors felt that the ascites, rather than the anemia, leads to fetal death. In a later contribution (1991) these investigators found parvovirus infection to be

FIGURE 16.19. Hydrops caused by fetal human parvovirus B19 infection. The villi were edematous and the fetal capillaries filled with normoblasts. Many normoblast nuclei have smudged amphophilic, intranuclear inclusion bodies (arrows). H&E  $\times 400$ ;  $\times 640$ .

responsible for numerous spontaneous abortions. Aside from the so-called lantern cells (the inclusions resemble Chinese lanterns), the authors identified the DNA by hybridization in NRBCs. Myocardium and most other tissue were negative; hydrops was found in 14 of the 15 spontaneous abortuses occurring between 20 and 30 weeks. Further, these investigators suggested that mothers are asymptomatic in 75% of fetal infections. Other case reports and literature review were provided by Vogel et al. (1997). Of interest is the description of dichorionic twins by Pustilnik and Cohen (1994). One twin developed hydrops and died, and the other remained negative for the infection. A fetus papyraceus accompanied a normal fetus and placenta. Burton and Caul (1988) emphasized that the placenta represents "a most fruitful source of nucleated red cells containing parvovirus inclusions and is worthy of study in all cases of hydrops fetalis caused by infection with human parvovirus B19."

Macroscopically, the placenta is not different from that in other cases of hydrops fetalis. It is pale, friable, enlarged, and edematous. A complete review of the topic is available elsewhere (Anand et al., 1987). Rodis et al. (1988), in their study of pregnant women during an outbreak in Connecticut, drew attention to the potential dangers of this disease for pregnant teachers because of their contact with infected children. Further annotations are provided by Stocker and Singer (1988). Anderson et al. (1988) reported a hydrops due to this infection, and Porter et al. (1988) showed by immunohistochemistry that fetal myocardial nuclei are also infected, whereas Metzman and colleagues (1989) showed that this infection may cause severe liver disease. They reported a neonatal death with growth retardation and severe hepatic destruction in an infected infant whose mother suffered a rash during the 21st week of pregnancy. It has now also been reported that villous destruction may be the result of parvovirus infection. Samra et al. (1989), who reviewed the world literature of this fetal infection, observed that there is "a high risk to the fetus once the virus crosses the placenta." Their 20 weeks' gestation hydropic stillborn was accompanied by a placenta that showed villous necrosis and calcification.

#### *Hydrops of Unknown Etiology*

As the previous discussion has indicated, more and more causes of fetal edema and hydrops have become known. Therefore, this baffling entity is shrinking rapidly and the indications are that, with careful prenatal sonographic surveillance and with the help of more sophisticated genetic and autopsy techniques, this entity may vanish in the future. The recognition of syphilis as one such occasional cause (Barton et al., 1992) is representative of the many unusual etiologies one must consider. We believe that the term **idiopathic hydrops fetalis** should be used with restraint. It merely betrays that we have not as yet discovered its etiology and must probe further to assign a specific cause. Drogendijk (1963), who considered this topic in some detail, was of the opinion that hydrops of unknown etiology probably results from some placental malfunction.

He illustrated trophoblastic mitoses and other microscopic alterations of villi, but it is our conviction that these are all secondary to the fetal condition and that placental edema follows fetal decompensation. Mostoufi-Zadeh et al. (1985) have compiled a thoughtful review of the topic and brought together much of the literature of this "challenge to the perinatal pathologist." Other reviews and a presentation of 11 cases (Evron et al., 1985; Rodriguez et al., 2002) consider many different types of defects, including diabetes, hygroma, congenital heart disease (CHD), twin-to-twin transfusion syndrome (TTTS), arteriovenous anomalies, etc. Congenital herpes virus 6 was later added as a possible cause of fetal hydrops (Ashshi et al., 2000). Both cases also had chromosomal anomalies and it remains speculative which caused the edema. Some of the rarer entities identified to cause fetal hydrops are discussed by Gloster et al. (1984). These include the Beckwith-Wiedemann syndrome with omphalocele and unusual tumors. Hydrops and placentomegaly in Beckwith-Wiedemann syndrome were also described by Lage (1991) and Drut and Drut (1996). Lage found it in one definite and two suspected cases of Beckwith-Wiedemann syndrome; remarkably, the villi had lacunar, hydropic expansion and focal chorangiomatosis. Flow cytometry showed all of them to be diploid. Similarly, McCowan and Becroft (1994) found placentomegaly and focal hydatid changes in stem villi (once) that were sonographically visible in three cases of this syndrome they studied. In one of their cases the grape-like villous tissue was detached from the main placental mass. The authors thought of it as a specific placental feature of Beckwith-Wiedemann syndrome and also drew attention to an association with proteinuric hypertension. The Druts identified the frequent and characteristic trisomy 11p15 in placental slides with the fluorescent in situ hybridization (FISH) methodology, a useful adjunct in differential diagnosis. We have seen four placentas of definite Beckwith-Wiedemann syndrome (Fig. 16.20). In one singleton and two twins there were venous thrombi (one calcified) in surface vessels; three discordant monozygotic twins were among this group, with one normal twin and one with the syndrome. None had gross or microscopic villous vesicles. Drut and colleagues (1998) found two nodules of a yolk sac tumor in the enlarged placenta of a 4200-g neonate with Beckwith-Wiedemann syndrome.

Ginsburg and Groll (1973) and Rice et al. (1984) found fetal Gaucher's disease as a cause. Godra et al. (2003) incriminated sialidosis III as a cause, and Davis (1982) presented a long list for the differential diagnosis. It included fetal G-6-PD deficiency (in male fetuses) with hemolysis resulting from maternal ingestion of fava beans and ascorbic acid (Mentzer & Collier, 1975) or sulfonamides (Perkins, 1971), myocarditis, renal vein thrombosis, achondroplasia, and other conditions. Glycogenosis IV was the cause in three familial cases of hydrops and arthrogryposis described by Cox et al. (1999). We have seen a case of myocarditis causing hydrops in an 18 weeks' gestation pregnancy. The mother had a "bad cold" in early pregnancy. In the fetus, myocarditis and thyroiditis were present with many plasma cells. The placenta was edematous but otherwise normal. Coxsackie B<sub>5</sub> virus infection was believed to be responsible (Benirschke et al., 1986). Ravindranath et al. (1987) identified glucose-phosphate-isomerase deficiency as a cause of hydrops fetalis. Appelman et al. (1988) found I-cell disease (mucopolidiosis type II; see Chapter 18), pterygium syndrome, and  $\alpha$ -thalassemia as causes of hydrops and suggested that elevated optical density levels ( $\Delta OD_{450}$ ) may be associated with hydrops fetalis of non-immune etiology. Other essays on hydrops of nonimmune etiology have been provided by Verger et al. (1963), Giacoia (1980), and Maidman et al. (1980). The latter authors encountered five cases in 12,830 deliveries (1:2566) and suggested management principles, as did McCoy et al. (1995). A case of hydrops with unknown etiology was successfully managed by abdominal albumen injection (Shimokawa et al., 1988). Several perplexing instances of recurrent hydrops of unknown etiology have been reported by Silverstein and Kanbour (1981). We have seen such a case in which there were large thrombi in the umbilical cord vessels whose ultimate etiology remained elusive. Cumming (1979) had two recurrent cases. We autopsied three imma-

FIGURE 16.20. Villous alteration in the Beckwith-Wiedemann syndrome. Massive cistern, chorangiosis, congestion, placentomegaly (600 g at 36 weeks). There was a 69-cm-long cord with true knot, thrombosis of veins with calcification, and the neonate had adrenal cytomegaly and pancreatic nesidioblastosis. Masson trichrome  $\times 160$ .

ture infants with hydrops in whose livers (only) there was massive and unexplained iron deposition. The anemic fetuses had numerous prenatally acquired encephaloclastic lesions, although in one the hematocrit was 23%. This condition may be similar to the perinatal hemochromatosis described by Silver et al. (1989) and Hardy et al. (1990) in several sibships. Although some of their cases had neonatal edema and ascites, hydrops was not described. The placentas of four of their cases was described as being hydropic, with numerous NRBCs in vessels. The iron and copper contents were not increased in them. Schwartz et al. (1981) had two of their four cases in a sibship; they suggested that hypoproteinemia is an important aspect and that this is perhaps the reason for successful therapy with albumen. Turski et al. (1978) also found marked decrease in serum albumen in a case of unexplained hydrops with hepatosplenomegaly and a 1900-g edematous placenta. Although it may have been speculated that fetal deficiency of AFP could be a cause of fetal hydrops, this has not been found to be so in two cases with such deficiency described by Greenberg et al. (1992). Seeds et al. (1984) attempted, unsuccessfully, to prevent pulmonary hypoplasia in an hydropic fetus with single umbilical artery. They placed a shunt from the peritoneum to the amniotic sac, at 29 weeks' gestation. The measured amniotic fluid pressure ranged from 17 to 26 cm H<sub>2</sub>O. The investigators determined various constituents in the ascitic fluid as well. Other genetic metabolic diseases have been associated with hydrops, but it is not always certain that the disorder was also the true cause of the hydrops. Thus, Meizner et al. (1990) found it in Niemann-Pick disease, Uno et al. (1973) reported hydrops in Wolman's disease, Gillan et al. (1984) found it in another lysosomal storage disorder, and glucuronidase deficiency has been the apparent cause in cases described by Nelson et al. (1982) and Irani and colleagues (1983). Apparently thyrotoxicosis can be a cause of fetal hydrops as well. Thus, Watson and Fiegen (1995) detail the development of fetal thyrotoxicosis and hydrops development in a euthyroid mother who had radioactive ablation of the thyroid for Graves' disease, presumably because of the transplacental transfer of maternal IgG antibodies that ultimately lead to fetal tachycardia. Treadwell et al. (1996) described another such patient whose previous three fetuses died in utero with hydrops, secondary to her Graves' disease. In the next pregnancy, propylthiouracil therapy led to resolution of fetal tachycardia and the resulting hydrops. We were shown the placenta of a 29 weeks' gestation with Graves' disease, necessitating thyroidectomy. The fetus suffered fetal tachycardia and thyrotoxicosis; the neonate died. There was thrombosis of one umbilical artery, massive necrosis of arteries in the cord from meconium damage (see Chapter 11), and an excessive number of NRBCs. Because meconium discharge does not

otherwise occur that early in gestation, one wonders if it was the result of thyrotoxicosis.

# Transplacental Hemorrhage, Cell Transfer, Trauma

## Transplacental Blood and Cell Transfer

In the 19th century ago, considerable controversy raged as to whether the fetal and maternal circulations were united or separate. In an interesting essay, von Baer (1828) discussed this dispute in great detail and, in order to settle the issue “once and for all,” he performed experiments on dogs. These showed conclusively that the two vascular beds are separate one from another and illustrated his findings well. The history of this topic is covered in excellent detail in the historical review of de Witt (1959).

Although transfer of maternal cells to the fetus is an exceptional event, the fetus often bleeds into the maternal circulation, despite the anatomic separation of the two circulations. The reason for this fetal bleeding is often obscure. It is an important aspect of placentation, however, whose pathogenesis must be further explored. Pathologists who examine placentas must make the appropriate observations at placental examination, as will soon be explained. They must also be familiar with the methodology that enables them to make a positive diagnosis of fetal blood loss, and they may then be in the position to add new knowledge about the mechanism of transplacental fetal bleeding from the detailed study of relevant cases.

## Trauma

A very large retrospective study of trauma in pregnancy has been published by Kady et al. (2004). It enumerates the frequency of fractures to mother and fetus, suicides, fetal death, etc. in a California population from 1991 to 1999 and emphasizes the need to carefully evaluate falls in pregnancy. Fetal bleeding across the placenta occurs for many different known reasons, one of which that has been well substantiated is trauma to the placenta. In fact, **transplacental fetal bleeding** and **abruptio placentae** are

the two major complications of severe trauma during pregnancy. It has been alleged that “blunt abdominal trauma during pregnancy occurs in 0.62 per 1000 deliveries, with 26% of such cases involving assault” (Rodgers et al., 1992). These authors presented such a case in which a conviction for negligent homicide was obtained. A 60-mL (46%) fetomaternal hemorrhage had occurred after the patient had been kicked in the abdomen. A complete overview of blunt trauma during pregnancy can be found in the review by Pearlman et al. (1990a). The same group of authors also undertook a prospective study of 85 women with trauma during pregnancy (Pearlman et al., 1990b). They found significantly more fetomaternal hemorrhages than in controls, especially when the placenta was located anterior in the uterus. Abruptio occurred also frequently and could not be predicted by the severity of the trauma. Dahmus and Sibai (1993), on the other hand, found in 233 hospitalizations for blunt trauma to the pregnant abdomen preterm delivery in 1%, fetal distress in 1.7%, and 2.6% of abruptio. In their experience, Kleihauer tests were not predictive of outcome, and Dhanraj and Lambers (2004) found positive Kleihauer tests to be as frequent in a control population. They suggested that “a positive KB [Kleihauer-Betke] test alone does not necessarily indicate pathologic fetal–maternal hemorrhage in patients with trauma.” Williams et al. (1990) found that preterm labor was the principal sequela of trauma during pregnancy. They studied 84 relevant cases and observed abruptio and rupture of uterus but found no cases of delayed abruptio. Premature labor occurred in 28% of their cases, but there were no fetal injuries. Schultze et al. (1998) described fetal death from abruptio occurring despite deployment of an airbag in an automobile accident.

On the other hand, it has been substantiated that the fetus may sustain injuries, such as skull fracture, or that it may have significant brain damage, even after seemingly minor accidents (Anquist et al., 1994). The placenta itself may also actually rupture from various insults.

Buchsbaum (1968, 1979) and Crosby (1974) have competently reviewed the numerous descriptions from the literature. Buchsbaum pointed out that abruptio is only rarely caused by trauma (0.49% to 1.30%). Much more commonly it is the result of maternal vascular disease, appearing as a complication of preeclampsia. These studies must be consulted for a comprehensive overview of the topic; they are not restricted to physical trauma but include topics such as hypovolemia and sports injuries. Crosby emphatically stated that if abruptio from accidents leads to fetal demise, it usually occurs within 48 hours. Moreover, it was his opinion that a causal relation between trauma and fetal injury is often difficult to establish. Extreme care must be exercised, however, in being categorical in such judgments. Thus, a serious central nervous system (CNS) injury occurred to a 29-week fetus following a minor car accident that had even deployed an airbag (Karimi et al., 2004). Goodwin and Breen (1990) studied 205 patients with noncatastrophic trauma during pregnancy and found complications in 18 (8.8%). Premature labor was seen in 10, abruptio in five, fetal injury in one, and fetal death in two. Although fetal hemorrhage occurred significantly more commonly than in a control population, the authors opined that when no obstetric complications are evident, the quantitation of transplacental bleeding is unnecessary.

Amniocentesis is a frequently discussed topic when considering placental trauma, as transplacental hemorrhage not infrequently occurs after amniocentesis. It happens not only when amniocentesis is done for genetic diagnosis during the second trimester (Blajchman et al., 1974; Goodlin & Clewell, 1974; Young et al., 1977; Lele et al., 1982) but also near term, when it is done to determine fetal maturity or to evaluate the status of Rh disease (Zipursky et al., 1963a,b). With improved localization of the placenta by sonography, this hazard has diminished. Nevertheless, it remains an important complication that may lead to fetal exsanguination, stillbirth, and maternal immunization against fetal Rh antigens (Bowman & Pollock, 1985). Herrmann and Sidiropoulos (1986) found a 1.5% incidence of transplacental bleeding when amniocentesis was done in the second trimester (vide infra), whereas Bombard et al. (1995) reported that risk to the fetus is not greater when the placenta is transgressed during a tap. They found a 1.3% overall loss rate in 1000 procedures.

Examination of the placenta in such cases may be rewarding, as is shown in Chapter 12, Figure 12.37. In that patient, repeated amniocentesis for the assessment of fetal maturity in a diabetic patient had led to several disruptions of the fetal surface vessels; it eventually necessitated cesarean section because of fetal bleeding. Bleeding of the fetus may take place into the amniotic cavity or transplacentally into the mother. For its avoidance, the value of placental localization prior to amnio-

centesis has been well established. Pauls and Boutros (1970) localized the placenta with chromium-51-tagged red blood cells. They found that bleeding of the fetus occurred much more frequently when the placenta had not been localized (11% versus 0%). Ultrasonographic localization has achieved the same results but is more easily accomplished (Gottesfeld et al., 1966; Mennuti et al., 1983). Herrmann and Sidiropoulos (1986) evaluated their results in 209 Rh-negative women who came to amniocentesis during the second trimester. Significant hemorrhages occurred in three patients, that is, Kleihauer-positive findings of more than 2 per 100 cells in the maternal circulation. There was no correlation with anterior placentas and bloody amniotic fluid. It was the authors' opinion that the rarity of this occurrence, the ability to predict sensitization accurately with Kleihauer stains, and the use of prophylactic RhoGAM therapy have made amniocentesis a safe procedure.

A positive Kleihauer-Betke test (Kleihauer et al., 1957) quickly establishes the presence of fetal blood in the maternal circulation. Assessment of maternal serum  $\alpha$ -fetoprotein (MSAFP) levels also reflecting fetal blood transfer, as done by Mennuti et al. (1983), is perhaps preferable. Lele et al. (1982) found this test to be more sensitive than the Kleihauer technique. For example, when maternal/fetal major blood group incompatibilities exist, the fetal red blood cells may quickly lyse in the mother's circulation, which causes misleading results in Kleihauer tests. Other studies also indicated that raised MSAFP levels often result from fetomaternal hemorrhage (Los et al., 1979; Christmas et al., 1994). Placental injury following amniocentesis has also been described by Goodlin and Clewell (1974). They found two defects in a large placental surface vein from which the fetus had exsanguinated into the amniotic cavity. Figure 17.1 shows the placenta of a stillborn fetus at 30 weeks. This fetus was transfused 4 days before delivery as therapy for Rh

FIGURE 17.1. Fetal surface of a placenta from a 30-week gestation with three holes through which exsanguination occurred. The fetus had been transfused 4 days earlier. There were many hemosiderin-laden macrophages in the chorion and amnion that obscure the vascular architecture.

disease. Three large defects (holes) were found on the fetal surface. Exsanguination had thus occurred. The placenta had a posterior (!) uterine location; hemosiderin macrophages were located near the sites of injury. Retro-membranous hematomas have also been identified following amniocentesis, a complication that is discussed in Chapter 11.

Fetal bleeding into the mother often occurs during **therapeutic abortion**, even in early pregnancy (Voigt & Britt, 1969; Walsh & Lewis, 1970; Lakoff et al., 1971; Leong et al., 1979). Because there is complete disruption of the placenta, the bleeding is not surprising. Curettage for abortion of Rh-negative women is thus now routinely followed by prophylactic RhoGAM therapy. Warren et al. (1985), in a study of 161 chorionic villus sampling (CVS) procedures, found that fetomaternal hemorrhage occurred as often as in 49%. They found all Kleihauer-test evaluations to be negative and therefore judged this procedure to be too insensitive. Positive results were obtained by measuring  $\alpha$ -fetoprotein levels in maternal blood before and after the curettage. Los et al. (1993) observed the first case of fetal demise following transabdominal CVS, occurring 1 week after the procedure, while Pozniak et al. (1988) observed rapid retromembranous bleeding during CVS from "venous lakes." However, it was apparently composed of maternal blood. Litwak et al. (1970) reported that 32% of patients with spontaneous abortion had fetal bleeding. More surprising is that 11% of women with threatened abortion before 20 weeks' gestation had a positive Kleihauer test, as opposed to 4% of the controls (Stein et al., 1992). Fernandez-Rocha and Oullette (1976) depicted the placenta in a fetal hemorrhage, produced by insertion of a pressure catheter. In an effort to secure fetal monitoring, the catheter was introduced with a stiff guide. The amniotic cavity contained much blood and the fetal surface had disrupted vessels and contained a hematoma.

That the placenta bleeds into the mother during labor and delivery has long been recognized (Lloyd et al., 1980), and it is the reason for prophylactic, passive immunization with RhoGAM. In 14.5% of the patients reported by Lloyd et al., fetal cells were recognized in postpartum maternal blood; in 1% of deliveries a larger hemorrhage was diagnosed. Manual removal of the placenta was even more disruptive.

Doolittle (1963) studied placentas after delivery to identify the nature of the fetal vascular disruptions. He first cannulated the umbilical veins during labor and then measured pressures of 30 to 60 mm Hg, which increased to 90 to 115 mm Hg just prior to extrusion of the placenta. The cannulated placentas were then insufflated with air under water while the pressures exerted were recorded. In 23% of these placentas, air leaks were identified, usually near the chorionic surface. Pressures of up to 300 mm Hg did not burst the villous circulation within

intact vessels. Doolittle opined that traction on the cord was a probable mechanism of the frequent placental disruption that leads to fetal bleeding. He suggested that most such bleeding would be prevented by opening the cord clamp before extrusion of the placenta. This measure, in his experience, allowed an average of 70 mL of fetal blood to escape.

**Cesarean section** may also allow fetal bleeding to occur from the placenta. This fact was recognized as early as 1888 according to Smith and Benjamin (1968). Feldman and her collaborators (1990) found that in 18% of patients undergoing cesarean section some fetal hemorrhage occurred, with 2.5% losing more than 30 mL of blood. They discussed at some length the possible mechanism of this bleeding and could exclude that blood loss occurred during manual separation of the placenta. Alternatively, since Pilkington et al. (1966) had identified fetal bleeding **before** cesarean section, the possibility remains that the clinical reasons for the section are in part responsible for the hemorrhage. The important aspect of this study is to recognize that a single dose of RhoGAM may not suffice for immunoprophylaxis after cesarean section.

Pollack (1968) first found that external fetal version, done for breech presentation, may injure the placenta with fetal bleeding into the mother. This report described a pregnancy at 35 weeks' gestation in which the patient experienced hemoglobinuria 4 hours after version. The placenta showed "a small area of separation." This cause of fetal bleeding is an infrequent but serious event. To prevent the risk of exsanguination, external fetal rotation is now commonly followed by fetal monitoring and Kleihauer studies. Gjode et al. (1980) found that, in the first attempt of version, which they investigated in 50 women, 28% had fetal hemorrhage of between 0.1 and 1.5 mL. In Rh-negative women, therefore, prophylaxis is needed. A fatal case of transplacental bleeding after fetal version was described by Luyet et al. (1976). In a case of "spontaneous" massive fetomaternal hemorrhage with a meconium-stained but otherwise normal placenta, the fetus developed extensive infarctions of various organs (Naeye et al., 1964).

Buchsbaum and Staples (1985) reported two patients with self-inflicted **gunshot injuries** that caused fetal death, and they reviewed many other similar cases. The placenta was not described in this report but, in Buchsbaum's extensive summary of 1968, several placental injuries from gunshot wounds were cited. Awwad et al. (1994) reviewed 14 cases of penetrating wounds of the pregnant uterus. Two women died and one half of the fetuses were stillborn. Fetal fractures were witnessed; abruptio placentae and placental tears were also seen. Overstreet et al. (2002) described a gunshot wound in a 27-week pregnancy that led to surgery within 2 hours. The 1000-g fetus suffered wounds with humerus fracture that proved non-fatal; the placenta was not injured. Interestingly, there

were two old hematomas with hemosiderin deposits in the membranes from former spouse abuse.

**Automobile accidents** are now the commonest cause of traumatic transplacental hemorrhages. Skull fractures, fetal death, and vaginal bleeding were reviewed with a case reported by Theurer and Kaiser (1963), but the placenta of that case was not discussed. In a case of apparently minor trauma sustained in an automobile accident reported by Anquist et al. (1994) that resulted in severe cerebral damage, the placenta was reported only as being small and diffusely calcified. Brill (1995) took exception to this interpretation, saying it was unproven. Abruptio placentae and uterine disruption led to fetal death in a case reported by Eaton and Danzinger (1967). Exsanguination into the amnionic sac from a complete radial tear of the placenta occurred in the case of Peyser and Toaff (1969). We have documented another case of blunt trauma received in an automobile accident during the 34th week of a normal pregnancy (Benirschke & Gille, 1977). Fetal heart tones were absent 3 hours after the accident. The uterus and spleen were lacerated, and the placenta had a 50% retroplacental hematoma with early infarction 2 days after the accident. Figure 17.2 shows a relevant case. This term pregnancy eventuated in the precipitous birth of a stillborn infant with cardiac arrest and intraventricular hemorrhage. A 7-cm fresh retroplacental hematoma was found that had compressed a large portion of placenta, causing it to be acutely infarcted. The mother had worn a seat belt.

Crosby and Costiloe (1971) found that pregnant women who are involved in car accidents have a high fetal loss. Separation of the placenta was found to be the most common cause of fetal death when the mother lived. Fetal death was commonest in car accidents as a result of maternal demise. The question of the efficacy of wearing seat belts to avoid possible uterine injury was also answered in this study of Crosby and Costiloe. They concluded that, despite occasional fetal loss from abruptio,

seat belts should be worn by pregnant mothers. Crosby (1968) had earlier found that abortion occurred in 20% of patients pregnant 20 weeks or less when they were in automobile accidents. Pearlman and Phillips (1996) found that only one third of women use seat belts or wear them incorrectly during pregnancy. In unselected cases of car accidents, fetal loss was 25%, but 50% of these were due to maternal death. In an apparently trivial car accident near term, suffered by a patient described by Cumming and Wren (1978), multiple fetal surface placental hemorrhages were identified, and fetal skull fracture led to fetal death. Larroche (1986) has provided evidence of a relation between car accidents and prenatal encephaloclastic lesions. A 75% placental abruptio, with a surviving immature infant, occurred in a pregnancy in which a delayed retroplacental hemorrhage had developed. The patient had not worn a seat belt and suffered a steering wheel injury to the abdomen (Lavin & Miodovnik, 1981). Delayed abruptio was also reported by Higgins and Garite (1984). It occurred 5 days after an automobile accident, and there was old, clotted blood behind the placenta. Kettel et al. (1988) reported varying amounts of abruption in three patients who were in car accidents. Crosby (1974) had opined that abruptio following trauma usually leads to fetal demise within 48 hours or not at all. Parida et al. (1999) reported bowel injury in two fetuses following car accidents. Regrettably, as in most case reports, the placentas were not described, but many additional cases were cited by these authors.

Murray (1964) described a patient with fetal death, who delivered 6 hours after a car accident and where the mother suffered severe fibrinogenopenia, presumably from consumption coagulopathy. Because defibrination with disseminated intravascular coagulation is often a sequela of eclampsia, and hypotheses relating the two have been formed, it is relevant to emphasize that this patient had no evidence of preeclampsia. She was a gravida 14 without hypertension. Chibber et al. (1984) have docu-

FIGURE 17.2. Retroplacental hematoma after an automobile accident at term. The infant was stillborn with intraventricular hemorrhage. The placental area of abruptio is depressed and there is early infarction. See text.

mented that inapparent placental injury during a car accident may lead to transplacental bleeding with rhesus immunization. The placenta of their case was not described. In a woman who delivered a 2100-g infant, a transplacental hemorrhage of 42% estimated blood volume occurred after a car accident; despite this bleeding, Bickers and Wennberg (1983) judged the placenta to be normal, grossly and microscopically. Stafford et al. (1988) described eight cases of fetal death following automobile accidents; they found four abruptios, three placentas with severe infarction, and miscellaneous lacerations. Umbilical thrombosis was present in one fetus. Cardwell and Snyder (1989), in reply, drew attention to the perhaps more important aspect of transplacental hemorrhage in such cases. A patient with whom we are familiar had a car accident with immediate cessation of fetal movements. The patient received a blow to the right abdomen, whereupon she noted the fetus to have shifted to the left. She was admitted to the hospital 12 hours later, where fetal monitoring recorded a sudden drop of heart rate. An emergency cesarean section was performed 6 hours after the accident. The 7 months' gestation fetus was stillborn, and a small laceration of uterus and placental contusions were noted. No abruptio was found, and there was no blood in the amniotic sac. Portions of the placenta were dark (Fig. 17.3). The mother had been wearing a lap belt and cross-chest seat belt. This fetus clearly exsanguinated into the mother, as the Kleihauer stain yielded 2.05% of fetal red blood cells in the maternal circulation, representing 60 to 75 mL of fetal blood; his hematocrit was 36%.

The nature of placental injury that may lead to transplacental bleeding in car accidents is depicted in Figure 17.4. This patient had an automobile accident at 33 weeks'

gestation; she was admitted and was found to have normal fetal heart tones. She was then discharged, but precipitous labor ensued and she delivered 14 hours after the accident. The infant's depressed Apgar scores (5/5), subsequent stormy course, and intraventricular hemorrhage presumably stemmed from the acute anemia (hemoglobin 8 g/dL, hematocrit 24%). Some nucleated red blood cells in the fetal circulation indicated the fetal response to anemia. There was a large bruise of villous tissue with focal massive intravillous hemorrhage. In addition, an intervillous hematoma and small laceration of the placenta were found. If Kleihauer studies had been done shortly after the accident, they would have forewarned the treating physician of the fetal blood loss. Low and his colleagues (1996) also saw a patient with blunt trauma from a car accident and delivered the child 2 hours later. Her hematocrit was 30%, Kleihauer-Betke 12%, retroplacental hematoma. The neonate died at 28 hours with extensive CNS damage.

Fetal hemorrhage occurred in 28% of patients who experienced **other types of abdominal trauma**, such as falling. Rose et al. (1985) reviewed this subject in one of the few reports with case controls. The extent of bleeding (average volume 16 mL) was not related to the nature of the trauma or to the gestational age. Fort and Harlin (1970) produced similar figures and discussed the poor fetal prognosis of such trauma. When reading these various reports, one is impressed by the frequency with which relatively minor trauma can cause fetal transplacental hemorrhage. "Spontaneous" hemorrhage also occurs. We have always believed that such spontaneous hemorrhages may result from trauma to the placenta inflicted by the fetus, such as by kicking. This assumption

FIGURE 17.3. Placenta at 37 weeks after an automobile accident 6 hours earlier, with fetal death from exsanguination. Note the dark, hemorrhagic areas of the villous tissue that had intravillous hemorrhages. Bleeding into the decidua basalis had also occurred, although there was no abruptio. Fetal hematocrit was 36%. (Courtesy of Dr. D.J. Carlson, Exeter, New Hampshire.)

FIGURE 17.4. Massive, focal villous hemorrhage (“bruise”) in an immature placenta 14 hours after an automobile accident. The mother had been discharged, but fetal hemorrhage into the mother led to severe, disabling anemia. H&E  $\times 40$  (left);  $\times 160$  (right).

was strengthened when Eden (1987) reported two cases of maternal vaginal bleeding during pregnancy, associated with severe pain that was caused by fetal movements. Upon sonographic study, it became apparent that the fetus was “punching” the area of the placenta from which (marginal) bleeding occurred. Rare cases of umbilical cord hemorrhage and laceration, following trauma, have been summarized by Buchsbaum (1968). The management of trauma during pregnancy has been detailed by Higgins (1988).

Quintero et al. (1993) have searched for fetal trauma by embryoscopy. They found hemorrhagic lesions of the fetus, especially of the skull, in 30% of cases during CVS. Thrombi were not seen. Shulman and colleagues (1990) felt that it was the amount of villous tissue sampled, rather than the method employed, that correlated with the extent of fetal—maternal bleeding during CVS. Unfortunately, in most cases the cause of spontaneous transplacental hemorrhage remains obscure. Punching or turning by the fetus may injure the placenta, much as the placenta is occasionally injured with external version of a fetus in breech presentation. We have seen a stillbirth in a near-term pregnancy that was complicated by sudden maternal hemoglobinuria. A Kleihauer-Betke stain was done and 15mL of fetal blood were detected in the

maternal circulation. The baby died shortly thereafter. It was blood group A+, and the mother was O Rh-negative. The placenta was very pale and had several intervillous thromboses but no other lesions to account for the transplacental hemorrhage.

Other causes of transplacental hemorrhage include placental disease, such as chorangioma, choriocarcinoma in situ (placental choriocarcinoma), placenta previa, and abruptio placentae. Perhaps other conditions exist that need yet to be identified. Huff (1988) found that “fetal” (placental) bleeding occurred more often after cesarean section when the placenta had not been “drained” of fetal blood from the cord. Parenthetically it should be mentioned that occasionally fetal brain may be deported to the placental vasculature (Baergen et al., 1997). In this, and rare other cases described, head trauma was presumably incurred during forceps delivery and embolic brain tissue was also found in the fetal lung. More often such deportation has been seen in fetal lung sections, but Silver and Newman (1998) reported cerebellar embolism to placental vessels with a surviving normal infant. There had been a skull fracture. Other causes are discussed with four cases, especially relative to alloimmunization by Zizka et al. (2001), but the publication is difficult to access.

## Placenta in Hemorrhage

One should suspect transplacental bleeding when the villous tissue of the placenta is unusually pale. This observation presupposes that the examiner is familiar with the “normal” color of the placental tissue at the different stages of gestation. Immature placentas are paler than are those at term. The presence of intervillous thrombi may be another clue signaling that bleeding through the placenta has occurred; the thrombi may even signify the point of origin of hemorrhage and should be noted for that reason. The temporal aspects of the development of fetal anemia from transplacental hemorrhage are usually not known. One might think that a given hematocrit and hemoglobin value of the newborn should give detailed information as to the precise time when the hemorrhage took place. This is, unfortunately, not true, as specific studies to ascertain the decrease of hematocrit have not been made. It would be desirable to collect information in cases where the timing is well known (from trauma) and the amount estimated (from Kleihauer stains), in order to estimate just how long it takes to reduce the hematocrit to a given level. This would aid in assessing doubtful cases, some of which end in litigation. When placental or neonatal anemia are apparent, the maternal blood must be studied promptly for the possible presence of fetal red blood cells, and perhaps also for  $\alpha$ -fetoprotein levels.

Another concern is how rapid the response of red cell replacement is when blood is lost. It is known that **nucleated red blood cells** (NRBCs) appear in the circulation of anemic fetuses, best exemplified by erythroblastosis fetalis. The same happens when acute blood loss occurs and when fetuses are hypoxic. This feature plays an important role in current medicolegal decisions. What we need to know is how rapid the response of the appearance of NRBCs is to the loss of red cells and hypoxia, and whether this response is quantitatively reflected in the number of the NRBCs in the circulation. Considerable confusion exists as to the number of NRBCs in the neonatal circulation. It is our opinion that in the histologic evaluation of placentas NRBCs should not be observed in the term placenta. When NRBCs are present in the fetal blood, and it is obviously important that they be diagnosed correctly, it is a distinctly abnormal finding. The pathologist should then try to find the reason for their presence. Geissler and Japha (1901) stated emphatically that, “contrary to the dogma,” NRBCs are not found in young children. Ryerson and Sanes (1934) undertook incisive studies of NRBCs in placentas. They attempted to ascertain the parameters that allowed one to decide the age of gestation histologically. All NRBCs had disappeared at the end of the third month of pregnancy, and if more than 1% NRBC are found, this indicated to them immaturity. Fox (1967) also published on this phenome-

non and related NRBCs to hypoxia or asphyxia. We concur with the interpretation of a relationship to fetal tissue hypoxia; indeed, it is our practice to take note of the presence of NRBCs when examining placentas. Green and Mimouni provided criteria and suggested that “a value  $> 1 \times 10^9/L$  should be considered as a potential index of intrauterine hypoxia.” Normally, there were no NRBCs in term neonates, and the 95th percentile had 1.7 in absolute counts. Diabetic mothers’ babies had increased numbers, as did infants with hypoxia and growth-retarded neonates. Shurin (1987) concluded that there are about 200 to 600 NRBCs/mm<sup>3</sup> and 10,000 to 30,000 WBCs; she also stated that the normal infant has 4% to 5% of NRBCs in cord blood samples, which is higher than is our experience. Shurin reflected that this number indicates the erythroid hyperplasia due to high levels of erythropoietin (EPO) production. In general, it is our belief that because of the complex sequence of signals to initiate erythropoiesis and release of NRBCs, many hours have to pass from a hypoxic (anemic) stimulus to the appearance of NRBCs in the circulation. Thus, the identification of NRBCs suggests a significant fetal problem many hours prior to birth. Quantitative and temporal sequences must be obtained in future studies, and two relevant cases that provide some guide are discussed in Chapter 26. Shields et al. (1993), in the laboratory of R.A. Brace, have reviewed what is known of this aspect of red cells restoration after hemorrhage in sheep. Despite an initial rise in EPO level, a significant hemorrhage (40%) is not followed by a significant increase in reticulocyte count, nor are the former blood volume and hematocrit restored before birth. In a later study, Shields et al. (1996) further showed the recovery from hemorrhage with an expanding red cells mass, elevation of reticulocytes and EPO, correlated with iron availability, but nucleated red cells were not addressed. Similar temporal findings as recorded here urgently need to be collected for human fetuses, as the ovine model may not be entirely adequate to understand the physiology of this important topic (see Chapter 8 for further information on nucleated red blood cells).

Jauniaux et al. (1990) have made an important clinico-pathologic correlation in a case of significant fetal-maternal hemorrhage. They observed sonographically a 3 × 3 cm heterogeneous, hypoechoic placental lesion when, at 18 weeks’ gestation, a pregnant patient was found to have elevated MSAFP levels. The Kleihauer test was positive. At 22 weeks there was only peripheral turbulent flow around the lesion, which, at about 30 weeks’ gestation, was found to represent a laminated white lesion of fibrin. It was the presumed area of intervillous thrombosis whence the fetal hemorrhage occurred.

It should also be mentioned that intervillous thromboses are not necessarily due to fetal-maternal hemorrhages. When the bloods are compatible, agglutination

may not take place. Conversely, intervillous hematomas may occur for entirely different reasons also. They can result when the intervillous perfusion is significantly altered, as for instance because of the presence of placental edema (erythroblastosis, Chapter 15; hydatidiform moles, Chapter 22), and also for local, structural reasons. This type of intervillous thrombosis is considered in greater detail in Chapter 9.

#### TECHNIQUE FOR IDENTIFICATION OF FETAL RED BLOOD CELLS

Fetal red blood cells in the maternal blood are best identified with a technique named after the inventors, Kleihauer and Betke (Kleihauer et al., 1957). Since that seminal contribution, the original method has undergone many refinements. Moreover, there are several commercial kits available for the detection of fetal cells in the maternal circulation (e.g., Boehringer Mannheim; Simmler, St. Louis, MO; Fetaldex of Ortho Diagnostics, Raritan, NJ; Sure-tech Diagnostics Associates, Inc. St. Louis [ST 101-C], and others). Some of these were mentioned by Virgilio and Simon (1977), who evaluated several different methods. Simon et al. (1978) used two techniques to evaluate the risk of fetal bleeding in 200 Rh-negative women. Six women experienced significant fetal hemorrhages that necessitated RhoGAM administration. The Fetaldex and Kleihauer techniques compared favorably in the assessment. For the purposes of rapidly identifying mothers in need of RhoGAM immunoprophylaxis, Nance and her colleagues (1989) have presented a flow cytometry methodology that is effective in identifying quickly and accurately the contamination with D+ cells in maternal blood. The use of flow cytometry has now frequently been preferred to the more cumbersome enumeration of red cells in blood smears. It compares favorably with the older method as a detailed contribution by Pelikan et al. (2004) has shown.

The Kleihauer-Betke technique depends on the fact that fetal hemoglobin, in an acid milieu of a pH 3, is less soluble than maternal (adult) hemoglobin. For its execution, air-dried maternal blood films are first fixed in 80% alcohol for 5 minutes and then eluted in one of several possible buffers for 7 to 10 minutes. Usually, the buffer is freshly made from 0.2M  $\text{Na}_2\text{PO}_4$  and 0.1M citric acid. The slides are rinsed twice with water, stained for 10 minutes in hematoxylin solution, rinsed, and covered with a 1% eosin solution (or a similar dye) for 10 minutes. They are then rinsed in water and air dried. Palliez et al. (1970) suc-

cessfully used 1% safranin and a 1:20 dilution of Ziehl fuchsin. Fetal red blood cells maintain their color but, because the maternal hemoglobin is largely eluted, the maternal cells appear as mere shadows (Fig. 17.5). From counts at 250 $\times$  magnification of 10 fields of these respective cell populations, the quantity of fetal blood loss can be estimated as follows: If the total number of fetal red cells counted is 25 among 4000 maternal red blood cells, the ratio would be 0.006. Total maternal blood volume (RBC + plasma) at term is approximately 5000 mL. One can thus calculate:

$$\frac{\text{Fetal red blood cells [25]}}{\text{Maternal red blood cells [4000]}} = \frac{X \text{ (mL fetal blood in maternal circulation) [in this case 30m]}}{\text{Maternal blood volume [about 5000 mL at term]}}$$

Mollison (1972) also suggested a formula that simplified for him the estimation of fetal blood loss. In this careful survey of stains, executed under standard conditions by various laboratories, Mollison emphasized that any enumeration of the fetal (stained) cells alone underestimates the fetal blood loss, since only 90% of fetal cells stain positively; the remainder already possesses hemoglobin A. He recommended a standardized approach to the estimation of fetal blood loss, as otherwise large errors would invalidate the results. The method of enumeration used by Kleihauer, for instance, would underestimate the amount of fetal blood lost. Mollison suggested that five fields be counted under low power and compared with an appropriate reference slide. If more than 10 darkly stained cells are found in a field, then a quantitative analysis was recommended. Grobbelaar (1968) also quantitated the red cell contamination of maternal blood and recommended that 50mm<sup>2</sup> of blood film be scanned, and that reports give the precise methodology of enumeration; it is recommended lest the results not be interpretable. In a thoughtful review of the results of 523 Kleihauer-Betke procedures done in their institution, Emery et al. (1995) evaluated its usefulness. They suggested that a prevailing opinion exists that this test may have little value for clinical management but concluded that the test should be performed when a positive screening test exists in Rh-negative women with Rh-positive fetuses and in trauma cases. Unexplained increased maternal  $\alpha$ -fetoprotein levels, fetal distress with abnormal heart tracings, fetal demise, and unexplained fetal anemia constituted other recommended applications of the technique, whereas abruptio placentae was not a condition for which the Kleihauer reaction

FIGURE 17.5. Kleihauer stain of maternal blood. The darkly stained cells are fetal erythrocytes. The percentage of fetal cells in this blood film is approximately 5%. Eosin stain; Kleihauer preparation  $\times 1000$ .

was found to be of benefit. In another study, Veyver et al. (1993) also ascertained that Kleihauer tests were useful for ascertainment of fetal hemorrhage in trauma cases but that the clinical therapeutic decision had usually been made by the time the test result was known. In England, Kleihauer tests were done after delivery of every RhD-negative woman gives birth to an RhD-positive infant. To evaluate the efficacy of various techniques, Bromilow and Duguid (1997) compared three types of Kleihauer tests and two flow cytometry techniques. Although considerable differences were found, a simple stain was judged to be helpful; flow cytometry, however, was most efficient for quantitative assessment of the hemorrhage.

Zipursky et al. (1959) found that 21% of postpartum patients had fetal cells in the circulation, but other authors have found that a much greater percentage of postpartum women has fetal red cell contamination (McLarey & Fish, 1966; Sullivan & Jennings, 1966). Fraser and Raper (1962) made the important observation that ABO-incompatible cells disappear much more rapidly than do compatible cells. Their finding was affirmed later by the results of a study by Palliez et al. (1970). Indeed, Ziliacus (1963) found occasional agglutinated and partially disintegrated packets of fetal cells in maternal blood in women who had experienced transplacental hemorrhage from the fetus. An important study of fetal blood transfer to the mother comes from Owen et al. (1989). These investigators undertook a prospective analysis of Kleihauer stains before and after normal delivery in 66 patients. They found that "three patients (4.6%) had a massive fetomaternal hemorrhage. None of the postdelivery stains showed evidence of a significant fetomaternal hemorrhage unless results of the antepartum stain had also been positive. We conclude that the delivery process itself does not stimulate a massive fetomaternal hemorrhage in cases of fetal death." Massive fetal hemorrhage occurring in three women presented as decreased fetal movements, nonreactive fetal heart rates, and positive Kleihauer tests (Kosasa et al., 1993). This led the authors to recommend immediate delivery for such pregnancies. The cause of the hemorrhage remained unknown.

Some authors have doubted that the Kleihauer test truly evaluates fetal cells in the maternal circulation. This aspect was studied, and the techniques verified, by the large investigation undertaken by Freese and Titel (1963). They made some modification of the Kleihauer technique and reviewed improvements of methods from other authors that they collected from the literature. As with other investigators, these authors found a high incidence of fetal blood contamination in postpartum maternal circulating blood, and they established a quantitative relationship of this contamination to the ABO status of mother and infant. When the mother was blood group O and the fetus A, B, or AB, then the fetal cells disappeared more rapidly from the maternal blood. Other authors have demonstrated frequent but small "leaks" of fetal blood; they have also made modifications of the technique (Lewi et al., 1961; Browne & Cowles, 1963; Keenan & Pearse, 1963; Fielding, 1968). Virgilio and Simon (1977) provided a quantitative assessment of the number of red cells and compared commercial kits with the original method. Two reports specifically evaluated the methods that enumerate very small numbers of contaminating fetal red cells. Thus, Schneider and Ludwig (1963) showed that they were able to quantitate fetal blood volumes of between 50 mm<sup>3</sup> and 50 mL in the maternal circulation with the Kleihauer technique. Jones (1969) described a simple "machine" that obtains comparably thin blood films for the better quantitation of fetal blood loss. Stonehill and LaFerla (1986) emphasized that in 25% of pregnancies, from 10 to 28 weeks' gestation, the maternal blood contains increasing amounts of fetal hemoglobin, a finding originally emphasized as a possible cause of erroneous Kleihauer tests by Pembrey et al. (1973). During that gestational period, maternal cells with fetal hemoglobin should not be confused with fetal cells. Woodrow and Finn (1966) also studied the staining reaction of red cells in pregnant and nonpregnant women. They concluded that, because of occasional staining of cells in nonpregnant women, only findings of more than two cells per 50 low-power fields are of significance. They found

no increased transplacental bleeding in the third trimester, and suggested that most cases of Rh-immunization take place during labor. Finally, Leiberman et al. (1989) also noted that 25% of pregnant women produce hemoglobin F. Other interfering factors are the prevalence of  $\alpha$ -thalassemia minor, which occurs in 1.4% of African Americans, and the fact that 1.7% of white Americans may have increased numbers of hemoglobin F containing red blood cells. These findings make it mandatory that elevated Kleihauer results be carefully evaluated. They have also suggested the use of the more sensitive measurement of  $\alpha$ -fetoprotein for an evaluation of cases with presumed transplacental bleeding. The possible confusion here, in cases of fetal anomalies that may be another cause of elevated  $\alpha$ -fetoprotein levels, is obvious.

That errors in assessment of transplacental bleeding occur was shown in a case described by LaFerla et al. (1981) and these errors are the reason why the authors recommended that the Kleihauer test be supported with findings from other tests. These other techniques, however, have fully validated the concept of transplacental bleeding. This is true for the test developed by Ness (1982), an enzyme-linked antiglobulin reaction, which can also be useful for evaluation of the potential recipients of Rh-immune globulin. Tomoda (1964) demonstrated that fluorescent antibodies against fetal hemoglobin can be employed to enumerate the fetal cells in the maternal circulation. Streiff et al. (1964) used a variety of techniques to demonstrate fetal cells in the maternal system; Ziliacus et al. (1975) found that fluorescent-Y chromosome stains often showed fetal (male) lymphocytes in pregnant mothers' blood; and Lee and Vazquez (1962) showed that fluorescent antibodies against the A and B blood groups stained appropriately marked fetal cells in maternal blood with blood group O. Thus, the warning issued by Stonehill and LaFerla (1986) may have been too cautious. It is imperative that the quantity of fetal cells be assessed accurately for the judgment of quantities of antiglobulin administration in rhesus-negative mothers (Eich & Tripoldi, 1974).

The transfer of fetal cells into the maternal circulation has taken on greater importance with the recognition that the fetal karyotype may be ascertained from the study of DNA of fetal NRBCs lifted from the maternal circulation. A symposium publication reviewed the principal mechanisms and results (Simpson & Elias, 1994). Aside from NRBCs, maternal blood has long been known to contain syncytial cells, swept from the placenta to the maternal lung. The process is described in detail in Chapter 19. Studies suggest that some of these cells may escape pulmonary entrapment and serve as possible precursors for DNA amplification (Hawes et al., 1994). Gänshirt-Ahlert et al. (1992b) showed that umbilical vein blood contained the same ratio of fetal/maternal DNA as did peripheral maternal blood, paving the way for further fetal DNA study. Elegant techniques have since been devised for the enrichment and study of this fetal DNA from maternal blood, relying principally on NRBCs, as they will not be perpetuated into future pregnancies, as lymphocytes might be (Adkinson et al., 1994; Bianchi et al., 1994, and many others). The survival of fetal cells into adult life is now being considered as possible basis of systemic sclerosis (scleroderma) (see Chapter 19). The rate of disappearance of fetal NRBCs from the maternal circulation was documented by Hamada et al. (1995). Three months after delivery, NRBCs would have disappeared, even after fetomaternal hemorrhage.

The life span of fetal cells in the maternal circulation has been studied by Kleihauer and Brandt (1964). It is often stated that fetal red blood cells have a decreased longevity, but these authors determined that fetal cells can be maintained for a long time in the maternal circulation. Although the life span of fetal cells in the maternal circulation is somewhat shorter than that of normal cells, the cause of neonatal anemia from transplacental bleeding may be ascertained for as long as 4 to 6 weeks after delivery, by Kleihauer tests alone, so long as no ABO incompatibility exists. Fetal red blood cells can also be identified in amniotic fluid and vaginal blood with the aforementioned techniques (e.g., in cases of presumed placenta previa).

Occasional failure to identify fetal red blood cells by the Kleihauer technique, in cases that strongly suggest their presence, has led to the development of alternate methods. Thus, failing to identify fetal cells in blood-stained amniotic fluid in a patient with elevated  $\alpha$ -fetoprotein levels, led Ahmed and Brown (1986) to perform hemoglobin electrophoresis; they thereby identified predominantly fetal hemoglobin. Chamberlain et al. (1982) compared the results from Kleihauer stains with  $\alpha$ -fetoprotein levels. They found that the latter method gave more accurate results. In this connection, the **Apt test** is occasionally mentioned, without there generally being a clear understanding of the usefulness of this test. The Apt-Downey test was primarily designed to differentiate between fetal and maternal blood in the stomachs of newborns; it has also been used for the examination of vaginal blood. Apt and Downey (1955) first described the method to allow a rapid determination of the origin of blood in stool of neonates (melena). The method is generally less satisfactory than the others mentioned for distinguishing fetal red blood cells from maternal cells. The procedure depends on alkali-denaturation of hemoglobin. Crissinger et al. (1987) described it as follows: "Specimen is mixed with tap water (1 part of hemorrhagic fluid to 5 parts water), centrifuged, and 1 mL of 0.25M sodium hydroxide is added to 5 mL of the supernatant. Brown-yellow color indicates adult hemoglobin, and pink indicates fetal hemoglobin."

Another method for the identification of fetal red blood cells was employed by Kaplan et al. (1982). These investigators were interested in ascertaining whether placental intervillous thrombi (IVT) are composed of fetal or maternal erythrocytes. Potter (1948) had earlier assumed them to be made up of mainly maternal cells. She based her deduction on macroagglutination findings with differing ABO blood groups of mother and fetus. Cells that were presumably NRBCs were interpreted as lymphocytes. Javert and Reiss (1952) had shown that the so-called red infarcts of earlier nomenclature were intervillous coagulation events. Because they found in 48.7% of these thrombi NRBCs, they discouraged the use of the term *intervillous thrombus*. Kaplan et al. (1982) used Sternberger's technique of peroxidase labeling to study histologic sections with intervillous coagulation. They found that over 85% of intervillous thrombi contained irregularly distributed fetal erythrocytes (Fig. 17.6). Often, they were present in large numbers, and the authors deduced from these findings that intervillous thrombi may be one entry point for fetal cells into the maternal circulation. Devi et al. (1968) had previously established that a good correlation exists between the presence of fetal red blood cells in the maternal circulation and the number of intervillous thrombi.

## Significant Transplacental Hemorrhage

The diagnosis of anemia in the newborn, due to occult hemorrhage, was first seriously considered by Wiener (1948). He had observed three newborns with low hemoglobin values, two of them being 6.5 and 8.7 g. One patient had been delivered by cesarean section for a placenta previa, one was born normally, and the third patient was an unusual case of erythroblastosis, a disease that was under intensive study at that time, and whose cause was then being defined. There was much interest in this new phenomenon of a putative transplacental passage of fetal blood to the mother. Wiener stated, "The main objection to this concept is the difficulty of demonstrating such postulated placental defects in pathologic specimens." He referred to the known hemorrhages from vasa previa, but found no good explanation for his observations of neonatal anemia. This "interesting and recent hypothesis" was discussed by Wickster (1952). He reviewed some cases of abruptio and placenta previa. He also presented the case of an unexplained fetal blood loss, enough to cause shock in the neonate, but recent enough not to have caused isoimmunization of the mother. Only after Chown's papers were published in 1954 and 1955 did wider interest develop in the topic of prenatal bleeding. Chown (1954) reported two cases of neonatal anemia. I (K.B.) examined the placentas and found intervillous thrombi, and noted also many NRBCs in the fetal circulation. A transfusion reaction had occurred in one mother; the other suffered "pain at 8 months gestation."

It is now widely recognized that significant fetomaternal hemorrhages may cause fetal anemia, even exsanguination, hydrops fetalis, maternal isoimmunization, and fetal cardiac rhythm irregularities, and that fetal death may result from it (Saber, 1977; Shahar et al., 1981; Laube

FIGURE 17.6. Section of intervillous thrombus, stained with anti-fetal hemoglobin peroxidase methodology. The dark cells are fetal hemoglobin-containing erythrocytes, particularly evident in the fetal capillaries (right). Numerous fetal red cells are present in the fresh intervillous thrombus (left). & Schauburger, 1982; Fay, 1983; Almeida & Bowman, 1994). Indeed, there is a report of a patient who had at least three consecutive pregnancies complicated by this event, without explanation for the recurrence of their significant transplacental hemorrhage (Catalano & Capeless, 1990). It is also not an uncommon cause of fetal demise. Biankin et al. (2003) estimated that such significant fetomaternal hemorrhage occurs once in 2800 pregnancies. Samadi et al. (1996) surveyed their 319 cases of fetal demise (above 500g weight) in which Kleihauer-Betke tests had been done. They found massive hemorrhage (more than 1% Kleihauer positive cells) in 4.7% of these stillborns. The neonate often displays significant morbidity; severe anemia and shock are common in the neonatal period (Moya et al., 1987; Li & Bromham, 1988; vide infra). It has also been reported that cerebral palsy has resulted from prenatal hemorrhage (Fay, 1983; Kirkendall et al., 2001) presumably due to acute hypotension, and neonatal death is frequent (Griffin, 1969; others). The documentation of fetal microcephaly following such an event is especially important. Del Valle and colleagues (1992) documented a fascinating event of this nature. The patient sustained a motor vehicle accident at 27 weeks with fetal distress ensuing. Kleihauer tests were negative but amniocentesis yielded bloody fluid, and cordocentesis disclosed a hematocrit of 17%. The fetus was transfused and a mature fetus delivered at 37 weeks. Its Apgar scores were 8/9 and the hematocrit 50%. There was a 25% infarction of the placenta that the authors believed to have been caused by a rupture of a fetal vessel at the time of the accident. It may well also have been the cause of hemorrhage and the CNS insult. Direct trauma to the fetus from stabbing at 29 weeks' gestation with CNS injury and bleeding was described by Avenarius et al. (1999). The frequency and magnitude of transplacental hemorrhage were well evaluated in a large study by Almeida and Bowman (1994). They stated in their comprehensive study that "there appear to be two important factors in clinical outcome: the amount of and rate of bleeding." Montgomery et al. (1995) identified 6% Kleihauer positive cells in the maternal circulation and a hydropic fetus with hematocrit of 16.4%. They transfused the fetus five times intraperitoneally and intravascularly over 24 days, and also supplied platelets. They delivered a healthy premature infant who needed no blood replacement. The cause of transplacental hemorrhage was not established and, except for hydropic changes, the placenta appeared normal. Interestingly, after the last transfusion, fever developed and gram-positive rods were observed at amniocentesis, leading to cesarean section delivery. Rijhsingani and Smith (1997) described a patient at 31 weeks' gestation following a severe rear-end collision. The fetus developed transient hydrops 2 days after the accident and the maternal blood contained 1.6% Kleihauer-positive cells (96mL fetal blood). Also, clots

were found in the amniotic cavity. And abruptio was suspected, the fetus was delivered (hematocrit 27%) and did well. The placenta was not described. Pourbabak et al. (2004) emphasized that major transplacental hemorrhage may occur with the absence of clinical suspicion. While they described the identification of fetal red cells (Kleihauer, flow cytometry) of their three cases in some detail, they did not mention placental findings.

To make the precise diagnosis of fetal hemorrhage prenatally may be difficult in the clinical arena. Cardwell (1987) has reviewed this aspect and also provided management suggestions (see Leiberman et al., 1989). Similarly, Mor-Yosef and his colleagues (1984) considered the sinusoidal rhythm of fetal heart tracings as being the result of massive transplacental hemorrhage near term. The anemic neonate had a marked reticulocytosis and elevated globin synthesis; the cause may have been an exceedingly tightly entangled cord. Ellis and Kohler (1976) found marked thymic atrophy in these neonates at autopsy. The thymic atrophy certainly is not specific for hemorrhage, but is found in a wide variety of infants who have experienced prenatal "stress." It should be considered a result of adrenocorticotrophic hormone (ACTH)-cortisol stimulation, as is also the maturation found in the fetal adrenal cortex. Following an initial review of the topic by Fynaut (1960), Renaer et al. (1976) gathered many of the reported cases of significant prenatal hemorrhage into a large review article. There were 11 cases of massive transplacental transfusion. The reviewers concluded that the incidence of transfer of blood increases with gestational age, and that it is as common as in 1 of 300 pregnancies. The phenomenon accounts for the fetal death in approximately 1:2,000 deliveries. Renaer et al. (1976) also observed one maternal transfusion reaction, and described a wide range of hematocrits and hemoglobin values of the newborns. Etiologic factors included cesarean section, external fetal version, amniocentesis, placement of a Drew-Smythe catheter, trauma, and tumultuous labor (see also Zipursky et al., 1963a,b; Finn et al., 1963). A catalogue of other associated or causative conditions, including the large number of European references, may be found in Rosta's review (1978).

Separate from the aforementioned literature, many other cases have been described in individual case reports. Gunson (1957) provided six such observations. Borum et al. (1957) reported two cases, one of which had a normal placenta, and in the other a cord that was wrapped twice around the neck. Perhaps the venous congestion from this obstruction caused the transplacental bleeding. Mannherz (1960) observed a neonatal RBC count of 2.05 million and 7.3% Kleihauer-positive cells in the maternal circulation. He estimated that, over time, the fetus must have lost 250mL of blood. The placental surface was brownish and the villous tissue pale. Grimes and Wright (1961) reported an anemic, distressed newborn

from an uncomplicated pregnancy. They drew attention to a case in which the mother suffered hemolysis, fibrinogenopenia, and acute renal tubular necrosis. In that case, there was an ABO incompatibility between mother and fetus. Donaldson (1962) found a recently stillborn, post-mature baby who had died from transplacental hemorrhage and whose placenta had a large retroplacental hematoma. In this case, the retroplacental bleeding occurred in the absence of toxemia. Rudolph et al. (1962) had a fetal death in whose placenta an intervillous thrombus was locally accompanied by hemosiderin deposits. Paros (1962) described an anemic term infant in whom he estimated that 400 mL of fetal blood had been lost into the maternal circulation over a period of time. Willis and Foreman (1988) observed massive, chronic fetal bleeding with fetal cardiac irregularities and later, persistent late decelerations. The Kleihauer-Betke stains showed 14.5% fetal cells in the maternal circulation, an estimated 700 mL of fetal blood; the fetus had a hematocrit of 17%, hemoglobin of 5.1 g/dL, and was meconium-stained, but had a normal neonatal course. It must have bled over a prolonged time period. These authors reviewed several other cases not listed here, and found an essentially normal placenta in their case. No untoward events had been noted during the 38-week pregnancy. Rouse and Weiner (1990) saw the development of fetal hydrops and attempted treatment with serial transfusions. The placenta they found was large, but it had no characteristic lesions to explain the fetal hemorrhage. Other cases of significant fetal—maternal hemorrhage treated with repeated transfusion were reported by Fischer et al. (1990) and Lipitz et al. (1997). In the first case, a sinusoidal pattern of heart tracings was observed; the fetus's movements improved immediately after transfusions. The placenta had a subchorionic hematoma 2 cm from the cord insertion, perhaps from needle insertion. Thrombi were found in stem vessels of the placenta. The second case took place following blunt trauma from falling; bleeding had not occurred. The Kleihauer test yielded 3% to 5% of fetal cells in the maternal circulation (at 27 weeks!) and treatment with 30 mL packed red blood cells was performed. The fetus did well. Van Kamp et al. (2005) reviewed intrauterine transfusion results of 254 fetuses and found it to be a safe procedure. They had 89% survival.

Cohen et al. (1964) stated that the placenta rarely accomplishes a perfect separation of maternal from fetal blood streams, and estimated that 1% of pregnancies are complicated by significant fetal bleeding. Despite these repetitious reports in the literature, Keller et al. (1980) still considered this entity to be a frequently overlooked cause of perinatal morbidity and mortality. They reported on five cases with two deaths, and one of the infants had cerebral infarcts at birth. Schellong (1969), who discussed the causes and therapy of neonatal anemia, felt that

transfusion of the neonate is indicated only when the observed neonatal hemoglobin value falls below 8% to 10% of normal. Shiller (1957) observed shock in an anemic neonate whose placenta had a retroplacental blood clot. He drew attention to the presence of many NRBCs in the fetal circulation, in a maternal vein, and in the intervillous space. Because of the known risk factors for transplacental bleeding (cesarean section, trauma, etc.), Ness et al. (1987) prospectively studied a cohort of D-negative women for fetal hemorrhage and isoimmunization. The investigators were unable to predict reliably the occurrence of such hemorrhage, nor were they able to use historical events from the patient to form a basis for the administration of prophylactic antibodies (RhoGAM). Fliegner et al. (1987) also felt that occult fetomaternal hemorrhage was an important cause of fetal mortality and morbidity that should be investigated in otherwise unexplained stillbirths.

## Fetal Consequences of Massive Hemorrhage Across the Placenta

Severe fetal anemia is a prominent sequela of transplacental hemorrhage. A cross section of the placenta from such a case is shown in Figure 17.7. The villous tissue is unusually thick and pale, and one large, fresh intervillous hematoma is seen within the middle section depicted. The villous capillary bed of this placenta was markedly distended and had the appearance of chorangiosis. This was the first pregnancy of a patient whose 2040-g infant had Apgar scores of 8/8, a neonatal hemoglobin level of 4.5 g, and a hematocrit of 14%. An excessive number of NRBCs was present in the fetal blood. The maternal and fetal blood groups were compatible. The child was edematous and had cardiomegaly but improved markedly after prompt transfusions were given. By Kleihauer stains, there were 3% to 5% of fetal cells in the maternal circulation. No history of trauma or other untoward event had occurred during the pregnancy that could have been held responsible for the massive fetal bleeding. Many cases like this have been reported in the literature (e.g., Debelle et al., 1977; Pourbabak et al., 2004), and every perinatal pathologist has seen cases of this entity (review by Freese, 1965; McGowan, 1968; Smith & Benjamin, 1968; Pai et al., 1975). For example, Carper and O'Donnell (1967) described a neonate with shock attributable to protracted fetal anemia; there were 4.5% positive cells in Kleihauer stains of maternal blood. The mother and fetus were blood group compatible, and the infant survived after transfusion. The placenta was not overtly unusual, but the mother had sustained two falls in pregnancy that may have been the cause of trauma to the placenta. Naeye et al. (1964) observed a neonate with prenatal exsanguination, manifested by a hematocrit of 15%, hemoglobin of

FIGURE 17.7. One slice of formalin-fixed placenta of neonate with edema and severe anemia (hemoglobin 4.5 g; hematocrit 14%) from transplacental hemorrhage. Note the thickness of the placenta, the severe pallor and the large intervillous hematoma.

7.4 g%, and 48 NRBCs per 100 WBCs. Despite therapy, the infant died. Autopsy findings included widespread infarctive necroses in many organs. The placenta was meconium stained, but was not otherwise described. It is important to emphasize in this connection that it may be very difficult for the pathologist to identify fetal anemia in a stillborn at autopsy. Thus, in every stillborn coming to autopsy, the possibility of fetal transplacental hemorrhage should be considered, and it must be properly excluded if such cases are not to be missed. This is the point of the contribution by Laube and Schauburger (1982). They found that 3.4% of all fetal deaths and 0.04% of all births among 9223 deliveries were due to this cause. Walter et al. (1965) found a severely anemic 3100-g newborn, rapidly and successfully treated with transfusion, whose placenta weighed 1920 g. It had no specific lesions, other than distention of all villous vessels. Because transplacental bleeding may result in necrosis of a variety of fetal organs, including the brain, its documentation is of particular importance at a time when medicolegal claims abound. Reference to such cases has been made in an earlier portion of this chapter. It must be remembered also that fetal blood is often transferred across the placenta at the time of delivery. This is the basis for the RhoGAM prophylaxis after delivery. Owen et al. (1989), conscious of the possible misinterpretation of fetal hemorrhage (as evidenced by Kleihauer stains) in being the cause of prenatal death, compared predelivery vs. post-delivery Kleihauer stain results. Their findings indicated that puerperal collection of blood for Kleihauer stains is satisfactory. Their contribution and others suggested that 10% to 15% of otherwise unexplained fetal deaths and perhaps 4% of all fetal deaths were the result of massive transplacental hemorrhage. Only Biankin et al. (2003) produced a series of five autopsy findings in massive hemorrhage (between 443 and 104 mL). There were few findings other than a marked increase in NRBCs in all organs and placental tissue. Intervillous hematomas with NRBCs

and collapse of veins were seen, as well as thrombosis of placental vessels.

Prenatal blood loss has been associated with the clinical identification of some very specific prenatal disturbances. Thus, Clark and Miller (1984) observed a sinusoidal fetal heart rate patterns during labor that they associated with the occurrence of a fetal to maternal hemorrhage. The mother had spontaneous rupture of membranes and, because of the fetal heart rate patterns, a cesarean section was performed. The neonate had a hematocrit of 16%, and Kleihauer stains showed 7.6% fetal cells in the maternal circulation. Because of the large quantity of fetal blood in the mother (265 mL), a chronic hemorrhage was suspected. In a pregnancy where fetal tachycardia, atrial dilatation, and atrial fibrillation were present, Bacevice et al. (1985) observed 45 to 60 mL of fetal red cells in the maternal circulation, before birth. This led to digitalization, cesarean section, and the delivery of an infant with a 37% hematocrit. Unfortunately, the placenta was not described. There had been no risk factors associated with the fetal hemorrhage.

In the cases of fetal bleeding that complicates **cordocentesis** (Feinkind et al., 1990; Ghidini et al., 1993), local hemorrhage or abruptio can sometimes be identified. It is the risk of this procedure that can lead to exsanguination and also to tachycardia (Seligman & Young, 1996). Usually it is a benign procedure with little bleeding, but depending on whether the procedure is done for transfusion or blood sampling, fetal sequelae differ substantially (Pielet et al., 1988). It also carries an increased risk of transplacental hemorrhage and, thus, the possibility of maternal alloimmunization (Bowman et al., 1994). These authors recommended that cord puncture for genotyping be done only when vessels are of sufficient size to allow immediate transfusion, if needed. It is often impossible to clearly identify, by detailed pathologic examination, the site of fetal hemorrhage. Most of the pathologic changes found in their placenta **result** from the fetal anemia,

rather than being their **cause**. The pallor, the edema, the chorangiosis, and the placentomegaly all result from prolonged fetal cardiac failure. Many of the placentas cannot be shown to have overt abnormalities that could be the cause of the fetal bleeding. This was, for instance, the case in the well-studied infant described by Láwi et al. (1965). This infant had a neonatal hematocrit of only 17% and a hemoglobin concentration of 4.8g%. Likewise, Desbuquois et al. (1962) observed a normal placenta associated with fetal anemia in a 3400-g neonate; they cited similar cases from the literature. We have observed an exsanguinated, term stillborn infant in whose subamniotic space a large amount of fresh blood separated the amnion (4cm) from the chorion. At cesarean section, 500 mL of blood could be removed, and the placenta was 50% abrupted. No risk factors were identified. To be sure, many of the placentas of cases with fetal exsanguinations also possess intervillous thrombi. These have often been thought of as the possible sites of the fetal bleeding; as suspected in the earliest cases described by Chown (1955), the case of DeBelle et al. (1977), and in the case illustrated in Figure 17.7. Devi et al. (1968) studied the placentas of 120 normal deliveries, 264 complicated deliveries, and 98 pregnancies of Rh-negative women without and 35 Rh-negative patients with antibodies. Their findings indicated that the so-called Kline's hemorrhages (vide infra) positively correlated with the presence of fetal cells in the maternal circulation. The more frequently such lesions were present, the greater was the size of the transplacental hemorrhage. The authors presented their findings in several tables. Those results impressively support the notion that Kline's lesions, intervillous thrombi, operative delivery, infarcts and abruptio placentae statistically correlate with fetal bleeding.

Kline had described in 1948 that specific microscopic lesions in the placenta correlate with bleeding of the fetus. In the placentas of 15 erythroblastotic fetuses, he found "numerous breaks," with NRBCs in the adjacent intervillous space. He deduced that these breaks occurred in the peripheral capillaries, or even in larger blood vessels. After agglutination of red cells and deposition of fibrin, the overlying trophoblastic epithelium appeared to degenerate, serving as a nidus for clots to form. We believe that this alleged causality of the capillary occlusion is incorrect. In many fetal vascular occlusions, there is no trophoblastic degeneration, nor can breaks in blood vessels and villous surfaces be identified. It is also noteworthy that, despite the presence of a 2.7-cm spherical "cyst" with NRBCs in one of Chown's cases (1955), no trophoblastic damage was found on the villous surfaces. The integrity of the villous surface trophoblast is dependent solely on the intervillous circulation (e.g., hydatidiform moles). It is not dependent on the fetal circulation. Occlusions of fetal capillaries do not cause trophoblastic necrosis; they cause the villus to atrophy, occasionally to

become edematous, and eventually they make it fibrotic. Nevertheless, the term **Kline hemorrhage** has become associated with the putative lesions that are believed to initiate transplacental hemorrhage. When defects in the trophoblast occur, fibrinoid deposits across the defects; the trophoblast disruptions increase in frequency with advancing gestation normally, as does the fibrin (see Chapter 9). The fibrin so deposited may calcify and eventually become part of the diffuse microcalcification of term placentas. Breaks of villi also occur frequently throughout gestation. Presumably, they are "healed" by this maternal fibrin deposition.

We believe that, in vivo, the fetal blood flow and its pressure maintain the placental villi in an "erected" position (accounting for the thicker placenta seen sonographically as compared to when dissected). They are thus more susceptible to injury from fetal kicking than if they are empty, or "deflated." We can readily envisage that small breaks can then occur spontaneously and when the villi are injured by the fetus. To us, this more readily explains the frequency of fetal bleeding in otherwise normal placentas. Wentworth (1964) has advocated the use of flat and large ("Gough") sections of the delivered, and formalin-fixed, placenta for the observation of Kline hemorrhages. The cases he studied were correlated with Kleihauer stains of maternal blood, and the Kline hemorrhages could be evaluated by gross inspection. A positive correlation between the number of Kline lesions and the finding of positive Kleihauer stains was observed by Wentworth. Some of the illustrated "lesions" indicate that the author considered the normal villous lakes to be Kline lesions. These are the sites of primary injection of the maternal jets, the "holes" one observes in most delivered placentas. Wentworth (1964) found no correlation with infarcts, calcification, or other placental lesions.

Large intervillous thrombi may occur during labor (Fig. 17.8). They are then fresh clots, and without structure. There may be older, laminated clots with a similar appearance (Figs. 17.9 to 17.11). When these contain fetal cells, their older age may be revealed by the presence of macrophages that have engulfed fetal red blood cells (Fig. 17.12). We are here referring to intervillous thrombi that occur in the centers of the villous mass, and that do not relate to lesions in the floor of the placenta, such as those shown in Figs. 17.9 and 17.10. The latter intervillous thrombi are associated with maternal vascular lesions, often occur in preeclampsia, and are frequently laminated and pale. They differ from infarcts, which are granular in macroscopic appearance and invariably involve villi. Typical intervillous thrombi merely displace adjacent villi. If intervillous thrombi become large, or if they are of longer duration, the compressed adjacent villous tissue will also become infarcted. Other intervillous thrombi occur beneath the fetal surface. Those subchorionic fibrin masses increase with gestation and result from

FIGURE 17.8. Fresh intervillous thrombus in the center of villous tissue and presumed to have occurred during the delivery. Note the extreme pallor of this placenta from an erythroblastotic infant.

FIGURE 17.9. Somewhat older intervillous thrombus in center of term placenta. Note the laminated fibrin at right.

FIGURE 17.10. Layered fibrin residue of old intervillous thrombus originating from cotyledonary septum.

FIGURE 17.11. Layered fibrin in basal type of intervillous thrombus, associated with decidual necrosis and thrombosis of decidual vein. There is no adjacent infarction yet. H&E  $\times 6$ .

FIGURE 17.12. Old intervillous thrombus. At arrow is a maternal erythrophagocytic macrophage. H&E  $\times 400$ .

eddy of the intervillous blood as it is reflected beneath the chorion. In some placentas, they protrude into the amniotic cavity and may become so-called Breus' moles. These features are discussed in Chapter 9. Finally, more remarkable subchorionic fibrin deposits occur in some maternal cardiac diseases. These are shown in the Chapter 19. In addition, subchorionic fibrin deposits are regularly present in the immature placentas delivered after intra-amniotic saline and urea instillation for therapeutic abortion. It is of parenthetic interest here to note that intervillous thrombi and placental infarcts never undergo the repair process known to pathologists as "organization." That is to say, unlike other organs, the placenta

never manifests the fibrous tissue ingrowth, and the neovascularization that occurs in other organs, whose infarcts organize and become scars. Even the larger thrombi of surface vessels and in the umbilical cord do not "organize" frequently.

In occasional cases of fatal fetomaternal bleeding, the placenta has exhibited specific lesions that may explain the hemorrhage. Thus, Santamaria et al. (1987) found a choriocarcinoma in situ in the pale placenta of an otherwise normal stillborn. The trophoblast was clearly invasive and had presumably caused some fetal vascular discontinuity. More importantly perhaps, the lesion was not identifiable by macroscopic examination as a tumor. Small "infarcts" were seen and sampled, but they were not deemed grossly to be exceptional. The discovery of this (and other) placental choriocarcinomas in situ was fortuitous (see Chapter 23). Perhaps other "unexplained" transplacental hemorrhages would have yielded similar lesions, had the placenta been examined in more detail. A small chorangioma of the placenta was found in another fetus with transplacental hemorrhage (Fig. 17.13). There was no tumorous destruction of villi in this case, but the adjacent vessels were severely distended. These may have bled. Stiller and Skajish (1986) also reported on transplacental hemorrhage in association with a chorangioma of the placenta, fetal distress, and maternal hemolysis. Brown (1963) found that very large placentas, and excessively calcified organs, have an increased association with transplacental hemorrhage. Pollack and Montague (1968), on the other hand, stated that postmature placentas did not allow fetal hemorrhage to occur more frequently. The occurrence of fetal hemoglobin ( $>5\%$ ) in retroplacental hematomas was demonstrated in 29 of 93 cases by Oehlert et al. (1960).

FIGURE 17.13. Small chorangioma in mature placenta (maternal sickle cell disease) having caused transplacental hemorrhage (hematocrit 22%; 120-mL blood loss). Markedly distended fetal

vessels seen at right with extreme thinning of their walls, possibly the sites of hemorrhage. H&E  $\times 12.5$  (left);  $\times 50$  (right).

## Other Fetal Blood Elements Passing Through the Placenta

Although transplacental red blood cell passage may have the most serious consequences (anemia, immunization), transplacental white blood cell transfer is also of interest and has now become important because of the sequelae of the developing maternal microchimerism. For instance, do tumor cells readily pass the placental villi? As is reviewed in Chapter 19, maternal leukemia cells do not usually pass the placental “barrier” but on occasion have led to neonatal demise (Maruko et al., 2004). Of the solid neoplasms, only occasional melanoma cells are known to have traversed the placenta to the fetus with certainty. It is thus surprising to learn that some studies have suggested that lymphocyte traffic may occur across the placenta, and that it is alleged to take place in both directions. The topic has been reviewed in some detail by Schröder (1975), who concluded that the question of fetal leukocytes in the maternal circulation was still controversial, at least it was at that time. In part, the results of such studies are difficult to interpret because the mitotic inhibition of maternal leukocytes, when admixed with fetal lymphocytes, prevents ready identification of fetal cells (Olding et al., 1974). The conclusion, however, of Schröder was that fetal lymphocytes frequently pass to the mother, and that they probably do so in most normal pregnancies. They may be found up to years postpartum in the maternal blood or bone marrow, but they do not respond to the usual mitogens (Schröder et al., 1977). Selyes and Lorenz (1988) have developed a new methodology with which to identify fetal lymphocytes in the maternal circulation. They used this technique for the identification of fetal sex and diagnosis of possibly aberrant fetal karyotypes. Even newer techniques are now being pursued for the identification of fetal cells in the maternal blood.

Adinolfi et al. (1989), and Lo et al. (1989) used polymerase chain reaction (PCR) for DNA amplification and the identification of Y-chromosome-bearing cells in maternal venous blood. No contamination with fetal cells was found in six samples of pregnancies between 24 and 36 weeks’ gestation by the first investigators, although deported syncytiotrophoblast was trapped in the maternal lung. Their deportation had long been known (Schmorl, 1893, 1905; Raafat et al., 1975). When we studied lungs from a patient dying shortly after pregnancy, numerous apparent syncytiotrophoblastic cells were present in pulmonary capillaries, but staining with anti-human chorionic gonadotropin (hCG) antibodies failed because the cells had already lost their cytoplasm. There was neither a reaction nor thrombosis associated with these deported placental cells (Fig. 17.14). In the investigation by Lo et al. (1989), Y-sequences were found in the cells of all 12 women with male conceptuses, but in none of those seven cases with female fetuses. The possibility of contamination in this study was criticized by Holzgreve et al. (1990). Isolation of fetal DNA from maternal blood, contaminated by fetal NRBCs has been amply documented also by Bianchi et al. (1990). In later studies she suggested that these cells traverse the placenta at different times (Bianchi et al., 1991). The reliability of Lo’s technique was further questioned by the study of Suzumori et al. (1992). On the other hand, a carefully designed and cautiously executed study of peripheral blood for Y-specific ZFY sequences showed conclusively that nucleated fetal cells nearly regularly contaminate maternal blood (Kao et al., 1992). In a prospective study, Hamada et al. (1993) found by fluorescent in situ hybridization (FISH) in 50 male conceptuses that NRBCs were regularly found in the maternal circulation after 15 weeks. In the first trimester there were 1:100,000 nucleated cells, whereas 1:10,000 were seen at term. Elias and colleagues (1992) have even made

FIGURE 17.14. Syncytiotrophoblastic cells trapped in pulmonary capillaries of patient, dead from pulmonary hypertension shortly after delivery. The syncytial cells have lost their cytoplasm. H&E  $\times 400$ .

the diagnosis of trisomy 21 and trisomy 18 by the FISH method, the demonstration of three fluorescent markers in nucleated cells from maternal blood. Cell sorting of nucleated cells and other techniques are now in use to enrich the fetal cells contaminating the maternal blood (Gänshirt-Ahlert et al., 1992a,b). Very surprisingly, Bertero et al. (1988) have found some maternal (definitely **not** fetal) antigens on the surface of these circulating cells. They deduced from this that the prenatal diagnosis of  $\beta$ -thalassemia they attempted was not feasible. When the fetal DNA, however, was amplified from only a few NRBCs in the maternal circulation, sickle cell disease and  $\beta$ -thalassemia were successfully diagnosed prenatally by Cheung et al. (1996). Other single gene disorders are similarly susceptible. The topic of prenatal diagnosis from maternal blood contaminated by fetal cells continues to be under intense study. As indicated above, many different types of approaches were evaluated at the conference edited by Simpson and Elias (1994). It seems likely that the nearly regular, if small contamination of NRBCs in the maternal circulation even in early pregnancy will be most suitable for this purpose. Concentration methods steadily improve, clinical trials are ongoing, and verification of the cells under study as being cells from the current fetus are assured. Less optimal, because somewhat invasive, are the methods to obtain cells from washings of the endocervical canal.

#### MOTHER-TO-FETUS TRANSFER OF CELLS

Although occasional cases of such cellular exchange have been well documented, much less good evidence has been adduced that maternal cells frequently pass to the fetus in significant numbers. Schröder (1975), in the same review mentioned above, recited the observation of Kadowaki et al. (1965) of the prenatally incurred lymphocytic chimerism, in a neonate with presumed immunologic incompetence. This child later developed graft-versus-host disease as a result of his lymphocyte chimerism. Similar chimerism, induced by prenatal maternal lymphocyte transfer in a child with thymic aplasia, reported by Githens et al. (1969), had no ill effect. More deleterious consequences were described from transfer of malignant maternal cells into immunocompromised fetuses by Barth et al. (1972) and Pollack et al. (1982). Oehme et al. (1966) were able to show maternal leukocyte transfer to the rabbit fetus, with striking accumulation of these cells in the fetal lung. A few other reports of 46,XX cells in the circulation of male fetuses have been forthcoming (El-Alfi & Hathout, 1969; Moszkowski et al., 1971). Such passage is clearly exceptional, and graft-versus-host rejection of the immunologically compromised fetus, as in Kadowaki's case, must be exceedingly uncommon. Moreover, when lymphocyte cocultivation of maternal and fetal cells is experimentally studied, the maternal cell response is markedly reduced (Kawagoe et al., 1971; Olding et al., 1974). This may also have been the cause of Olding's failure to identify 46,XX cells in the cord blood of male infants (1972).

Interestingly, there have been occasional reports of fetal plethoria that were apparently due to mother-to-fetus blood transfer. Wong and Cann (1972) described a fatal transfusion reaction with fetal renal tubular necrosis in such a putative case of maternal-fetal transfusion. The child was born at 43 weeks' gestation, after a normal pregnancy, and the placenta was not infarcted or abrupted. The neonatal hemoglobin

concentration was 16.8g%, there was hemoglobinuria, and the fetal blood did not clot. Immunologic studies of the fetal red blood cells suggested that maternal cells were circulating at birth. Chronic maternal-fetal transfusion was found in a case of hydrops fetalis described by Bowman et al. (1984). The mother had received fetal cells transplacentally (5.4% Kleihauer positive cells). The hydropic infant was plethoric, with a hemoglobin of 20.5g and a hematocrit of 63%. The placenta accompanying this fetus had extensive areas of infarction and intervillous thrombi, and microscopically there were torn fetal vessels. The authors concluded that such cases must be exceedingly rare, and they were able to refer to only one previously described report with fetal plethoria, that of Michael and Maurer (1961). They suggested that this bidirectional exchange was possible only because of the disrupted large fetal placental vessels, an otherwise uncommon phenomenon. Michael and Maurer found three newborns of normal pregnancies with hematocrits of 73%, 79%, and 80% respectively, and hemoglobin values of 21.2, 21.8, and 24.6g%. In two of these, the fetal and maternal blood groups differed, and differential agglutination allowed proof of maternal red cell transfer to the fetus. The placentas were not described, and the mechanism of transplacental transfer was only speculated upon. There are, however, numerous studies that affirm the nearly regular transfer of **some** maternal red blood cells to the fetus, albeit in smaller numbers than those needed to induce fetal plethoria. They are not accompanied by abnormal placentas, have also been found to occur in mice (Holliday & Barnes, 1973), and they obviously embody the importance of possible fetal Rh-immunization, when the fetus is Rh-negative and the mother is Rh-positive (Jennings & Claus, 1978). Messer et al. (1966) found that parenteral administration of carbazochrome to the mother decreased the transfer. Red cell transfer from mother to fetus was affirmed by Smith et al. (1961) and Zarou et al. (1964) using chromium-labeled red blood cells. Macris et al. (1958) and Fujikura and Klionsky (1975) identified such transfer with the marker being sickled erythrocytes. Many other studies are summarized by additional investigators (Megapanos et al., 1966; Eimer & Weiland, 1969). These leave no doubt that this is a relatively frequent and perhaps an occasionally important phenomenon. Mayer et al. (1956) demonstrated in an impressive electron micrograph the apparent passage of a red blood cell through a fetal villous capillary.

## Fetal Storage Disorders

Many of the so-called errors in metabolism, the storage diseases, produce inclusions or vacuoles in the tissues of affected individuals. The placenta is often similarly involved, and chorionic villus sampling (CVS) biopsy is now more often employed to make the diagnosis prenatally, as for instance in diagnosing lipofuscinosis (Rapola et al., 1990). Electron microscopy and special enzyme studies are usually helpful for the precise diagnosis of the defect involved. Thus, appropriate fixation is needed when such disease is suspected and it must also be anticipated at the time of CVS, as many of the inclusions are highly water and lipid-soluble. Because many of these diseases are the cause of fetal hydrops, the cases of nonimmune hydrops fetalis warrant special attention. An excellent ultrastructural study of 11 cases has been published by Jones et al. (1990) that details procedures and findings, and Fox (1997) has shown other material. These publications depict the findings in admirable detail and provide additional literature. Table 18.1 summarizes the current status of placental studies in various storage disorders.

**Gaucher's disease**, as mentioned in Chapter 16, may cause fetal hydrops. It is a heterogeneous disease whose genetics and clinical manifestations were well described by Sidransky and Ginns (1993). In the case described by Ginsburg and Groll (1973), polyhydramnios complicated the second pregnancy of a patient in the second trimester. At 34 weeks, she delivered a macerated, hydropic fetus. The large and edematous placenta had the macroscopic features of erythroblastosis fetalis. The mother's third pregnancy also resulted in neonatal demise due to Gaucher's disease. The fetal findings were characteristic of type II Gaucher's disease in the hydropic 21-week fetus described by Rice et al. (1984). The placenta was not described. Gillan et al. (1984) and Bouvier and Maire (1997) provided additional insight with numerous diverse cases. Soma et al. (2000) illustrated a characteristic case with recurrent hydrops fetalis in a Japanese pedigree.

**Mucopolipidosis type II, or I-cell disease**, is a rare and fatal disorder whose genetic transmission is autosomal recessive. Gellis and Feingold (1977) delineated the principal features of affected children. Hanai et al. (1971) emphasized the abundance of periodic acid-Schiff (PAS)-positive lysosomal inclusions in the cells of affected children. In 1974, Granström et al. and Rapola et al. separately reported that affected newborns may have coarse features similar to those of patients with Hurler's syndrome, and demonstrated inclusions in leukocytes. Aula et al. (1975) made the first prenatal diagnosis of this disease from an increase of amniotic fluid hydrolases. Later, they used fibroblasts of the aborted fetus to confirm the diagnosis. The investigators emphasized that paraffin sections do not allow the visualization of the inclusions; they are obvious, however, in epoxy-embedded material. The inclusions of this disorder are preferentially located in kidney and mesenchymal cells. Terashima et al. (1975) presented an extensive differential diagnosis of these inclusions in their description of three cases. Placental involvement with inclusion-bearing cells was first demonstrated in a case report of Powell et al. (1976). The syncytium and Hofbauer cells were primarily affected; the vacuoles of formerly mucolipid-containing lysosomes were readily apparent in paraffin sections of the placenta (Figs. 18.1 and 18.2), but the features were much enhanced by processing the tissues in epoxy resin. The authors of this paper emphasized that only **fetal** cells contained the vacuoles. Affected tissue included the X cells of cell columns and the placental floor. There were no inclusions in decidual cells, and they used this to further identify X cells as being of fetal origin. The placenta was grossly pale and somewhat enlarged; the fetus was not hydropic. The same report contained three additional and similar storage diseases that affected the placenta but the precise nature of their storage disorders could not be identified. Abe et al. (1976) and Nagashima et al. (1977) described other morphologic studies. Several investigators further elaborated on placental aspects of mucopolipidosis type II.

TABLE 18.1. Summary of placental findings in various storage diseases

Disease	Findings	Reference
Glycogen storage type II Pompe's disease	Vacuoles full of glycogen in EM in stroma, endothelium, cytotrophoblast, lysosomes	Bendon and Hug, 1985 Jones et al., 1990 Roberts et al., 1991
Mucopolysaccharidosis Hurler's disease Sanfilippo's disease	Vacuolization of fibroblasts and syncytium  Vacuolated syncytium, absent heparin-N-sulfatase in CVS	Jones et al., 1990  Jones et al., 1990
Morquio's disease, type IV $\beta$ -glucuronidase deficiency Sialic acid storage Salla's disease	Edema of villi Hofbauer cell vacuolization, hydrops Vacuolated syncytium and Hofbauer cells with amorphous and fibrillar material, vacuolated extravillous trophoblast and amnionic epithelium	Kleijer et al., 1986 Applegarth et al., 1987 Nelson et al., 1993 Gillan et al., 1984 Jauniaux et al., 1987 Jones et al., 1990
Gaucher's disease	Hydrops	Roberts et al., 1991 Ginsburg and Groll, 1973 Gillan et al., 1984 Rice et al., 1984 Sidransky and Ginns, 1993
Sphingomyelin storage Niemann-Pick's disease types A and C; Type B may have inclusions Gangliosidoses GM 2, gangliosidosis type I, Tay-Sachs' disease	Vacuolization and laminated inclusions (myelin bodies) in syncytium, stroma, Hofbauer cells, umbilical cord fibrocytes, hydrops  Vacuolated trophoblast and Hofbauer cells, amnion Absent hexosaminidase in CVS	Sarrut and Belamich, 1983 Vanier et al., 1989 Meizner et al., 1990 Schoenfeld et al., 1985 Lowden et al., 1973 Grebner et al., 1983 Roberts, 1991 Benirschke and Kaufmann, 1995 Fox, 1997
Type II Sandhoff's disease Fabry's disease Glycosphingolipidosis Mucopolipidoses Type I Sialidosis	Multiple parallel arrays in lysosomes of stroma, vacuolated syncytium, myelin bodies Lamellar lysosomal inclusions in decidual cells, chorionic cells normal, in heterozygous carrier Vacuolated trophoblast and stroma, normal amnion	Popli et al., 1990  Riches and Smuckler, 1983
Type II I-cell disease	Vacuolated syncytium, vacuolated Hofbauer and X cells Occasional myelin figures in EM	Laver et al., 1983 Stevenson et al., 1983 Gillan et al., 1984 Baldwin et al., 1985 Mahmood and Haleem, 1989 Bouvier and Maire, 1997 Powell et al., 1976 Rapola and Aula, 1977 Sarrut and Belamich, 1983
Type IV Galactosialidosis Neuronal ceroid lipofuscinosis	Vacuolated stroma with lamellar inclusions of endothelium Vacuolated trophoblast and stroma, hydrops Vacuoles in syncytium, amnion, endothelium with "fingerprint" inclusions	Sekeles et al., 1978 Scully, 1997 Rapola et al., 1988 Conradi et al., 1989

CVS, chorionic villus sampling; EM, electron microscopy.

Thus, Rapola and Aula (1977) beautifully demonstrated the ultrastructural changes of the syncytium and suggested that the diagnosis could easily be made from this material alone (Fig. 18.3). With CVS biopsy, this would now be possible without having to resort to enzymatic study. Gehler et al. (1976) reported biochemical studies of I-cell disease. The differential diagnosis of mucopolipidoses types I and III was discussed in a study by Herd et al. (1978). Hug et al. (1984) have shown that maternal serum hexosaminidase levels are increased in pregnancies

affected by I-cell disease, which allows diagnosis without uterine invasion. We strongly disagree with the interpretation of Cozzutto (1983), however, who reported on a macerated stillborn whose placenta also had extensive vacuolar changes. The placenta was structurally typical of I-cell disease. Cozzutto found vacuolated "stromal decidual cells," but he did not depict these. He interpreted the changes as "convincingly demonstrating" that the foam cells are a transformation secondary to edema or fetal death. In our experience, such vacuolation never results

FIGURE 18.1. Villus (left) and X-cell column of placenta, affected by mucopolipidosis II (I-cell disease). Note the abundance of vacuoles in the syncytium and Hofbauer cells; similar inclusions are present in the cytoplasm of X cells. H&E  $\times 240$ .

from fetal death or edema. The abundance of foam cells, the disposition of trophoblastic vacuoles, and irregular calcifications observed by him (and us as well) all are indicative of an unidentified fetal storage disorder. Because the cellular glycolipids are highly water-soluble, the empty appearance of the vacuoles is the usual finding in many fetal storage disorders. We saw another case with

extensive and typical syncytial vacuolization (courtesy of S. Romansky, Los Angeles). The neonate was well and had no signs of disease when 4 months old. The enlarged placenta had also numerous vascular lesions, mostly in the villous stem arteries, varying from fibrinoid necrosis to complete obliteration, with occasional histologic findings of the nonspecific “hemorrhagic endovasculitis”. In

FIGURE 18.2. Syncytium in case of I-cell disease. Note the extensive, fine vacuolation, the storage site of washed-out glycolipids in the syncytial cytoplasm. EM  $\times 6700$ . (Courtesy of Dr. J. Rapola, Helsinki, Finland.)

FIGURE 18.3. Appearance of villi in I-cell disease (mucopolipidosis II). The syncytium is characteristically uniformly finely vacuolated. (Courtesy of Dr. Scott Hyde, 1999.)

addition, there were numerous foci of villous calcifications. Because of the simultaneous presence of numerous myelin figures in electron micrographs, the diagnosis of I-cell disease was thought unlikely; moreover, neonatal screening tests were negative. Follow-up with skin biopsies at herniorrhaphy at age 8 months showed vacuolar changes in fibroblasts and coarse facial features became evident. Very high levels of lysosomal enzymes were then found and I-cell disease was diagnosed. The infant became severely retarded.

**Hurler's syndrome** (mucopolysaccharidosis I) showed "striking vacuolation of stromal cells," including Hofbauer cells (Jones et al., 1990).

Other storage diseases affect fetal and placental tissue. By amniocentesis at 14 weeks, Lowden et al. (1973) identified, the absence of  $\beta$ -galactosidase. That absence is diagnostic of type 1  $G_{MI}$  **gangliosidosis**. The pregnancy was terminated; typical inclusions (zebra bodies) were ultrastructurally identified in the fetal ganglion cells. Although other fetal cells were unremarkable in paraffin sections, vacuoles were seen in epon-embedded material. The placenta showed numerous "empty vacuoles" in the syncytial cytoplasm, extravillous trophoblast, and Hofbauer cells (Roberts et al., 1991). They were visible even in paraffin sections. Presumably, these contain the water-soluble storage product, and galactose-rich mucopolysaccharide. Other case descriptions of the disease do not include descriptions of the placenta (Giugliani et al., 1985).

Absence of  $\alpha$ -galactosidase A results in **Fabry's disease**, a disorder of glycosphingolipid metabolism. The tissues accumulate ceramide trihexose. A pregnancy in a patient with this disease was described by Popli et al. (1990) after she had received a renal allograft. The placenta of the

term fetus was normal but the decidual cells contained argyrophilic granules that electron micrographically had the appearance similar to zebra bodies. The fetal portions of the placenta were normal. O'Brien (1982) reviewed many lysosomal disorders and their enzymatic deficiencies and provided details of the enzymatic defect.

In the studies by Jones et al. (1990), **Tay Sachs' disease** ( $G_{M2}$ -gangliosidosis type I) was found to produce vacuolation of syncytiotrophoblast, with occasional myelin bodies in villous stromal cells. In **Sandhoff's disease** (type II), "the most striking feature . . . was the occurrence of parallel membranous arrays in occasional lysosomes within stromal cells." Myelin bodies were found in trophoblast and endothelium.

**Mucopolipidosis IV** (Morquio syndrome type B) is due to the deficiency of  $\beta$ -galactosidase and also referred to as  $G_{MI}$ -gangliosidosis. This disease has been diagnosed from cultured amniotic fluid cells by Kohn et al. (1977). The amnion cells contained multiple single-membrane bounded inclusions. Mesodermal elements, however, were negative. Although it may appear superficially that this disease is similar to I-cell disease, in this condition the amnion, not syncytium and Hofbauer cell, has the vacuolation. The placenta of a case we saw was much enlarged (950 g) and much paler and softer than normal. Its amnionic epithelium, trophoblast, Hofbauer cells, and circulating lymphocytes showed striking vacuolation, similar to those of I-cell disease. Calcified thrombi were found in large surface vessels. The 4050-g neonate had massive ascites but no organomegaly. Another case of mucopolipidosis IV, supplied by Dr. P. J. Cera, also had surface vessel calcified thrombi, ascites, and massive trophoblastic vacuolization. We have seen endothelial

damage, perhaps secondary to lipid accumulation, in other cases of storage disease. In a case of  $G_{M1}$  gangliosidosis (mucopolipidosis IV) fetal endothelial vacuolization was demonstrable in villous stem vessels (K. Winn, personal communication, 1974).

**Morquio's disease** (mucopolysaccharidosis type IV A) has also been diagnosed from enzyme analysis of chorionic villus biopsy (Applegarth et al., 1987). Within the family reported by these authors, nonimmune hydrops fetalis had occurred in previous pregnancies. The authors drew attention to previous reports of hydrops with Gaucher's, Wolman's, and Salla's diseases, with sialidosis and mucopolysaccharidosis type VII. In their family, they had a hydropic fetus with a bulky placenta. Vacuolar villous edema and prominent Hofbauer cells were found, but there was no histologic evidence of storage products in the trophoblast.

Maroteaux et al. (1978) and See et al. (1978) have described the general features of **sialidosis** ("nephrosialidosis"; mucopolipidosis type I). They depicted the inclusions in the neuraminidase-deficient cells, but did not describe the placenta. In other case reports (Aylsworth et al., 1980; Stevenson et al., 1983), the inclusions of tissues and cultured cells are all well depicted, but these authors did not describe the associated placentas either. Laver et al. (1983) found typical storage vacuoles in Hofbauer cells and the villous syncytium. Amniocyte morphology in this disease has been reported to be normal by electron microscopic study (Stevenson et al., 1983). In a similar disorder, hydrops fetalis resulted in two pregnancies from a combined deficiency of neuraminidase and  $\beta$ -galactosidase (Kleijer et al., 1979). The placenta of these fetuses was not described. Gillan et al. (1984), who discussed congenital ascites in various storage disorders (sialidosis, Salla's disease, gangliosidosis, Gaucher's disease), depicted a placental villus with vacuolated syncytial cytoplasm of a fetus with Salla's disease.

**Niemann-Pick** disease (type C) does not result in visible storage products of the placenta. When tissue is obtained from CVS and cultured under special conditions, however, the tissue-cultured cells of affected fetuses have been shown to accumulate laminated inclusions of nonesterified cholesterol (myelin bodies), which can then be stained with filipin for unesterified cholesterol, and the diagnosis may thus be secured (Vanier et al., 1989; Jones et al., 1990). Nonimmune hydrops with hydramnios, commencing at 19 weeks' gestation, has been described by Meizner et al. (1990) in Niemann-Pick disease. Fetal death occurred at 36 weeks and the inclusions were identified electron microscopically in the enlarged spleen. The placenta was not described. Niemann-Pick disease type A, due to sphingomyelin diphosphodiesterase deficiency, can be diagnosed from absent enzyme in amniotic fluid. Unusual echogenic densities in the placentas of several cases that also had thick chorionic plates

were sonographically demonstrated by Schoenfeld et al. (1985). Vacuolated syncytium, Hofbauer cells, and fibrocytes of the umbilical cords contained accumulations of sphingomyelin, as did the chorion laeve.

Desai et al. (1985) found lysosomal lipid deposits in **cholesterol ester storage disease** in which the fetal adrenal glands had foci of necrosis and many other tissues possessed a vacuolated cytoplasm. In a detailed Case description in the *New England Journal of Medicine*, Scully (1997) described a child with hydrops of unknown etiology whose placenta had extensive vacuolation of the syncytium and stromal cells. Because of deficient levels of  $\beta$ -galactosidase and  $\alpha$ -neuramidase from cultured cells obtained at amniocentesis the diagnosis of galactosialidosis was established. This discussion included a consideration of the pathogenesis of the fetal hydrops that is still not clarified for most storage diseases.

Bendon and Hug (1985) reported placental abnormalities in five cases of **Pompe's disease** (glycogen storage disease type II;  $\alpha$ -1,4-glucosidase deficiency). In routine examination of the placenta, the only unusual finding was the cytoplasmic vacuolation of amniotic connective tissue cells and the villous capillary endothelial cells (Roberts et al., 1991). Electron microscopy, however, showed typical membrane-bounded, glycogen-filled inclusions in capillary endothelial cells and in the villous stroma. They were present even in middle trimester abortuses. Hug et al. (1991) described the diagnosis from CVS at 10 weeks. The previous pregnancy had resulted in an affected child. Electron-microscopic examination 5 days after biopsy identified the typical glycogen-packed membrane-enclosed inclusions in many fetal cells, including fibrocytes that appear as vacuoles in histologic study. These authors insisted that the demonstration of vacuoles alone is insufficient for the diagnosis. Jones and her collaborators (1990) made similar findings of lysosomal glycogen accumulation. These were seen in cytotrophoblast, endothelium, fibrocytes, and pericytes. We have seen the placenta of a neonate with **glycogen storage disease, type IV** (amylopectinase deficiency). It had vacuoles in amniotic epithelium, but no specific lesions were identified. There were none of those cells that had been identified in Pompe's disease. The pregnancy was complicated by hydramnios. The newborn had Lafora bodies in heart, liver, and muscle, had pleural transudate, was dysmorphic, and suffered fatal pulmonary hypoplasia. The placenta was enlarged. A second pregnancy was similarly involved.

Similarly, in **sialic acid storage disease**, Jones et al. (1990) identified the Hofbauer cells, endothelium, and syncytium to be packed with clear, membrane-bound vacuoles (Jauniaux et al., 1987). Roberts et al. (1991) also found vacuolization in extravillous trophoblast and amniotic epithelium. And from chorionic villus biopsy material, more sophisticated culture methods we can anticipate more complex storage diseases to be identified in the

future, just as had been anticipated by Nadler and Gerbie many years earlier (1970). Thus, Menkes' disease was diagnosed by the absence of copper from CVS samples (Tønnesen et al., 1985).

It is apparent from these descriptions that many congenital enzyme deficiencies can be diagnosed from amniotic fluid cultures, and chorionic villus samples, and that they may be accompanied by placental manifestations. The location and type of inclusion cannot always be anticipated. Thus, the inclusions of lipofuscinosis were mainly in the fetal capillary endothelium, although they had earlier been suggested to be in syncytiotrophoblast (Rapola et al., 1990). The villus specimens, therefore, should be processed for optimal ultrastructural studies. Chorionic villus biopsy has become of great value in selected cases, especially for prenatal counseling. In this area of research, some published animal models closely parallel the human disease. Most known animal models of storage disease and spontaneous occurrences of inborn errors of metabolism were reviewed by Jolly and Walkley (1997). Their use may be of value, particularly in attempts at therapy, but also for the study of their placentas (Baker et al., 1976).

# Maternal Diseases Complicating Pregnancy: Diabetes, Tumors, Preeclampsia, Lupus Anticoagulant

Numerous diseases may complicate pregnancy. The most important of those that affect placental development and function are herein reviewed. Our own experience with some of these entities is cited. With some of these complications of pregnancy, the placental findings may simply be confirmatory of the disease. With others, placental pathology may be the first indication of an abnormality. Despite many reports of diseases that complicate pregnancy, associated placentas are often not examined, or they are not reported in the descriptions. That is unfortunate because those placentas could aid in diagnosis and knowledge of the pathogenesis of these conditions. Moreover, a better understanding of the placenta could allow us better insight into the mechanisms of the effects that certain conditions have on the fetus. Burrow and Ferris (1988) have written a comprehensive text on medical complications of pregnancy but have also almost totally excluded placental considerations; the general texts on obstetrics and perinatology should also be consulted. Because of their particular importance, some entities (e.g., Rh-immunization disease and hydrops, pyelonephritis, and infections in general), are presented in separate chapters.

## Maternal Diseases

**Scleroderma**, also called systemic sclerosis, is characterized by the deposition of fibrous tissue in many organs and the production of autoimmune antibodies. Its etiology is currently under very active study. This disease has been reported on many occasions to occur in pregnancy, although the usually late onset of scleroderma makes it an uncommon association. Slate and Graham (1968) observed six patients with generalized scleroderma and followed their nine pregnancies. When reviewing all pregnancies of their scleroderma patients, irrespective of the time of onset of the disease before or during pregnancy, stillbirths, abortions, and premature births were found to

be common. Pregnancies occurring after the onset of scleroderma ended in two premature births, two stillbirths, and 12 abortions. When they reviewed the literature, these authors also found five maternal deaths among 72 women. These investigators thought that preeclampsia was not an unduly common complication of scleroderma. In the discussion following their paper, additional cases were presented. None, however, was accompanied by a placental description.

Spellacy (1964), who reported a case with premature labor, found that the placenta had small infarcts, and he gathered 11 additional cases from the literature. Abruptio placentae was described in a case by Hayes et al. (1962). Maternal (decidual) vascular changes have not been described with scleroderma, which is remarkable because scleroderma is occasionally complicated by lupus erythematosus, and abruptios have been reported to occur with scleroderma. The two patients in whom we saw extensive fibrinoid deposits gave the appearance of "maternal floor infarction." One such placenta is shown in Figure 19.1. This 34-year-old gravida IV, para I, aborta II, had a precipitous labor at 38 weeks' gestation. Her obstetricians suspected abruptio placentae. The pregnancy terminated with a growth-restricted stillbirth. The placenta was also unusually small (310g) and had numerous infarcts and X-cell proliferations. Many nucleated red blood cells (NRBCs) were present in the fetal circulation, and marked X-cell proliferation was accompanied by many cysts. A similarly cystic placenta had been seen by us previously in scleroderma, but that pregnancy was associated with a normal child. Neither placenta had decidual vascular lesions. Gunther and Harer (1964) observed three pregnancies in a patient with scleroderma. Each was complicated by placenta previa. Doss et al. (1998) observed 13 placentas from eight women with scleroderma. They found decidual vasculopathy commonly, lesions that simulated those found in maternal hypertensive disorders. In addition, abruptio, infarcts, and decidual fibrin deposits were more frequently observed than in normal placentas.

FIGURE 19.1. Placenta of a patient with scleroderma at 38 weeks' gestation. Numerous infarcts, "gitterinfarkts," maternal floor infarction, and X-cell proliferation were seen. The placenta and stillborn fetus were growth-restricted. (Courtesy of Dr. Bonnie Bobzien.)

Studies to further elucidate the etiology of scleroderma have taken an unexpected turn with the finding by Artlett et al. (1998) that the disease may be the result of fetal graft-versus-host disease (GVHD) rejection. They identified fetal DNA (by demonstration of Y-specific sequences) in women who had previous male births and suggested that competent fetal lymphocytes (CD3 cells) had traveled transplacentally to set up colonization of the mother. This is an attractive hypothesis for a condition with some features having a resemblance to cases with known GVHD, and it further delineates "microchimerism" (Mullinax, 1998; Nelson, 1998, 2004; Nelson et al., 1998). Murata et al. (1999), in contrast, found no Y-chromosomal signals in Japanese patients with systemic sclerosis. Perhaps other autoimmune diseases fall into the same category, as transplacental transfer of fetal cells to the mother is common (see Chapter 17) and there is also an excess of autoimmune diseases in women. This has been proven for postpartum thyroiditis and, remarkably, in one patient even the thyroid epithelium was "repaired" by fetal cells, most likely deriving from stem cells (Srivatsa et al., 2001; Ando & Davies, 2003). This is an exciting new field and several diseases are under suspicion of being caused by the transplacentally developing microchimerism.

**Dermatomyositis**, another autoimmune disease with primarily cutaneous expression, was reported during pregnancy by Barnes and Link (1983). The patient became ill at age 15, had a therapeutic abortion at age 22, and developed significant subcutaneous calcinosis while being treated. The successful pregnancy occurred at age 24, 3 months after cessation of methotrexate medication. Vaginal spotting took place at 3 months, but she remained normotensive and had no proteinuria. A cesarean section was performed at 42 weeks with a healthy infant delivered. The placenta had "subamniotic necrosis and hemorrhage involving 30% of the fetal surface." There also was an infarct, but no decidual arteriopathy was present. The authors referred to a few other case reports, with similar findings of infarcts in the placenta the only pathologic lesions. We saw the placenta of such a patient who had spontaneous demise of a growth-restricted fetus at 38 weeks. The placenta had the typical appearance of massive Gitterinfarkts (see Chapter 9).

**Ehlers-Danlos syndrome** is not a homogeneous disease entity. Many types have been differentiated, and a foundation concerned with this disease collects data, including those of pregnancy. One or another form occurs occasionally during pregnancy. Atalla and Page (1988) estimated Ehlers-Danlos disease to occur once in 150,000 pregnancies, of which 35% were of type II. Barabas (1966) found that 14 of his 18 patients delivered prematurely because of premature rupture of the membranes. He suggested that the membranes were exceptionally fragile, but there are no actual measurements of the strength of membranes, nor are there pathologic data. Normal members of the families did not suffer from this putative lack of membrane strength. In the pedigrees reported by Barabas, the premature membrane ruptures were nearly always restricted to affected fetuses. Atalla and Page (1988) reported a case of Ehlers-Danlos syndrome type III with pregnancy and reviewed the sparse literature. Their patient never developed abdominal striae, but because of increasing pains during pregnancy, she had a cesarean section at 35 weeks' gestation. Her membranes were then ruptured artificially. Thus, with the possible exception of a true increased fragility of the fetal membranes in affected offspring, the placenta has not been reported to be abnormal.

**Rheumatoid arthritis** has rarely been observed during pregnancy, according to the report of Duhring (1970). He described the successful outcome of pregnancy in a para III patient who had suffered the disease for 17 years. The fetus was markedly growth-restricted, and the placenta was small, infarcted, and calcified. The umbilical cord was grossly virtually devoid of Wharton's jelly, but a histologic study was not reported.

Nine cases of **periarteritis nodosa** had been reported before Nagey et al. (1983) described another case. Their patient was a 28-year-old woman who had experienced

many complications of the disease for 5 years. This mother had one previous abortion, and her pregnancy was therapeutically terminated at 16 weeks. The placenta appeared to be normal by light and electron microscopic examination. Decidual vessels, however, were not present in the specimen. Previous reports had commented on the high risk for maternal survival but did not include descriptions of the placenta. Owen and Hauth (1989) reported another case, but they did not include a description of the placenta.

A report of maternal **Takayasu's arteritis** complicating pregnancy indicates that normal gestation may yield a normal infant. Winn et al. (1988) observed a woman who had this disease diagnosed 3 years earlier and who had significant arterial disease as a consequence. She was delivered of a healthy infant at 33 weeks. The placenta was not described.

A patient with progressive, severe **myositis ossificans** posed serious problems in pregnancy management but the mother delivered a healthy neonate. The pregnancy was complicated by premature rupture of membranes and infection with group B  $\beta$ -hemolytic streptococci. The placenta was not described (Thornton et al., 1987).

Patients in **acute renal failure** from whatever cause not only may now survive pregnancy and have normal infants when appropriately managed, but their placentas are found to be normal (Soyannwo et al., 1966; Jones & Hayslett, 1996). This is the case only when the renal failure is independent of pregnancy-induced hypertension and its frequently accompanying decidual vascular disease. Renal injury may occur after spider (Martinez, 1967) and snake bites (James, 1985). The latter author suggested that the venom may cross the placenta and kill the fetus. Renal failure and abruptio placentae have also been produced by the bite of *Bothrops jararaca*, a species of snake (Zugaib et al., 1985). This accident occurred during the 32nd week of gestation and, despite antiserum administration within 6 hours, the fetus died in utero from a 75% abruption. Mushroom poisons (amatoxins) have been described to cause maternal intoxication, but they do not cross the placenta. A fetus appeared to progress normally after such intoxication, and there was no detectable amniotic fluid toxin; the placenta was not described (Belliardo et al., 1983).

Pregnant women with **chronic renal failure** have a high perinatal mortality rate (Hou, 1985). Many placental lesions are found. Most notable among them is retarded growth of the placenta, presumably secondary to maternal decidual vascular disease and hypertension.

Patients with successful **renal transplantation** have a 30% incidence of preeclampsia during pregnancy and suffer occasional rejection of the transplant (Penn et al., 1980; Davison, 1987). It is interesting that toxemia of pregnancy develops so frequently in these patients who usually are medicated with steroids and immunosuppres-

sive agents. Intercurrent infection is a serious hazard, but cyclosporine immunosuppression apparently does not interfere with placentation. The placenta, however, is rarely described (Burrows et al., 1988). Beller et al. (1976) made efforts to differentiate the clinical identification of **malignant nephrosclerosis** from preeclampsia but did not provide information on the placentas in the two patients they described.

Although **acute fatty liver of pregnancy** has a dismal outcome (the survival rate has improved to between 18% to 23%), placental abnormalities remain undescribed (Kaplan, 1985). Hemolysis, coagulation, and other disturbances occur clinically, and toxemia may result with its complications, but the primary disease does not apparently affect the placenta. When maternal bilirubin is high, gross examination of the placenta can identify the pigmentation, particularly in the perivascular connective tissue of the fetal surface. Microscopically, however, no abnormalities are detected, and visible pigment-laden macrophages are rare.

**Cholestasis of pregnancy** has been associated with a high rate of stillbirth and other perinatal complications. Fisk and Storey (1988) reviewed 83 such cases and found meconium staining in 45%, preterm labor in 44%, and fetal distress in 22%. In their opinion, the low mortality achieved (three of 83) was due to intensive monitoring of the end stages of pregnancy and the result of judicious intervention. Other than the frequent meconium staining of the placenta, there were no abnormal placental findings. One wonders whether some of the "meconium-staining" may not have been bilirubin-staining. Matos et al. (1997), who lost a fetus at 37 weeks, found that it had extensive cerebral hemorrhage, presumably related to the cholestasis. The placenta was entirely normal and not abrupted.

Patients with **hyperemesis gravidarum** who were treated with total parenteral alimentation were studied by Levine and Esser (1988). Their fetuses all matured to at least 38 weeks' gestation and were not growth-restricted. Examination of the placentas showed no lipid deposits or other abnormalities.

A direct effect of **alcohol** on the placenta is disputed, although fetal growth restriction and other consequences of the fetal alcohol syndrome are well delineated in the offspring of patients with alcohol abuse during pregnancy (Jones et al., 1973). Several studies have shown that the placenta is smaller than that of controls. Kaminski et al. (1978) found the placentas to weigh 591 g when 45 to 67 mL of alcohol were consumed daily, and 581 g when more than 67 mL were consumed daily. Control placental weights were 611 g for less than 44 mL daily alcohol consumption. That the placenta transports alcohol readily has been shown on numerous occasions (Ditts, 1970), with fatal fetal intoxication having been reported (Jung et al., 1980). The influence of alcoholism on the length of

umbilical cords (shortening in experimental systems) was mentioned in Chapter 12. Baldwin et al. (1982) reviewed placentas of pregnancies with alcohol abuse and found an increased incidence of chorioamnionitis, chronic villitis, meconium staining, chorangiomas, and, especially, with persistence of embryologic remnants in the umbilical cords. The significance of these lesions is unknown. The inflammatory complications indicate that the social circumstances of the population differed from those of the controls. Other investigators (Sokol et al., 1980) observed no abnormalities in placentas of alcoholics. Marbury et al. (1983), on the other hand, found a significant increase in the incidence of abruptio placentae and a correlation with the amount of alcohol consumed. Blakley (1983), who reviewed the topic extensively, referred to evidence that alcohol consumption leads to fetal hypoxia and compensatory placental enlargement.

The use of **cocaine** (benzoylecgonine) and crack (the free-base smokable form of cocaine) during pregnancy has continued. A survey conducted in Florida indicated that some 15% of pregnant women tested positive for urinary metabolites of controlled substances (Chasnoff et al., 1990), but in a community study of South Carolina it was only 1% (Weathers et al., 1993). Consuming cocaine in pregnancy has been linked to abruptio placentae (Acker et al., 1983; Chasnoff et al., 1985; Dombrowski et al., 1991; Hoskins et al., 1991). In vitro enzymatic studies by Roe et al. (1990) showed that placental microsomal fractions biotransform cocaine to inactive compounds. Fetal growth restriction, transient hypertension, severe placental vasoconstriction (Lederman et al., 1978), and other deleterious outcomes of pregnancy are reported (Cregler & Mark, 1986). Mercado et al. (1989) observed a patient with repeated abruptios, abortions, and continued cocaine use who ultimately had a postpartum cerebral hemorrhage, presumably from hypertension. Page et al. (1989) found in the placentas of 20 crack users that 12 of them had abruptio placentae (10 with large clots, one with retroplacental depression, six with recent and old clots). Eight had normal placentas, and 10 of the abrupted placentas had liveborn babies; two had placenta previa and five had chorioamnionitis. Much of the effect of cocaine, at least during pregnancy, seems to be mediated through its known hypertensive and vasoconstrictive activity (Woods et al., 1987). A large retrospective study by Sprauve et al. (1997) showed that only decreased birth weight resulted when confounders were removed; abruptio was not increased. Specific effects on placental structure have not been reported, nor have they been present in our experience; moreover, the frequency of abruptio placentae is, in our experience, not as excessive as given in the many reports (Gilbert et al., 1990). The reported series of abruptio placentae that are a complication of cocaine exposure (occasionally remote exposure!) do not provide data on the pathologic examination of the pla-

centas. Thus, it cannot be ascertained whether the alleged abruptios are recent or old, and whether they are related to chorioamnionitis, as this is more frequent in these patients. A study by Miller et al. (1995) found a significant excess of abruptio, vaginal bleeding, marked growth restriction and premature rupture of membranes (PROMs). Moreover, there was a strong association with maternal smoking, which may have additive effects on lowering fetal weight. Chorioamnionitis, as discussed in Chapter 20, often causes marked deciduitis with bleeding and clots from that site that mimics abruptio, but it is a different mechanism. Therefore, we are still skeptical that cocaine exposure produces abruptio placentae often (Gilbert et al., 1990). Moreover, the vasculature that might be affected by the putative constriction of cocaine, the spiral arterioles, should be inviolate because of the structural change from trophoblast infiltration. However, there is no question of the increased frequency of fetal growth restriction. Little et al. (1989), who studied outcome in 53 cocaine abusers, found a significant increase only of prematurity and preeclampsia. There was also a slight increase of congenital heart disease, but in contrast to other studies they reviewed and that showed more abruptios, this was not found in their population. The authors suggested that it may be due to the fact that placentas are not routinely examined or are examined only when stillbirths occur. It must be admitted also, and was commented on by these investigators, that cocaine abuse is often combined with alcohol and other drug abuse and with maternal cigarette smoking; this has also been pointed out by Donvito (1988), Frank et al. (1988), Miller et al. (1995), and Ness et al. (1999). Moreover, the social makeup of the population may predispose to intrauterine infection. The vasoconstriction caused by these agents may be transmitted to the fetus, in whom cerebral infarction has occasionally been observed (Chasnoff et al., 1986). In a study of 75 pregnant women with cocaine use, the patterns of preterm delivery, growth restriction, and abruptio were affirmed, but the cause of abruptio was questioned (Chasnoff et al., 1989). When women stopped using cocaine after the first trimester, there was no reduction in the incidence of abruptio placentae. Fulroth et al. (1989) reported a significantly higher incidence (34%) of meconium staining when compared with that (10%) of a control population. The cardiovascular effect of cocaine injection has been studied in pregnant sheep by Moore et al. (1986). They found a rise of maternal arterial pressure (32% to 37%), combined with a 36% to 42% reduction of uterine blood flow, lasting 15 minutes after injection, at levels comparable to those seen with human usage. Fetal arterial pressure also rose to 12.6%. Chávez et al. (1989) reported that offspring of cocaine abusers suffer an increased risk of urinary tract anomalies, but that has not been our experience. Bailey (1997) found that cocaine is strongly bound to placental homogenates and sug-

gested that the placenta might serve as a reservoir for cocaine. Shiono et al. (1995) found few adverse effects from cocaine and **marijuana** usage during pregnancy and attributed most reduction of birth weight to cigarette smoking.

Effects on pregnancy somewhat similar to those seen with cocaine usage have been seen with maternal **heroin** abuse. Naeye et al. (1973) studied this complication of pregnancy in detail and found that 60% of these mothers had intrauterine infection (chorioamnionitis) as the principal finding. Also, there was frequent meconium staining of the fetus and placenta, and growth restriction.

**LSD** (lysergic acid diethylamide) administration during pregnancy is associated with an increased abortion rate (McGlothlin et al., 1970), but the placenta has not been described to be abnormal. The abortions and fetal damage have been inferred to be secondary to chromosome breakage (Warren et al., 1970). Later studies have negated this effect. An extensive investigation of drug-related injury on the placenta was undertaken by Freese (1978). He found that no consistent changes take place, and that any effect is one of direct action on the fetus, rather than on the placenta. Blanc et al. (1971) described a case of amniotic bands with amputations of digits in an LSD user. This finding prompted their review of six malformed infants born to LSD users and led them to caution that a causal relation may exist between LSD and amniotic bands.

**Smoking** during pregnancy has been the topic of numerous studies and many have yielded contradictory results. Two comprehensive, useful reviews were written by Werler (1997) and Page et al. (1997). Smoking is often considered to be the cause of an increased frequency of abortions (Kline et al., 1977), low birth weight, and some minor morphologic placental changes. A study of 7651 patients from California indicated that smokers' placentas had more calcifications and more subchorionic fibrin deposits (Christianson, 1979). This investigator found the placental weight not to be decreased, as did so many other authors. He likened the result to placentas of higher altitude and made reference to the self-selection of smokers and the difficulties inherent in ascertaining true alterations that might be due only to smoking. An early review of the topic (Editorial, 1968) suggested that the adverse effects may be mediated through reduced blood flow to placenta and fetus. When umbilical and uterine blood flow velocities were studied, the effect on fetal growth appeared to result from a highly significant rise in fetal placental vascular resistance (Morrow et al., 1988). Studies on isolated stem villous arteries shows them to be more responsive by constriction when exposed to endothelin-1 and other vasoactive peptides (Clausen et al., 1999). Other causes (hypoxia and cation changes) have also been held responsible. The data relating to reduction of birth weight, often considered as being

controversial, were reviewed by Murphy et al. (1977) and Alberman et al. (1977). Asmussen (1979) found fetal weight to be reduced by 325 g and the placenta by 123 g, similar to the later findings of Wen et al. (1990). The relative hypoxia was incriminated as a cause of significantly elevated fetal erythropoietin levels with maternal smoking (Jazayeri et al., 1998). In addition to growth restriction, Raymond and Mills (1993) found abruptio placentae significantly increased, as well as congenital heart disease. Studies of the endothelium obtained from umbilical arteries and vein showed widening of the basement membrane; in heavy smokers this change is said to have been visible even by light microscopy. Additionally, there were deposition of other materials, edema, reduction of the smooth endoplasmic reticulum of muscle cells, and loss of intercellular junctions between endothelial cells. Heavy smokers had marked dilatation of the rough endoplasmic reticulum. The microvillous surface of the syncytial cells was reduced, and there was a reduction in cytotrophoblastic elements. The villi had decreased vascularization and increased collagen content. The authors inferred that similar changes may take place in the vessels of the fetus. Wingerd et al. (1976) reported that the placental/fetal ratio was increased in smokers, presumably due to the reduced fetal weight. On the other hand, Teasdale and Ghislaine (1989), who undertook a careful quantitative morphometric study with appropriate controls, found only minor changes in the placenta. There was a "tendency for the placentas...to contain proportionally more nonparenchymal and less parenchymal tissue." The authors concluded that the effect of smoking was more related to ischemic or toxic effects of several compounds in tobacco smoke than to significant alterations in the functional structure of the placenta. This opinion was also voiced in an editorial (Anonymous, 1989b), whose author pleaded that "it is dishonest to say there is serious evidence that her fetus is at risk if she does not give up smoking." Jauniaux and Burton (1992), on the other hand, found that smokers developed increased mean thicknesses of the villous membrane and trophoblast. They believed that these changes may account for the biologic disturbances in gestation. Isaksen et al. (2004) reported a relation to trophoblast apoptosis. Horn et al. (1994) are the only authors to suggest that chorangiosis is a sequel of smoking (and of the fetal demise they reported). Unexpectedly, a huge study from the Swedish Medical Birth Register (Cnattingius et al., 1997) indicated that smoking reduces the incidence of toxemia of pregnancy. When it was found in smokers, however, then the perinatal mortality, abruptio placentae, and number of small-for-gestational-age (SGA) neonates were increased.

Naeye (1978) has reported an increased frequency of single umbilical artery (SUA) and abnormal cord insertions in the anomalous fetuses of smokers. Kuhnert et al. (1987a) showed that placental cadmium and zinc levels

were increased in smokers, with a 9% reduction in zinc levels of fetal red blood cells (and a decrease in fetal weight) (Kuhnert et al., 1987b). A significant reduction of umbilical arterial prostacyclin production was reported by Dadak et al. (1981) in the umbilical cords of smoking mothers. They likened this effect to a similar finding in women with preeclampsia and speculated that this potent vasodilator may be involved in growth restriction of the fetus. The immunohistologic study of Sanyal et al. (1993) indicated that smokers' placentas have an increased activity of hydrocarbon hydroxylase within the trophoblast, presumably stimulated by the toxins within the smoke. Rubin et al. (1986), as well as some other authors, have reported that significant passive smoking has a similar deleterious effect on fetal development. The difficulties of such correlation were examined by Chen et al. (1989), who conducted a study in Chinese women. They did not find that passive smoking posed a risk to the fetus.

A variety of ultrastructural observations were made on the umbilical blood vessels in smoking women's pregnancies. Thus Asmussen (1978) found the intima and media of the vein to be edematous, and the elastic membranes were partially destroyed. Fewer changes were identified in the umbilical arteries (Asmussen, 1982a); but in heavy smokers, scanning electron microscopy delineated more general changes (Bylock et al., 1979). Intercellular "holes" were seen in the intima that were interpreted to result from cellular injury, and Asmussen (1982b) found glycogen and lipid accumulation in the muscular wall cells. He also reported an increase of mitochondria in the endothelial cells of arteries of smoking mothers (Asmussen, 1984). In the villous basement membranes of such pregnancies, this author observed thickening and an increase in villous stromal collagen (Asmussen, 1980). Pinette et al. (1989) reported that the placentas of smoking mothers had increased maturation, as graded by sonographic scanning methodology. Pfarrer et al. (1999) also used scanning electron microscopy of freshly injected capillary beds of placentas from women who smoked more than 20 cigarettes daily. They found an increased capillary bed and increased branching of capillaries, presumably in response to smoking.

Additionally, there have been numerous investigations concerning the putative relation of abruptio placentae to smoking; most of these have suggested that a relation exists. It is troublesome, however, that very few of these studies have actually examined the placentas, that an increased frequency of premature rupture of membranes was also found, and that it is thus possible that chorioamnionitis may be the mechanism of possible so-called abruptio. Voigt et al. (1990) did a population-based case-control study of smoking and abruptio, using data from birth certificates, that endeavored to ascertain if smoking, abruptio, and SGA status were correlated. Importantly,

the placentas were not examined. An increased frequency of abruptio was found with smoking and an increase of SGA infants, but the latter was not correlated with smoking. These authors suggested that 38% of abruptios were "attributable to maternal smoking." Perhaps the first authors to suggest an increase of "accidental hemorrhage" (abruptio) with smoking were Andrews and McGarry (1972), whose paper is replete with a variety of tabular information. Goujard et al. (1975) opined that abruptios were perhaps due to "serious spasm, the release of which, by surge of blood, would cause arterial rupture." Their point is difficult to follow as the rate of stillbirth in smokers was much increased (250%) in their study population but the rate of abruptios was lower than in controls. In a later study (Goujard et al., 1978) the authors provided additional evidence for a relation to stillbirths and made further correlation with alcohol intake. But, as is true for most studies, the placentas were not studied for inflammation and the cause of true abruptio is thus difficult to evaluate. Meyer and Tonascia (1977) found a dose-related increase in abruptio, placenta previa, and premature rupture of membranes. Most of the abruptios occurred before 32 weeks' gestation, which leads us to consider that inflammation, rather than true retroplacental bleeding, may be the significant problem. The increase in placental ratio in smokers, studied by Wingerd et al. (1976), was found to be the result of lower fetal weights, rather than larger placentas. Naeye et al. (1977) reviewed the data from the Collaborative Study for the influence of smoking on placental/fetal development. They found an increase of abruptios, infarcts, and lighter placentas in smokers. All in all, there appears to be a large body of evidence to suggest that smoking has some deleterious effect upon placenta and fetal development, but that it is not a large one. Bernstein et al. (2000) opined from their study of growth-restricted infants of smoking mothers that the effect was most pronounced on abdominal circumference.

Few other **drugs** have shown well-recorded effects on placental structure, the notable exception being **methotrexate** (Li et al., 1956; Goldstein & Berkowitz, 1987) with its severe trophoblast toxicity. Severe fetal growth restriction occurred with a patient who attempted to cause abortion by taking much **aminopterin**; the placenta was not described (Shaw & Rees, 1980). Alkylating agents have been used successfully for the therapy of malignancies during pregnancy, and usually they have been attended without ill-effect. Lacher and Geller (1966) reported a successful gestation in a pregnant patient with Hodgkin's disease who was given therapeutic doses of cyclophosphamide and vinblastine. The placenta was not specifically mentioned. The size of the infant (3060 g) and its development, however, suggested that the placenta must have been normal. Hennessey and Rottino (1963) concluded from personal observations on 35 patients

with **Hodgkin's disease** complicating pregnancy that there was no need to interrupt the pregnancy. They did not describe the associated placentas. Knörr et al. (1969) found no abnormalities of placental structure after therapy with alkylating agents during pregnancy, and Nordlund et al. (1968) also found that pregnancy progresses without fetal toxicity. Nicholson (1968) reviewed the cytotoxic agents used during pregnancy. In the villi of a therapeutic abortion of an **epileptic** patient medicated with **diphenylhydantoin**, large clusters of lymphocytes were found in the fetal capillaries; it is unknown if this finding resulted from the lymphoproliferative effect of the drug (Greco et al., 1973), as the specimen did not contain an embryo.

**Irradiation** during pregnancy is usually avoided because of the deleterious effects it has on the fetus. In two gestations complicated by squamous cell carcinoma of the cervix, Driscoll et al. (1963) reported the effects of therapeutic irradiation on two fetuses, 16 and 22 weeks' gestational age. In the first, hydronephrosis was present, and the decidua showed foci of necrosis and inflammation, as well as necrosis of the amnion and chorion laeve. In the older fetus, scattered degenerative changes were observed, but the placenta was normal. Likewise, when rat placentas were irradiated with the fetus shielded, the exposure had no effect on fetal growth. Relative "radioresistance" of the gestationally older placenta was inferred from these experiments (see also Brent, 1960).

Whether treatment with the  $\beta$ -adrenergic blocking agent **propranolol** has an effect on placental development is uncertain. Fiddler (1974) described the pregnancy of a patient who had been taking 30mg of propranolol three times daily for 3 years for treatment of obstructive hypertrophic cardiomyopathy. The patient delivered a severely growth-restricted infant accompanied by a 200-g placenta. He quoted other authors who found no ill-effect from this medication and yet others who witnessed spontaneous abortions. Reduction of maternal cardiac output was speculated to have caused this fetal growth restriction, but the disease itself may also have been causative.

The consequences that maternal **heart disease** has on pregnancy have been the topic of many studies. Because of their complexity, the outcome of fetal growth and placental development is variable. Only one of five patients with aortic stenosis was reported to have fetal growth restriction (Easterling et al., 1988). McFaul et al. (1988) found no increased fetal mortality, growth restriction, or congenital anomalies among 519 pregnancies of 405 women treated for heart disease during pregnancy. Feraboli (1951) described placental infarcts and intervillous thromboses in six patients with "cardiopathy" and opined that the lesions are not specific but resulted from "slowing of the general circulation." He suggested that the fetal vessels were sclerosed, and that placental villous

fibrosis occurred. We have seen several placentas of patients with severe rheumatic cardiac disease, especially with mitral stenosis, in whose placentas there were large subchorionic intervillous thromboses. In some of them adjacent infarcts were present. Nuñez (1963) studied 15 placentas of women with cardiac disease properly classified according to New York Heart Association standards. He performed a quantitative assessment of villous structures and found the villous surface to be reduced, with simultaneous reduction of the fetal/maternal placental weight ratio. Because the villous capillary bed was expanded, Nuñez inferred that there was an expanded fetal blood volume. Kerber et al. (1968) found a normal placenta and normal-sized fetus with choanal atresia in a patient who was being treated with warfarin and heparin for a prosthetic mitral valve.

Pregnancy complicated by **hypercholesterolemia** resulted in an entirely normal placenta, despite fetal growth restriction (Barss et al., 1985). Cholesterol deposits were sought but not found. In **hypobetalipoproteinemia** also, a normal placenta was found (Parker et al., 1986). Numerous lipid-laden macrophages were present in the intervillous space of a patient with extreme **hyperlipemia** that complicated pregnancy (Nielsen et al., 1973). The foam cells measured up to 35 $\mu$ m in diameter and were concentrated at the maternal floor of the placenta. No foam cells were found within the placental villi. The infant delivered normally, had a birth weight of 3650g, and was normal. The placenta also had a normal gross appearance. The placenta of a patient with "well-controlled" **phenylketonuria**, provided by Dr. B.H. Landing, was entirely normal. In a case of **Gordon's syndrome** (short stature, defective dentition, hyperkalemic hyperchloremic acidosis, and chronic hypertension), Kirshon et al. (1987) reported normal fetal development and, it is assumed, a normal placenta. We have seen a patient with **Smith-Lemli-Opitz syndrome** whose pregnancy ended prematurely (courtesy of Dr. S. Sadowinski, Los Angeles). The placenta showed slight edema but had no other findings of note. As is regrettably so often the case, the placental findings were not documented in a case of **cystic fibrosis**, reported by Rosenow and Lee (1968). The infant developed normally. So did two term infants in a patient with **Wilson's disease**, but the placenta was not reported (Dreifuss & McKinney, 1966). Oga et al. (1993) reported on the birth of a child who had hepatomegaly from this maternal disease and continued to suffer abnormal liver function tests. The "maternal side of the placenta" had an increased copper content. Their illustration suggests that the copper is contained in the cytoplasm of the decidua basalis cells.

With **pruritus gravidarum**, the associated cholestasis is frequently accompanied by premature birth and fetal death; the placenta is commonly meconium-stained (Sasseville et al., 1981). The same authors discussed many

other dermatoses in pregnancy and reported that **impetigo herpetiformis** is associated with frequent stillbirths and “placental insufficiency.” With **papular dermatitis of pregnancy**, it has been suggested that the lesions are due to a “hypersensitivity reaction to an abnormal placenta.” High human chorionic gonadotropin (hCG) levels are believed to reflect this abnormality, but the evidence does not appear to be firm. Moreover, in subsequent pregnancies, this dermatologic disorder does not recur. **Pruritus** during pregnancy (of undefined etiology) was thought to be the cause of hyperplacentosis (placentas of more than 600 g) with increased hCG levels (Goodlin et al., 1985). This association, however, also seems ill-defined, and specific placental lesions were not reported. We have observed the placenta from a patient whose hCG levels were 260,000 IU in the last half of pregnancy; she had developed huge cystic follicles and elevated testosterone levels. Placenta and offspring were normal and the patient’s hCG titer fell rapidly. The reason for this elevated titers remained unexplained.

Several contributions have elucidated the pathology of **sarcoidosis** during pregnancy. This is a chronic granulomatous inflammation of systemic nature but life-limiting primarily because of pulmonary granulomatosis. The individual granulomas have a superficial similarity to tuberculosis but organisms have not been identified. Altchek et al. (1955) found uterine involvement by sarcoidosis granulomas and established that, despite active, widespread sarcoidosis, normal pregnancy may ensue. Dines and Banner (1967) and other authors they quoted found that the pulmonary complication of sarcoidosis may improve during pregnancy. From his review of 54 pregnancies, O’Leary (1968) was unable to agree. Kelemen and Mándi (1969) were the first authors to report typical sarcoid granulomas in the term placenta of a normal infant. Small, grossly visible granulomas were seen in the floor of that placenta. Boggess et al. (1995) found little ill-effect on pregnancies from restrictive maternal lung disease but did not observe placentas.

In maternal **cystinosis** that had much earlier been complicated by nephropathy and renal allografts at age 8, normal fetal development occurred. The maternal cells in the decidua capsularis had numerous vacuolated, cystine-containing cells. The placenta was normal (Reiss et al., 1988). **Cystinuria**, on the other hand, has occasionally been associated with mild fetal growth restriction. **Fetal cystinosis** may be diagnosed from placental specimens. Smith et al. (1989) found that homozygous cystinosis patients’ placentas had significantly elevated cystine content, as did fetal leukocytes; heterozygotes could not be clearly distinguished from normals. Maternal **hyperhomocysteinemia** is associated with intrauterine growth restriction (IUGR), thromboembolism, pregnancy-induced hypertension (PIH), and abortion. The placenta of seven such pregnancies showed nonspecific

changes, such as atherosclerosis, small placenta, thromboses, and accelerated maturation (Khong & Hague, 1997).

Maternal **Gaucher’s disease** (a storage disease due to enzyme deficiency; see Chapter 18) complicating pregnancy has been associated with hemorrhagic complications that resulted from thrombocytopenia. Houlton and Jackson (1978) described it to be due to extensive infiltration with foamy macrophages throughout the marrow spaces. In another case (Addleman & Gold, 1963) with good outcome, the placenta appeared grossly normal (Addleman, personal communication, 1963). Watov and de Sandre (1964) reported another four pregnancies, two of which resulted in placenta previa. The authors did not report the placental histology. These reports referred to other cases in the literature, but a definitive study of the placenta with maternal Gaucher’s disease has only recently come to our attention. It describes 43 patients (17 treated; 26 untreated) with 66 pregnancies and, additionally, it presents a complete overview of reported cases (Elstein et al., 2004). In general, treated patients had fewer abortions but more postpartum hemorrhage and infection; overall live birth rates were 78.3% in the treated and 86% in the untreated group.

Maternal **Niemann-Pick disease** (another genetic storage disorder) has been reported perhaps only once (Porter et al., 1997) and was not associated with placental or fetal disease. When the fetus suffers this disease, extensive placental lesions have been reported and are reviewed in Chapter 18.

**Pheochromocytoma** complicating pregnancy has serious implications for the fetus and mother. A review made in our department (Russo, personal communication, 1986) encountered 120 case reports with 45% fetal deaths, 12% abortions, and 25% maternal mortality. Thrombosis of the umbilical cord was found in one case (Fox et al., 1969) and abruptio placentae in four cases (Pestelek & Kapor, 1963). Most of the deaths could not be adequately explained. The disease is often mistaken for toxemia of pregnancy because of the hypertension and frequent albuminuria (Cannon, 1958). Cannon described several abortions that occurred in a patient with pheochromocytoma. Combs et al. (1989) found that there was a marked fall (40%) in cardiac output during paroxysmal attacks due to pheochromocytoma and suggested that it may compromise the fetus. Others have seen few complications with pregnancy, even with a recurrent pheochromocytoma (after adrenalectomy) (Sweeney & Katz, 1994). This tumor occurs as part of Sipple’s (multiple endocrinopathy) syndrome, which, absent this tumor, has no placental or pregnancy-related complications (Wax et al., 1997).

In a case of **fetal Letterer-Siwe’s disease** described by Ahnquist and Holyoke (1960), the placenta was entirely normal. The stillborn fetus had widespread involvement of reticuloendothelial cell proliferation with numerous

giant cells. The mother had been vaccinated against poliomyelitis and influenza during pregnancy, but the authors considered a causal relation unlikely.

## Hematologic Disorders

**Sickle cell anemia** occurs, with few exceptions, in Blacks. It is characterized by the presence of sickle-shaped red blood cells, which result from crystallization into “tactoids” of the abnormal hemoglobin S, particularly under conditions of reduced oxygen tension. Formalin fixation usually allows the microscopic identification of sickle cells in histologic sections (Fig. 19.2), and often NRBCs can be found in the intervillous space. Fujikura and Froehlich (1968) suggested that the hypoxia of postpartum placental separation induces sickling in the intervillous space. They examined 2117 placentas of black women and found sickling in 9.4%. They remarked that formalin fixation was superior for preservation; Bouin’s solution causes too much red blood cell lysis, and Zenker’s solution causes a reversal of the sickling phenomenon. No associated pathologic findings were reported in their large study. It has been our experience that placental infarcts are more common in maternal sickle cell disease; Pantanowitz et al. (2000) found a chorangioma with a normally grown infant and impressively showed the sickled red cells in the intervillous space.

The heterozygous condition (“trait”) of S hemoglobinopathy occurs with a frequency of 9% in the United States African-American population and is as high as 45% in central Africa. In infants with sickle cell thalassemia (hemoglobin SC disease), infarcts of the placenta have been reported (Bentsi-Enchill & Konotey-Ahulu, 1969).

Patients with the homozygous sickle cell disease have many serious problems. Urinary tract infection (45%), preeclampsia (25%), and puerperal sepsis (20%) are the main complications. In heterozygotes, these complications are significantly less frequent and less severe (Winston & Mastroianni, 1953). Whalley et al. (1963) found no difference in the outcome of pregnancy in heterozygotes when compared to controls. Platt (1971) found increased perinatal mortality, and Brown et al. (1972) observed lower birth weights. Fetal growth restriction was also a finding (21%) in the large study summarized by Smith et al. (1996). Mortality was not increased. They did not report on placentas. “Blister cells” (erythrocytes with vacuoles) were found in a patient with sickle cell disease who died after giving birth to a growth-restricted child (Krayalcin et al., 1972). Prophylactic transfusion reduces the frequency of painful crises but does not secure a beneficial pregnancy outcome (Koshy et al., 1988), presumably because the significant placental lesions have already been produced prior to this therapy.

The placentas of patients with hemoglobin SS disease may have “Tenney-Parker” changes, infarcts, increased fibrin, abruptio, and villous edema (Anderson et al., 1960; Shanklin, 1976; Koshy et al., 1988; Dunn et al., 1989). These placentas are relatively small, and the associated fetuses have growth restriction. Fox (1978) did not encounter those lesions; he reported that most of the changes are the histologic alterations of the intervillous red blood cells. A single pregnancy with hemoglobin SE disease has been reported, but the placenta was not described (Ramahi et al., 1988). The 2310-g neonate had hydrocephalus. Fujikura (personal communication, 1976) found that maternal sickle cells occasionally traverse the placenta to the fetal side. He indicated that in about half

FIGURE 19.2. Sickle-shaped red blood cells in the intervillous space of a patient with hemoglobin SS disease at term. The fetal capillaries contain normal red blood cells, with mostly fetal hemoglobin. H&E  $\times 640$ .

of the placentas examined sickle cells were found in aspirated cord blood; in addition, he identified occasional deported villi (Fig. 19.3) in this blood. Doubtless, it is a traumatic feature of delivery of the placenta and has no bearing on normal fetal life.

Mordel et al. (1989) reviewed the literature of pregnancy complicated by maternal  $\beta$ -thalassemia. Their patient was transfusion-dependent but delivered a normal term infant. They referred to other patients who suffered fetal growth restriction and abortion. A larger study by Aessopos et al. (1999) of well-treated patients with this disease showed little ill-effect from this hemoglobin defect. The placentas of both studies, however, were not described.

**Idiopathic thrombocytopenia (ITP)** is a rare complication of pregnancy. It carries with it the risk of postpartum hemorrhage and, less commonly, it has neonatal hemorrhagic complications (Jones et al., 1961; Payne et al., 1997). The latter may be a hazard when obtaining fetal scalp samples for the purpose of fetal pH determination. Cordocentesis has been practiced successfully in maternal thrombocytopenic states so as to assess the fetal platelet counts (Kaplan et al., 1990). That cordocentesis is not without risk, however, was detailed by Paidas et al. (1995) in their study of **fetal alloimmune thrombocytopenia** (Bussel et al., 1997). Fetal platelet counts were significantly depressed and exsanguination was observed after cordocentesis. We saw a similar event and one with complete obstruction and death of one artery. On rare occa-

sion the placenta has had intervillous thrombi in maternal thrombocytopenia, but most commonly the disease is not associated with placental lesions (Kaibara et al., 1985). In a few other cases, infarcts and decidual vascular lesions have been reported in the placenta (Scott, 1966; Mercer et al., 1988). It is not clear, however, whether they were caused by the ITP or were perhaps the result of preeclampsia and steroid therapy (Schenker & Polishuk, 1968).

**Thrombotic thrombocytopenic purpura (TTP)** during pregnancy has been described by Wurzel (1979). The pregnancy ended with a macerated fetus. The placenta showed many "hyaline thrombi" in the decidual arterioles that presumably caused the fetal death. Thrombotic thrombocytopenic purpura is a serious disease and carries a high mortality rate. Fewer than 70 cases have been described, according to Ambrose et al. (1985). Often the disease is mistaken for severe preeclampsia; perhaps some aspects of their clinical presentations are shared because of the similarity of their occlusive vascular lesions. In a case of maternal TTP we have seen fibrin deposits in decidual vessels, resembling atherosclerosis. An apparently normal placenta with an infant having no thrombocytopenia was described in the first report of **Evans syndrome** during pregnancy (Silverstein et al., 1966).

Neonatal thrombocytopenia has many causes, including the transfer of maternal **human leukocyte antigen (HLA) antibodies** (Sharon & Amar, 1981; Sørensen et al.,

FIGURE 19.3. Mature villi and sickle cells in aspirated blood from the umbilical cord. It is probably an artifact that occurred during the delivery of the placenta. H&E  $\times 150$ . (Courtesy of Dr. T. Fujikura.)

1982; Morales & Stroup, 1985), maternal **thiazide** administration (Rodriguez et al., 1964), and **alloimmunization** (Deaver et al., 1986). The latter condition has special dangers of fetal intracranial hemorrhage and is now being treated with prenatal platelet transfusions (Daffos et al., 1988; Mueller-Eckhardt et al., 1988). Despite these advances, the placenta remains usually unstudied or it was found to be normal.

Messer (1987) and Handin (1981) have reviewed **bleeding disorders** during pregnancy. **Leukoagglutinins** cause neonatal neutropenia but have no known effect on the placenta (Payne, 1964). Pregnancies complicated by **von Willebrand's disease** were reported by Leone et al. (1975) and Watanabe et al. (1997), but the placentas were not reported; the infants were normal and, with adequate therapy, the patients did well. A patient with **factor VII deficiency** was successfully treated by Fadel and Krauss (1989), whose main concern was possible abruptio. A retrospective study of pregnancy outcome of 32 patients with **hemorrhagic hereditary telangiectasia** showed a slightly higher frequency of abortions. The placentas were not reported (Goodman et al., 1967). **Protein C deficiency** during pregnancy was studied by Vogel et al. (1989). They reported no complications to have occurred. In a pedigree that contained 15 pregnancies no excess fetal loss but an increased incidence of thrombosis were observed (Trauscht-Van Horn et al., 1992). The effect of various **thrombophilic defects** (factor V Leiden, deficiency of antithrombin, protein C, protein S) upon fetal losses was studied by Preston et al. (1996). They found no increased losses when the father had the condition, and from the **factor V Leiden mutation**. Younis et al. (2000a,b, 2003; Sarig et al., 2002), however, found increased fetal losses in patients with "activated protein C resistance" (APCR), whereas Göpel et al. (2001) determined that successful in vitro fertilization (IVF) is increased when the factor V Leiden mutation is present. Lakasing et al. (1999) found no increase in poor pregnancy outcomes when the antiphospholipid syndrome exists in their immunocytochemical study of villi with antibodies to thrombomodulin and annexin V, similar to the retrospective review undertaken by Mooney et al. (2003), which correlated "cushions" and mural thromboses in the placentas of 72 cases of neonatal encephalopathy. Subsequently, these authors (McDonald et al., 2004) found neonatal encephalopathy to be related to fetal thromboses and, especially, to infection and meconium staining. To complicate matters, Infante-Rivard et al. (2002) found no relation to IUGR and thrombophilia and, in a large study of gene polymorphism and intrauterine fetal death (IUFD), Hefler et al. (2004) were adamant that "our data represent the largest study and... we challenge the importance of thrombophilia and vascular gene polymorphism in the pathogenesis of this condition." The problems of understanding these relations are also borne out by the

meta-analysis of 31 studies undertaken by Rey et al. (2003). They found that "exclusion of women with other pathologies that could explain fetal loss strengthened the association between factor V Leiden and recurrent fetal loss." Another meta-analysis was undertaken by Howley et al. (2005) from which they concluded that "factor V Leiden and prothrombin gene variant both confer an increased risk of giving birth to an intrauterine growth restricted infant, although this may be driven by small, poor-quality studies that demonstrated extreme associations. Large well-controlled prospective studies are required to determine definitively whether an association between thrombophilia and intrauterine growth restriction is present." Martinelli et al. (2000) saw tripling of late fetal losses when factor V Leiden and the prothrombin gene mutations were present and found 24% of placentas to be normal, and in the remainder were thrombi, decidual vascular lesions, necrosis, and infarcts. We have also found thrombi, decidual vascular lesions, chronic deciduitis, infarcts, and increased perivillous fibrin in placentas of mothers with various thrombophilias (Baergen et al., 2001). An interesting report of three pregnancy losses with thrombophilia comes from Heller et al. (2003). They found large subchorionic hematomas as the cause of fetal demises and suggested that this was the result of increased maternal coagulability. It is especially relevant because these subchorionic hematomas are otherwise relatively uncommon but are observed now sonographically. The lesion is occasionally described as a Breus' mole and has been associated primarily with chromosomal errors, but that may need to be reconsidered, as the accumulated blood has now been shown to be definitely of maternal origin (Wright et al., 1999). Thus, there are still outstanding issues to be understood for a conclusive interpretation of various types of thrombophilia and their effect on gestational success. When the **fetus** has evidence of thrombophilic mutations, no placental lesions or thromboses were found (Ariel et al., 2004).

Other conditions, especially when combining as thrombophilia, elevated the fetal loss rate in the study by Preston et al. (1996). Regrettably, there is no report on the placentas of the study population. Greer (1999) indicated that thrombosis in pregnancy has much increased in England and reviewed the fetal and maternal consequences. The single commonest cause of deep vein thrombosis is activated protein C resistance (APCR), due to a point mutation in the factor V gene and referred to as "factor V Leiden" (Ridker et al., 1995). There has been much interest in this mutation, and the worldwide distribution has been assessed by Rees et al. (1995). The allele frequency is highest in Europeans (especially Greeks), while it is absent from many non-European populations. Several groups (Gratton et al., 1997; Walker et al., 1997) have warned that activated protein C resistance (factor V Leiden) rises in pregnancy and that falsely high levels

may be misinterpreted. Because of reduced intervillous flow and increased fibrin deposition, so hypothesize Dizon-Townson et al. (1996), there is a significant increase in the predisposition to preeclampsia in women with factor V Leiden. Dizon-Townson et al. (1997) reported a significantly higher Leiden carriage with occurrence of repeat abortion, and even more increase in the fetal side of the placenta when numerous infarcts were present (see also Wiener-Megnagi et al., 1998; Kupferminc et al., 1999). Pauer et al. (1998), however, found no such correlation in their material. From the fetal vantage point, Goodwin et al. (1995) found that even heterozygous protein C deficiency can lead to serious peripartum thrombosis in the fetus. Thus, a somewhat different outcome may occur in fetal protein C deficiency (and protein S deficiency); they are discussed in Chapter 12 (see Thromboses of the Fetal Circulation). The histologic features of placental specimens with thrombophilias were recently presented by Horn et al. (2004) and Baergen et al. (2001). These reports provide an overview of the lesions identified (infarcts, decidual necrosis, inflammation, thrombosis) and suggest that the features are nonspecific and “may not differentiate between women with antiphospholipid syndrome and antiphospholipid-like syndromes.” Alonso et al. (2002) considered thrombophilias to be important causes of fetal losses in a Spanish population and drew special attention to the frequency of placental infarcts, whereas McCowan et al. (2003) did not consider these conditions as being responsible for IUGR gestations. An excellent review of all aspects of the pathophysiology of the antiphospholipid syndrome may be found in Levine et al. (2002). It includes features to be found with therapeutic measures. We conclude from this array of conflicting reports that much additional information is needed before firm conclusions can be drawn as to the direct effects of the various types of thrombophilia on placental structure and fetal outcome.

Milo et al. (1989) reported on a patient with acute intermittent **porphyria** during pregnancy believed to be secondary to the antiemetic drug metoclopramide. When the drug was discontinued, the symptoms disappeared and a normal infant was delivered. We saw a case of alleged porphyria developing during pregnancy that, after examination of the placenta, was shown to be due to acute cytomegalovirus infection.

**Folate deficiency** has been incriminated in many complications of pregnancy, including abortion, abruptio placentae, and other diseases (Streiff & Little, 1967; Hibbard & Hibbard, 1968). In two large studies of women with folic acid deficiency severe enough to cause megaloblastic anemia in the mother, no measurable effect on fetal well-being or placentation was observed (Kitay, 1968; Pritchard et al., 1970).

Beischer et al. (1970) evaluated the effect of **anemia** on pregnancy and the placenta. They prospectively studied a

large number of placentas that were obtained from different localities. The investigators found that severe maternal anemia caused highly significant placental enlargement. In their interpretation, the “anemia causes inadequate oxygenation of the fetoplacental unit, which in turn, in a proportion of patients, evokes a physiological response which results in compensatory placental hypertrophy.” Some placentas weighed in excess of 700 g. We have seen, however, placentas of severely anemic patients, with hemoglobin values of 4 g/dL, that were small and had pronounced “Tenney-Parker changes,” that is, increased knotting of the syncytium. An enlargement of placentas and an increased placental ratio were confirmed in mild maternal iron-deficiency anemia and thalassemia trait by Lao and Wong (1997). Enlargement was largely dependent on maternal hemoglobin concentration and it correlated with gestational age. In an histomorphometric study of placentas in women with iron-deficiency anemia, Reshetnikova et al. (1995) found no placentomegaly. In fact, they found a reduction in size of the villous tree, with thinning of the diffusion membrane. To explain the difference of their finding from that reported in the literature (enlargement), the authors suggested that simultaneously existing malnutrition may be the answer, as it is nearly always associated with severe anemia.

The finding of placental hypertrophy with anemia has raised the question as to what changes may be observed in placentas of chronic oxygen deficiency at **high altitude**. Metcalfe et al. (1966) have summarized the adaptation of the pregnant organism to the rarified atmosphere; placental changes were not then identified with certainty. Alzamora (1958), on the other hand, has reported that the placenta at high altitude is considerably larger than normal. This point is of particular interest, in relation to the important studies carried out by Tominaga and Page (1966). These investigators experimentally studied placental effects of oxygen deprivation. They exposed explanted human placental tissue to low and high oxygen tension in vitro, and found that low oxygen exposure led to increased syncytial “knotting” (the Tenney-Parker change of preeclampsia). Contrary to the findings of later investigators (Ong & Burton, 1991), they found a reversibility of this phenomenon. This trophoblastic change was believed to cause thinning of the exchange membrane and was thus considered to enhance oxygen transfer to the fetus. Quantitative studies on the effect of high altitude on the placenta were carried out by Jackson et al. (1987, 1988) and their results are quite different. They also reviewed the relevant literature and found that infants at high altitude were smaller, but that the placental weight was not enlarged (at 3600 m in Bolivia). There was, however, a histologic (measured and quantitated) alteration in the disposition of villous capillaries. Mean villous length was reduced at high altitude, whereas villous capillaries were thinner and cross sections of

capillaries more numerous. This effect (presumably due to chronic hypoxia) led to an altered capillary/villous ratio at high altitude in these Bolivian samples. The capillaries were also more closely applied to the trophoblastic surface than is the case at sea level. This finding was particularly evident in the histometric study of Reshetnikova et al. (1996). These investigators found a significantly larger capillary volume in placentas of high altitude; the findings were at times similar to chorangioma, presumably representing chorangiosis (see Chapter 24). Kaufmann et al. (1993) reviewed this topic in some detail and suggested that a first effect of hypoxia is an effect on cytotrophoblast with its proliferation, to be followed by syncytiogenesis ("knots"). They suggested that various cytokines of yet undetermined nature and sequence affect the connective tissue of the villi (perhaps Hofbauer cells) to mediate these effects.

## Endocrine Disorders

**Thyroid diseases** have no direct known impact on placental structure and function but many thyroid disorders enhance the probability of preeclampsia. Placental infarcts and abruptio are thus found more commonly than normal. Scott (1966) stated that hyperthyroidism is not infrequent during pregnancy and mentioned that hydramnios occasionally complicates such pregnancies. Davis et al. (1989) found an incidence of hyperthyroidism of one per 2000 deliveries. Vulsmä et al. (1989) suggested that substantial amounts of maternal thyroxine may be transferred to the fetus; however, Bachrach and Burrows (1989) provided evidence that the amounts transferred in fact may be much smaller than was suggested. Infants of hyperthyroid patients may be growth-restricted or hyperthyroid (Elsas et al., 1967; Cove & Johnson, 1985). They also more frequently have prenatal distress, meconium staining, and fetal demise (Page et al., 1988). These authors encountered chronic villitis in one of their perinatal deaths, but it probably bears no relation to the maternal hyperthyroidism. Diabetes is also more frequent in hyperthyroid patients during pregnancy (Bruner et al., 1988). All aspects of the physiology of thyroid metabolism and thyroid diseases are well reviewed elsewhere (American College of Obstetricians and Gynecologists, 1993). Hydrops fetalis has been reported in a number of patients with treated Graves' disease (Watson & Fiegen, 1995). Apparently maternal immunoglobulin G (IgG) thyroid antibodies are transmitted transplacentally, induce fetal hyperthyroidism and tachycardia (see Chapter 16). The placental physiology of iodine and thyroxine handling is discussed by Burrow et al. (1994).

Untreated hypothyroidism renders most patients anovulatory. It is therefore not often encountered as a complication of pregnancy. Davis et al. (1988) reviewed

14 pregnancies in overtly hypothyroid patients. Anemia (31%), toxemia (44%), abruptio (19%), and postpartum hemorrhage (19%) were found. Fetal death occurred in 12% and growth restriction in 31%. The frequent abortions, congenital anomalies, and maternal infertility associated with hypothyroid states were discussed in some detail by Hoet et al. (1960). When pregnancy is complicated by **Sipple's syndrome**, the outcome is good, so long as pheochromocytoma has not occurred (Wax et al., 1997).

**Cushing's disease** rarely complicates pregnancy. Grimes et al. (1973) adequately reviewed the literature of 26 reported pregnancies that resulted in only 11 term births. There were four abortions and four stillbirths; premature deliveries made up the remainder. The placentas of these pregnancies were not reported. Likewise, Aron et al. (1990), in an extensive review of complications of this disease, failed to indicate if placental pathologic features are seen. These authors, as well as Buescher et al. (1992) suggested that the adrenocorticotrophic hormone (ACTH)-like material from the placenta and its corticotropin-releasing hormone-like compound may exacerbate the clinical state of Cushing's disease during pregnancy. Occasionally, Cushing's disease has its onset during pregnancy and disappears after its termination. Wieland et al. (1971) reported such a case and referred to others in the literature. Upon termination of pregnancy during the 14th week, their patient improved remarkably. Normal placental tissue was obtained.

**Diabetes insipidus** is also a most uncommon disease during pregnancy. Hanson and colleagues (1997) have reported such a patient who presented with the classic symptoms of the disease and severe oligohydramnios. Treatment with desmopressin acetate promptly relieved symptoms and oligohydramnios; the disease was assumed to be a congenital hypoplasia of the posterior pituitary. The placenta was not described.

**Zollinger-Ellison syndrome** is compatible with normal fetal development and represents a rare complication of pregnancy (Harper et al., 1995). Apparently no adverse influence on the placenta takes place.

## Diabetes Mellitus During Pregnancy

Abnormalities of glucose metabolism, such as gestational and overt insulin-dependent diabetes, are among the commonest medical complications of pregnancy. These conditions cause increased fetal wastage such as abortion, prematurity, macrosomia, and some types of congenital anomalies (Cheung et al., 1990; White & Beischer, 1990). A comprehensive review of these complications with a classification of the disease is to be found in Viscarello et al. (1993). The consequences of maternal diabetes for the placenta are reviewed in detail by Desoye and Shafrir

FIGURE 19.4. Plethoric, thick, and somewhat edematous placenta of a patient with treated class A diabetes.

(1964, 1996). Susa et al. (1984) were able to mimic most of the fetal consequences of maternal diabetes in rhesus monkeys fetuses infused with excess amounts of insulin.

The placenta of women with diabetes is often severely abnormal (Singer, 1984). The results of placental investigations, however, must be considered with caution as they are subject to many variations, mostly the degree of diabetic control during gestation. There have been dramatic changes in the management of maternal diabetes and in surveillance for gestational diabetes over the years. Thus, the results of older placental studies are not necessarily expected to be found currently. Also, because of the high fetal mortality during the last 2 weeks of pregnancy, most pregnant diabetic patients are now delivered before term, which perhaps helps explain why most diabetic mothers' placentas are not so calcified in current observations; older publications state that diabetic mothers' placentas showed increasing amounts of calcium deposits. We have the impression, however, that the usual

calcifications in the floor of the placenta and in the septa are decreased in diabetics' placentas. Perhaps for the same reasons we see these placentas to be less frequently meconium stained. Haust (1981) provided a comprehensive review of diabetic pregnancies, fetal outcome, anomalies, and placental changes. It is thoroughly referenced and illustrated, and contains a large section on placental changes in maternal diabetes. In particular, there is a detailed consideration of the ultrastructural pathology of the associated placenta.

The placenta of most poorly controlled diabetics is enlarged, thick, and plethoric (Fig. 19.4), which are generally thought to be manifestations of fetal hypervolemia and maternal hyperglycemia. The hypervolemia is also reflected in the considerably higher residual blood volume of the delivered placenta (Kjeldsen & Pedersen, 1967; Klebe & Ingomar, 1974a,b). An altered fetal cardiac activity and blood flow were observed sonographically by Rizzo et al. (1995) and may result from fetal cardiac hypertrophy. When diabetes is well controlled during pregnancy, the placental weight does not deviate from that of normal organs (Clarson et al., 1989) and the villous structure is normal (Fox, 1978). By contrast, in other cases the villous structure of the placenta in maternal diabetes may be focally "dysmature" or relatively immature-appearing; increased numbers of villous trophoblast cells, pointing to increased incidence of trophoblast proliferation, may be observed (Fox, 1997). An increased frequency of cytotrophoblastic mitoses may be observed. These placentas are also sometimes edematous, and their appearance has occasionally been likened to that of placentas from erythroblastotic pregnancies (Maqueo et al., 1965), although the fetuses lack the anemia. Maqueo et al. also observed a high frequency of preeclampsia in this population, which is not our observation. There is frequently some degree of chorangiosis in the placentas of diabetic patients (Figs. 19.5 and 19.6). In the offspring,

FIGURE 19.5. Focal immaturity and villous edema of the placenta in class A diabetic mother. Note the large Hofbauer cells in the edematous villus. H&E  $\times 160$ .

FIGURE 19.6. Placenta of a diabetic mother with marked plethora and chorangiosis. H&E  $\times 160$ .

there is a slight increase in the frequency of single umbilical artery (3% to 5% in diabetic progeny compared to a ~1% average incidence; Driscoll, 1965). This is particularly so in gestations that were complicated by acidosis (Emmrich et al., 1974). When the pregnancy is complicated by nephropathy (class F diabetes), fetal growth restriction and placental infarcts may be found with increased frequency. Infarcts are otherwise uncommon in diabetic mothers' placentas. It is our opinion that none of these changes is specific for maternal diabetes and that they reflect primarily the altered glucose availability and fetal adjustments to the intermittent excessive glucose load. Perhaps most characteristic of diabetes is the greater probability of fetal and placental vascular thrombosis. This problem is occasionally reflected in fetal renal and adrenal vein thrombosis, and it may also be the cause of thromboses in the fetal placental surface and mainstem vessels. The umbilical cord is usually more "edematous" or, more accurately, it contains more Wharton's jelly. Since Mvumbi et al. (1996) observed that the midportion of umbilical cords contains normally the highest glycogen content (in the fibrocytes), one may speculate that the thicker cords are related to that storage, but it has not been studied. No specific placental anomalies are associated with the one highly characteristic fetal anomaly of maternal diabetes, sacral agenesis (the so-called caudal regression syndrome). Not all cases of this anomaly, however, are the result of maternal diabetes; some may have an environmental toxic heritage (Rojansky et al., 2002). Salafia and Silberman (1989) made the point that funisitis is common in diabetic pregnancies and that it is correlated with irregular fetal heart rate patterns. The placentas they studied were also heavier.

There is no longer doubt that the placenta possesses specific insulin-binding receptors (Haour & Bertrand, 1974), and that these receptors are reduced in number in placentas of SGA babies (Potau et al., 1981). By contrast, in insulin-treated diabetes, but not when treated with diet alone, more insulin receptors were found on the maternal surface of the placental villi, that is, the trophoblast plasma membrane; this was verified also in isolated trophoblast preparations (Desoye et al., 1992). It is unclear whether the increased number of receptors is elicited by insulin-treatment of the mothers, or whether they are a response to other factors in the circulation that are altered on diabetes. The consequences of the greater receptor density on the trophoblast are also unknown, because no clear-cut effect of insulin on the placenta has been identified yet. At present it remains an open question whether or not the expression of insulin receptors located at the surface facing the fetal circulation, that is, the endothelium (Desoye et al., 1994), shows respective changes in maternal diabetes mellitus. Despite earlier assertions that transplacental insulin traffic occurs (Gitlin et al., 1965), it is now clear that insulin does not normally pass the placenta in quantities sufficient to have a metabolic effect (Adam et al., 1969; Wolf et al., 1969; Kalhan et al., 1975). There is, however, antibody-bound insulin transferred in significant quantities and this correlates with fetal macrosomia (Menon et al., 1990). This suggested to the authors that immunogenic insulin should not be used in pregnancy, a recommendation that meanwhile is followed in nearly all civilized countries. Another interpretation of the data was provided by Kimmerle and Chantelau (1991). Glucose passes the placenta readily, and the fetus responds to hyperglycemia with hyperplasia of the islets of Langerhans (Driscoll, 1965) and increased insulin secretion (Jørgensen et al., 1966; Thomas et al., 1967), the primary reason for fetal overweight in maternal diabetes. The hyperplastic islets contain an increased amount of insulin (Steinke & Driscoll, 1965). Periodic hyperglycemia was thought to be the cause of fetal polyuria and hydramnios. That this assertion is probably an oversimplification has been demonstrated by the ultrasonographic study of fetal urination in the presence of diabetes-induced hydramnios (Wladimiroff et al., 1975).

A paradoxical finding is the increased deposition of glycogen in the placenta of diabetics (Desoye et al., 1992), whereas in all other organs diabetes results in a decreased glycogen content. Robb and Hytten (1976) have rigorously studied placental glycogen content throughout gestation and in maternal diabetes. They found that glycogen concentrations normally decrease toward term, when it was around 1.5 mg/g of blood-free placental tissue. There were no significant changes when diabetic mothers' placentas were compared with those of normal pregnancies (for review see Shafir & Barash, 1991) or those from

toxemic gestations (see also Fischer & Horky, 1966). Thus, the larger size of the placenta is not attributable to glycogen storage, but the results of Mvumbi et al. (1996) should be considered before definitive conclusions are drawn. Most of the large fetal size is due to obesity. A valuable test to ascertain maternal hyperglycemia during pregnancy is the concentration of glycohemoglobin in maternal blood. It adequately reflects the degree of maternal control, and higher concentrations significantly correlate with abortions in diabetics (Miodovnik et al., 1985). When strict control is exercised, pregnant diabetics are no more liable to lose a pregnancy than normal women, and they have normal amounts of glycosylated hemoglobin in their circulation (Mills et al., 1988). In pregnancies complicated by maternal diabetes, there is also much enhanced secretion of hCG by the placenta, as reflected in blood and amniotic fluid levels. Elkind-Hirsch and colleagues (1989) have found that the placenta of diabetics contains more gonadotropin-releasing hormone than do normal placentas. The hCG concentration, on the other hand, was not elevated. Greco et al. (1989) asserted from their immunocytochemical studies of proteins in diabetic placentas that  $\beta$ -hCG staining was increased, while other proteins (PLAP, SP1, and hPL) were decreased. It must be cautioned that the evaluation of these staining reactions is subjective and visual only. Moreover, the endocrine data are very likely to depend on the control of the diabetes, as does the villous structure.

Thomsen and Lieschke (1958) were among the earliest investigators to study the placental structure in maternal diabetics. They found increased weight, plethora, calcifications, and "villous regenerations." The latter manifests as "immaturity" of the villi, more abundant and obvious cytotrophoblastic investment of villi, and villous edema. These nonspecific changes were found randomly distributed throughout the placenta. Burstein et al. (1963) claimed that major fetal vessels of the placenta have insulin bound to their walls. They studied diabetic placentas using insulin antibodies and fluorescence microscopy. They observed that placentas from diabetics had increased knotting of the syncytium. Aladjem (1967a,b) examined villi with phase contrast microscopy and found no specific changes in diabetes, although many minor placental alterations were described. Vogel (1967), on the other hand, believed that he found changes that he considered to be so characteristic that he coined the term **plakopathia diabetica**. This condition consists of persistent embryonic villi, discordant maturation of villous structure, disorders of villous ramification, and chorangiosis. Decreases in collagen content and mucopolysaccharides in diabetic mothers' placentas were found by Liebhardt (1968). We also believe that collagen content is much decreased, as these placentas are remarkably friable. The basement membrane may be thicker in diabetes as compared to normal pregnancies, probably because of a higher degree of nonenzymatic glycosylation (Ilioka et al., 1987) or due to an increased amount of the most prominent type of basal lamina collagen, that is, type IV (Laureti et al., 1982; Leushner et al., 1986). Greater contents of DNA, triglycerides, phospholipids, and cholesterol are also characteristic features of the placenta in diabetes (for review see Desoye & Shafir, 1996).

Winick and Noble (1967) observed that an increase in the number of normal-sized cells caused increased placental size. In the study of 48 placentas from diabetic mothers, Fox (1969) observed some abnor-

malities of villous maturation, as well as "obliterative endarteritis of fetal stem arteries," thickening of trophoblast membrane, and an increase in villous fibrinoid necrosis. He speculated that these changes may result from "an immunologic reaction." Thickening of stem arterial walls was shown by Samaan et al. (1974); they correlated it with the degree of the diabetic metabolic disturbance. Jácomo et al. (1976) described similar vascular changes and attempted to quantitate them. In our experience quantitation is a difficult endeavor, and to evaluate villous vessels without establishing some rigid criteria for measurement produces problematic results. Thus we do not believe that they are "real" changes, and most certainly none is specific for maternal diabetes. If they were real, they could be related only to fetal hypervolemia, perhaps to a higher fetal blood pressure.

Differences of opinion and interpretation, reflected in a voluminous literature on the placenta of diabetic pregnancies, have been reviewed by Teasdale (1981, 1983, 1984), who studied, with carefully controlled quantitative tools, the histomorphometry of placentas of diabetics from classes A, B, and C, classified according to White (1978). Teasdale's principal findings were that the placental exchange membrane (fetal vascular and villous surfaces) increases with maternal diabetes, but that few other significant changes (other than enlargement) could be detected.

Somewhat similar findings of an increased surface membrane for exchange were observed with planimetry by Björk and Persson (1984). These investigators paid particular attention to the taking of samples from similar areas of the placenta, as the villous structure differs so much in the center of a cotyledon from that at its periphery. This normally orderly organization of the cotyledonary structure was found to be somewhat disrupted in diabetic mothers' placentas. Driscoll (1965) found that the weight increase of placentas from class F diabetics was smaller than that from nondiabetics. This difference of class A to C from class F placentas is mostly subject to the influence of maternal renal disease. Driscoll also observed that the decidua is often unusually thick, and with preeclampsia and hypertension the decidual vessels show characteristic arteriolar angiopathy (see also Horky, 1968). Parenthetically, it may be mentioned that the placentas of experimentally induced diabetes in rats share the enlarged size with the human counterpart (Pitkin et al., 1971). In addition, Padmanabhan et al. (1988) found cystic degeneration in the labyrinthine area. They interpreted it to result from glycogen depletion and coalescence of cellular degenerations. Both investigators observed preservation of normal architecture when insulin therapy was instituted. The cystic degenerations occurred even in the placentas of spontaneously diabetic BB-Wistar rats (Brownschidele & Davis, 1981).

A number of electron-microscopic studies have been undertaken to gain a better understanding of the morphologic alterations of diabetic mothers' placentas. Okudaira et al. (1966) found no specific changes in these placentas. Minor, irregular degenerative changes were recorded, such as mitochondrial and endoplasmic reticulum degeneration in the syncytial cells. Some thickening of the basement membranes was observed, but it was not uniform. Widmaier (1970) added the finding of persistence of a nearly complete Langhans' cytotrophoblastic layer. Jones and Fox (1976) were more emphatic about ultrastructural changes in placentas of diabetics. Although they investigated mainly gestational diabetes, these investigators described patchy syncytial necrosis, dilated rough endoplasmic reticulum, cytotrophoblastic hyperplasia, focal thickening of basement membranes, and narrowing of small vessels. Others had reported dilatation of capillaries to be a prominent finding. Jones and Fox (1976) suggested that the changes they observed may occur only patchily, and that they were similar to those of overt diabetes. Interestingly, at the ultrastructural level in diabetes, glycogen deposits greater than normal were found in the endothelium of placental capillaries in diabetes (Jones & Desoye, 1993). Laurini et al. (1984) reported that, despite strict control of diabetes during pregnancy, ultrastructural changes in the placenta—"blebs," thickened basement membranes, endothelial proliferation, and

increased collagen content—continue to persist. Their deduction was that the commonest pathologic feature is “dysmaturity,” defined as relative immaturity of the placenta. Kaufmann and Stark (1977) also reported that characteristic placental alterations occur in maternal diabetes. During cesarean section, they obtained biopsies of the placenta for electron microscopy. In these tissues they observed the following characteristic features: 75-Å-thick intratrophoblastic filaments, an abundance of smooth endoplasmic reticulum, and collapsed mitochondria in relatively edematous cells. Thus, there is good evidence that the placenta, in a somewhat variable fashion, undergoes some minor morphologic alterations in response to maternal diabetes. The significance of these findings remains uncertain, especially vis-à-vis their relation to the altered physiologic states experienced by mothers and infants affected by this condition.

Congenital, hereditary **fructose intolerance** during pregnancy was studied by Marks et al. (1989), who also discussed the difficult management of such patients. Two children succumbed neonatally, and the most recent pregnancy was associated with a livebirth and a “calcified placenta.”

## Maternal Neoplasms

Many maternal neoplasms have complicated pregnancy and some have caused placental disease. Pulitzer et al. (1985) have even reported that, on rare occasion, implantation takes place upon endometrial adenocarcinoma; there was no associated placental development, however. Implantation over leiomyomas caused abruptio placentae in 57% of cases observed by Rice et al. (1989). We have seen placenta accreta in such locations. Carcinoma of the breast and cervix, gastrointestinal neoplasms, and melanoma has occurred during pregnancy, in that order of frequency (Donegan, 1963). Delerive et al. (1989) reported the metastasis of a pulmonary oat cell carcinoma to the placenta. In their review they found that 39% of the 38 cases of placental metastases reported were of melanoma. The tumor of their case lay free in the intervillous space and had not invaded the villi; the neonate was free of disease. Macroscopically, the placenta was entirely normal. In our experience, metastasis to the fetus is rare. Although metastases of several cancers and lymphomas have been found in the placenta, and in leukemias the intervillous space may be filled with leukemic cells, few neoplasms have traversed the placental “barrier” and seeded to the fetus. This is well described in the report by Lentz et al. (1998). In their maternal lymphoma case, the intervillous space was crowded with malignant cells, but the villi were devoid of these cells. Conversely, the fetal circulation was crowded with malignant cells in a fetal proliferative disorder, not the intervillous space. Only Barth et al. (1972) and Pollack et al. (1982) have reported rapidly fatal fetal disease, transferred from maternal lymphoproliferative disorders, assuming that the fetal immune incompetence allowed

proliferation of the cells. Since then a few other reports have shown that maternal tumor cells can travel to the fetus through the placenta. Catlin et al. (1999) reported the transplacental transmission of a natural killer (NK) cell lymphoma. It caused neonatal demise in 2 months and was not “rejected” by the neonate presumably because of similarity of HLA markers. There were tumor cells in the decidua of the placental specimen, and, by special techniques (only), some tumor cells were later shown to exist in villous capillaries. No obvious neoplastic cells were evident in the placental examination. In addition, a metastatic B-cell lymphoma arising in the mother and filling the intervillous space has been described by Maruko et al. (2004). In this case, the neoplasm infiltrated the villi in a major fashion, disseminated into the fetus and eventually caused its neonatal demise.

The most important of these neoplasms is **malignant melanoma**. A melanoma metastasis was described and well illustrated by Holland (1949); Reynolds (1955) also found a placental metastasis of another malignant melanoma. The placenta appeared grossly normal but contained many microscopic amelanotic nodules. The infant remained normal for at least 10 months. George et al. (1960) reviewed 115 cases of melanoma that complicated pregnancy. They found two cases with placental metastases; all of the infants remained normal. The difficulty cells have in traversing the placenta was studied experimentally. Working with experimental melanoma cell lines, Retik et al. (1962) were able to induce widespread maternal metastases, but the placenta and fetuses remained free of tumor. Cavell (1963) identified melanoma metastases in an infant of 2 months. Apparently, the infant had acquired the metastases transplacentally from the mother, but they disappeared spontaneously. The placenta was described as having been scarred and infarcted, but it did not undergo microscopic study. Aronson (1963) observed a muscular swelling that contained melanin pigment in an infant whose mother died from melanoma 4 days after parturition. Those lesions also disappeared spontaneously. Another case of transplacental metastatic melanoma was described by Brodsky et al. (1965). In umbilical cord blood, cells were identified that were consistent with melanoma, and many placental intervillous spaces were filled with melanoma cells. The maternal surface of the placenta appeared brown, with “rare foci of black pigmentation.” Both mother and infant died with widespread metastases.

Heite and Kaden (1972) collected 27 cases of metastatic placental cancer, three of which were placental melanoma metastases, of which two metastasized to the fetus. A case of metastatic amelanotic melanoma in the placenta, the ninth reported melanoma of the placenta, was published by Sokol et al. (1976). These authors found that 28 cases of metastatic cancer in the placenta had been reported, five of which had involved the fetus. Their

patient had undergone a cesarean section at 31 weeks. She died with widespread tumor 8 days postpartum. The neonate, who died from respiratory disease, had no tumor. Multiple firm nodules, 0.5 cm in diameter, were found in the villous tissue. They were composed of cells that contained melanin and were similar to the maternal tumor cells. The placental villi were focally invaded by the neoplasm.

The placental melanoma metastasis shown in Figure 19.7 was as described in a patient by Freedman and McMahon (1960). Despite villous infiltration with melanophages and some tumor cells, no fetal metastases were found, nor did the infant have melanuria. Widespread placental metastases from a maternal melanoma were found by Stephenson et al. (1971). The infant developed hepatomegaly, but metastatic tumor was never found. Melanoma metastases in the placenta were identified immunohistochemically with the S-100 protein probe by Machin (1987). The infant was growth-restricted but had no evidence of tumor. A maternal melanoma was first diagnosed by placental metastases in the case described by Anderson et al. (1989). The tumor was metastatic to the intervillous space and present in villi; the infant remained normal, but the mother died 6 months after delivery. The authors suggested in their review of 16 cases that a more unfavorable prognosis exists when the maternal age is under 30, when the tumor is present in the lower extremity, and when the neoplastic disease commenced during the 3 years before the affected pregnancy. They asserted that the extent of villous involvement had no influence on prognosis.

FIGURE 19.7. Term placenta with malignant melanoma metastasis. Pigmented tumor cell invade the villous tissue, and many pigmented Hofbauer cells are present. H&E  $\times 160$ .

Placental metastases from an ocular choroidal melanoma were described by Marsh and Chu (1996). The only microscopically discovered pigmented tumor cells were found in the intervillous space and had not invaded villi; the neonate was free of tumor. A comprehensive review of melanoma metastatic to the placenta comes from Baergen et al. (1997). Our patient with extensive metastases died soon after delivery, but the fetus remained normal. We summarized the world literature of 19 cases in this report, with five neonatal deaths due to transplacentally acquired melanoma.

**Fetal giant pigmented nevi** were described by Holaday and Castrow (1968) and later by Demian et al. (1974), and then by Campbell et al. (1987). In the placenta of the first case, multiple foci of pigmented nevus cells were present in the villi. The neoplasm was considered to be benign despite these deposits. In the second case of extensive **fetal giant nevus**, the placenta was grossly unremarkable but was extensively involved microscopically (Fig. 19.8). Because of this large amount of placental tumor, the authors suggested that the cells had arrived there by early neural crest cell migration. The last case may actually have been a malignant melanoma. At autopsy, metastases were found in the fetus. Its skin lesion, a large “nevus,” was detected sonographically. By light microscopy, the enlarged but grossly normal placenta was densely infiltrated with neoplastic cells. In contrast to the finding of maternal melanoma, these cells were confined to the villi. They did not invade the intervillous space, nor were they metastatic to the mother.

An example of metastatic **breast carcinoma** is depicted in Figure 19.9. It was confined to the intervillous space. Similar cases have been described by Cross et al. (1951) and Rewell and Whitehouse (1966). Many adenocarcinomas of the breast have metastasized to the placenta, according to the reviews of Freedman and McMahon (1960), McGowan (1964), Lemtis and Hörmann (1969), Potter and Schoeneman (1970), Salamon et al. (1994), and Ackerman and Gilbert-Barness (1997a). The latter authors reviewed all metastatic lesions to the placenta, and Lemtis and Hörmann (1969) drew attention to the absence of vascularization of these intervillous tumor colonies. For that reason, they suggested that these deposits be called “pseudometastases.” Many authors have commented on the finding of a grossly normal placenta riddled with metastatic lesions. Therefore, it is recommended that patients suffering from tumors in the past have placental examination when they become pregnant. It appears that those patients with advanced disease and thus a large tumor load are most likely to develop placental metastases. This explains the frequency of metastatic melanoma in placental metastases in spite of the rarity of melanoma in pregnancy women. The following other **solid tumors** have been found in the placenta:

FIGURE 19.8. Widely disseminated **fetal** giant cell nevus cells in placental villi. H&E  $\times 250$ . (Courtesy of Dr. G. Monif.)

1. Pancreas (Smythe et al., 1976)
2. Lung (Jones, 1969; Read & Platzer, 1981)
3. Ovary (Horner, 1960)
4. Rectum (Rothman et al., 1973)
5. Skin: squamous cell carcinoma (Orr et al., 1982)
6. Medulloblastoma (Pollack et al., 1993)
7. Rhabdomyosarcoma from the orbit (O'Day et al., 1994)

Several of these reviewers referred to single additional cases of rare other tumors that were present in the placenta but that did not metastasize to the fetus. With the exception of melanoma, no documented case of transplacental seeding by a malignant maternal neoplasm has

been identified. Hörmann and Lemtis (1965a,b) gathered a number of cases of metastatic tumors. They opined that the placenta has “remarkable defense mechanisms” against passing neoplasms from the mother to the fetus. A report by Sironi et al. (1994) on a placental teratoma represents in our opinion an acardiac amorphous twin and will be discussed in Chapter 25.

In the rare cases where **multiple myeloma** has complicated pregnancy, the placentas were not described. The associated fetuses and infants developed normally, despite maternal chemotherapy with urethane (Kosova & Schwartz, 1966; Rosner et al., 1968). When **Hodgkin's disease** was treated during pregnancy, the infants also developed normally. Of the 35 cases reviewed by

FIGURE 19.9. Adenocarcinoma of the breast, metastatic to the intervillous space (arrow). Note the absence of vascularization of the tumor cells nests. H&E  $\times 160$ .

Hennessy and Rottino (1963), the placenta was not studied, except in the case of non-Hodgkin's lymphoma described by Tsujimura et al. (1993). The placenta showed numerous yellow, partially necrotic lesions and the tumor had massively invaded the intervillous space; the premature infant succumbed. It is unknown whether the placental substance was invaded and whether the fetus became affected by the tumor. On occasion, though, it has been described that the fetus has acquired the disease transplacentally (Priesel & Winkelbauer, 1926). A pregnancy complicated by a diffuse cavernous **hemangioma of the uterus** was described by Lotgering et al. (1989). They delivered the patient at 35 weeks and found the placenta to separate only with difficulty and with much loss of blood. Possible hemorrhage from placental invasion of the angioma is a possibility in this condition, although placenta accreta is more likely.

Many reports have dealt with the question of transplacental transfer of cells in maternal **leukemia**. At times the intervillous space is filled with leukemic cells (Fig. 19.10), and yet no malignant cells can be identified in the fetal vessels of the placenta. Usually, these cells are not present in blood aspirated from the umbilical cord. Extreme idiopathic maternal leukocytosis occasionally occurs during pregnancy only to disappear after parturition. The intervillous spaces may then be crowded with maternal leukocytes, giving the appearance of leukemia. Care must thus be taken to differentiate this phenomenon from maternal leukemia. Bierman et al. (1956) found 50 reported cases

of maternal leukemia during pregnancy. Not a single infant had been affected with the disease. In their case of acute lymphocytic leukemia, the maternal white blood cell count at birth was  $154,000/\text{mm}^3$ , but that of the neonate was only  $3300/\text{mm}^3$ . The placenta had extensive leukemic cell infiltration that was confined to the intervillous space. Similarly, Chrisomalis et al. (1996), who described the unusual event of chronic lymphocytic leukemia in a pregnant young woman, found the intervillous space to be crowded with tumor cells, but a normal infant. Ask-Upmark (1964) followed six children born to leukemic mothers for 9 to 41 years. Leukemia developed in none. Rigby and his colleagues (1964) quinacrine-labeled the buffy coat cells of a mother with acute myelogenous leukemia and reinjected them before birth. They then examined the fetal blood 7 hours after injection, when the infant had delivered. Occasional fluorescing forms were seen. Such findings, however, are not convincing evidence of transplacental transfer of leukemic cells. Diamandopoulos and Hertig (1963) studied the placenta of a leukemic patient and the offspring of 48 pregnancies. They did not find any transfer of cells. These authors estimated that about 400 patients with leukemia complicating pregnancy had been reported. Only a few cases of transplacental transmission seemed possible, but they were not well supported. One such case is that of a mother who was diagnosed as having lymphocytic leukemia postpartum. Her child developed leukemia at age 9 months (Cramblett et al., 1958). The placenta and neonatal studies

FIGURE 19.10. Placenta at 36 weeks' gestation of patient who died from acute myelogenous leukemia the day after cesarean section. The white blood cell count at delivery was  $147,200/\text{mm}^3$ .

The child was well at 10 years. Note the large number of leukemic cells in the intervillous space but not within the villi. H&E  $\times 160$  (left);  $\times 640$  (right).

were not described. Thus, there can be only speculation as to transplacental transfer of leukemic cells in that particular case. Other larger reviews of the literature also have shown no fetal acquisition of the disease, despite the presence of large numbers of leukemia cells in the intervillous space and despite the fact that a variety of maternal leukemia types were studied (Ask-Upmark, 1961; Lee et al., 1962; Johnson, 1972; Nummi et al., 1973). In another case, despite massive intervillous invasion by myeloid leukemia cells, the villi of a partial hydatidiform mole were not invaded (Honoré & Brown, 1990). That some maternal cells do pass the placenta occasionally is discussed in Chapter 17, and by Nelson et al. (1998).

Primary fetal leukemia has been reported only rarely, the Cabot case No. 37-1976 of myelogenous leukemia in a neonate being a good example (Scully et al., 1976). Finally, intrauterine growth restriction and a meconium-stained placenta were found by Ohba et al. (1988) in a patient with adult T-cell leukemia/lymphoma. On the other hand, transient fetal leukemia associated often with fetal hydrops occurs characteristically in some cases of trisomy 21. In one of our cases, the neonate had 940 NRBCs/100 WBCs. The cause of hydrops is so far obscure (see also Zipursky et al., 1997).

## Hypertensive Disorders

### Preeclampsia

This common disease of pregnancy is now most frequently referred to as pregnancy-induced hypertension (PIH). The terms are interchangeable and it must be stated that not all PIH cases are equivalent to preeclampsia, as is usually assumed. One other reason to be as specific as possible about the terminology is that the disease process may produce symptoms similar to those of circulating lupus anticoagulant, discussed below. Moreover, our veterinary colleagues denote "toxemia" as a different disorder, usually a condition of ruminants. In fact, classic PIH is uncommon in animals. It has there been diagnosed primarily in some catarrhine primates, especially in Patas monkeys (Gille et al., 1977; Palmer et al., 1979), but its effects are seen in other primate species, such as gorilla, chimpanzee, and langurs. Chesley (1985), a master of this disease, is adamant that strict criteria should be used in the definition of this condition. He asserted that many patients with mild preeclampsia later suffer eclampsia. He also emphasized that all of the abnormal clinical findings in the pregnancy-induced disease disappear after gestation and that there are no sequelae to be expected in renal or vascular involvement in the future lives of the patient. This contrasts with the report of Epstein (1964), who found that women with a history of PIH had a significantly higher risk of developing "late hypertension."

An extensive review of prevalent theories to explain the pathogenesis has been published by Beek and Peeters (1998). More recently, Sibai et al. (2005) inclusively reviewed in great detail the theories that have been advanced and are especially helpful in the immunologic considerations.

Two classifications of preeclampsia and hypertensive disorders of pregnancy have been devised. These include a relatively simple definition, primarily based on blood pressure changes and put forth by Redman and Jefferies (1988), and the more complex systematics published by Davey and MacGillivray (1988). Both proposals are aimed at providing a better delineation of the various hypertensive diseases, so that the effect of treatment can be more meaningfully assessed. These classifications may simplify diverse designations of the past and make some order of chaos, but that they are unlikely to be generally useful has been the topic of an editorial (Anonymous, 1989a), and correspondence by Davey and MacGillivray, Roberts, and Lilford (1989). Whether hypertension is primary or due to an impaired removal of placental serotonin production was explored by Gujrati et al. (1996). These investigators found that in preeclampsia and eclampsia monoamine oxidase was reduced in syncytial cytoplasm and translocated into nuclei, thus perhaps inducing a hyperserotonomic state.

Pregnancy-induced hypertension presents clinically as hypertension, edema, and proteinuria. Typically, after the uterus has been emptied of fetus and placenta, the disease ceases. Indeed, Hunter et al. (1961) found that an immediate postpartum curettage of the placental bed causes maternal blood pressures to return to normal much more quickly than when curettage was not done. Inasmuch as PIH occurs in the absence of a fetus (as in hydatidiform moles), it is clearly dependent on the presence of placental tissue. The ultimate pathogenesis of PIH, however, has not yet been fully defined. Easterling and Benedetti (1989) have suggested that the disease is the result of a "hyperdynamic condition in which the characteristic hypertension and proteinuria are mediated by renal hyperperfusion." Numerous other possible etiologic factors exist, and these were analyzed by these authors. Zhou et al. (1997) proposed that the basic defect lies in an inadequate "epithelial-to-endothelial conversion" of the invading trophoblast, which is also emphasized in the review by Burton and Jauniaux (2004). The implanting cellular trophoblast, normally replacing the endothelium of the spiral arterioles was shown to change a number of epithelial markers [platelet endothelial cellular adhesion molecule (PECAM), vascular endothelial (VE)-cadherin, vascular cell adhesion molecule-1 (VCAM-1), several integrins] and assume endothelial characters. Absence of this conversion is thought to be the basis for the disease. Indeed, currently this endothelial disease is in the foreground of considerations that attempt to explain the etiology of PIH. Chaiwo-

rapongsa et al. (2004) found a significant increase in vascular endothelial growth factor receptor-1 (VEGFR-1) in the plasma of PIH patients and found that the quantity corresponded to the severity of the disease. Other studies of the intricate relationships between endothelium, vascular growth and circulating cytokines in PIH have come from Levine et al. (2004), who found a decrease in VEGF and increased levels of a tyrosine kinase in PIH; they relate these and suggest a possible causal mechanism for PIH. The role of complement activation in the pathophysiology of preeclampsia is currently under investigation. There are so many factors now isolated that a clear understanding of the ultimate mechanism for PIH still eludes us. We found of interest the demonstration by Taylor et al. (2003) that placental serum growth factors were reduced in PIH, relating it to villous angiogenesis and, secondarily to IUGR of the fetuses, whereas Leach et al. (2002) had postulated that their finding of a fivefold reduction of the epidermal growth factor-like growth factor (heparin-binding (HB)-EGF) expression in placentas of PIH might be the cause of cytotrophoblastic underperformance (deficient arterial remodeling and invasion). Similarly, Graham and McCrae (1996) showed that an altered expression of gelatinase and surface-associated plasminogen activator activity of trophoblastic cells characterizes preeclamptic pregnancies, perhaps being instrumental in altered invasiveness of the cells. The most recent entrant in this confusing array of factor that could have a causal or mediating effect on the development of PIH is "syncytin." This gene derives from a retroviral entry after the separation of platyrrhine primates from the catarrhine primates. It has the postulated ability to fuse cells and lead to the trophoblastic syncytium whose nuclei, as a consequence, have then become unable to divide. Knerr et al. (2002) promptly found markedly reduced gene expression in PIH (see letters by Keith et al., 2002). One may cautiously state that this enthusiasm for involvement of new proteins, genes, or their expression is understandable mostly because a clear-cut understanding of what causes PIH is yet elusive.

#### ANIMAL MODELS

Because of the frequency of toxemia, and to better understand its pathogenesis, several animal models have been used with the intent to simulate the human disease. This has been a difficult undertaking, and many of these models have primarily addressed the mechanism of abruptio placentae. Haynes (1963) induced abruptio placentae in the rabbit by temporary occlusion of the inferior vena cava. Fibrinoid degeneration and aneurysmal dilatation were produced in the decidual vessels; this simulated human toxemic pathology. An interesting discussion of the paper further elucidated this relationship. Abitbol et al. (1976a) have used the rabbit in a more extensive model study. They constricted the lower aorta; this caused hypertension, proteinuria, and fetal growth restriction. They also demonstrated changes in liver and kidney, similar to those of human PIH. The placenta contained infarcts and other changes resembling PIH, but these were also seen in some animals that did not exhibit toxemic symptoms (Abitbol et al., 1976b).

Two decades before, Howard and Goodson (1953) produced abruptio placentae in dogs when they ligated their lower vena cava in pregnancy. Combs et al. (1993) constricted the aorta in rhesus monkeys and also produced a "syndrome resembling preeclampsia," presumably because of the reduced lower aortic blood pressure. Interestingly, this group of investigators found that in these animals the depth of cytotrophoblastic infiltration into the endomyometrium was markedly enhanced (Zhou et al., 1993). When Hodari (1967) constricted uterine arteries of dogs before their pregnancy occurred, progressive hypertension and proteinuria were produced, which ceased after delivery. Abitbol et al. (1976c) also used strictures (of aortas) before dogs became pregnant; they observed proteinuria, hypertension, and some fluid retention. The placentas of these animals showed diffuse hemorrhagic infarction; in addition, typical renal lesions were induced. Many investigators have attempted to produce PIH and placental abruption in nonhuman primates. Thus, Myers and Fujikura (1968), in the course of studies on the effect of ligation of intercotyledonary vessels in rhesus monkeys, found that ablation of the "accessory lobe" invariably led to fetal death. They found that ligation of intercotyledonary vessels caused placental villi to continue their growth, and to develop increased syncytial knotting, a common feature of PIH. Wallenburg et al. (1973b) identified and ligated from one to four uteroplacental arteries in the floor of rhesus monkey placentas. This was invariably followed by necrosis and typical infarction. The earliest identifiable lesions occurred 23 hours after ligation. The infarction closely resembled that seen in human placentas with PIH. Cavanagh et al. (1974) have long worked to develop a suitable model in baboons, and placed clips about uterine arteries before pregnancy. Primarily renal lesions were thus produced. In later experiments, the investigators obtained hypertension and proteinuria that simulated human PIH (Cavanagh et al., 1977). When they subsequently constricted aortic blood flow in baboons, fetal and placental growth restriction and a reduction of amniotic fluid were induced; the placental morphology was not described (Cavanagh et al., 1985). Abitbol et al. (1977) also induced PIH in rhesus monkeys. They restricted aortic flow only in the last month of gestation. Resultant lesions included diffuse hemorrhagic infarction of the placenta, aside from renal and hepatic lesions. In general, the primate models more closely simulated the disease of PIH of women; certainly the placental infarcts and glomerular lesion were identical. Spiral arterioles in the placental bed, characteristically altered in human PIH, however, have usually not been investigated in these experiments. In the sporadic cases of primate toxemia that we have seen, the atherosclerosis lesions were not fully expressed.

#### Placental Pathology of Preeclampsia

The principal pathologic changes of the placenta in PIH include (1) decidual arteriopathy, (2) infarcts and ischemic change in central portions of the placenta, (3) abruptio placentae, (4) "Tenney-Parker changes," and (5) restricted fetal growth. These pathologic features are not all invariably present but they are significantly overrepresented in PIH, whereas chorioamnionitis is decreased in frequency (Moldenhauer et al., 2003). Also, one observes occasional cases with severe placental changes, in which no maternal symptoms relative to PIH have been elicited. Fetal and placental growth restriction, Couvelaire uterus, defibrination, and the nephropathy of "glomerular capillary endotheliosis" are frequently encountered manifestations of PIH and some are perhaps secondary features. Pampus et al. (1999) found that "hemostatic abnormalities" with the risk of thrombosis

are much overrepresented in patients with severe PIH, and PIH is much commoner with multiple pregnancy (Sibai et al., 2000). Wynn (1977) concluded correctly that “conventional gross and histologic examinations of the fetal portion of the placenta have not uncovered a pathognomonic lesion of preeclampsia.” This statement is particularly pertinent now that the lesions of “lupus anticoagulant” have been found to be identical to those previously ascribed solely to toxemia. Sletnes et al. (1992) studied preeclamptic women and found that 19% had antiphospholipid antibodies, with growth restriction of the offspring a prominent feature. A central question in the understanding of pathologic changes in PIH is whether these placental features allow a clean differentiation of PIH from other states of hypertensive disease. Wynn’s review is one of the most critical essays that examines this question. Other reviews may be consulted. For example, that by Muller et al. (1971) is based on their study of 168 cases of PIH. They attempted to make a correlation of the villous changes with the severity of PIH. The studies by Schuhmann and Geier (1972) and Hölzl et al. (1974) also examined the severity of the clinical disease in relation to perfusional and villous alterations. Another review of the placenta in toxemia came from Soma and his colleagues (1982). It gives the following tabular presentation of placental lesions in 53 cases of severe toxemia:

Lesions	%	Controls (%)
Infarcts	54.7	32.8
Intervillous thrombi	20.7	10
Circumvallation	26.4	10
Abruptio	11.3	0
Decidual necrosis	16.9	9.6
Abnormal cord insertion	12.1	4.1
Meconium staining	18.9	12.8

Decidual Arteriopathy

Hertig (1945) was the first investigator to describe the pathologic changes of PIH in the spiral arterioles at the implantation site. Since then, “atherosis” has become one of the hallmarks of the disease, and it is generally believed that the other major placental changes are the result of specifically altered placental bed arterial vessels (Figs. 19.11 and 19.12). Zeek and Assali (1950) found “acute atherosclerosis” in the placental bed of 34 toxemic patients; none was present in 37 other cases, and only three of 143 nontoxemic patients had early atherosclerosis. Eighteen nontoxemic hypertensive patients did not have atherosclerosis. They considered the lesion to be an early change of the spiral arterioles; fibrinoid necrosis and lumen obstruction by thrombosis were considered to be later events. Zeek and Assali believed this lesion to be the primary cause of placental infarcts. They also emphasized that the fetal circulation does not maintain the integrity of the placental villous tissue; rather, this integrity is contingent upon the intervillous blood flow. This is the maternal blood supply, bringing oxygen and nutrients. When the fetal circulation is obliterated, the villi merely shrink. Only much later do they atrophy and degenerate, with typical hyalinization of the stroma. The typical infarcts, however, have a maternal vascular disruption as their cause. Many other investigators have made the same observations, and they have summarized the vast literature of this topic. Here, the systematic studies of Marais (1962, 1963) must be mentioned. He was the first investigator to describe the appearance of spiral arteries in some detail, using the colposcope. Marais determined, by simultaneous injections of maternal and fetal circulations of an intact uterus, the nature of intervillous flow; he reaffirmed the independence of the two circulations. He delineated atherosclerosis, fibrin deposition, and

FIGURE 19.11. Atherosclerosis in decidual arteriole of patient with preeclampsia. Note that the vessel wall has been replaced by fibrin, the intima is replaced by cholesterol-laden macrophages, and there is mural thrombosis. H&E  $\times 250$ .

FIGURE 19.12. Hyalinized vessels with thrombosis and old atherosclerosis in decidua capsularis; adjacent decidual necrosis. Pregnancy at 33 weeks (920g small for age infant), severe pregnancy-induced hypertension (PIH), abruptio. H&E  $\times 60$ .

arteriosclerosis, and contended that acute thrombosis of placental bed vessels is the principal lesion that ultimately leads to placental ablation. Because he observed obliterative lesions in the absence of hypertension, Marais also concluded that the obliterative changes of these vessels were not caused by the maternal hypertension. Nadji and Sommers (1973) found decidual vascular changes in 14% of induced first-trimester abortuses and suggested that they represent precursors of future PIH lesions. Likewise, Lichtig et al. (1984) described atherosclerosis in the first trimester of pregnancy, whose significance also remains uncertain. Shanklin and Sibai (1989) undertook a systematic electron-microscopic study of maternal vessels in PIH with controls. They found extensive endothelial injury especially in placental site venules, with some fibrin deposition. No relationship to degree of hypertension could be established, and they found no atherosclerosis. They emphasized that the lesions they found were venous endothelial, and not confined to the placental site, let alone the arterioles. Most recently, Schmidt et al. (2005) studied placentas of PIH in 350 patients. Lesions were seen in 21.4% and they were most readily identified in the decidua capsularis of the membrane roll, not the decidua basalis. Nevertheless, 130 of 350 had villous infarcts. When Salafia and her colleagues (1995) examined a variety of histologic factors associated with preterm preeclampsia, they were impressed by the frequency of

inflammatory changes they found, such as vasculitis, chronic villitis, and “hemorrhagic endovasculitis.” From this they argued for an immunopathologic, vasculo-occlusive process to occur in PIH. Indeed, inflammation and activation complement may also play a role in the vascular damage and sequelae seen in PIH and antiphospholipid antibody syndrome (Salmon et al., 2001).

The decidual vascular changes are not always easily found, especially in the delivered placenta, or in the decidua capsularis of the rolled membranes. For that reason, Khong and Chambers (1992) proposed an improved method for sampling. They suggested the preparation of en face sections of the maternal floor in order to obtain more cross sections of maternal arterioles. While this makes intuitive sense, we have practiced this methodology for some time and found it not to enhance our ability to diagnose atherosclerosis or other lesions.

Brosens et al. (1967, 1972) and Robertson et al. (1967) have led a major group of investigators who studied the pathogenesis of the decidual vascular lesions in PIH. They documented the normal response to implantation of placental bed vessels, and the alterations that occur in hypertensive pregnancies. The principal tenet of these investigators is that, under physiologic conditions, trophoblast of the placental shell infiltrates the arterial beds of decidua and myometrium, and destroys the walls with fibrinoid changes. This infiltration of the 100 or so arterial

mouths of the implantation site ultimately renders these vessels incapable of reacting to mediators by constriction, as they normally would have. In preeclampsia, on the other hand, the invasion of the proximal, myometrial branches is impeded, a feature that was supported with *in vitro* experiments by Pijnenborg et al. (1996). They found that trophoblast of preeclamptic women's placentas had a reduced *in vitro* capacity for attachment to fibronectin and vitronectin. De Groot et al. (1996) studied CA 125 and insulin-like growth factor binding protein-1 concentrations in plasma from preeclamptic patients and found them to be reduced when compared to those of normal controls. Whether this failure of the "second wave" of invading cells is an intrinsic trophoblastic failure or is mediated by maternal (decidual) influences, is still unknown. In PIH, trophoblast merely penetrates the decidual vessels, but it fails to alter the myometrial vasculature's constrictive reactivity to mediators. Under "physiologic" conditions, the arteries are changed into "large, tortuous channels by replacement of the normal musculoelastic wall with a mixture of fibrinoid material and fibrous tissue" (Brosens et al., 1967). This is illustrated by Kim et al. (2001), who found abnormal transformation frequently in patients with preterm labor and intact membranes. The interactions of toxemia with or without preexisting hypertension were also detailed and well illustrated by Brosens and his investigators (1967). The changes and interpretations are complex and hypothetical. They must be read in the original text or in the summary review (Brosens et al., 1972). Similar findings were made in subsequent investigations by Gerretsen et al. (1981). De Wolf et al. (1975) made electron-microscopic studies of the decidual vasculature in PIH. Their findings are important as they illustrated the imbibition of plasma constituents, proliferative activity of intimal and muscle cells, and the damage to the vascular endothelium. Labarrere and Faulk (1994) made the important observation that the vascular invasion of trophoblast expresses completely different staining characteristics in preeclamptic vessels when compared to normal vessels and provided thus a means of clearly differentiating these populations of cells. Fatty infiltration was first observed in the endothelial cells; later, macrophages phagocytose fat from degenerating lipid-laden myogenic foam cells; eventually, medial necrosis occurs. Haust et al. (1977) also found that muscle cells accumulate lipid in PIH. Their description, however, is not quite clear. Although they refer to myometrial cells as having accumulated lipid droplets, the electron micrograph suggests this to occur in the muscular wall of the arterioles at the decidual-myometrial interface of the placental bed. The difficulties of differentiating smooth muscle cells from lipid-laden macrophages in atherosclerotic lesions have been further investigated by Schaffner et al. (1980). At present it is not absolutely certain, we believe, that the

altered elements in atherosclerosis represent typical muscle cells, rather than macrophages. The conclusion that the lipid-laden cells are mostly, if not totally, composed of macrophages was also reached in the immunologic studies conducted by Klurfeld (1985) on atheromatous plaques. In further studies of the vascular damage of PIH, Khong et al. (1992) observed that the normal endothelial coat of uteroplacental vessels is disrupted in eight of 10 patients with PIH. Pijnenborg et al. (1991) observed vascular changes in 47 hypertensive and 17 normal pregnancies. Various states of hypertensive disease, not only PIH, were a cause of atherosclerosis. It had been suggested that the transformation is mediated by expression of PECAM-1, but a detailed study by Lyall et al. (2001) failed to confirm this. Zhou et al. (1993) showed in rhesus monkeys with aortic ligatures that the depth of cytotrophoblastic invasion was enhanced, perhaps being mediated by blood pressures.

Because there is so much apparent "fibrinoid" deposition at this site (Fig. 19.13), Kitzmiller and Benirschke (1973) undertook fluorescent labeling studies of placental beds from normal patients and from those with PIH. They found a heavy deposition of gamma globulin and complement C3 in the vascular lesions of PIH (Fig. 19.14). Some fibrin could also be demonstrated, but neither Hageman factor nor albumin was found here. Two hypertensive patients without preeclampsia, and a diabetic primigravida also showed negative staining. In subsequent studies of PIH, Kitzmiller et al. (1981) invalidated the possibility that these deposits were the result of an immunologic "rejection" phenomenon. Only 53% of patients with PIH had such lesions, and some non-PIH patients with hypertension or diabetes had indistinguishable vascular changes. Similar investigations published by Weir (1981) also showed very variable deposits and a predominance of fibrin and C3, but no immunoglobulins. Parenthetically, it may be mentioned here that skin biopsies in patients with PIH have shown deposits of immune complexes (Houwert de Jong et al., 1982). The review by Wells and Bulmer (1984) should be consulted for additional considerations of the possible immunologic delineation of atherosclerosis. Also, Branch et al. (1989) have shown that patients with severe, early-onset toxemia have circulating antibodies to phospholipids. They drew analogies to the lupus anticoagulant syndrome (*vide infra*), further enhancing the notion that this common disorder has an immune-mediated background. Parenthetically it might be pointed out that the term **lupus anticoagulant** is a misnomer, as the majority of patients with systemic lupus erythematosus (SLE) lack this antibody (Ackerman et al., 1999) and coagulation is more commonly an issue.

Although the decidual blood vessels in PIH are often accompanied by a sparse number of lymphoid cells, plasma cells are conspicuously absent (Fig. 19.15). Bradeguez et al. (1991) studied the T-lymphocyte population in 62 primigravidae. They found a significant decrease

FIGURE 19.13. Acute atherosclerosis, fibrinoid degeneration, early mural thrombosis of decidual vessel in PIH. H&E  $\times 160$ .

FIGURE 19.14. Atherosclerosis and mural thrombosis in decidual vessel of patient with PIH. (Source: Kitzmiller & Benirschke, 1973, with permission.) H&E  $\times 800$ .

FIGURE 19.15. Decidual vessels in PIH with lymphocyte and macrophage infiltration, atherosclerosis, and old mural thrombosis (arrowhead). Globulin and complement were localized in these vessels. H&E  $\times 250$ .

in T-helper cells in the second trimester of those women who later developed PIH. This decrease occurred long before clinical symptoms became evident and disappeared 6 to 10 weeks postpartum. Other immune response studies are cited by these authors. Absence of a significant lymphocyte population from the decidua of PIH patients was the finding in the ultrastructural study of Shanklin and Sibai (1989). On occasion, we have observed a granulomatous reaction at this site (Fig. 19.16). This is exceptional and may be explained on the basis of a possible immune vasculitis, and not related to PIH. The occasional presence of lymphoid cells at the implantation site and many other features of PIH, have repeatedly suggested an immunologic basis for this disease. Gusdon et al. (1977), therefore, studied the percentage distribution of T and B cells in normal and toxemic patients. They found no significant differences between the two populations. With the recent greater interest in genetic factors of disease, many studies of antigen expression and reactions thereto have been undertaken and were reviewed by Roberts and Cooper (2001) without resolution. Esplin et al. (2001) found that "both men and women who were the product of a pregnancy complicated by preeclampsia were significantly more likely than control men and women to have a child who was the product of a pregnancy complicated by preeclampsia." O'Shaughnessy and colleagues (2000) found concordance of PIH expression among monozygotic twins. One can also argue that the

known much greater risk of first pregnancy to develop PIH has an immunologic reason and it is thus of interest that women who had never been exposed to the sperm antigens and conceived with IVF had a much increased risk for PIH (Wang et al., 2002). Chaiworapongsa et al. (2002) suggested from the increase of CD45RO+ lymphocytes and decrease of CD45RA+ cells that patients with PIH had an earlier antigenic exposure of unknown nature. Ariel et al. (2001) used microarrays to survey 588 genes in pregnant women and found that 79 were expressed in toxemic women but not in normal patients. Moses et al. (2002) find a locus on chromosome 2 that perhaps exposes to PIH susceptibility. Recurrence of PIH in second gestations was lower with the same paternity and smoking, but higher with longer intervals, diabetes, and other variables (Mostello et al., 2002).

Many studies of the vascular lesions in the placenta of patients with PIH have been made of the decidua capsularis that accompanies the membranes (Fig. 19.12), rather than on the decidua basalis. The latter is often markedly altered and, at times, it is necrotic and thus less useful for investigation. These findings of often-significant atherosclerosis in the decidua capsularis brings into question whence their perfusion derives. In our view this is not the decidua vera of the opposite site from implantation, and therefore the great variability of positive findings may find an explanation. Placental bed biopsies have been examined to great advantage. The results from a three-center study,

FIGURE 19.16. Granulomatous reaction around decidual vessels in 21-year-old patient with eclampsia following severe preeclampsia at 31 weeks' gestation. Anti-factor VIII stains (left) show the association with vessels. In the center several multi-

nucleated giant cells are present; at right are typical toxemia changes. (Anti-VIII, and H&E  $\times 160$ ,  $\times 240$ . (Courtesy of Dr. R. V. O'Toole, Columbus, Ohio.)

and extending over 30 years, have been published by Robertson et al. (1986). They emphasized that such biopsies, usually taken at cesarean section, should include the myometrium. They gave precise details as to how the biopsy should be obtained and processed in order for it to be useful. Even in their experienced hands, decidual bed biopsies were acceptable for interpretation in only 70%. These investigators found the decidua vera to be the most useful tissue for the observation of atherosclerosis and, remarkably, they consider the membrane-associated decidua to be decidua vera. This group of investigators pays special attention to the lack of physiologic vascular changes in the myometrial vessels, and to the occurrence of vascular thickening ("spasm") in PIH (Fig. 19.17). Similar changes have been reported in otherwise unexplained fetal growth restriction. When considering all these reports, it must be remembered that the findings made in patients with lupus anticoagulant (vide infra) may explain some of the still inexplicable results of the past. In these studies, they have not yet been considered as possibly confounding the results. Robson et al. (2002) took placental bed biopsies successfully transcervically before terminations and from cesarean section placental beds without ill effects. They also summarized the previous results of such efforts, illustrated in color with the normal vessels, but they did not address the altered arterioles.

Khong et al. (1987) attempted a statistical analysis from the study of decidual vessels in 39 patients with PIH. They were unable to relate the lesions to parity, degree of proteinuria, severity and duration of hypertension, or its therapy, and found an incidence of 46% atherosclerosis in PIH. This is similar to that of other workers cited. Stillbirths, SGA infants, and fetal distress occurred slightly more often in pregnancies whose placentas had atherosclerosis.

These results differ from the findings of some other studies, wherein there was a more appreciable increase of pregnancy complications (McFayden et al., 1986). Khong et al. (1987) reaffirmed their conviction that hypertension was not the cause of atherosclerosis and suggested that inappropriate immune reactions may be causative. They also found that the presence of atherosclerosis did not affect fetal outcome. The final pathogenesis of this lesion, however, remains unresolved.

Labarrere (1987) also found macrophage and T-cell infiltration, as well as deposits of immunoglobulins and complement around the spiral arterioles of PIH decidual beds. His observations challenge some of the assertions made by Robertson et al. (1986). They mainly indicate that the pathogenesis of atherosclerosis, as well as that of PIH, is still unresolved. Gerretsen et al. (1983) observed, in placental bed biopsies, that the physiologic change of spiral arteries was present in 95% of normal pregnancies, but occurred in only 19% of those that were complicated by PIH or fetal growth restriction. They observed, nevertheless, that the trophoblastic syncytial giant cell infiltration of the uterine wall in PIH, occurring adjacent to the uterine vessels, was of normal magnitude. The findings of Gerretsen et al. (1983) reaffirmed that pregnancy alterations of the uterine vascular walls are not due to ingrowth of trophoblast from the outside. Rather, this physiologic change of vessels is accomplished by upstream growth of cells that originate at the mouths of these vessels. The histochemical studies performed by these investigators confirmed that the cells in the vascular walls are not of the syncytial type but that they represent extravillous trophoblast or X cells. We have seen a patient who died from eclampsia and who had typical lesions of atherosclerosis and thrombosis in the central portion of the myometrium under the placental bed. This indicated to us that, on

FIGURE 19.17. Myometrial vessel of case in Figure 19.12 showing the thickened artery, presumably exhibiting "spasm," as suggested by Robertson et al. (1986). H&E  $\times 220$ .

occasion, the second wave infiltration of X cells takes place in patients who develop preeclampsia. As mentioned earlier, atherosclerosis, infarcts, and IUGR all can take place long before clinical manifestations allow the diagnosis of preeclampsia.

## Infarcts

Placental infarcts are the commonest and most conspicuous lesions observed by the pathologist. They represent necrotic villous tissue. There is no longer any doubt that the tissue has died because of deficient intervillous (maternal) circulation. Infarcts are firm, condensed dead areas of villous tissue that often encompass the entire thickness of the placenta (Fig. 19.18). More frequently, however, they involve mainly the base of the placenta and are particularly common at the placental edge. Here, they signify that the placental edge is “plastic.” That is to say, placental edges often atrophy in later gestation, with the histologic picture of infarction ensuing (Fig. 19.19). Thus the underlying etiology of these peripheral lesions is fundamentally different from that of central lesions, which represent true infarction. When infarcts are found in the central portions of the placenta, and particularly when they are randomly thus distributed, PIH or the condition of circulating lupus anticoagulant with anticardiolipins are almost invariably present. This is particularly true when infarcts are found in the first and second trimesters, at which time they are otherwise extremely uncommon. The earlier in pregnancy they appear, the more likely the lupus anticoagulant syndrome is to be expected. Placental infarcts differ grossly from intervillous thrombi. They have a granular surface and are much firmer. Intervillous thrombi, in contrast, are either fresh red clots and shiny, or they are laminated and light tan-gray. Their periphery

commonly has some infarction of villous tissue. These disturbances of placental perfusion can now be evaluated by echoplanar imaging (Francis et al., 1998).

Placental infarcts are initially dark red. They can be distinguished from living tissue by their firmness and by their lack of a spongy texture (Fig. 19.20). As they age, infarcts lose their fetal hemoglobin and become yellow, and then tan-gray. Unlike infarcts of other organs (kidney, spleen), they are never invaded by “organizing” fibrous tissue; in their subsequent evolution, they only become atrophic. Hemosiderin is sometimes found in early infarcts. The color changes (“red and white infarcts”) have been especially studied by Bartholomew and his colleagues (1961), who advocated a special method of examining the placenta for the presence of infarcts. They suggested that the entire organ be fixed in formalin and later serially sliced. The value of this method is supported by the studies of Steigrad (1952), in his evaluation of 716 unselected placentas. He suggested a complex division of infarcts, grading them from types A to H, and attempted a correlation with PIH, especially with its nephropathy. Shanklin (1959), who studied 767 unselected placentas, found no relationship of “white or red” infarcts to toxemia. This is very inconsistent with the experience of other authors. He was correct, however, when he emphasized the occurrence of increased trophoblastic knotting (“senescence,” as he called it) in PIH, the “Tenney-Parker change.” Javert and Reiss (1952) studied “red infarcts” (intervillous thrombi); they found them most frequently in erythroblastosis, but in toxemia, their 49% incidence was substantially increased over the average of 17.6%. These investigators pleaded that the designation “intervillous thrombus” is a misnomer. Because of the frequent (48.7%) contamination with NRBCs, they wished to draw attention to the admixture of maternal and fetal cellular

FIGURE 19.18. Macroscopic aspects of “white” infarcts, scattered throughout the placental tissue and amounting to 40% in this patient with PIH. Note that most infarcts involve primarily the placental floor.

FIGURE 19.19. Macroscopic and histologic aspects of old marginal infarct that is not related to preeclampsia. H&E  $\times 10$ .

FIGURE 19.20. Macroscopic aspect of multiple infarcts in placenta of patient with severe PIH and stillborn fetus. Varying ages of infarcts are shown as dark red (fresh), dark gray (intermediate), and white (old). Patient eventually had abruptio placentae.

components (further discussed in Chapter 17). Fox (1963) asserted that the term “white infarct” should be abolished because it is often confused with laminated fibrin/clot accumulation. He found a percentage of subchorionic fibrin plaques (15%), perivillous fibrin (28%), true infarcts (22%), central intervillous thrombus (12%), and basal intervillous thrombus (6%) in a series of 200 normal pregnancies. Huber et al. (1961) also found that intervillous thrombi result from a disturbance of decidual vein perfusion, but suggested that they represent different lesions from true infarcts. Bartholomew differed with this view in the discussion of this paper. Marais (1962c) illustrated the lesions in excellent color photographs and succinctly described their pathogenesis. Carter et al. (1963a) presented excellent photomicrographs and affirmed the villous dependence on maternal oxygen supply via the intervillous circulation. In a subsequent contribution (1963b), the same authors presented a complex classification of infarcts and described a novel entity, the “divergent villous lesion.” We believe that there is no need to make such complex distinctions, as they do not aid in prediction or understanding of infarcts, nor do they aid in diagnosis of maternal disease. The “divergent” lesion described is simply an expanding intervillous thrombus with adjacent villous infarction. Torpin and Swain (1966) interpreted laminated subchorial intervillous thrombi as “infarcts” and thereby confused the nomenclature even more. Stark and Kaufmann (1974) have studied the early changes of placental infarction and examined them with fine structural methods and enzymatic analysis. They found that an early process in the genesis of infarcts is the development of “plasma polyp” formation from the syncytium and beautifully demonstrated this by scanning electron microscopy.

Several investigators have attempted to relate the presence of infarcts to preeclampsia. Thus, Budliger (1964)

reviewed the older literature and made a planimetric and histologic study of 95 formalin-fixed placentas. Hemorrhagic and white infarcts were significantly more common and they were larger in PIH than in controls. Intervillous thrombi were not more common but, when present, they were also larger. This author deduced from his findings that a minimum of 190g of placental tissue is needed for fetal survival. Wentworth (1967) examined 679 consecutive placentas with a large section technique, after prolonged formalin fixation. Of these, 77 came from patients with mild PIH and 12 from those with severe PIH. He found the following: red infarcts, 1.3%; old, true infarcts, 6.2%. There was a significant increase of infarcts (67%) in the severely toxemic patients, whereas the mildly toxemic patients had only a 11.7% incidence of infarction. Some of the villi adjacent to infarcts showed also impressive chorangiosis (Figs. 19.21 and 19.22; see Chapter 24). In fact, the massive congestion seen in these early lesions is a necrobiotic change and it often results in villous hemorrhage before complete infarction takes place. Wallenburg (1969) also found a significant increase of infarcts with toxemia and noted that the infarcts are commonly found centrally in the placenta. He also noted a significant correlation with low Apgar scores and low birth weight. In a later contribution, this group of investigators concluded that an infarct represents the death of a fetal cotyledon due to the occlusion of a single decidual blood vessel (Wallenburg et al., 1973a) (Fig. 19.23). Brosens and Renaer (1972) found in their placental bed biopsy study of the spiral arterioles underlying infarcts that the lesions lacked normal trophoblastic invasion (and thus the physiologic reaction of myometrial vessels), and had occlusive thrombosis.

The most ambitious study of the relationship of infarcts to perinatal outcome comes from Richard Naeye (1977). He evaluated 31,494 placentas from the prospective Col-

FIGURE 19.21. Very fresh infarct (right) with marked congestion and villous hemorrhages at 27 weeks' gestation in patient with PIH and abruptio two days earlier. H&E  $\times 60$ .

laborative Study and endeavored to separate infarction from abruptio placentae, and then to determine their influence on fetal outcome. He deduced that placental infarction caused 2.26/1000 perinatal deaths. “Fatal infarcts were strongly associated with diastolic pressures

over 90 mmHg in the gravida,” and this was augmented when accompanied by proteinuria. Moreover, fatal infarcts were five times commoner in abruptio placentae, and they were also more common in older and overweight gravidas. He believed that infarcts often serve as a nidus for the inception of abruptio. It may also be mentioned here that infarcts and abruptios are not infrequent in patients with sicklelemlia.

### Abruptio Placentae

Abruptio placentae, the detachment of the placenta from its decidual seat, has had many different names. Holmes (1908) called it ablatio placentae; it has also been referred to as accidental hemorrhage, premature separation of the normally situated placenta, and perhaps other names. Gruenwald et al. (1968) suggested that the terms **abruptio** and **premature separation** should not be used interchangeably. He proposed that the former be used only for the cases recognized before birth, and the latter be reserved for the pathologically diagnosed cases. Overlaps occur, which Gruenwald and colleagues acknowledged, and we consider the terms to be identical. It is commonly assumed that this complication of pregnancy represents a sudden and very painful event. In total abruptio, or when a very large retroplacental hematoma suddenly forms, there may indeed be pain due to sudden stretching of the uterine peritoneal covering. More often, abruptio is partial and painless. These cases would be classified as “premature separation,” according to Gruenwald et al. (1968). Notelwitz et al. (1979) described three cases of “painless abruptio placentae,” characterized by vaginal bleeding and accompanied by backache and a nontender uterus. Because ultrasonographic recognition of this placental separation prevented fetal mortality in their cases, the authors advocated this for diagnostic evaluation.

There are many causes of abruptio, such as trauma from accidents or amniocentesis, abnormal uterine structure, separation at the edge in partial placenta previa and, prominently, preeclampsia. In an occasional placenta, one may also recognize the abnormal shape of a bicornuate or otherwise irregular uterus by the configuration of the abrupted placenta (Fig. 19.24). Kramer et al. (1997) enumerated the many factors that are correlated with or can cause abruptio placentae. They suggested that about 1% of pregnancies are complicated by detachment of the placenta. An unusual cause, congenital hypofibrinogenemia, with recurrent abruptio placentae was described by Ness et al. (1983). In our experience, when one half or more of the placenta detaches suddenly, the fetus dies. Lemtis (1967) has referred to similar estimates. He made reference to the very rare case of fetal survival with as much as five-sixths abruptio. Lemtis places much reliance on the irregular nature of placental perfusion for survival of the fetus. Delivery should be accomplished rapidly in cases of recognized abruptio. If placental detachment takes place over a long period of time, in stages and with infarcts ensuing, then the fetus may survive but will suffer from deficient transplacental oxygen and nutrient supply. It has been shown that trophoblast releases a factor that inhibits platelet aggregation (O'Brien et al., 1987) and it has been postulated that this factor is needed for normal placental blood flow. When it is decreased, abruptio may take place. Toivonen et al. (2004) found that the low-activity haplotype C-A (His113-His139) of the microsomal epoxide hydrolase gene was less frequent in women with abruptio.

The frequency of abruptio placentae in unselected series of pregnancies is estimated to be between 0.17% and 0.96% (Waddington, 1957; Halberstadt et al., 1969). Such figures reflect the obstetrician's ability to make the clinical diagnosis; they are not based on recognition by placental examination. It must be admitted at the outset, however, that the pathologist cannot recognize reliably the presence of a very acute abruptio placentae; thus, the overall incidence is underestimated by anatomic review. The diagnosis of a very recent abruptio can only be made clinically. The pathologist relies on alterations in placental structure, and on color changes of the retroplacental blood clot. These take time to develop. When we studied 7038 consecutive placentas past the 20th week of pregnancy, 3.75% of them were found to have features of some degree of abruptio placentae (Benirschke & Gille, 1977). Niswander and Gordon (1972) found evidence of abruptio in 2.12% among the prospectively collected cases of the Collaborative Study. They were usually described as "retroplacental hematomas." Because not all abruptios bleed externally (the "concealed hemorrhage") or produce the classical signs of a painful, rigid abdomen, the clinical diagnosis is bound to be made less frequently. Our series encountered trauma of various kinds only rarely, whereas preeclampsia and eclampsia were present in 13%; nevertheless, clinically uncomplicated pregnancies predominated (Fig. 19.25). Trauma and, recently, allegedly cocaine abuse are thought to be frequent causes of abruptio. They are covered in other chapters of this book. With regard to trauma, we here relate findings of an important case. The patient had been in a car accident. Her newborn delivered at 37 weeks, had an Apgar score

FIGURE 19.24. Delivery of baby "en caul," with abruptio of a growth-restricted placenta. The bicornuate nature of the uterus is reflected in the abnormally shaped membranes.

FIGURE 19.25. Causes of abruptio placentae, pathologically identified.

of 0/1 and a hematocrit of 17%, and required transfusion. The maternal Kleihauer test was negative. A fresh, large retroplacental hematoma contained 60% fetal cells. Higgins and Garite (1984) impressively demonstrated that late abruptio is an important sequel of trauma in pregnancy. It may even occur after deployment of airbags (Schultze et al., 1998). Abdella et al. (1984) found that abruptio was most common with eclampsia (23%), chronic hypertension (10%), and preeclampsia (2.3%). Clinical “abruptio” is also mimicked by active peripheral bleeding that ultimately leads to circumvallation, by marginal hemorrhage associated with severe ascending infection, and by the unusual entity of “marginal sinus thrombosis” (Fig. 19.26). The mechanism of marginal sinus thrombosis was explored and well depicted by Bartholomew (1961). He believed this to be the outstanding cause of first trimester bleeding, but it was also frequent in later pregnancy. In marginal abruptions, Harris et al. (1985) felt that the site of bleeding was venous in nature. In other cases, though, it is undoubtedly related to decidual necrosis and inflammation (Fig. 19.27). Elliott et al. (1998) went so far as to create a new syndrome: chronic abruption–oligohydramnios sequence (CAOS). They found a high frequency of prematurity and premature rupture of membranes, but were unable to explain the etiology of the new entity.

That abruptio is not diagnostic of preeclampsia, as was earlier contended, has been emphasized by many investigators (Tatum, 1953; Dyer & McCaughey, 1959; Hibbard

FIGURE 19.26. “Marginal sinus thrombosis,” actually a marginal abruption with layered blood clot in an immature placenta.

FIGURE 19.27. Immature placenta with velamentous insertion of the cord and long-standing abruption beneath the cord insertion. Clot is of different ages and has brown, yellow, and red color; there is associated chorioamnionitis.

& Hibbard, 1963). Tatum (1953) discussed the wide spectrum of associated pain and symptoms, whereas Dyer and McCaughey (1959) were more concerned with the appropriate therapy. Hibbard and Hibbard (1963) also denied the overwhelming frequency of toxemia as the etiology of abruptio placentae; they considered folic acid deficiency and grand multiparity to be important etiologic factors. Morgan and his colleagues (1994) found that neonatal outcome of infants with abruptio due to toxemia is not better than that from other causes, a long disputed point.

The placenta in classic abruptio placentae has fresh clot attached at the maternal surface. The villous tissue may be compressed and, because of the frequent association with toxemia, infarcts are often additionally found. Placental abruptions are most prominent beneath a gradually developing infarct and frequently they are associated with well-formed infarcts in other portions of the placenta (Fig. 19.28). The clot may be firm, if the ablation is older. It may be dry, and become brown after many hours. Eventually, the clot retracts and has the appearance of fibrinous strands. Initially, there is a depression with the clot, but this disappears as the overlying placenta infarcts and then atrophies. In very old and small abruptions, only minor color changes and infarcts will be

seen at the maternal aspect of the placenta. When toxemia is the cause of abruptio, the hemorrhage presumably begins with the decidual vascular lesions described above. Thrombosis of the decidual arterioles may lead to decidual necrosis and to subsequent venous hemorrhage (see also Harris et al., 1985). Although rough estimates can be made about how long the retroplacental clot has existed, exact figures cannot be given, despite frequent legal questions. Boe (1959) illustrated the rupture of a spiral arteriole with thrombosis, as the cause of a case of abruptio. The patient was not described as being preeclamptic, and several smaller decidual hemorrhages were found. When Hill and Brunton (1968) performed arteriography in pregnant patients, their results suggested that future abruptions could be anticipated because of poor vascular perfusion. It is now agreed that abruptio placentae occurs with increasing frequency in patients with chronic hypertension. Whether the ablation is due to hypertension or from a putative release of vasoactive agents after abruption has been discussed by several investigators. Abdella et al. (1984) favor the hypertension as causing the hemorrhage, a point that we also espouse. It is further supported by the relatively common findings of abruptions attending pregnancies that are complicated by pheochromocytomas.

FIGURE 19.28. Abruptio placentae with layered retroplacental clots and several infarcts (yellow to white) in preeclampsia. With this much acute abruption, the fetus dies.

Because abruptio poses a major threat to fetal and maternal survival, therapeutic regimens have been carefully considered. Sholl (1987) suggested that treatment should be given according to the gestational age at which the abruptio occurs. Preterm abruptions, which often are associated with poor obstetric history and with maternal smoking, may respond to tocolysis; but this is a complex clinical problem, not easily discussed fully in this context. Sholl found that his overall fetal mortality was 17%. He advised the use of ultrasonography. Cardwell (1987) also made the diagnosis by ultrasound examination in eight patients, and found significant fetal-maternal hemorrhage with the abruptio. One fetus lost 72 mL into the maternal circulation. Coen et al. (1974) described the remarkable survival of a 1630-g premature infant delivered after 75 minutes of complete abruption. They believed that the attending hypothermia may have aided this infant. Equally remarkable is the patient described by Lopez-Zeno et al. (1990). In their case, the fatal injury to the mother occurred 47 minutes before cesarean delivery, and the infant was born 22 minutes after maternal cardiac arrest had occurred. Follow-up at 18 months revealed no neurologic deficit, although focal central nervous system (CNS) infarction was seen by computed tomography (CT) scan at 5 weeks. Neonatal shock, from anemia or hypoxia, is often the life-threatening problem for the fetus (Haupt, 1963). Waddington (1957) found 254 abruptions of normally implanted placentas among 26,358 deliveries (1:104). There was a maternal death and an 83.5% fetal survival when aggressive management was used, but only a 72.7% fetal survival with passive management. Waddington observed three cases of Couvelaire uterus (enlarged uterus with massive interstitial hemorrhage) and one coagulation defect, in this group of patients. In a prospective study, Naeye et al. (1977) found

an incidence of 3.96 per 1000 perinatal deaths due to abruptio. They identified a high usage of cigarettes in the mothers and poor maternal weight gains during pregnancy. Fetuses often suffered growth restriction. Important maternal complications are defibrination (Wisot, 1969) and renal necrosis from disseminated intravascular coagulation (DIC) (Sanerkin & Evans, 1965; Carter, 1967). Impressive deposits of fibrin may be found in the renal vessels as well as in other organs of such patients (Schmorl, 1893; Schneider, 1951). Endotoxin shock is often observed. This has led to considerations that toxemia of pregnancy results from a generalized Schwartzman reaction (McKay et al., 1959). Vassalli et al. (1963) observed deposits of fibrin and some gamma globulin in the glomeruli of patients with preeclampsia. The clinical relevance of this was discussed by Dunlop et al. (1978), who found no coagulation problems in patients with essential hypertension.

Kåregård and Gennser (1986) reported an 0.44% incidence of abruptio in a large Swedish cohort, with a 20.2% fetal mortality. Of interest in this study is that a history of abruptio increased the risk for a subsequent abruptio 10.2-fold. Male conceptuses and twins were overrepresented in abruptions. In discussion of this paper, Grossman and Goldberg (1987) suggested that recurrence rate may relate to high anti-H-Y antibodies, which they found in a patient with three abruptions. On a rare occasion, abruptio with defibrination may occur long after fetal death has occurred (Schneider, 1953). One type of abruptio that has been referred to in the obstetric literature is that associated with marked prematurity and chorioamnionitis (Vintzileos et al., 1987). We believe that this is misdiagnosed as "abruptio" because of the presence of a clot accompanying the placenta. When the placenta is carefully examined one finds that the hemorrhage and clot

came from the inflamed decidua capsularis, rather than from a retroplacental location. Thus, the appellation abruptio is inappropriate.

### Fetal Effects of Abruptio Placentae

Older studies have suggested that maternal eclampsia may result in vascular damage of their fetuses (König, 1956). This author demonstrated hyalinization and coagulation of small cerebral vessels in such an infant. In a study of 34 cases of placenta previa and 64 cases of abruptio placentae, Robbins et al. (1967) found a high incidence of late cerebral abnormalities of the infants at 1 year of age. Haile (1940) described an infant with "eclamptic liver necrosis" and referred to the few other reports in the literature of similar injuries. The kidneys were normal, and it is doubtful to us that a similar coagulation disorder existed in the fetus as that observed in maternal DIC. It is not uncommon for neonates, dying from many different disorders, to suffer DIC, as was shown by Bleyl and Büsing (1969) and other authors. There are many sporadic reports, however, of thrombocytopenia and other hematologic disorders in neonates of mothers with preeclampsia (Mirro & Brown, 1982; Schmidt et al., 1986). Severe defibrination (unmeasurable levels) following abruptio was reported by Edson et al. (1968). The relationship of fetal coagulation events in preeclampsia was studied more systematically by Weiner and Keller (1986). They found lowered antithrombin III activity and higher fibrinopeptide A concentrations in preeclamptic women; paired samples from fetuses showed normal values. Lau et al. (1964) found abruptio primarily with toxemia, and reported a 68% fetal mortality and 35 maternal mortality in their 100 cases studied.

### Other Placental Changes in Preeclampsia

Aside from the liability of infarcts, abruptio, and the frequent decidual vascular alterations, the placenta of toxemia of pregnancy undergoes some additional and mostly minor structural changes. More often than not, the placenta is smaller and "drier" than expected for that gestational age. When sectioned, the toxemic patient's placenta is much darker than normal organs, reflecting the hemoconcentration of the fetus. Siegel (1962), who unsuccessfully attempted to correlate preeclamptic retinal changes with the degree of toxemia, depicted most of the classic degenerative changes in the placenta. Teasdale (1985) performed histomorphometric studies of the placentas in patients with severe preeclampsia and with moderate fetal growth restriction. He measured a variety of structural features and found only minor quantitative differences from normal controls. Schumann and Lehmann (1973) correlated maternal urinary estriol excretion, DHA-conversion and placental morphology,

with fetal outcome. They found a lack of any such predictability for fetal outcome and suggested that the outcome is primarily dependent on clinical management. Considerably lighter placentas and fetuses were found in hypertensive patients in a study of Cibils (1974). He made teased villous preparations and observed them with a stereomicroscope. There was considerably increased budding of the syncytium in these placentas, representative of the Tenney-Parker change discussed.

Prominence of syncytial buds has been observed ever since Schmorl (1893) first drew attention to these cells in the pulmonary vessels of patients who died from eclampsia. Earlier, these cells had been interpreted as necrotic, embolized liver cells, but this was not borne out by Schmorl's detailed studies. Syncytial embolism to the lung is now accepted to be a normal feature of all pregnancies (Bardawil & Toy, 1959; Attwood & Park, 1961). Because these cells have no reproductive potential, they die in situ, after first losing their cytoplasm. Remarkably, there is neither fibrin deposition nor an inflammatory reaction. Perhaps all this happens because of the normal apoptosis that is proceeding in these cells. Trophoblastic apoptosis in PIH has now been the topic of several incisive studies. Thus, Huppertz and Kingdom (2004) accepted it as a normal feature of trophoblast turnover and suggested that "during preeclampsia there seems to be an altered balance between proliferation and apoptosis of villous trophoblast leading to a dysregulation of the release from the syncytiotrophoblast." They called it "aponecrotic shedding." Other studies by Crocker et al. (2003) and Ishihara et al. (2002) made similar incisive observations in toxemia and growth restriction, whereas the results by Battistelli et al. (2004) are less convincing that apoptosis is a significant ingredient of IUGR. Many et al. (2000) related this phenomenon to oxidative stress (see also DiFederico et al., 1999). Jauniaux et al. (2003) examined Doppler flow in abnormal placentation and found restricted flow with oxidative damage in "shallow" implantations and placental damage as a result.

In toxemia, and particularly in eclampsia, there is enhanced embolization of syncytial cells and it is likely that the much increased level of fetal DNA in the maternal circulation (Cotter et al., 2004) is its result although these authors, cautiously, interpreted the finding to increased fetal transplacental cell traffic. Occasional authors have even suggested that excessive pulmonary embolization with syncytial buds may be a cause of maternal death (Marcuse, 1954; Roffman & Simons, 1969). The association of these giant cells in these cases with fibrin thrombi is impressive but does not prove that they have been the cause of DIC in the patients. Jäämeri et al. (1965) found a markedly increased number of circulating syncytial cells in the blood of toxemic patients when compared to that in normal pregnant women. Iklé (1961, 1964) provided a methodology for the isolation of

these cells from the blood and estimated that approximately 100,000 such cells are liberated daily in pregnancy. More recent quantitative studies are discussed elsewhere. Wagner (1967) and Wagner et al. (1964) felt that release of these cells was uncommon, unless the uterus was “manipulated,” and showed an impressive degree of embolization during curettage for hydatidiform mole. Tedeschi and Tedeschi (1963) showed experimentally that these cells were swiftly disposed of in the lung. These cells have been studied with flow cytometry, and their DNA content displayed, and the suggestion has been made that they might serve as means for prenatal cytogenetic diagnosis (Covone et al., 1984). Rushton (1984) rightly pointed out, however, that the syncytium has no reproductive potential and is, at present at least, incapable of serving this cytogenetic purpose. It could serve for polymerase chain reaction (PCR) and fluorescent in situ hybridization (FISH), but the cells rarely traverse the lung to become accessible in peripheral blood. Cameron and Park (1965) showed embolized decidua in the lung at necropsy of two pregnant women. Cockell et al. (1997) showed that in preeclamptic patients deported trophoblastic microvilli impair the maternal vascular relaxation response to acetylcholine, which suggests an altered endothelial response in the omental vessels obtained during cesarean section.

Tenney and Parker (1940) had emphasized that the increased budding of placental syncytium is very characteristic of preeclampsia. It is so significant and common in PIH that we now call this finding the “Tenney-Parker change.” It features bunching of syncytial cytoplasm and agglomeration of nuclei. This produces characteristic “knots” at the villous surface (Fig. 19.29). Although some

such knots are normally found in preterm and term placentas, their number is much increased in toxemia. In addition, these knots are often larger and contain more nuclei than those found in the term placenta. Often, this change has been referred to as “premature aging” of the villous tissue, incorrectly we believe, as there is only the microscopic appearance, not real aging. Stallmach et al. (2001) examined “defective placental maturation” with respect to late fetal mortality in archival material and suggested it to be the cause of hypoxia. The knots may result initially from the loss of villous fluid, and secondary buckling of the covering trophoblast follows; apoptosis has also been demonstrated. There are also changes of the amount of cytotrophoblast proliferation with subsequent proliferation of syncytium, as discussed earlier. The mechanism of this villous change was studied in vitro by Tomimaga and Page (1966). They perfused human placental tissue and observed the response to varying oxygen concentrations of the perfusate. Hypoxia led to vasodilatation of fetal capillaries, and high O<sub>2</sub>-saturation produced fetal capillary vasoconstriction. In long-term organ culture, the reduction of oxygen saturation from 26% to 6% led to the bunching of syncytial nuclei and thinning of the villous trophoblastic covering. This change was found to be reversible when oxygen was increased again. Others have not been able to repeat the reversibility aspect of these experiments (Ong & Burton, 1991). There are light-microscopic similarities between the maternal vascular disease of preeclampsia and that of circulating lupus anticoagulant. It must be emphasized that these changes of toxemia are also present in very immature placentas in which, ordinarily, little syncytial budding would be seen. In our experience, when more than 30%

FIGURE 19.29. Excessive syncytial “knotting” (budding, sprouting) in 30-week-gestation preeclamptic patient. Almost every tertiary villus has a densely clumped agglomeration of syncytial nuclei, possessing little cytoplasm. H&E  $\times 160$ .

of tertiary villi possess syncytial buds, especially in the premature placenta, this is diagnostic of a perfusional compromise. Such features may be associated with abruptio placentae (Fig. 19.30), and can also be seen in the vicinity of fresh infarcts (Fig. 19.31). Alvarez and his colleagues (1967, 1969, 1970) related knotting to an altered maternal arterial pressure and further supported the notion that this is a diagnostic feature of toxemia; they also quantitated the budding by use of phase contrast microscopy. Aladjem (1967b) made similar observations, but they suggested that this syncytial change is not caused by cell degeneration. There is also no occlusion of fetal vessels. The sprouting is considered to be an adaptive change to altered maternal blood flow or oxygen content of intervillous blood. Aladjem differentiated between “buds” and “sprouts,” and called this phenomenon “sprouting.” Fox (1970) kept villi in organ culture for 10 days; he found markedly increased tritiated thymidine incorporation into cytotrophoblast when the organ culture was hypoxic. This suggested to him that the response represents repair of damaged syncytium. A later study by Howard et al. (1987) showed that cotyledons, perfused in vitro, responded to hypoxia with acute vasoconstriction, rather than the earlier suggested dilatation. This accords well with findings by Doppler velocimetry, in which maternal and umbilical arterial blood flows were found to be reduced in hypertensive patients who ultimately deliv-

ered growth-restricted infants (Giles et al., 1985; Ducey et al., 1987; Hanretti et al., 1988; and critique by Pearce & McParland, 1988). Indeed, evidence has been obtained now that an abnormal umbilical artery waveform strongly predicts bad neonatal outcome in preeclamptic patients (Yoon et al., 1994). Such clinical studies have led to new insight and a more reliable categorization of risk in hypertensive pregnancies. Rauramo and Forss (1988) have used Doppler velocimetry to show that exercise in toxemia and in pregnancy diabetes may have significant deleterious effect on uterine blood flow. Lin et al. (1995), likewise, have shown by Doppler velocimetry abnormal uterine artery flow velocity in toxemia, and related this to abnormal trophoblast invasion into the spiral arterioles. When Matijevic et al. (1995) studied flow in spiral arterioles in early pregnancy, they found that remodeling is finished at 17 weeks of pregnancy. And, because nitric oxide (NO) regulates placental blood flow, Myatt et al. (1997) studied the expression of endothelial NO in placentas of growth-restricted pregnancies and preeclampsia. They found “significantly more basal distribution of endothelial nitric oxide synthase (eNOS) in syncytiotrophoblast . . . [while] it was intense in the endothelium of . . . IUGR and preeclampsia.” They interpreted this as an adaptive response to increased resistance and poor perfusion. Ghabour et al. (1995) had made similar observations in their earlier studies, and Pascoal et al. (1998) investigated the pharma-

FIGURE 19.30. Placenta of 30 weeks' gestation with preeclampsia and abruptio placentae (left). Typical “Tenney-Parker” change is present in the prematurely “aged” villi. H&E  $\times 16$  (left);  $\times 100$  (right).

FIGURE 19.31. Very fresh placental infarct, perhaps 1 day old. Intervillous space is obliterated, many villi lack circulation, and a preexisting syncytial knotting (Tenney-Parker change) is present. Patient had toxemia of pregnancy. H&E  $\times 16$ .

cologic response of omental vessels in this condition. A large review by Granger et al. (2002) links the placental ischemia to microvascular dysfunction and incriminates various cytokines and endothelial factors to PIH.

Maternal fibronectin levels are elevated in preeclampsia, but Anunciado et al. (1987) showed, with fluorescent antibodies, that the villous vascular fibronectin content is decreased. By the use of histochemical techniques, Wielenga and Willighagen (1966) demonstrated that toxemic placentas have characteristic losses of enzymes; this was apparent in areas that required histochemical methods for detection of tissue ischemia. In severe toxemia, the disease process was manifested by increased placental lactate production (Ginsburg & Jeacock, 1967). Further, there are profound microangiopathic alterations of maternal erythrocytes (Cunningham et al., 1985).

Several electron-microscopic studies have compared villi of normal placentas with those from preeclamptic patients. No characteristic findings were made in the PIH study reported by Zacks and Blazar (1963). Anderson and McKay (1966) found an increase in cytotrophoblast, thickening of villous basement membranes, and an increase in "bulbous syncytial microvilli." They suggested that only quantitative changes occur, but none that characterize the diseased organ. When MacLennan et al. (1972) kept villous tissue in culture for prolonged periods, degenerative changes occurred in the syncytium. The appearance resembled hypoxic alterations seen in preeclampsia. To avoid secondary artifacts, Pavelka et al. (1979) took biopsies of preeclampsia patients' placentas at cesarean section. They observed a loss of architecture, fibrin deposition, reduction in microvilli, and dilatation of endoplasmic reticulum and of the Golgi apparatus of the syncytium. Their photographs provided superior detail.

Similar results were obtained by Jones and Fox (1980); like most authors, they came to the conclusion that the lesions are all explicable on the basis of reduced perfusion by maternal blood.

#### ETIOLOGY OF TOXEMIA, PREGNANCY-INDUCED HYPERTENSION, OR PREECLAMPSIA

Preeclampsia is a common complication of pregnancy (7% to 10% of primigravidae) that is characterized by elevated blood pressure, edema, and proteinuria. Although characteristically all three components are present, they are variably expressed. The clinical manifestations may come about slowly or, occasionally, explosively. If untreated, preeclampsia (also known as pregnancy-induced hypertension, PIH) may result in eclampsia, that is, convulsions. The disease is infinitely more common in first pregnancy, in very young gravidas, and in multiple pregnancy as indicated earlier. The fetus is commonly growth-restricted because of fairly characteristic placental alterations that result from a disturbed interaction of trophoblast with maternal uterine blood vessels. Placental delivery nearly always terminates the illness abruptly. Preeclampsia has many serious complications, such as placental infarction, abruptio placentae, and fetal demise. Because of cerebral hemorrhage or DIC, preeclampsia can lead to maternal demise. PIH can also become associated with the HELLP syndrome (Fagan, 1994) and it has also become a compartment of the so-called syndrome X, hypertension with hyperinsulinemia (Roberts, 1994; Duda, 1996; Martinez et al., 1996; Himmelmann et al., 1997). An important and inclusive review comes from Sibai et al. (2005).

The principal cause of preeclampsia is still unknown, although inroads are being made by the employment of modern molecular tools (Duda, 1996). Heterogeneous causes as the etiology of PIH (such as preexisting maternal conditions, reduced placental perfusion) have been suggested by Ness and Roberts (1996) and were subsequently discussed in letters to the editor. Although it is certain that the disease relates to the presence of placental tissue, the proximate cause is still obscure. The fact, however, that the delivery of the placenta (or hydatidiform mole) ends the disease process speaks for this causal relationship, and many theories have been advanced to explain the mechanism that leads to the symptomatology and pathologic features of toxemia. We will briefly describe only the most recent hypotheses and give refer-

ences to the general literature. General reviews of etiology and pathogenesis are those by Cunningham and Lindheimer (1992) and Duda (1996).

Lueck et al. (1983) proposed that preeclampsia was the result of an infection by a worm-like "agent." They identified these structures from the peripheral blood of toxemic patients. In a later paper (Aladjem et al., 1983), the authors believed they have shown that they induced a toxemia-like syndrome in dogs, by injecting these animals with blood from toxemic patients. These observations caused much subsequent work and provoked intense discussion. Several investigators then found that males have similar structures in the serum (Gau et al., 1983). The structures are now considered to be artifacts of the preparative procedures (Long et al., 1984; Ayala et al., 1986). They do not represent the cause of preeclampsia.

The possibility that toxemia of pregnancy represents an immune-mediated disorder has long been an attractive consideration. As was previously discussed in this chapter, immune complexes have been localized in the spiral arterioles of the placental bed and in the renal glomeruli of patients with preeclampsia. Moreover, the lesions of lupus anticoagulant, a condition with identifiable "irregular" antibodies, are often indistinguishable from those of toxemia of pregnancy. Hulka and Brinton (1963) suggested that circulating fluorescein-conjugated antibodies localize on trophoblast and signify an immunologic conflict. That subsequent pregnancies of patients with toxemia in their first gestation are usually not affected, was overlooked. Sophian (1964) appropriately criticized this simplistic explanation. Much conflicting evidence of the alleged immunopathologic etiology has since been gathered in efforts to clarify this situation. Kitzmiller et al. (1973), Balasch et al. (1981), and Rote and Caudle (1983) all found no elevation of complement titers in toxemic pregnancies. This was countered by studies of Vasquez-Escobosa et al. (1982) and Massobrio et al. (1985), who found significant levels of various immunoglobulins and also of immune complexes in patients with severe toxemia. Alanen et al. (1984), on the other hand, found only a slight increase in circulating immune complexes in patients with severe preeclampsia. Perhaps the tests are not sensitive enough, or they are too dissimilar for the consistent demonstration of an immune reaction. At present, they do not offer much support for the idea that toxemia has an immunologic origin.

Two large reviews in 1976 weighed the evidence for and against an immunologic disorder. Although Scott and Beer found some relationship to a disturbance in the blocking antibodies that, normally, are believed to protect against placental rejection, their conclusion was that there is no major immunologic etiology to explain toxemia. Reid (1998) provided some additional considerations for a better understanding of the nonrejection of the placenta. Simultaneously, he seeks an explanation for how the maternal-fetal balance is disturbed that enhances the occurrence of some unusual infections to occur in pregnancy. Scott and Jenkins (1976) elicited evidence for a genetic predisposition; they concluded that the disease probably has a "multifactorial" etiology. Some support for a genetic predisposition also came from the findings of Redman et al. (1978), who found that toxemia occurred more often in women who had only one HLA-B antigen locus. Perhaps homozygosity at the HLA locus enhances the possibility of developing the disease. Against a simple genetic etiology is the finding of occasional discordance in monozygotic twins and other observations recorded by Thornton and Sampson (1990). Thornton and Onwu (1991) suggested from their retrospective survey of putatively monozygotic twins that the frequent discordance of PIH speaks against a simple genetic disorder. Totally unexplored was the HLA status of the respective husbands and other aspects one would want to know if an immunologic model as the basis for PIH were to be scrutinized. It has been shown, however, that the level of HLA-G expression in placental tissue is reduced in patients with preeclampsia, apparently related to the quantity of trophoblast (Colbern et al., 1994). Now some evidence has been generated that there is an alteration of the messenger RNA (mRNA) splice forms in PIH (Emmer et al., 2004) that affects the remodeling of spiral arterioles.

Blaschitz et al. (2001) and Le Bouteiller et al. (2003) have also investigated the variable expression of HLA-G by extravillous trophoblast. This topic is now under very active investigation and it is too early to say whether this altered HLA antigen mechanism is the principal reason for placental nonrejection. Future findings from more detailed studies of paternal and fetal HLA antigens and maternal response should provide more definitive answers as to this possible mechanism that may be altered in PIH. Scott and Jenkins (1976) and Willems (1977) postulated a relationship to an inadequate production of blocking antibodies in PIH and suggested a possible immunization procedure for the prevention of preeclampsia. Circulating antigen-antibody complexes were sought in toxemic patients by Knox et al. (1978), but none was found. McLaughlin et al. (1979), on the other hand, did find circulating complexes in toxemic women and offered suggestions for a resolution of the discrepancies that exist in the literature. We have been interested to find that in dichorionic twin placentas or those of higher multiples, the severity of the alterations (infarcts, Tenney Parker change) often differs in their placental portions. Perhaps this relates to some differences in antigen presentation by dizygotic twins; others have been less impressed with such differences. There is no doubt, however, that twin- and higher multiple pregnancies are much more frequently complicated by (a somewhat abnormal) form of preeclampsia. Hardardottir et al. (1996) reviewed this topic and summarized the experience published earlier of incidences from 6% to 46%. Also discussed was the probably erroneous notion that the explanation for this increase simply lies in the presentation of more placental mass. An altered immunologic maternal response is also suggested by the studies of Robillard et al. (1994). An increased exposure to multiple sperm before first pregnancy, they suggested, so alters the immunologic response to trophoblastic invasion into spiral arterioles (that usually exists) that PIH is avoided. The topic is further explored in an editorial by Clark (1994) and is an attractive way of interpreting the complex disease process that was earlier mentioned from the study by Wang et al. (2002).

Much attention was then directed toward the study of the great variety of cellular components at the placental/uterine interface. Scott et al. (1978) reviewed that evidence. They found many articles to support the notion that a disturbed lymphocyte function exists in toxemia. Specifically, it was suggested that patients who exhibit the disease have a high degree of immunologic compatibility with their fetus. Thus, Hoff and Bixler (1984), from ABO-antigen studies of a large cohort, deduced that "the greater the potential for an immune response of the mother to the ABO and HY antigens, the lower is the likelihood of preeclampsia developing in the first pregnancy. . . ." The extensive reviews by Daunter (1992) and MacLean et al. (1992) should be read for greater details to explain the unusual immunologic phenomenon of placentation. Slukvin et al. (1998) discussed in some detail the confusing elements of the various classes of major histocompatibility complex (MHC) antigens, especially HLA-G and their recognition by the mother. Birkeland and Kristofferson (1979) observed that, in toxemia, there is a marked hyporesponsiveness of maternal lymphocytes to phytohemagglutinin (PHA) stimulation. Subsequently, similar findings by Griffin and Wilson (1979) favored the interpretation that this alteration in lymphocyte behavior "may be a consequence rather than the cause of their clinical disease." It should be noted, however, that Musci et al. (1988) found in the serum of preeclamptic patients an increased amount of mitogen. They postulated that this is the result of release from damaged endothelium occurring in this disease. Although Sridama et al. (1983) found a significant decrease in circulating T cells with preeclampsia, there was no good correlation of the severity of the disease with the number of T cells. Moreover, the ratio of helper to suppressor cells was undisturbed. Toder et al. (1983) found the NK cell activity to be increased with toxemia, and that these cells had been preactivated. The question of a change in lymphocyte populations was addressed by Gusdon et al. (1984), with monoclonal antibodies against specific subpopulations of cells. They found that the OKM1 population was normally significantly reduced in the third trimester, but not in preeclamptic patients.

These cells mediate NK cell activity and antibody-dependent cellular cytotoxicity. Khong (1987) investigated the *in situ* population of cells that infiltrates the placental attachment site. He was unable to identify any quantitative or qualitative difference between the populations in normal vs. preeclamptic patients and suggested that the large population of macrophages may downregulate a maternal immunologic response. Many other contradictory investigations could be cited that only serve to emphasize that the simple notion of toxemia as an immunologic disorder may be erroneous. Kilpatrick (1987) effectively summarized some of these arguments. It should also be noted that evidence shows that the "labor-related stress significantly decreases the total number of neonatal T-lymphocytes and the CD4 (helper) T-cell subpopulation in cord blood" (Pittard et al., 1989). Finally, it has been suggested that placental isoferritin, known to be located in the syncytiotrophoblast, acts as an immune mediator in pregnancy. Maymon et al. (1989) found that, in preeclampsia, placental isoferritin concentration in serum was low (7.5 U/mL), as compared to 81.6 U/mL in normal pregnancy, and 54.8 U/mL in term delivery. They suggested this as a useful marker for toxemia.

More attention is now being paid to the possibility that preeclampsia may be the result of reduced prostacyclin production or at least that an imbalance of prostaglandin secretion exists. Moreover, as Brosens et al. (1974) pointed out, the response of uterine vessels to vasoactive agents may be significantly different in toxemia, because the "second wave" of trophoblast invasion fails to alter myometrial vessels and thereby leaves them responsive to constrictive agents. Specifically, lowered prostacyclin production by the placenta and enhanced thromboxane  $A_2$  production, have been delineated in numerous detailed studies. Prostacyclin binding and its half-life are reduced in pregnancy. O'Brien et al. (1988) have shown that this decrease is variable, perhaps accounting for some of the conflicting results obtained in the past. There is a significant decrease of prostacyclin in hypertensive pregnancy, which may explain some of the clinical findings in this disease. These aspects have been reviewed, and Ylikorkala and Mäkilä (1985) and Mäkilä et al. (1986) discussed their clinical implications. In a more recent review of the remodeling of spiral arterioles, especially in the endometrial/myometrial junction zone, Brosens et al. (2002) suggested that the normal decidual alteration of the spiral arterioles (endothelial edema, separation of the musculoelastic layer-complex cytokine-regulated changes) is disrupted and leads to "a cascade of events resulting in failed deep implantation."

Demers and Gabbe (1976) found that placentas from preeclamptic women have significantly less prostaglandin E (PGE), and vasoconstrictive PGF is much increased. A marked reduction of prostacyclin production was found in growth-restricted neonates whose mothers had suffered hypertension and preeclampsia (Stuart et al., 1981). Importantly, this reduction was not confined to patients with toxemia. A review of prostaglandins in pregnancy (Anonymous, 1982) brought all findings together and suggested that experimental prostacyclin infusion in preeclampsia may have a beneficial effect. In this review it was suggested that "if normal pregnancy, like normal processes in general, is under the fine control of enzyme systems, abnormal pregnancy, like many other disease states, may reflect the relatively uncontrolled activity of free radicals." Hollister et al. (1988), on the other hand, found that prostacyclin infusion into pregnant sheep did not increase placental vasodilation. Mäkilä et al. (1984) showed that the deficiency of prostacyclin ( $PGI_2$ ) in preeclampsia is specific for the disease and that it is not the result of the mode of delivery or anesthesia. Erskine et al. (1985) found evidence to suggest that altered ratios of certain plasma phospholipids may be a useful predictor for the likely development of preeclampsia. In a detailed study of prostacyclin production by placenta, amnion, and chorion, Walsh et al. (1985) showed a marked reduction of the toxemic placenta to produce this enzyme; amnion and chorion did not show this alteration. Jeremy et al. (1986) confirmed this study and offered comments. The deficiency of prostacyclin in toxemia correlates well with its known platelet aggregation effect and hypertension.

Prostacyclin has the effect of preventing both of these. Walsh (1985) had suggested that preeclampsia represents an imbalance of prostacyclin ( $\downarrow$ ) and thromboxane  $A_2$  ( $\uparrow$ ) production. He supported this with experimental findings. The recognition of these complex interactions has led to successful preventive therapy by Beaufrils et al. (1985). Early in pregnancy, they gave antiplatelet medication (150 mg aspirin and 300 mg dipyridamole daily) to mothers who were at high risk for toxemia. They suggested that this treatment prevented toxemia and fetal growth restriction. More extensive studies have borne this out, selectively suppressing maternal platelet thromboxane  $B_2$  (or  $A_2$ ) production (Benigni et al., 1989; Schiff et al., 1989; Uzan et al., 1991). It has also been found that low-dose aspirin inhibits the production of thromboxane from placental surface arteries, whereas the production of prostacyclin is not disturbed (Thorp et al., 1988). Friedman (1988) provided a comprehensive review of all these aspects concerning mediators and their relationship to PIH. Rosenfeld (1988) added to this review; he pointed out that, during pregnancy, angiotension is vasoconstrictive rather than vasodilatory. The primary derangement of these enzymatic changes remains unknown. The interactions of endothelial cell prostanoid release with leukotrienes and complement are probably important (Lundberg et al., 1986; Pober, 1988; Fitzgerald et al., 1990). These topics are most actively being investigated in an attempt to unravel the mysteries of this common disease.

Other theories concerning the etiology of PIH are too numerous to mention. The idea of excessive salt intake as a cause of toxemia was reviewed by Robinson (1958), and Chalmers (1988) has commented about this. The conclusion is that, although salt regulation in pregnancy has not been accorded needed attention, its causal role for PIH is not secure. Bartholomew et al. (1957) opined that the toxemic aspects of the disease were due to necrosis of placental tissue. This is most unlikely, because many patients with severe toxemia may have few or even no placental infarcts at the time of their first symptoms, and the death of one twin's placenta does not induce the disease. Redman and his colleagues (1999) believe that the endothelial damage and pathologic changes result from a more generalized inflammatory reaction that involves the clotting system and they summarize studies that support this notion. Importantly, they opined that the abnormal placentation is secondary to these disturbances.

## Lupus Erythematosus and Lupus Anticoagulant

### Lupus Erythematosus

Systemic lupus erythematosus (SLE) occurs primarily in young women and it occasionally complicates pregnancy. It has been speculated that this autoimmune disorder is so much more common in women than in men (10:1) because of their sensitization to nuclear antigens to which they are exposed during menstruation (Dameshek, 1958; Grimes et al., 1985; Hulka, 1985). Estrogens exacerbate the disease, because they have a "potent influence on the immune system and therefore an effect on disease processes" (Hayslett & Reece, 1985). These authors reviewed reports of the influence of pregnancy on the course of SLE and found that, in 25% to 50% of patients with SLE, the disease exacerbates or relapses with pregnancy. In addition, their review indicates that fetal survival is reduced because of an increased number of abortions, maternal renal insufficiency, and placental pregnancy

complications. They suggested treatment regimens for women with SLE and pregnancy. It is now believed that pregnancy itself does not constitute a risk to patients with SLE. Low-dose aspirin therapy is being used but is not very effective (Editorial, 1991). Mund et al. (1963) found a 30% abortion rate when SLE began after conception, as opposed to a 14% rate when the disease was already established. A 66% fetal loss in SLE was reported by Schenker et al. (1972), who asserted that toxemia and renal disease were the most common complications.

Systemic lupus erythematosus (LE) is accompanied by a variety of circulating antibodies, the best known of which is the antinuclear antibody (ANA) that also elicits the LE phenomenon. That the destruction of nuclei and DNA is due to this antibody has been shown by Bennett et al. (1986). These authors identified a "functionally defective receptor for DNA" in the majority of patients with SLE and were able to induce this defect by incubating healthy mononuclear cells with the circulating antibodies of patients with SLE. The defect was manifest by an impaired binding of exogenous DNA to the surfaces of peripheral mononuclear cells. It must be remembered, however, that up to 50% clinically normal, pregnant women have ANAs at least once during the course of their pregnancy (Rosenberg et al., 1986). Lymphocytotoxic antibodies have been found in about 80% of patients with SLE (Pritchard et al., 1978). Other investigators have reported that these antibodies possess antitrophoblastic activity. This may possibly explain the poor pregnancy outcome that attends the disease (Bresnihan et al., 1977). This idea was particularly attractive because other inflammatory diseases such as rheumatoid arthritis and scleroderma do not have a high rate of abortion. When Ornoy et al. (2003) used the IgG purified sera of patients with lupus erythematosus and the antiphospholipid syndrome for the culture of rat embryos and placentas, they observed damage to the yolk sac and reduced trophoblastic growth with increased apoptosis.

The placentas of five patients with SLE were studied by Grennan et al. (1978). They identified fluorescent antibodies against complexes to nuclear antigens on placental villous basement membranes. Grimmer et al. (1988) have undertaken further studies to define this antitrophoblastic activity. They found IgM antitrophoblast antibodies in a patient with thrombocytopenia and a rash, who also experienced circulating lupus anticoagulant activity, twins, and an intrauterine fetal demise. By immunofluorescent antibody techniques, they localized the factor to the placental syncytium and found C3 to be deposited on the basement membranes of villi. The studies were done with the patient's placenta as well as with normal placentas; small vessel deposition of the antibodies was also observed. IgG, IgA, and C3 deposits were not localized

to these areas. The twin placenta of this pregnancy was 10% infarcted and had decidual necrosis, but it lacked vascular disease. Perhaps the absence of vascular disease was due to sampling technique, but the authors were cautious in interpreting the findings as having an etiologic relationship to the fetal demise. This is particularly pertinent because deposits of C3 on the villous basement membranes have been observed in normal placentas (Johnson et al., 1977). The recognition of other circulating antibodies in SLE as possible causes of pregnancy mishaps will be discussed below. It must be said, however, that despite all the findings of abnormal placentas in SLE, one encounters occasional patients who have neither decidual vascular lesions nor infarcts or fetal growth restriction with this condition. Presumably, these patients are in remission, despite the presence of specific antibodies. The SLE patients who have no anticoagulant antibodies have fewer abortions (24.7%) than do those with such antibodies (58.7%), according to the retrospective study of Loizoll et al. (1988). In an immunologic study of placentas from a variety of patients with immunologic disorders, Ackerman and Gilbert-Barnes (1997b) found fluorescent antibody localization (fibrinogen, IgG, IgM, IgA, and C3) to the trophoblastic basement membranes. Electron microscopically the basement membrane was thickened. In a subsequent contribution on placentas in maternal connective tissue diseases (Ackerman et al., 1999), five SLE, one rheumatoid arthritis, and two with mixed connective tissue disorders were described. Decidual vasculopathy or thrombosis was not seen, but three SLE patients' placenta showed thickening of the trophoblastic basement lamina electron microscopically. Magid et al. (1998) prospectively studied 40 placentas from 33 women with SLE. The decidual vasculopathy (17%), VUE (28%), and infarcts (18%) were principally associated with the simultaneous presence of antiphospholipid antibodies. Ischemic/hypoxic changes (diminutive and sparse villi) were prominent and depicted by these authors.

Some antibodies of patients with SLE are transferred to the fetus, which is often growth-restricted. These antibodies may cause thrombocytopenia, discoid lupus, and a variety of other conditions, including the LE phenomenon. We have seen a full-term infant weighing 2000 g of a mother with discoid lupus whose placenta possessed many infarcts and weighed only 320 g. There was intensive chronic deciduitis in the decidua basalis and decidua vera, with foci of old abruptio placentae. Atherosclerosis was absent, but most decidual vascular walls were infiltrated by chronic inflammatory cells, among which plasma cells predominated. There also was diffuse, moderate chronic villitis. Beck et al. (1966) observed ANA titers in neonates of women with SLE, at approximately the same titers as in the mother. Despite this, the three neonates

they observed remained healthy. The LE cells were repeatedly observed in the neonates of mothers with SLE, as reported by Mijer and Olsen (1958) and Gött (1969). These cells disappeared within 7 weeks after delivery, and the infants subsequently developed normally. Jackson (1964) described a third case of a newborn with discoid lupus, delivered by a mother with SLE. The neonatal lesions disappeared within 5 months but left small scars. Congenital heart block in such offspring has caused concern and is estimated to occur in 1 of 60 SLE pregnancies (Editorial, 1991). Hull et al. (1966) reported a neonatal death; the mother had suffered SLE for 13 years and had been treated with chloroquine throughout pregnancy. The 2500-g neonate was hydropic at birth, had a complete heart block (45/168 ventricular to atrial contractions), and had skin lesions. At autopsy, there was patchy fibrosis of the myocardium. The placenta was bilobed, edematous, and "fibrous-friable." This constellation is now considered to be the neonatal lupus syndrome. Provost et al. (1987) described two cases and reviewed the literature. In almost all cases, neonatal complications are associated with anti-U<sub>1</sub>RNP antibodies, and the mother has anti-La(SS-B) or anti-Ro(SS-A) IgG antibodies. For this and other reasons, fetal surveillance has been recommended (Druzin et al., 1987). Another case of heart block was documented by Richards et al. (1990). Their primigravida was not known to have SLE when her fetus developed a complete heart block at 23 weeks' gestation and ascites at 26 weeks. Her ANA titers were then found to be 1:1024. Incipient hydrops led to treatment with betamethasone and was followed by reduction of signs of fluid accumulation, which the authors attributed to transplacental steroid antiinflammatory action. The neonate delivered at 37 weeks with retained heart block but did well. Another case of fetal heart block was detailed by Silver et al. (1992a). It caused fetal death, presumably secondary to the very extensive placental infarction (>80%) found. Thrombosed vessels with and without atherosclerosis were present in the decidua basalis. In the atrial septum near Koch's triangle, dense fibrosis and calcification were identified and believed to have been responsible for the heart block. The mother possessed anti-Ro and anti-La antibodies. Seip (1960) and Cruveiller et al. (1970), among other investigators, have observed hemolytic anemia, rashes, thrombocytopenia, and leukopenia in neonates of mothers with SLE. Klippel et al. (1974) found inexplicable tubuloreticular cytoplasmic inclusions in the lymphocytes of neonates whose mothers had SLE.

The placenta of patients with SLE may be normal. More often it shows changes that are frequently impossible to differentiate from the lesions of preeclampsia (Magid et al., 1998). It must be appreciated, however, that preeclampsia is also more frequently seen in patients with

SLE. It is thus difficult, at times, to know whether the placental pathology is due to preeclampsia or to SLE. The infarctions and retarded placental growth are the result of decidual vascular lesions that, in turn, are the cause of the fetal growth restriction of SLE. Abramowsky and his colleagues (1980) studied 10 placentas from patients with SLE, and one placenta of a patient with discoid lupus. They found vascular lesions in five placentas. Two placentas had over 25% infarction; others showed only discolorations. The outstanding lesion was decidual arteriopathy, with fibrinoid necrosis and infiltration by inflammatory cells. Some vessels appeared aneurysmally dilated and had atherosclerosis. No abruptions were seen grossly, but microscopic study indicated this in two cases. Infarction and "premature aging of villi" were the only other pathologic findings. In two patients, immunofluorescent study showed massive deposition of IgM, and a lesser amount of C3 in the decidual vascular walls. We have had similar experiences with SLE (Benirschke & Driscoll, 1967) and have suggested that the decidual lesions are best observed in retroplacental curettings. Alternatively, the place to find most decidual arterioles with these pathologic changes is in the decidua capsularis of the membrane roll. These vessels have lesions that are similar to those in the maternal floor of the placenta. They are usually less readily found in the decidua basalis that comes with the delivered placenta because not enough of that decidua separates with delivery of the placenta. Moreover, in the floor of the placenta, fibrin and old clot from partial abruptions usually preclude adequate study. One would need to do postpartum curettage or placental bed biopsy in order to obtain sufficient material for proper evaluation. But that is not often practical and should probably be avoided because of the potential for creating future accretas. Vascular lesions, including atherosclerosis and thrombosis, are clearly the cause of the placental infarcts, the associated abruptions, and the reduced weights of placenta and fetus. Between the infarcts of affected placentas, the villous tissue displays Tenney-Parker changes, the increased syncytial knotting, best known in preeclampsia and due to reduced maternal perfusion of the intervillous space. This histologic state is often referred to as "enhanced aging," but it is simply a reflection of reduced oxygen availability from the decreased intervillous blood flow. Thus, there is no need to postulate that specific antitrophoblastic antibodies exert an additional or specific destructive effect. Figure 19.32 shows the macroscopic appearance of the placenta in a patient with SLE. It has numerous infarcts (55%), which caused fetal death. The placenta was multilobulated because numerous infarcts had caused atrophy of many areas. The placenta of the case described by Hull et al. (1966) was bilobate, perhaps for the same reasons. Our patient had a previous spontaneous abortion, and a placenta with many decidual vascular lesions. Figures

FIGURE 19.32. Placenta in systemic lupus erythematosus (SLE) near term. The placenta has many infarcts (55%) of varying ages, separated lobules (succenturiate lobes), and, microscopically, many arteriolar lesions. The fetus was stillborn and growth restricted.

19.33 to 19.36 illustrate vascular lesions of two other patients with SLE. In both cases, fetal death occurred at about 19 weeks' gestation. The macerated fetuses showed no lesions. The placentas were extensively infarcted and had several areas of abruptio and Tenney-Parker changes. Although this change is most common in preeclampsia, it is usually not seen until the third trimester when pure preeclampsia complicates pregnancy most commonly. There was no clinical evidence of preeclampsia in these

patients. Interestingly, with one of these cases, mural thrombi were present in vessels of the umbilical cord and of the placental surface. Branch and Rodgers (1993) found that thrombosis occurred most likely as the result of antibodies to endothelial tissue factor expression.

Because many of these patients have had prednisolone therapy, it may be conjectured that some of the pathologic changes might be attributed to this therapy. This was investigated by Warrell and Taylor (1968). They studied

FIGURE 19.33. Decidual arteriopathy of SLE in decidua capsularis. There are fibrin infiltration of the wall, mural thrombosis, and minimal leukocytic infiltration. The pregnancy terminated at 21 weeks with stillbirth of a 215-g (!) macerated fetus. The placenta weighed only 60 g. H&E  $\times 16$  (left);  $\times 160$  (right).

FIGURE 19.34. Another case of decidual arteriopathy in SLE at 19 weeks' gestation with stillborn, macerated fetus. Several types of vascular lesions are seen in these vessels of the decidual basalis and capsularis: mural thrombosis, hyalinization, inflammation, thickening of spiral arterioles, organized old thromboses, and fresh thrombi with decidual necrosis. The fetal vessels also had mural thrombi. H&E  $\times 160$  (left);  $\times 250$  (right).

FIGURE 19.35. Microscopic aspect of villous tissue in SLE of previous case (Fig. 19.34) showing old and recent infarcts and Tenney-Parker change of viable villi. They have the appearance of term villi because of the loss of water and shrinkage. H&E  $\times 160$ .

FIGURE 19.36. Fresh abruptio placentae in SLE with minimal infarction of villous tissue (same case as Fig. 19.33). The retroplacental clot below is elevating the decidua basalis. These changes usually preclude one from observing the vascular lesions in the decidua basalis. H&E  $\times 60$ .

34 pregnancies of 30 women receiving prednisolone for asthma (18), ulcerative colitis (2), SLE (4), eczema/urticaria (7), and arthritis/sarcoidosis (3). There were eight fetal deaths, and nine fetuses that were at risk of "placental insufficiency." The authors concluded that the enhanced risk to the fetus may be explained by the experimental findings of Blackburn et al. (1965). These investigators had given large doses of prednisolone to pregnant rats and observed smaller placentas, fetal deaths, and "increased aging of the placenta." No decidual vascular lesions were seen, but the decidua was significantly underdeveloped. It is likely that the findings of Warrell and Taylor (1968) represent changes that are not related to SLE or its therapy. Why not all patients with full-blown SLE exhibit identical vascular lesions and destructive placental infarcts may relate to the severity of the disease or perhaps to the therapeutic regimen and its efficacy.

### Lupus Anticoagulant

This is the most commonly observed of several antiphospholipid antibodies; there are also anticardiolipin and antiphosphatidylserine. Aside from the ANAs mentioned

above, in SLE there exists a variety of less well defined immunoglobulins whose origin and determinants have been superbly reviewed by experts in this complex field (Asherson et al., 1989). The best known of these antibodies are the "lupus anticoagulant" and "anticardiolipin," a type of antiphospholipid antibody. The topic is difficult and has many contradictions. It is perhaps best to begin with a quote from Gleicher (1997): "Antiphospholipid antibodies are present in virtually every individual ... at higher levels in females." Thus, care is needed in interpretation of tests used for their determination, levels, types of antibody, and controls employed in critical studies. Moreover, when Kutteh and Franklin (2004) studied the results of assay findings from 10 different laboratories, only mild to moderate reliability was demonstrated. Averbuch et al. (1987) have found elevated levels of lupus anticoagulant in about 20% of SLE cases. Feinstein (1985) has incisively pointed out in his review that the term **anticoagulant** is clearly a misnomer. He writes, "It has become clear that the lupus anticoagulant is more frequently encountered in patients without lupus, and it is not associated with abnormal bleeding in most patients except when hypoproteinemia, thrombocytopenia, or a qualitative platelet defect is present." This antibody prolongs phospholipid-dependent coagulation tests by binding to epitopes on the phospholipid portion of prothrombinase (factors Xa and Va, calcium, and phospholipid). It was first described by Bowie et al. (1963) in four patients with SLE who had thrombotic complications. Since then it has been recognized that women with histories of repeated abortion and premature births often possess "circulating lupus anticoagulants" that may indirectly be held responsible for this excessive fetal wastage. For instance, Kowal-Vern et al. (1996) suggested, from reviewing the literature, that anticardiolipin antibodies are present (cause?) in 3% to 10% of women with recurrent pregnancy losses. Because of the variety of antibodies found, it has become customary to speak of the circulating lupus anticoagulant syndrome (CLAS). The heterogeneity of the antibodies and the difficulty in defining them have been presented in some detail by Triplett et al. (1985). They found that 2% of patients screened for activated partial thromboplastin times had this antibody, and they provided a detailed discussion of the tests available for the definition of the antibodies. In a later contribution, Triplett (1993) summarized the thrombotic sequelae of these antiphospholipid antibodies, especially those in the arterial circulation, and other reviews have been summarized above. Triplett went on to describe the placental anticoagulant protein-1 (PAP-1) with the potential of inducing thrombosis. Lazarchick and Kizer (1989) have given specific details of laboratory procedures necessary for the establishment of this diagnosis, an important issue. They found that dilute Russell viper venom time and the tissue thromboplastin inhibition test are

sensitive assays. Nevertheless, in several patients, the discordance of test results necessitated measurements of specific coagulation factors in order to establish the diagnosis. Apparently wide differences exist in laboratories reporting test results (Peaceman et al., 1992), which must be taken into consideration when prevalence figures and treatment results are evaluated. The antibodies are usually IgG molecules, but may be also be IgM and IgA, or combinations. They interfere with the phospholipid-dependent coagulation assays (see also Brandt et al., 1987). Usually considered to be *in vitro* phenomena (Woodhouse, 1984), their presence may be indicative of diverse clinical states, such as thromboses, pregnancy wastage, polyneuritis, and sundry others. As indicated, a comprehensive review of this complex topic has been provided by Triplett (1989, 1993), and another comes from Rote et al. (1998). The former papers not only summarize the basis for the action of various antibodies (see also Reece et al., 1990) but also provide a list of reports on pregnancies with and without therapy.

Numerous complications have attended pregnancies with CLAS antibodies, but then there are other cases in which no pathology is observed. At present there is no conclusive resolution of this complex topic; especially lacking are concrete results that link recurrent abortion to the existence of the antibodies. Indeed, the case-control study by Infante-Rivard (1991) indicated that "there is no apparent justification for considering lupus anticoagulants or IgG anticardiolipins to be risk factors for fetal loss among women who present with spontaneous abortion or fetal death and have had no previous spontaneous fetal loss." Balasch et al. (1997) came to similar conclusions. El-Roeiy and colleagues (1990) ascertained that in normal pregnancies, elevated levels of antiphospholipid antibodies are not observed. Their study also suggested that when these exist in low titers, they have little or no effect on pregnancy wastage; growth restriction of the fetus may be a sequel, however (Gleicher, 1997). Aside from fetal wastage, now recognized in some of these gestations, a maternal death (following fetal death) has also occurred. This happened in a patient who, one day following the diagnosis of fetal death, suffered disseminated small-vessel thrombosis. Myocarditis and pericarditis were present in the mother, who also had sickle trait and presumably "occult" SLE (Bendon et al., 1987). Farquharson et al. (1985) had reported life-threatening thrombosis that necessitated therapeutic abortion in a pregnant patient. The authors suggested that immunosuppressive therapy may have to be initiated before pregnancy occurs in order to avoid such complications. Other cases of severe maternal thrombotic events in this antibody syndrome are by Hochfeld et al. (1994) and Kupferminc et al. (1994). But not all such patients have clinical symptoms. When abnormal immunologic findings with irregular antibodies are present in pregnant patients,

such as an unexpectedly positive Venereal Disease Research Laboratory (VDRL) test, further investigation is required. This necessitates especially a search for the presence of lupus anticoagulant and anticardiolipins. In the patient just described, many myometrial vessels had lesions at the placental floor; one third of the placenta had infarcts (30%), and an abruptio placentae was found. The mother also had myocardial and renal lesions. Lockshin et al. (1989) evaluated therapy in 21 patients with high antiphospholipid antibodies and one prior fetal death. They concluded that prednisone does not improve outcome but in fact may worsen it. Branch et al. (1989) showed that an association of antiphospholipid antibodies exists also with severe toxemia of pregnancy and suggested that this is one more reason to consider an immune hypothesis for both diseases.

Although there is this well-known relationship of such "irregular" antibodies to recurrent fetal wastage, the prevalence of the various types has been disputed and, most importantly, it had not been known whether the existence of one or the other types of antibody spells a more sinister prognosis. The study conducted by Lockwood et al. (1989) corrected this deficiency. They ascertained the presence of lupus anticoagulant and anticardiolipin antibodies in a low-risk population and found two of 737 patients to have lupus anticoagulants and recurrent abortions. Conversely, 16 of 737 patients had anticardiolipins, and four of these had uncomplicated pregnancies. Twelve had various complications. They concluded that the presence of antiphospholipid antibodies was correlated with unfavorable pregnancy outcome, and that their prevalence is in the range of 0.3%. Two cases of fetal stroke, recognized only later in the neonatal period, were attributed by Silver et al. (1992b) to result from anticardiolipin antibodies. Many subsequent studies have tried to clarify the situation. Regrettably, few have availed themselves of a systematic examination of the placenta from the study population. For instance, Oshiro et al. (1996), who found that antiphospholipid antibodies correlated with fetal demise rather than early trimester abortion, did not evaluate the pathology, even though they referred to the proverbial "placental insufficiency." Branch et al. (1997) concluded that women with recurrent losses are no more likely to possess antiphospholipid antibodies once anticoagulant and anticardiolipins are excluded. They did not evaluate placentas. When such study was undertaken in patients with anticardiolipin antibodies (Kowal-Vern et al., 1996), no abnormal changes were detected. Thus, one needs to exercise caution in attributing many or all recurrent pregnancy losses to placental lesions in this syndrome. To better understand the effect of these antibodies on placental function, Silver et al. (1997a,b) have passively immunized mice with some of these human antibodies. Some fetal demises and resorptions were observed, but no clear relation was

found to explain the result; nevertheless, they provided a first insight into possible effects on intervillous circulation. More light comes from the investigation by Rand and coworkers (1997), who provided a basis for understanding that anticoagulants have a coagulative ability in the placenta. They found an interaction of the antibodies from three affected women with the annexin V (placental anticoagulant protein I) residing on the surface of cells of a trophoblast cell line. Their results suggest that the annexin levels are reduced after antibody exposure and that this may be the mechanism that leads to the thrombosis in the intervillous space in recurrent fetal losses. To understand these issues is especially important for potential preventive therapy in such patients, as Cowchock (1997) discussed in an editorial. Prednisone is thus less likely to be beneficial than heparin or anticoagulation of other types.

Investigations regarding the nature of the CLAS began with the identification of a patient by Nilsson et al. (1975). That mother experienced pregnancies with three intrauterine deaths and she had circulating lupus anticoagulants. The authors indicated that a relation may exist between this antibody and placental infarction. McVerry et al. (1980) then reported two patients with deficient prostacyclin (PGI<sub>2</sub>) production and SLE. Soon after, this was followed by a report of a patient with history of arterial thromboses, fetal death at 23 weeks, and CLAS (Carreras et al., 1981a). Decreased prostacyclin release could be elicited from that mother's IgG fraction, when aortic strips were incubated. The same authors found that two of 24 women with repeated abortions, intrauterine fetal growth restriction, and fetal death had lupus anticoagulants (Carreras et al., 1981b). Many reports of essentially similar findings have since followed, as for instance the demonstration by Xu et al. (1990) of the prevalence of low-titer ANA-positive serum in patients with pregnancy losses. There was also a controlled multicenter study by Out et al. (1992), which demonstrated conclusively that possession of antiphospholipid antibodies was "a risk factor for adverse pregnancy outcome." In their analysis of 47 placentas with intrauterine death, 16 had antiphospholipid antibodies (Out et al., 1991). Fibrosis in infarcts, areas of thrombosis, and Tenney-Parker changes were prominent findings. Buchanan et al. (1992), who investigated 100 lupus pregnancies with concurrent antiphospholipid antibodies, found an 81% pregnancy loss.

Once the causative relationship of CLAS to repetitive pregnancy failure had been suggested, various forms of therapy were tried. Lubbe et al. (1983), who treated six CLAS patients, successfully achieved suppression of the anticoagulant by prednisone therapy. On the other hand, Prentice et al. (1984) managed 15 patients who had three successful pregnancies without immunosuppressive therapy, whereas the results published by Carp et al.

(1989) were much less optimistic. This emphasizes the erratic nature of CLAS antibodies in predicting outcome and possibly differences in laboratory evaluation of these tests. In a later publication, Lubbe and Liggins (1985) reviewed their experience with 49 patients who had 160 unsuccessful pregnancies. They recommended prednisone (40–60 mg/day) and aspirin (75 mg/day) therapy for the management of such pregnancies. Prednisone and aspirin medication, beginning 4 weeks prior to ovulation, was shown to be effective in preventing recurrent early pregnancy failure in the study conducted by Geva et al. (1998). Rouget et al. (1982) observed a familial case of anticoagulant in mother and daughter. Branch et al. (1985) reported the frequency of preeclampsia in these patients, and recommended steroid and aspirin therapy to improve fetal outcome. The addition of immunoglobulin infusion in the therapy of such patients has been advocated by Wapner et al. (1989). Unander et al. (1987) studied the sera of 99 patients with habitual abortion and found elevated anticardiolipin antibodies in 42 patients. There was concomitant low C4 activity. Because it is well known that protein C deficiency may lead to thromboses, Cariou et al. (1986) studied the interaction of anticoagulants and protein C. They found inhibition of protein C activation by the antibodies and suggested that this acts against thrombomodulin or its phospholipid moiety. Considerations of the mechanisms of action of the different antibodies in CLAS have been reviewed by Reece et al. (1984) and Lockwood et al. (1986). Two reports have suggested that treatment with high doses of gamma globulin (IgG) not only lowers the levels of antiphospholipid antibodies but also results in improved fetal salvage in severely compromised patients (Carreras et al., 1988; Scott et al., 1988). A most interesting "natural experiment" was reported by Stormorken et al. (1988). A patient who had four consecutive miscarriages with the anticoagulant syndrome had a normal, term pregnancy because the mother had spontaneously developed antifactor II antibody. This had led to hypoprothrombinemia with marked anticoagulation. The authors suggested that one should infer from this case the need for anticoagulation in the usual cases of lupus anticoagulant that complicates pregnancy. Randomized trials and prospective studies of the efficacy of various modes of treatment have shown that low-dose aspirin is a preferable method over prednisone (Cowchock et al., 1992) and that fewer placental infarcts occurred with heparin therapy (Rosove et al., 1990). It has also been suggested that the frequently premature rupture of membranes is related to prednisone medication. Recent studies using a mouse model have also demonstrated a critical role of complement activation in pathophysiology of the antiphospholipid antibody syndrome (Salmon et al., 2003). In this model, significant fetal loss was associated with experimentally induced antiphospholipid antibody syndrome. Treatment with

heparin and other anticoagulants caused reversal of this fetal loss and growth restriction. The authors postulated that activation of complement leads to placental tissue injury and subsequent fetal loss and growth restriction. Likewise, Bose et al. (2004) found heparin to be helpful in preventing placental apoptosis in patients with lupus anticoagulant sera.

In most studies it has been shown that the placenta in patients with CLAS is morphologically indistinguishable from that of patients with severe preeclampsia. In CLAS, the extensive placental infarctions and decidual vascular lesions are often found at much younger gestational ages than is the case for preeclampsia. Frequently, the lesions occur before the 20th week of pregnancy. De Wolf et al. (1982) first drew attention to the decidual vascular lesions in this condition. They found multiple microthrombi and typical atherosclerosis in a placenta that had 50% infarction. The authors suggested that, because prostacyclin ordinarily is the most important inhibitor of platelet aggregation, antibodies to this agent may be held responsible for the thrombosis. Gleicher and Friberg (1985) and Silver (1988) also reported CLAS associated with atherosclerosis and massive placental infarction. The reviews by Triplett (1989, 1993) provide a good chronology of these discoveries. As was mentioned earlier, there is probably no need to incriminate the antitrophoblastic antibodies detected by Grimmer et al. (1988) in the causality of fetal demise. The degree of infarction and compromise of the intervillous circulation adequately explain resultant stillbirth and growth restriction (Polzin, 1991). It now needs to be learned whether this intervillous coagulation relates to the reduction of annexin V, as suggested by the study of Rand et al. (1997). Thus, sophisticated concomitant placental examinations should be undertaken. An example of such an abnormal placenta is shown in Figure 19.37.

This is the placenta of a severely growth-restricted fetus (30 weeks, 700 g) with placental abruptio and 50% infarction, in addition to a velamentous insertion of the umbilical cord. There were many decidual vessels with atherosclerosis, thrombosis and hyalinization of the thickened walls. The mother had anticardiolipin antibodies but no symptoms of SLE, and the fetus survived. We have also seen atherosclerosis in the decidual vessels of a patient with CLAS, whose pregnancy was considered to have been successfully treated; thus the degree of recognizable vascular lesions in the decidua often does not correspond precisely to the degree of growth restriction of fetus and placenta. Although the finding of vascular lesions confirms the diagnosis of CLAS when preeclampsia is absent, it is probably the extent of decidual compromise that determines the fetal and placental growth and pregnancy outcome. But, the degree of vasculopathy is highly variable. It is often difficult to assess quantitatively, unless one has adequate placental site curettings available for interpretation. Figure 19.38 shows mild arteriopathy in the floor of an extensively infarcted placenta. The fetus was stillborn at 25 weeks, but the extent of atherosclerosis poorly correlated with the 25% infarction found in the placenta. Several reviews of the vascular control of placental blood flow are available, especially those by Ylikorkala and Mäkilä (1985) and Mäkilä et al. (1986). These authors suggested that, because decidual spiral arterioles are already optimally dilated in pregnancy, two agents, prostacyclin and thromboxane  $A_2$ , are used in regulating the intervillous blood flow. A disturbance of their finely tuned balance, as accomplished by the anti-prostacyclin activity of lupus anticoagulant, may be the principal cause of hypoperfusion of placenta and the subsequent infarction of placental tissue. This is also the best explanation for the efficacy of treatment with

FIGURE 19.37. Retroplacental hemorrhage with 50% infarction of 30 weeks' gestation placenta with maternal anticardiolipin antibodies. The 700-g infant survived.

FIGURE 19.38. Decidua basalis of patient with lupus anticoagulant at 25 weeks' gestation. Decidual arterioles (arrows) show mild mural thrombosis and fibrin deposits, although the placenta was 25% infarcted. H&E  $\times 160$ .

aspirin (150mg/day) and dipyridamole (300mg/day) in preeclampsia and in CLAS. Peaceman and Rehnberg (1993) showed that with incubation of the immunoglobulin G fraction of patients having lupus anticoagulant, with placental extracts from normal gestations, thromboxane was significantly increased.

As recently as 2004, Kujovich reviewed the literature and found that although thrombophilia has a negative influence on pregnancy outcome, "definition of the magnitude of risk will require prospective longitudinal studies." In addition to decidual vessels with thromboses, vascular occlusions have also been observed in the fetus, when maternal CLAS was present. Sheridan-Pereira et al. (1988) reported a neonate with aortic thrombosis. We know of a similar case where the fetus had carotid artery obliteration and consequent brain necrosis. As mentioned earlier, Silver et al. (1992b) attributed the cerebral infarction in two infants to transplacentally transmitted antibodies. In line with what has been reported by Darnige et al. (2004), this is unusual. These investigators showed the occurrence of thrombocytopenia in the offspring of a mother with antiphospholipid syndrome. Trudinger et al. (1988) suggested that the abnormal umbilical artery flow velocity waveforms that they identified were the result of "vascular sclerosis evident in the small arteries of the tertiary villi." We have not been able to observe such lesions in the many cases of CLAS we have seen. In our opinion, the degree of infarction and shrinkage of surviving villi that are associated with the decidual arteriopathy are sufficient to explain the abnormal blood flow. Clearly, much more needs to be known of the numerous antibodies now identified and their effect on fetus and newborn before the issue is completely resolved.

Prenatal infections are important aspects of placental pathology. They are common and varied. Their pathogenesis and related circumstances must be understood if the pathologic lesions are to be interpreted correctly. Many types of infection cause placental changes, but in some types the infection may be difficult to prove from placental examination. Ultrastructural studies are especially lacking in this area and might be helpful, particularly when virus infection is suspected. Infections may ascend from the endocervical canal, or they may reach the placenta hematogenously through the maternal blood. Rarely are they acquired by amniocentesis, chorionic villus sampling, amnioscopy (Horky & Amon, 1967), percutaneous umbilical blood sampling (PUBS; Wilkins et al., 1989), or intrauterine fetal transfusion (Goodlin, 1965; Scott & Henderson, 1972). Many infections cause gross and microscopic changes of the placenta, but others, for example, the Coxsackie virus infection, leave few characteristic or specifically recognizable traces. This is also the case with parvovirus B19 infection, which often leads to fetal hydrops but has no specific placental alteration other than perhaps intranuclear inclusions in nucleated red blood cell precursors and endothelium, as a report by Hartwick et al. (1989) showed. Samra et al. (1989) described villous necrosis and calcification in the placenta from a 20 weeks' gestation with hydrops due to this infection (see Chapter 16).

This chapter first covers chorioamnionitis, followed by infections with specific organisms that correlate with chorioamnionitis. Syphilis and necrotizing funisitis (inflammation of the umbilical cord) are next discussed, and then the virus infections and villitides are discussed. Finally, rare infectious diseases such as malaria and parasitic infections are covered. A complete review of the early literature, especially the European references, may be found in the work of Flamm (1959). The comprehensive text on infections of the fetus and newborn infant by Remington and Klein (1983) can also be consulted. Excellent and complete reviews of fetal and placental infections have been provided by Blanc (1981), Altschuler (1984, 1996), Carroll et al. (1996), and Wigglesworth (1996). Most recently, Hirsch and Wang (2005) have produced a mouse model for the study of banal infections and comprehensively reviewed the literature. They propose that the process begins with toll-like receptors (TRLs) and, once the cascade is established it is difficult to interrupt.

## Chorioamnionitis

### Macroscopic Appearance

Typically, the placenta of the amnionic sac infection syndrome is premature. It lacks the blue sheen of the normal immature organ, and the membranes are obscured by an inflammatory exudate of polymorphonuclear leukocytes (PMNLs, neutrophils) (Figs. 20.1 to 20.3). The surface becomes yellow when much leukocytic exudate has accumulated and when the process has been of long duration. The amnion may be roughened or have lost the luster it normally possesses. The placenta is also frequently malodorous, and the astute observer may identify the prevailing organism by the odor. Thus, the fecal odor of fusobacterial and *Bacteroides* infections, and the sweet odor of *Clostridium* and *Listeria* infections are useful identifiers. The membranes are typically more friable, and the decidua capsularis is frequently detached and hemorrhagic and may even be absent in the placental specimen having been left in the uterus to be later discharged as lochia. These prematurely delivered placentas are often accompanied by an acute marginal hemorrhage that undermines the edge of the placenta and that originates from deciduitis. Harris (1988) has described this in greater detail. Although this mimics abruptio placentae, this hemorrhagic process (Figs. 20.4 and 20.5) markedly differs from the typical abruptio placentae of preeclampsia, the *retroplacental* hematoma. Vintzileos et al. (1987) believed that true abruptio occurs after premature rupture of the membranes. They found an incidence of 6.3% (control 2.7%) of normally implanted placentas with "indentations in the placental substance." Unfortunately, they did not discuss inflammatory reactions. Gonen et al. (1989) also provided evidence that abruptio (loosely defined) is frequently preceded by prolonged rupture of membranes. Darby et al. (1989) compared severe preterm abruptions with control women requiring preterm delivery. The former group had significantly more frequently chorio-

FIGURE 20.1. Near-term placenta with severe chorioamnionitis. Note the marginal hemorrhage at left, caused by deciduitis. The surface of the placenta is obscured by a whitish exudate that obscures the normal underlying blue color; the vasculature is also indistinct. Neonatal death.

FIGURE 20.2. Immature diamnionic, dichorionic twin placenta from a cesarean section. Twin A (left, one cord clamp) was located higher in the uterus; twin B (right), with a marginally inserted cord, was near the lower uterine segment and had significant chorioamnionitis. Compare the luster of the normal placenta (left) with the indistinct features of the abnormal placenta (right), which are due to inflammation. Neonatal deaths.

FIGURE 20.3. Immature twin placenta (19 weeks' gestation) from which twin A (right) had been delivered 1 week prior to twin B (left). Both twins had severe chorioamnionitis and fatal aspiration pneumonia. The placental surface was yellow, purulent, and malodorous.

FIGURE 20.4. Placenta at 21 weeks' gestation with massive chorioamnionitis and marked marginal/retroplacental hemorrhage caused by deciduitis.

FIGURE 20.5. Margin of immature placenta at 23' weeks gestation with marked chorioamnionitis and abruptio. The abruptio is represented by the dark marginal retromembranous hema-

toma which originates from marked deciduitis and its disrupted vessels. (H&E  $\times 3.5$ ).

FIGURE 20.6. Twin placentation with inflammation (stippled), explaining the ascending nature of the infection.

amnionitis and funisitis (41% versus 4%). They also believed that infection preceded abruptio, whereas Major et al. (1995) showed that rupture of membranes is often preceded by vaginal bleeding. This supports our notion that this decidual bleeding is secondary to deciduitis, and not the true abruptio placentae in the sense used in preeclampsia.

Touch preparations made from the fetal surface of placentas from women with prenatal infection may be used to identify the inflammatory exudate and the bacteria quickly, especially when the infection is due to *Listeria monocytogenes*. When chorioamnionitis is found in twin placentas, it is nearly invariably twin A whose cavity has inflammation or who has the more severely inflamed portion (Benirschke, 1960) (Fig. 20.6). We have considered this to mean that the amniotic sac infection is always ascending through the cervical canal. This correlation was questioned by Thiery et al. (1970), however, who found umbilical phlebitis in twin B as often as in twin A. These authors did not state how their twins were delivered, though, or how the twins were positively identified as to their intrauterine location. These specifications are crucial to the interpretation of such data.

### Microscopic Appearance

Perhaps the earliest investigators to delineate chorioamnionitis were Wohlwill and Bock (1929), who described nine cases of “coccal” infection, some of which clearly followed attempted (“criminal”) abortion. The reviews of Kückens (1938) and Müller (1956) made it clear that “round cell infiltration of the placenta” had been known before then. These authors suggested that infection of the fetus caused sepsis and then led to the placental inflammation. Wohlwill and Bock (1929) reviewed the placental inflammations that had been reported before their studies of chorioamnionitis (largely syphilis, tuberculosis, and

leprosy) and decided that the coccal infection they found was of a different character.

An extensive description of chorioamnionitis (“round cell infiltration”) was authored by Kückens (1938). He found the literature to be contradictory and came to the following conclusions: The decidua has some round cell infiltration in 60% to 70% of normal placentas; villi never have such cellular infiltrates or abscesses; chorioamnionitis, with leukocytic origin from the intervillous space, and funisitis are common perinatal phenomena. Kückens suggested that an ascending origin of the infection was the most likely pathway, and this was supported by Knox and Hoerner (1950) as well. Kückens found that, with funisitis, the umbilical vein is the first vessel to be involved, with arterial inflammation to follow. He identified cocci in the lesions, found an incidence of 20.4% chorioamnionitis, and related it to the length of labor and rupture of membranes. Interestingly, a correlation with ophthalmia neonatorum from gonorrheal infection had already been suggested.

Blanc (1953, 1957, 1959, 1961a) described chorioamnionitis in many important contributions and in great detail; he also coined the descriptive term **amniotic sac infection syndrome**, which is now widely used. Blanc indicated methods for early diagnosis (gastric aspiration of the neonate, touch preparation from amnion), and he clearly explained that this was an ascending infection of the amniotic sac (see also Müller, 1956, and Pisarski et al., 1963, for references to the early European literature). There have been numerous pathologic and clinical studies of this important entity since then (reviewed by Altshuler, 1989; Carroll et al., 1996). It should be mentioned that Genest et al. (1998) introduced the term **pseudovasculitis** for lesions seen in early pregnancy that were, or might be, confused with real inflammation. The lesions described were degenerative in nature. It should be noted that virtually all of their cases were before 20 weeks’ gestation,

a time when funisitis is normally not a common feature because the fetus is still sluggish in leukocytic reaction. It goes without saying, then, that “funisitis” is the *fetal* response to infectious agents within the amniotic fluid compartment.

Hallman et al. (1989) have shown that high concentrations of ceramide lactoside are contained in the amniotic fluid of patients with chorioamnionitis. They suggested that the lipid derives from phagocytosing granulocytes. Kirshon et al. (1991) found that patients with prenatal infection had amniotic fluid glucose levels of less than 10mg/dL. Romero et al. (1987b) showed that arachidonate lipoxygenase products are much elevated in this infection. In a later study, these authors (Romero et al., 1989b) identified as evidence of macrophage activation that infected amniotic fluid contained cachectin-tumor necrosis factor. Biggio et al. (2004) found that elevation of metalloproteinase-8 levels were strong predictors of subsequent prolonged premature rupture of membranes (PPROM). Many other intensive investigations have been published that clarify the role of amniotic sac infection in premature delivery. Importantly, Miyano et al. (1998) showed elevated fetal blood levels of a variety of complement components, lowered albumin, and other protein perturbations in chorioamnionitis. They then correlated these with “stages” of chorioamnionitis and necrotizing funisitis. The latter were thought to have “ended their initial active inflammatory states, but they still have subacute immune activation.” Shim et al. (2004) correlated chorioamnionitis with PPRM and suggested that *inflammation* rather than *infection* should be used to designate the state of affairs because in only a limited percentage of their study, organisms were found in the fluid; it must be said, however, that not all possible organisms were attempted to be cultured either. In a subsequent contribution by Kim et al. (2004), specific changes in the expression of “pattern recognition markers,” the Toll-like receptors 2 and 4 of amniotic epithelium were found. They suggested that these have a specific function of activating the immune system against very specific antigens. Interestingly, Akinbi et al. (2004) found that vernix caseosa and amniotic fluid normally contains numerous antimicrobial peptides in the absence of chorioamnionitis.

In our opinion, chorioamnionitis is *always* due to infection, and the work of Gibbs et al. (1992) and many others cited below support this notion. The speculations of Dominguez et al. (1960) are unfounded. They described umbilical cord inflammation (funisitis) in 10% of 1000 consecutively studied placentas and portrayed it as being “lymphocytic” (which it practically never is); they related funisitis to prolonged labor and meconium discharge. The complete absence of inflammation in most meconium-stained umbilical cords, the published negative findings of Fox and Langley (1971), and the personal experience

of most placental pathologists negate the notion that the common funisitis is caused by hypoxia, as was suggested. Widholm et al. (1963) stated summarily that meconium causes funisitis. It is granted that meconium discharge and funisitis are occasionally combined, but meconium per se is not an inflammatory agent. Maudsley et al. (1966), who presented a good description of the amniotic sac infection syndrome, also insisted that the term be reserved for cases with verified infection. Some other authors have neglected the consideration that fastidious organisms may cause chorioamnionitis (e.g., Olding, 1970). There is thus still lingering doubt and confusion as to the nature of chorioamnionitis (Anonymous, 1989a), but when Arias and colleagues (1993) studied the problem of preterm labor in 105 women, they found that essentially two distinct subgroups exist: those with infection ( $n = 63$ ) and those with decidual vasculopathy ( $n = 42$ ). Moreover, Oyarzún et al. (1998) have shown a remarkable increase in identifying the presence of microorganisms in amniotic fluid (46%) when they employed the organisms by polymerase chain reaction than when they attempted culture (12%). They developed a technique to screen for 16 different organisms simultaneously that should be more useful for future studies.

Chorioamnionitis is an acute inflammatory reaction in which PMNLs principally participate. Eosinophils are found at times but only in protracted infections; and macrophages may participate to a variable extent. Plasma cells are generally absent in the membranes, however, except in some of the very chronic infections to be discussed below. The leukocytes come from two sources: the intervillous space (and are then maternal), and fetal surface blood vessels (Fig. 20.7). The emigration of leukocytes is always directional, toward the amniotic cavity, presumably toward an antigenic source. Pankuch and his colleagues (1989) studied this “amniotropism” of infected amniotic fluid. They found it to be a better indicator of infection than Gram stains, culture, or chromatography.

Recently, Fraser and Wright (2002) defined an additional entity. They found 12 cases of single-vessel inflammation **without** amniotropism, and in these cases eosinophils and T cells were the major components. They occurred in term infants without chorioamnionitis and were generally confined to single chorionic (rarely cord) vessels. The cause of this unusual inflammatory process is so far obscure.

In young gestations, especially those prior to the 20th week of gestation, the PMNLs are mainly of maternal origin. By midtrimester, the fetus begins to be capable of producing leukocytes that participate in the inflammatory response to leukotoxins (Müller, 1956). Sampson et al. (1997) found XY chromosomes in over 90% of leukocytes from amniotic fluid aspirates in four pregnancies with male fetuses. Interestingly, the membranes were all unruptured and bacteria were found on smears of the

FIGURE 20.7. Placental surface in 30 weeks' gestation delivery. The patient had gonorrhea and her membranes had been ruptured for 40 hours. A 1200-g infant with pneumonia was delivered. Note the exudation of polymorphonuclear leukocytes (PMNLs) from the intervillous space (left), minimal vascular involvement (right), and amnion necrosis. H&E  $\times 240$  (left);  $\times 160$  (right).

aspirates in two cases. These investigators felt that emigration of leukocytes from maternal vessels was problematic, that emigration from cord vessels was hindered by the rapidity of blood flow, and suggested that leukodipidosis may occur across fetal pulmonary membranes. That is contrary to the histopathologic findings of most perinatal pathologists. Neonates, when compared to adults, still have reduced leukocyte counts, and their PMNLs are also less capable of ingesting microbes. Premature infants, therefore, may be prone to developing sepsis (Cairo, 1989). We have seen, however, premature infants with white blood cell counts of over 100,000, presumably because of stimulation by specific organisms. The maturation of the fetal lymphocyte system was studied by Berry et al. (1992). Fetuses had significantly fewer CD57<sup>+</sup> natural killer T cells, and other age-dependent changes are summarized in this study.

With funisitis, the inflammatory cells emigrate first from the umbilical vein and later from the arteries. They also migrate toward the amnionic surface, and only rarely toward the center of the cord. Many die during the migration. It has been suggested that they rarely reach the amnionic fluid but we believe that this suggestion is incor-

rect (Anonymous, 1989a). It is common, for instance, to find aspirated PMNLs in lung and stomach of neonates with chorioamnionitis, intermixed with squames. This pus is not produced in the fetal lung, as only late in the infectious process can one find an inflammatory accumulation within the alveolar tissue in response to infection. Pus can also, at times, be aspirated at amniocentesis. The dead inflammatory cells of the placental surface frequently accumulate in large quantities underneath the amnion in the potential space that exists between amnion and chorion (Fig. 20.8).

Experiments designed to identify the reason for the relatively slow permeation of the amnion by leukocytes have suggested that the type V collagen composition of the amnionic basal membrane prevents the ready transgression by PMNLs (Azzarelli & Lafuze, 1987). Some experimental evidence indicates that this amnionic sac infection reduces the strength of the chorion laeve (McGregor et al., 1987; Sbarra et al., 1987; Schoonmaker et al., 1989; Pressman et al., 2002). Sbarra et al. (1985) demonstrated that when membranes are incubated with lysolecithin or phospholipase A<sub>2</sub>, their bursting pressure decreases. Membrane "stripping" alone causes the release

FIGURE 20.8. Massive chorioamnionitis in a stillborn at 23 weeks' gestation. Exudate is mostly necrotic and has accumulated in amnion. The placenta had a purulent surface and marked funisitis. Stillborn. H&E  $\times 60$ .

of this enzyme (McColgin et al., 1993). It might parenthetically be pointed out that the term **amnionitis** is strictly speaking erroneous. The amnion has no blood vessels; thus inflammation, a vascular phenomenon, cannot take place in the amnion. It is only passively possible, by transmigration of leukocytes that originate elsewhere. Gleicher et al. (1979) have identified a blocking factor in the amniotic fluid that enhances leukocyte migration, presumably similar to the material that was studied by Schoonmaker et al. (1989).

The pus may reach the lung, stomach, and middle ears (Fig. 20.9). When chronic aspiration pneumonia occurs, the neonatal lung contains lymphocyte and plasma cell infiltrations. These result from an immunologic recognition of the antigen (Fig. 20.10). Benner (1940) found that 26% of stillborns had middle ear aspiration of pus. A strong correlation exists between chorioamnionitis and otitis. McLellan et al. (1962) found purulent exudate in 19 of 28 temporal bones of neonates weighing between

1000 and 1500 g. The widely patent eustachian tube of premature infants is believed to be a possible portal of entry of this aspirated infected amniotic fluid. Congenital pneumonia has been documented in numerous publications following Ballantyne's (1904) first description. It is correlated with chorioamnionitis and funisitis. Barter (1962) argued in favor of Dominguez' hypothesis of hypoxia as the cause of the inflammation (see letter from Osborn, 1962; see also Aherne & Davies, 1962; Browne, 1962). Anderson et al. (1962), Fujikura and Froehlich (1967), and Steiner et al. (1961), among many authors who studied the phenomenon, found that the "drowning in pus" correlates with chorioamnionitis, prematurity, and premature rupture of the membranes, and in long-standing infections, some plasma cell component may be found (Fig. 20.11). Some of the necrotic exudate underneath the amnion may ultimately calcify, but the fetus is usually delivered before this happens. Simon et al. (1989) undertook bacteriologic studies of infants born after premature rupture of membranes. They found that 26% had the same bacteria in placental arterial blood, ear swabs, and meconium, the predominant organisms being *Escherichia coli*, *Bacteroides fragilis*, and streptococci. A significant study of the nature of organisms that cause chorioamnionitis comes from Hillier et al. (1991). The organisms most frequently associated with preterm delivery and chorioamnionitis were group B *Streptococcus* and *Fusobacterium*; *Peptostreptococcus* was related only to preterm delivery, whereas *E. coli*, *Bacteroides*, and *Ureaplasma* were significantly related only to chorioamnionitis. Formerly considered to be a *Bacteroides* species, *Campylobacter* sp. is a newly recognized cause of severe chorioamnionitis. This gram-negative anaerobic organism is a common cause of periodontal disease and, not surprisingly, ascending infection leading to chorioamnionitis has followed oral sex (Edwards, et al., 1995; Hansen et al., 1995; Mikamo et al., 1996).

The fetal surface vessels partake in the inflammatory response to the leukotoxin, but generally little happens here before the 20th week of gestation. The maternal component of the leukocytic reaction originates in the intervillous space and in the maternal vessels of the decidua in the free membranes (Fig. 20.12). Even in dichorionic twin placentas, some exudate may be found in a part of the dividing membranes, where the PMNLs originate from persisting maternal vessels (Fig. 20.13). In this maternal response to amniotic sac infection, leukocytes first marginate beneath the fibrin under the chorionic plate. They then infiltrate the chorion and eventually the amnion. The subchorial accumulation has been designated "intervillositis," an unfortunate but often used term. It is true that other types of intervillositis occur (vide infra), but these are more chronic processes and they differ substantially from the acute infections. Infectious organisms are rarely seen in the intervillous space,

FIGURE 20.12. Placental membranes at term with early inflammation. Leukocytes are accumulating in maternal vessels, with direction toward the amnionic surface. Mural thrombosis is beginning. The patient was febrile, and funisitis was present. H&E  $\times 60$ .

although toxins may accumulate here. In acute chorioamnionitis the leukocytes merely react to the leukotactic signal that has permeated through the placental surface; they then accumulate in the subchorial space and finally migrate. Abscess formation underneath the chorionic plate and dissemination of exudate between villous trunks are rare (Vernon & Gauthier, 1971). When it is present, one must consider congenital listeriosis and *Campylobacter* sp. infection first; other infections are much less frequently the cause. With listeriosis, villous and intervillous abscesses occur frequently (vide infra). Intervillous abscesses occur occasionally in maternal septicemias. We have seen them with maternal staphylococcal and *E. coli* infections. The mothers are usually so ill that labor and delivery occur before abscesses develop. Indeed, staphylococcal infection has only rarely been reported. Negishi et al. (1998), who described such a case, found only one previous report. Their patient was at 38 weeks and mild fever ( $37.8^{\circ}\text{C}$ ) was noted, but the membranes were intact.

She had been treated with chloramphenicol for bacterial vaginosis. The fetus died suddenly. Cord blood and placental surface grew *Staphylococcus aureus*, and there was chorioamnionitis. Levy (1981) believed that a placental abscess he discovered could be the cause of the maternal fever. This abscess occupied 25% to 39% of the placental surface in a term pregnancy, but no bacteria were isolated, and listeriosis was not ruled out. Another placental abscess was due to *Proteus mirabilis* infection in a febrile patient, gram-negative bacilli being present in sections (Ravid & Toaff, 1976). In another pregnant woman an intravenous line had been placed at 12 weeks' gestation as treatment for hyperemesis. She developed *Serratia* sepsis and was appropriately treated. When she delivered at 34 weeks, an old abscess without organisms was identified in the placenta. Bendon et al. (1998) reported on two fetal deaths due to placental abscesses from maternal *E. coli* sepsis with disseminated intravascular coagulation (DIC). There was focal infarction around the abscesses,

FIGURE 20.13. Dividing membranes of a diamniotic/dichorionic (DiDi) twin placenta with inflammation in the right sac. H&E  $\times 25$ . (Courtesy of Dr. S.G. Driscoll, Boston.)

but chorioamnionitis was absent. **Villous** abscesses occur, as was reported, after intrauterine transfusion with infected blood (Scott & Henderson, 1972). The villi are otherwise almost never involved in common cases of chorioamnionitis, however severe that process may be. Subchorionic fibrin deposits are excellent sites from which to culture bacterial organisms, according to Aquino et al. (1984). These authors preferred to sample this site because it is not contaminated with vaginal organisms and because they experienced good recovery of bacteria from these specimens. They isolated group B hemolytic streptococci, anaerobic cocci, and “rods,” organisms that commonly cause endometritis, pelvic infection, and neonatal sepsis.

The exudate in funisitis may occasionally be visible macroscopically (Fig. 20.14). It must be emphasized, however, that funisitis (umbilical vasculitis) does *not* signify the existence of fetal sepsis, as is often believed. It *does* signify the presence of a fetal inflammatory response, however. Blanc (1961a) has specified the possible means by which fetal sepsis can take place. It is a relatively late event in the course of prenatal infection with bacteria. Blanc opined that fetal sepsis may result from invasion of organisms through lung and intestinal tract.

Prior to the delineation of the amnionic sac infection syndrome, funisitis was thought to be primarily related to congenital syphilis, and spirochetes were usually sought from endothelial scrapings by darkfield examination. This association is now no longer held to be firm (reviewed by Beckmann & Zimmer, 1931). With funisitis, the leukocytes marginate first at the vascular intima and then begin to dissect among the muscle bundles of the umbilical vein and arteries, finally infiltrating Wharton's jelly (Fig. 20.15).

They also reach the cord's surface and may accumulate there in substantial numbers. The fetal PMNLs have the same fine-structural features as those from adults. When they emigrate through the umbilical vein wall, degeneration of its inner elastic components is observed (Fig. 20.16). With some infections, notably that with *Candida albicans*, small accumulations of PMNLs are seen on the cord surface. They are often visible macroscopically and have a typical, granular appearance. Old exudate in the cord may accumulate in concentric perivascular rings, giving the appearance of Ouchterlony immunodiffusion plates (Fig. 20.17). This old exudate is more prone to developing mineralization than is the exudate of the fetal surface of the placenta. In fact, this calcification may reach extraordinary proportions at times, so that the cord cannot be clamped readily (vide infra). It is then referred to as necrotizing funisitis.

The microorganisms that have caused the inflammatory response may be seen in many infected placentas, particularly in cases of listeriosis, candidiasis, fusobacterial infection, and some of the infections with common cocci. But many cases of chorioamnionitis result from infection with organisms that are not so readily demonstrated histologically or that are not commonly considered. Examples include *Chlamydia* (Andrews et al., 2000) and *Mycoplasma* and *Ureaplasma* (Lu et al., 2001; Yoon et al., 2003). Mural thrombosis in chorionic vessels is frequently present when the infection has been of longer duration (see also Arias et al., 1997). It begins at the intima of veins, usually toward the amnionic surface, and gradually increases (Fig. 20.18). The thrombi may be grossly apparent as yellow-white streaks, and eventually the villous tissue of the involved vessels atrophies. In the umbilical cord, thrombi have a less characteristic macro-

FIGURE 20.14. Longitudinal and cross section of an umbilical cord at 30 weeks' gestation. The patient had no fever. A yellow streak was seen along the umbilical vein, and the cord appeared brownish. There is a prominent white ring of acute inflammatory exudate around the umbilical vein.

scopic appearance but may also involve arteries (Fig. 20.19). It is true, though, that most thromboses of large placental vessels have another etiology, mostly being secondary to obstruction of venous return. Finally, in the

FIGURE 20.20. Chorioamnionitis associated with amnion necrosis. H&E  $\times 160$ .

amniotic infection syndrome, the amniotic epithelium is frequently degenerated, especially in areas of severe inflammation (Fig. 20.20). Thrombosis of umbilical veins is rarely reported, and it is summarized by Wolfman et al. (1983), who saw it in a surviving neonate. It was associated with marked inflammation. These authors also review the sparse literature and draw attention to the greater frequency in diabetic gestations.

Chorioamnionitis is common. Fox and Langley (1971), for instance, found it in 24.4% of 1000 consecutive live-births. A study of Salafia et al. (1989) showed that some degree of chorionitis was present in 4% of uncomplicated term deliveries; in 1.2% the chorioamnionitis was "clinically silent." Inflammation of membranes and cord is much commoner still in the immature organs of spontaneous, premature births and in patients with premature rupture of membranes. Hillier et al. (1988) found infection in 67% of preterm deliveries, compared with 21% of term gestations. Guzick and Winn (1985) did a prospective study of 2774 women and found the overall incidence

FIGURE 20.19. Organized, partially occlusive arterial thrombus in an umbilical artery, associated with arteritis. Infant developed cerebral palsy. H&E  $\times 20$ .

of prematurity to be 5.4%. It was 11% when chorioamnionitis was present without membrane rupture, but 56.7% when premature rupture of membranes and chorioamnionitis coexisted. The authors concluded that 25% of premature deliveries were attributable to chorioamnionitis. Newton et al. (1989) showed in a large study that "duration of membrane rupture [was a] significant risk factor for intra-amniotic infection." The outcome of pregnancy in 59 patients with rupture of membranes before 26 weeks' gestation was studied by Bengtson et al. (1989). They ascertained chorioamnionitis in 45.8% (49.1% perinatal mortality) but also found that "there was a tendency for patients with extremely long latent periods to have lower rates of infection." Holcroft et al. (2004) found that chorioamnionitis and funisitis were not responsible for metabolic acidosis in preterm fetuses and that factors other than hypoxia (mostly culture positive infection) must be responsible for the frequent central nervous system (CNS) damage seen (see also Holcroft et al., 2004). Numerous other investigators have shown that chorioamnionitis is a significant risk factor for prematurity, CNS damage, fetal/neonatal sepsis, and fetal demise (deAraujo et al., 1999; Hansen & Leviton, 1999; Goldenberg et al., 2000; Yoon et al., 2001; Genen et al., 2002; Slattery & Morrison, 2002; Graham et al., 2004; Rouse et al., 2004). Duggan et al. (2001) showed that brain injury is more likely to occur in chorioamnionitis when fetal circulating levels of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukins (IL-1 $\beta$ , -6, and -10) as well as CD45RO<sup>+</sup>T lymphocytes are elevated (see also Cooper & Nuovo, 2005). Patrick et al. (2004) have created a guinea pig model to study the CNS effects of chorioamnionitis. Quintero et al. (1998) sought to assess and "cure" premature rupture by endoscopic study. They identified the funnel-like site of rupture and unsuccessfully attempted "amniopatching" by application of platelets and cryoprecipitate. More recently, the same investigators placed a collagen membrane patch over the rupture site in a patient, thus prolonging the pregnancy by 2 weeks (Quintero et al., 2002).

Many attempts have been made to "grade" the inflammatory process, with the hypothesis that different severities of inflammation might correlate with neonatal outcome and possibly other parameters. This has been only minimally successful, but a study by Redline et al. (2003) showed reasonable reproducibility among a number of pathologists judging placental inflammatory lesions. Not taken into consideration was a study by Ohyama et al. (2002) that suggested the existence of a subacute form of chorioamnionitis, a form that is especially marked by amnion necrosis and that was an infection they felt to be of longer duration. These authors showed that the neonatal outcome was worse with this form of inflammation, especially from a chronic respiratory point of view. Several investigators have shown that

the effect of funisitis (arteritis and phlebitis has a greater impact when merely membranitis is present (Kim et al., 2001; Mittendorf et al., 2003). Miyano et al. (1998), who assessed the cord blood levels of various protein components, came closer to a useful means of subdividing the degree of inflammation. Then there are observations such as, for instance, a case of massive chorioamnionitis, funisitis with necrotizing features and severe edema, neonatal white blood cell count of 100,000 at 26 weeks' gestation, and an apparently healthy neonate who survived; conversely, minimal inflammation associated with group B streptococcal infection can be devastating. These and many similar experiences make us believe that the most important features of ascending infection are the type of infectious agent and perhaps the time of onset, but not the degree or the precise nature of the inflammatory response. *Trichomonas*, for instance, can be enormously leukotactic yet have little effect on neonatal morbidity, whereas it is associated with low birth weight and preterm delivery (Cotch et al., 1997). Conversely, group B streptococcus may prevent leukocyte migration and have a devastating effect on fetal/neonatal life. Thus, the extensive investigations on grading the inflammatory response by van Hoven et al. (1996) and de Araujo et al. (1994), among other such studies, should be interpreted with this caution in mind.

The ascending nature of this infection is signaled by three pathologic findings, but is also supported by culture of intact sacs: (1) There is usually severe, acute deciduitis associated with the membranitis, and it often exceeds the degree of chorioamnionitis (Fig. 20.21). (2) When the intrauterine position of twins is known, including the location of the partition of their amniotic sacs, it is invariably twin A who has chorioamnionitis or whose membranes are more severely inflamed (see Figs. 20.2 and 20.3). (3) When membranes are rolled in such a manner as to have the point of spontaneous rupture on the inside, the degree of inflammation is most significant in the inner portions of the roll, that is, in the proximity of membrane rupture (Figs. 20.22 and 20.23) (Benirschke & Altshuler, 1971). It should be noted, however, that maternal fever **alone** is a poor indicator of the presence of chorioamnionitis, as many patients do not exhibit elevated temperature and others may have an intercurrent infection of other kinds.

It is well known that attempted abortion with nonsterile instruments is frequently followed by sepsis and chorioamnionitis (Studdiford & Douglas, 1956), but chorioamnionitis has also repeatedly been found with unruptured membranes (e.g., Miller et al., 1980b). A good example is the case of (amniotic fluid infection—"chorioamnionitis," according to the authors) with the uncommon organism *Eikenella corrodens* (Jeppson & Reimer, 1991). The 31-week gestation infant remained uninfected, perhaps because of prenatal antibiotic therapy when the

FIGURE 20.21. Acute and chronic deciduitis (decidua capsularis) in an immature placenta with chorioamnionitis. H&E  $\times 160$ .

Gram-negative rods were identified by culture from amniocentesis. The association of prenatal infection with intact membranes is easiest to show with the relatively common *C. albicans* infection of the amniotic sac. Further, Gyr et al. (1994) showed that, experimentally, *E. coli* organisms could penetrate viable intact placental membranes, with simultaneous changes in glucose and lactate concentrations. Also, many cases have been described in which chorioamnionitis, with or without fetal pneumonia, existed in the presence of intact membranous sacs (en caul). Although this is an uncommon occurrence, it is an important finding for our understanding of the pathogenesis of infection (Royston & Geoghegan, 1985). The

general experience that inflamed membranes usually rupture prior to delivery does not argue against the fact that chorioamnionitis can exist with an intact sac. The loss of membrane integrity, resulting from inflammation, makes rupture a probability (Schoonmaker et al., 1989). Numerous reviews exist on this topic (Altshuler, 1984).

The predominant opinion now is that amniotic sac infection is a primary cause of premature rupture of membranes and premature labor, at least in those pregnancies that terminate spontaneously before 30 weeks' gestation (Garite & Freeman, 1982; Toth et al., 1988). This is also our opinion, and we believe that this is the most important unresolved problem in gestation, the reason

FIGURE 20.22. Membrane roll of placenta with marked chorioamnionitis. The edge of the spontaneous membrane rupture is in the center. Note the dark exudate in the decidua and chorion in the center. H&E  $\times 12$ .

FIGURE 20.23. Intrauterine position of fetus and placenta. Infectious organisms ascend through an opened endocervical canal. They first infect the membranes that cover the internal os and then penetrate into the amniotic cavity.

being that it not only is often recurrent (Mercer et al., 1999; Lee et al., 2003), but also leads to the most premature infant deliveries, of infants who are difficult to treat and many of whom develop cerebral palsy (Wood et al., 2000; Yoon et al., 2000; Kumazaki et al., 2002a). There is also evidence that these infections have an important role in the causation of stillbirths and neonatal deaths (Quinn et al., 1985). The formerly held idea that chorioamnionitis might protect the neonate against developing hyaline membrane disease by the attending stress was invalidated by the controlled clinicopathologic study of Dimmick et al. (1976).

To make the clinical diagnosis of chorioamnionitis may pose problems for the clinician, as only some gravidas experience fever, uterine tenderness, or fetal tachycardia with amniotic sac infection. Bobitt et al. (1981) aspirated amniotic fluid for culture from women in premature labor and found microorganisms in 25%. Seven of eight patients went into labor within 48 hours, and 75% of positive women had no fever. These authors also advocated Gram stains for rapid diagnosis of organisms, a method found to be helpful in the management of patients with premature rupture of membranes and chorioamnionitis (Broekhuizen et al., 1985). Others have advocated the use of gas-liquid chromatography for the early diagnosis of the amniotic sac infection syndrome (Gravett et al., 1982; Wagner et al., 1985; Romero et al., 1988b). This rationale was based on the detection of short-chain organic acids, which are the by-products of bacterial metabolism. Romero et al. (1989e) found that this method is insensi-

tive, especially when gram-negative organisms cause the infection, which is why Pankuch et al. (1989) suggested the use of leukotaxis studies. Maternal pyrexia and leukocytosis are also unreliable predictors, as has been found in numerous studies, and now fibronectin assays seem to be more profitable.

Hawrylyshyn et al. (1983) found that elevated C-reactive protein (CRP) levels correlated better with infection than did maternal fever. Elevation of CRP levels in maternal serum, advocated by Evans et al. (1980) as a means to predict chorioamnionitis, has also not been universally helpful. Farb et al. (1983) identified two patients with verified infection and normal levels; false-positive results were also obtained. Ernest et al. (1987) reported problems of both false-positive and false-negative levels. Watts and her colleagues (1993) found that elevated CRP levels were useful in deciding when to do cultures of amniotic fluid but they found poor correlation with chorioamnionitis. Other investigators, however, have found excellent correlation with CRP levels and chorioamnionitis and have advocated its use in the clinical setting (Romem & Artal, 1984; Ismail et al., 1985; Potkul et al., 1985).

Because of the importance of this ascending infection, investigators have sought new means of predicting the existence of chorioamnionitis before birth. Egley et al. (1988) suggested that amniotic fluid esterase levels (derived from PMNLs) have high specificity (100%) and sensitivity (81%). But, as in bacterial studies of cerebrospinal fluid (CSF), lactate, esterase, etc. are no more sensitive than looking for PMNLs from which they are derived. A Gram stain takes 5 minutes to perform and may be much more useful. Ohlsson and Wang (1990) reviewed 39 studies and concluded then that "an ideal test to predict chorioamnionitis or neonatal sepsis was not found."

Romero et al. (1987a, 1988a) and Cox et al. (1988) found that quantitation of the lipopolysaccharide component of Gram-negative organisms (endotoxin) might be used for identification of these infections. Both groups of investigators found elevated levels of endotoxin in specific infections with the *Limulus* test; and when the test was combined with Gram stains, a more adequate means of prenatal diagnosis seemed possible. A variety of kinins, especially IL-1 and TNF were next being investigated as possible prime movers in initiating uterine contraction (Romero et al., 1989a,b; see reviews by Mitchell et al., 1993; Oláh et al., 1996; Kayem et al., 2004). In one of the few studies of cervical mucus (which we consider to be of great importance in uterine defense mechanisms), Platz-Christensen et al. (1993) found that concentrations of endotoxin and IL-1 $\alpha$  are significantly increased in vaginal fluid and cervical mucus of women with bacterial vaginosis. The primacy of cervical problems in ascending infection was related by Iams (1998), and Leppert (1998) sought cleavage of cross-linked collagen fibers as a pos-

sible early mechanism for cervical dilatation. We found markedly increased amounts of IL-1 and IL-1ra in several areas of placentas with chorioamnionitis (Baergen et al., 1994), indeed we believe that the principal problem is the absence of endocervical protective mucus. It is impressive to observe the quantity of this viscous mucus in the endocervical canal of hysterectomy specimens done for placenta percreta, and in animals that succumb during pregnancy at the San Diego Zoo from trauma or other unrelated causes. Moreover, Hein et al. (2001, 2002) in two excellent studies of the human endocervical mucus have shown its richness in defensive molecules and cells (Fig. 20.24). Genc et al. (2004) have measured the IL-1ra and IL-1 $\beta$  response in vaginal/cervical secretions and found that in women with various pathogens, the ratio of IL-1ra/IL-1 $\beta$  was decreased and was associated with preterm delivery. Similar observations of a decreased immune function of cervical secretions and subsequent chorioamnionitis were made by Simham et al. (2003).

Many other studies have since been conducted to further characterize the cytokine involvement of prenatal infection and premature labor (see review and new findings in Arntzen et al., 1998). Lockwood et al. (1994) found

increased cervical IL-6 levels to be poor indicators of maternal infectious sequelae, whereas Coultrip et al. (1994), Andrews et al. (1995), and Yoon et al. (1995) described how amniotic fluid IL-6 levels are useful as rapid diagnostic tests to predict premature labor with intact membranes. Menon et al. (1995) determined that the amnion and chorion are the sites of inflammatory cytokine (IL-1 and IL-6) production when they sought these by messenger RNA detection (see also Reisenberger et al., 1998). In a later contribution, Yoon et al. (1997a,b) suggested that IL-6 and IL-1 $\beta$  or TNF- $\alpha$  may “play a role in the genesis of brain white matter lesions” in infants delivered with chorioamnionitis (see also Grether & Nelson, 1997). Stretching alone of the membranes was sufficient to release IL-8 and collagenase activity (Maradny et al., 1996). IL-8 and IL-10 were incriminated as participants in premature labor by Osmer et al. (1995) and Greig et al. (1995), whereas IL-1 $\alpha$  was found to be elevated in studies by Dudley et al. (1996). Conflicting results concerning the cellular origin of many cytokines have been published. Thus, Reisenberger et al. (1998) found cultured amnion cells to produce IL-6 and IL-8 upon bacterial exposure; Steinborn et al. (1998) found the origin of TNF- $\alpha$  to be placental macrophages, whereas IL-1 and IL-6 came from placental endothelial cells. It is also of interest that women who had chorioamnionitis in an earlier gestation had significantly higher levels of TNF- $\alpha$  production after lipopolysaccharide stimulation than controls (Amory et al., 2001). It can thus be seen that the precise pathophysiology of the mechanism of premature labor and infection and the participation of various membranes and locales of cytokine production are under active study, without a final, agreed-upon resolution still forthcoming. Clearly, infection and inflammation are the most important aspects in the process. Most appealing to us, having long assumed that cervical/endocervical “competence” is an important aspect in preventing ascending infection, is the finding by Svinarich et al. (1997; also Quayle et al., 1998) that normally the endocervix is a rich source of defensin-5. This protein plays an important protective role against infection in other organs (bowel) and may become a significant player in the future. At present, the cervical/vaginal presence of elevated fibronectin levels seems to be the most practical way of monitoring progression of chorioamnionitis (Bartnicki et al., 1996; Garite et al., 1996; Rizzo et al., 1996; Goldenberg, 1997; Sennström et al., 1998). Simhan et al. (2004) have added elevated vaginal pH and neutrophils to this array of tests for PPRM, as it is now referred to. These tests have been commercially marketed and are highly successful in predicting delivery within a week (Peaceman et al., 1998). The fibronectin detected is thought to derive from the membranes.

Because labor is readily induced with prostaglandins, they have been studied as the possible main mediators of

FIGURE 20.24. Endocervix of uterus from cesarean section for placenta percreta at 37 weeks' gestation. Thick purple mucus fills the canal and interdigitates with the mucus glands.

the preterm labor associated with chorioamnionitis. Although prostaglandins are well-known mediators of many aspects of disease, and they are also the chemicals that have proved to be useful in initiating labor, there are reservations about their primacy in the initiation of normal labor. While seeking a possible link between premature labor and placental inflammation, we found that arachidonic acid was consumed in the process of labor (Curbelo et al., 1981). The testing was done by chromatography of phospholipids from placental membrane extracts obtained from various types of delivery. Arachidonic acid appeared to be electively stored in the amnion. Later, a large number of microorganisms were tested for phospholipase activity because initiation of labor was believed to result from phospholipase A<sub>2</sub> activation and because of its association with infection. It was then found that many organisms contain this enzyme in considerable quantities (Bejar et al., 1981; McGregor et al., 1991). This observation led to the hypothesis that bacterially mediated enzymatic conversion of arachidonic acid may signal the onset of premature labor in pregnancies complicated by chorioamnionitis. Others have since studied many more organisms and found that phospholipase is liberated from a large number of microorganisms, with release of prostaglandin from amnion (Lamont et al., 1990). Bennett and Elder (1992) found that bacterial infection cannot initiate labor from "intrinsic biosynthesis and release of prostaglandins . . . by the bacteria themselves." We now believe that there is an insufficient quantity of lipase to come from the usually relatively small number of bacteria to initiate and maintain labor. Rather, the enzyme is more likely being provided by the large number of leukocytes that are also known to possess phospholipase (Victor et al., 1981) and whose enzyme is activated by chemotactic peptides (Galbraith, 1988). The lipase also occurs in high concentrations in the placental membranes (review by Vadas & Pruzanski, 1986; Kredentser et al., 1995; Skannal et al., 1997). Okita et al. (1983) identified substantial stores of arachidonic acid in human amnion and concluded that it originates from amniotic fluid.

Lamont et al. (1985) also exposed amnion cells in culture to bacterial products and found prostaglandin E to rise markedly as a result. They thus affirmed that chorioamnionitis may cause premature labor. This finding was amplified by Bennett et al. (1987), who performed similar experiments. A correlation between chorioamnionitis and premature labor is additionally supported by findings of significantly elevated prostaglandin levels in infected amniotic fluid (Romero et al., 1986) and by the demonstration of markedly increased prostaglandin production from infected amnion (Lopez Bernal et al., 1987).

Despite these attractive findings of prostaglandin metabolism, attention has been paid to the increase of amniotic leukotriene concentrations during labor

(Romero et al., 1988c) and to the decidual IL-1 production during premature labor (Romero et al., 1989a,f) as well as many other proteins. Deciduitis, decidual macrophage activation, and PMNL exudation, in particular, play an important role in the initiation of premature labor. It must be admitted, however, that although the evidence of infection as a primary cause of chorioamnionitis and of premature labor is no longer in doubt, the precise chemical cascade that ultimately leads to myometrial contractions is not yet elucidated. A multifactorial mechanism for preterm membrane rupture is advocated by Parry and Strauss (1998). They reviewed the large literature and paid special attention to the loss of strength of the placental membranes. Further, the primacy of infection is supported by the meta-analysis of seven studies on prophylactic antibiotic therapy in premature rupture of membranes (Egarter et al., 1996). It indicated reduced neonatal morbidity from infections in mothers with premature rupture of membranes (PROM) treated prenatally with different antibiotic regimens. A comprehensive review, especially concerning prevention and therapy of bacterial vaginosis, premature delivery and PROM comes from McGregor and French (1997). Regrettably, metronidazole treatment to prevent premature delivery in women with bacterial vaginosis did not reduce its occurrence, nor did this therapy prevent preterm delivery from trichomonas infections (Klebanoff et al., 2001).

Many investigators have graded the inflammatory infiltration (e.g., Thiery et al., 1970; Naeye et al., 1983) so as to perhaps correlate it with clinical findings, for example, rupture of membranes and maternal fever. We have found this to be impractical for several reasons. For instance, there are severe prenatal infections with some types of organisms, in particular the group B streptococcus, that elicit little placental inflammatory reaction but that can produce devastating disease in the newborn. It is also likely that different organisms have differing ability to penetrate the membranes. This point was shown experimentally by Galask et al. (1984), who exposed membranes to bacterial cultures. They found that group B streptococci penetrated membranes more readily than did coliform bacilli and gonococci. We believe that the intensity of inflammation is more closely related to the nature of the organism, rather than to the chronicity of the infection. It seems also difficult to estimate how long the infection has been active. This uncertainty has hindered acceptance of the opinion that membrane rupture *follows* membranitis, rather than *causes* it (see Naeye & Peters, 1980). The prevailing view certainly is that membranes rupture first, to be followed by amnionitis.

The preponderance of chorioamnionitis in very immature pregnancies (20–30 weeks) is striking (Lahra & Jeffery, 2004). It has often been linked to the less effective bacteriostatic nature of amniotic fluid in immature preg-

nancies (Anonymous, 1989a). Thadepalli et al. (1978) showed that amniotic fluid of the first trimester is least inhibitory against anaerobic organisms. Schlievert et al. (1975, 1976a,b, 1977) had similar results using various organisms for analysis. Their studies showed that the inhibitory moiety of the amniotic fluid contains a zinc-dependent special peptide that develops mostly after 20 weeks' gestation. Others had identified immunoglobulins in amniotic fluid (Galsk & Snyder, 1970) and that the fluid from patients with chorioamnionitis had elevated immunoglobulin levels (Blanco et al., 1983). Specific inhibition against *Mycoplasma* and *Chlamydia* was demonstrated in amniotic fluid by Thomas et al. (1988), and Gray et al. (1987) concluded that even the small quantities of type-specific streptococcal antibodies in amniotic fluid that they demonstrated may protect the fetus against this infection. All of these points may explain why chorioamnionitis is much more common during early pregnancy than toward term. It is our view that the more important aspect of labor initiation resides with inflammation of the decidua, and that the bacteriostatic activity of amniotic fluid is not the primary event preventing labor and chorioamnionitis during later gestation.

#### GENERAL CONSIDERATIONS OF CHORIOAMNIONITIS

The amniotic sac infection syndrome develops from infection that commences in the endocervix and vagina and then ascends (Fig. 20.23). Abundant evidence supports this opinion, and there is also much evidence that prematurity is often caused by such an ascending prenatal infection. Premature rupture of the membranes (PROM) often results and is then a common accompaniment of infection. Garite (1985) labeled it the "enigma of the obstetrician" because of the controversial aspects of diagnosis and management. A further problem is the difficulty in predicting rupture of membranes and premature delivery. It has been suggested that assessment of vaginal fibronectin may provide such a clue (Lockwood et al., 1991; Iams et al., 1995), but Feinberg and Kliman (1992), and others have taken exception to this approach. Gibbs and Blanco (1982) found that PROM complicates 4.5% to 7.6% of all deliveries, and that 1% of all gestations have preterm delivery with PROM. This study reviewed the evidence favoring the notion that PROM is often the consequence of subclinical vaginal infection. They also gave detailed protocols for management. McDuffie et al. (1992) showed in an experimental model that intracervical administration of coliform bacilli in rabbits leads to rapid and marked elevation of the various mediators that are usually associated with labor. Elst et al. (1991) found elevated prostaglandins and leukocytes in amniotic fluids aspirated by fetuses from spontaneous premature labor and concluded that chorioamnionitis may initiate preterm labor. Lettieri and her colleagues (1993) suggested that "idiopathic" preterm labor can be explained in 96%. They incriminated faulty implantation in one half of cases, infection in 38%, immunologic factors in 30%, cervical incompetence in 16%, uterine factors in 14%, maternal factors in 10%, trauma (surgery) in 8%, and fetal anomalies in 6%. It is our impression that ascending infection is the most important cause of preterm labor and PROM, certainly so in the 20- to 30-week gestation group. There are now numerous studies that support this contention. Romero et al. (1989e) examined the amniotic fluid aspirated from 264 women with preterm labor and with intact membranes. They found positive cultures

in 91%; 42% delivered preterm neonates, 21.6% of which had positive amniotic fluid cultures. Preterm delivery was especially frequent when endotoxins were detected with the *Limulus* amoebocyte lysate assay. The commonest organisms isolated were *Ureaplasma urealyticum*, *Fusobacterium* sp., and *Mycoplasma hominis*, but later studies have indicated a spectrum of other organisms (Romero et al., 1992a). Inflammatory lesions (chorioamnionitis, funisitis) are essentially present only when microbacterial contamination can be shown to exist in the amniotic cavity (Harger et al., 1991). This study also emphasized that antimicrobial therapy failed to prolong pregnancy when chorioamnionitis was extant.

There is now a very large body of investigations that incriminates all sorts of mediators in the initiation of labor during the process of ascending infection. Interleukin-1 was found elevated and championed by Taniguchi et al. (1991), but no elevation of levels of IL-1-receptor antagonists were identified (Romero et al., 1992b). In addition to IL-1, IL-6 was found to be increased in infections studied by Matsuzaki et al. (1991), but not in normal labor. Kelly et al. (1992) suggested that the "final common step of prostaglandin and antiprogesterone action in parturition was decidual release of IL-8." Hillier et al. (1992) found several cytokines and prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) to be elevated in amniotic fluid during preterm labor and suggested their usefulness in predicting labor. Tumor necrosis factor activates the cytokine machinery and may well be at the starting point of labor initiation by stimulating prostaglandin production from the decidua (Norwitz et al., 1992a,b; Romero et al., 1992c). Suffice it to say that the cytokine system is intimately involved in premature labor when it is caused by infection; absent inflammation, the kinin levels are not significantly elevated (Romero et al., 1993).

When membranes are ruptured and the endocervical mucus plug has disappeared, the amniotic cavity may be quickly colonized by organisms of the cervicovaginal tract (Miller et al., 1980a,b). Wabbeh et al. (1984) found that anaerobic organisms play an important role in PROM similar to the results of a study by Bobitt and Ledger (1977). When Pankuch et al. (1984) attempted the isolation of bacterial and chlamydial organisms from 75 placentas, they found that 72% of placentas with chorioamnionitis had bacteria (82% with clinical chorioamnionitis), whereas only 15% of uninfamed placentas contained organisms. Almost 50% were anaerobic organisms. When, as is frequently the case, no organisms are identified histologically by the pathologist one must consider that they are either histologically not recognized (e.g., mycoplasma, trichomonas, etc.) or that cytokines (chemokines: GRO- $\alpha$  and IL-8) may be the chemoattractants (Hsu et al., 1998). Johnson et al. (1981b) found in their large study of PROM that unless chorioamnionitis intervened, rapid delivery was not necessary. They cautioned that, with modern management, the risk to the fetus is primarily one of prematurity. Earlier studies of the same group had shown that neonatal infections were much more common in preterm than term infants, but that the risk of PROM alone was insignificant (Daikoku et al., 1981). Teppa and Roberts (2005) have now developed an enzymatic test for the apparently common asymptomatic bacteriuria in pregnancy but they do not correlate it with ascending infections. Many authors have suggested that maternal bacteriuria is specifically related to PROM and to prematurity (Naeye, 1979a), but it has not been confirmed by some well-controlled studies of maternal bacteriuria (Bryant et al., 1964). The relation of asymptomatic maternal bacteriuria to low birth weight and preterm delivery was reaffirmed by a meta-analysis of Romero et al. (1989d). They also believed that ascending infection was the mode for infection. An anamnestic lymphocyte response to the organism of maternal infection was demonstrated in some infants judged to be at high risk of dying (Wallach et al., 1969). Still somewhat controversial is whether ascending infection can truly be prevented by antibiotics and also whether treatment is beneficial (Christmas et al., 1992; Seo et al., 1992; Kirschbaum, 1993). Unresolved also is whether aggressive tocolysis is beneficial to prolonging the survival of neonates or prolong-

ing pregnancy significantly. Thorp et al. (2002) saw a mixed outcome pattern in their meta-analysis of 14 reports, and Combes et al. (2004) found no benefit from tocolysis in PPROM before 34 weeks in 130 cases studied, and reported significant maternal complications. Dinsmoor et al. (2004) found some prolongation of gestation with expectant management, but poor outcome nevertheless. Gibbs (2002) advocated that this is a topic for prevention rather than therapy, with which we agree. His experimental studies (Gibbs et al., 2002) clearly showed that, in rabbits, antibiotic therapy was unable to eradicate organisms from amniotic fluid or the fetus.

Another presumed cause of PROM, abortion, and premature delivery has been the syndrome of "incompetent cervix," thought to have a congenital origin (review by Borglin, 1962). It has been suggested that 0.1% to 1% of pregnancies are thus complicated, and that up to 20% of midtrimester abortions result from an incompetent cervix (Anonymous, 1977b). Gans et al. (1966) suggested that trauma is the most common antecedent of an incompetent cervix, a notion with which we agree, especially when prior surgery is considered. They reported favorable surgical repairs of the defect. The alleged etiology of trauma is well supported by a review of the topic (Anonymous, 1983a). Hagen and Skjeldestad (1993) studied the outcome of cervical laser conization with a case-control approach. They reported an increased frequency (38% vs. 6%) of premature births in the operated cases and recommended that conization be done only in high-grade *in situ* neoplasia. Barford and Rosen (1984) were more cautious in their assessment of diagnosis and therapy, and Charles and Edwards (1981) listed the many serious infectious complications (e.g., puerperal sepsis, chorioamnionitis) that may ensue, particularly when the Shirodkar stitch is undertaken during the second trimester of pregnancy. Heinemann et al. (1977) and others (e.g., Dunn et al., 1959) have reported maternal sepsis after intraamniotic *E. coli* infection in such cases. Abundant bacillary growth was present in placental capillaries, but there was only minimal inflammation in the case of Heinemann et al. (1977). Romero et al. (1992d) advocated that amniocentesis with culture should be undertaken before a cerclage is placed in the midtrimester; they found a high frequency of bacterial invasion. In our opinion, it is not likely that incompetent cervix is frequently an inherited defect; rather, we believe that trauma and infection are more probable antecedents. The cervix, affected by severe chronic cervicitis, is often patulous and prone to premature dilatation, which may be the origin of many of the 20% incompetent cervixes cited to be associated with PROM. Leveno et al. (1986) published a study of gravid cervical dilatation that supported this assumption. They found that dilated cervixes tend to lead to premature delivery; recurrent PROM and premature delivery are then serious problems. Gomez et al. (2005) also suggested that a foreshortened cervix is a risk factor for microbial ascending infection and derived this finding from a study of women in premature labor. This premature labor, however, is quite likely to have been the cause of labor in the first place that subsequently shortened the measured endocervical length. Asrat et al. (1991) studied 255 pregnancies in 121 patients and identified a recurrence rate of PROM in about one third. Interestingly, Salafia et al. (1991) found about the same frequency of the amniotic sac infection syndrome in premature births. An abnormally short cervix, as ascertained by vaginal ultrasonography, was also found to be associated with preterm delivery (Iams et al., 1996). Papiernik et al. (1998) reported that cervical shortening or dilatation of the cervix is a prerequisite for ascending infection and premature delivery, but only when vaginal infection exists. They opined that a reduction of preterm delivery can only be hoped for when prophylactic antibiotic therapy is practiced. Seaward et al. (1998) found that chorioamnionitis and maternal colonization with group B streptococci were the most important predictors of subsequent neonatal infection. Since that summary, numerous additional studies on cerclage or indomethacin treatment for the prevention of prematurity have been published. A meta-analysis by Belej-Rak (2003) showed that cerclage has no benefit

for a sonographically identified short cervix, a finding subsequently confirmed by To et al. (2004). There are, however, different opinions on this very controversial and common dilemma faced by obstetricians. This is shown for instance by a series of papers that follow the one by Althuisius et al. (2000). Some authors find the Shirodkar operation to be a useful adjunct of therapy at the time of premature rupture of membranes, but others do not. Occasionally this treatment in the presence of active chorioamnionitis can have disastrous outcomes. This was shown in a set of twins of whom twin A died from *Actinomyces* sepsis after cerclage and treatment with various antibiotics; there was severe chorioamnionitis (Knee et al., 2004).

The presence of an intrauterine device (IUD) has been correlated with pelvic inflammatory disease (PID) in some studies (Lee et al., 1988). Other studies have been less convincing, and the large cooperative study published by Kessel (1989) asserted that the relation is mostly to the increased frequency of pelvic infections in general, noted since 1973, and not to IUD insertions. Generally, the device prevents pregnancy, but when it fails to do so (2% to 4%), premature labor and chorioamnionitis frequently ensue. The correlation of septic abortion and presence of an IUD has also been confirmed in the large study by Kessel (1989). In this context, Jewett (1973) reported a maternal death following *E. coli* infection at 22 weeks' gestation. Fatal maternal sepsis has also been reported as a complication of chorioamnionitis without an IUD (Webb, 1967). With cesarean section patients, myometritis is present in one third of asymptomatic patients whose inflamed membranes had ruptured for more than 6 hours (Azziz et al., 1988). An interesting association also exists between the occurrence of ectopic pregnancy and recurrent abortion (Fedele et al., 1989). It is likely that its basis is infection. Of parenthetical interest is the suggestion by Polunin (1958) that vaginal infection and birth practices in a North Bornean tribe (the Murut) caused sterility, and that it was the result of vaginal infection. In subsequent studies, an anaerobic coccus (probably streptococcal) infection was found to cause the vaginitis and PID found in this tribe (Hare & Polunin, 1960). Dinsmoor and Gibbs (1989) found that previous amniotic sac infection is not a risk factor for subsequent infection of the uterus.

Another topic of concern among the causes of premature labor, PROM, and fetal infections relates to the hypothesis that intercourse during late pregnancy may initiate premature delivery (Naeye, 1979b, 1980). Herbst (1979), in an editorial, reviewed evidence that meconium staining and risk of prematurity were greater when orgasm had been experienced during pregnancy. Naeye (1982) suggested that other causes of prematurity are smoking, parity, prior cervical surgery, and prior chorioamnionitis. There has been much criticism of these studies on coitus-related prematurity (e.g., Berg, 1980; Mills et al., 1981; Perkins, 1983), some of which has been answered by Naeye (1981, 1983, 1986). His finding of modal peaks of deliveries on certain days of presumed peak coital activity were used to further support a relation among coitus, infection, and premature labor. Klebanoff et al. (1984) could not accept this relation in their analysis of the same data, a study to which Naeye (1986) took exception. When Ekwo et al. (1993) studied coitus of late pregnancy to ascertain whether this bears risks for preterm rupture of membranes, they found that "most sexual positions and activities during late pregnancy are not associated with adverse outcomes." Neilson and Mutambira (1989) found no relationship of twin deliveries to coitus. Similarly, there was no relation to premature labor when frequent intercourse occurred in the patients studied by Read et al. (1993). This was so unless for some of those women who were already colonized with some specific organisms. Similarly, Kurki and Ylikorkala (1993) found that "in healthy nulliparous women, coitus during pregnancy is not related to bacterial vaginosis and does not predispose to preterm birth." The issue is currently not definitively decided, but additional data suggest that some relationship may exist between coitus and premature deliveries (Anonymous, 1984; Naeye, 1988a).

## Specific Microorganisms

*Neisseria gonorrhoeae* is the organism responsible for gonorrhea, which occasionally complicates pregnancy. In a cervical culture study of 1309 antepartum patients, Kraus and Yen (1968) found a 5.73% asymptomatic infection rate during pregnancy, with 32% puerperal morbidity. They were then primarily concerned with ophthalmia neonatorum and did not address the possible risk posed by chorioamnionitis. This study and others indicated that active cervical infection with this organism does not necessarily lead to chorioamnionitis. Baddeley and Shardlow (1973) saw two patients with normal deliveries after gonococcal arthritis during pregnancy. Infection of the amnionic sac with gonococci has been reported by Nickerson (1973) and Rothbard et al. (1975). We have seen several cases as well, and they were similar to other types of acute chorioamnionitis. In Nickerson's case, the infection was not recognized until the gastric aspirate was cultured. The febrile patient was near term and had spontaneous rupture of membranes and a tender abdomen. The placenta was not studied.

Rothbard and colleagues (1975) probably reported the first case of antenatally diagnosed and treated gonorrheal chorioamnionitis. The aspirated amnionic fluid was purulent, and gram-negative diplococci (gonococci) were identified at 35 weeks' gestation. Cesarean section, performed after ampicillin therapy, led to the birth of a normal infant whose neonatal course was uneventful. The placenta was not described. Smith et al. (1989) reported a case of acute gonococcal chorioamnionitis with sepsis. Their patient had a dark red vaginal discharge at 32 weeks, emesis, chills, migratory arthralgia, and abdominal pain. The membranes were intact, and at amniocentesis, gonococci were demonstrated. The 1960-g infant did well. The placenta had acute chorioamnionitis.

Even acute gonococcal salpingitis has been described to complicate pregnancy (Genardy et al., 1976). Their patient was operated on for presumed appendicitis at 14 weeks' gestation; the fallopian tube had pus with gonococci identified therein, and the patient was successfully treated with cephalothin and kanamycin. At 37 weeks, she delivered a normal infant and a normal placenta. This event is rare, however, and when present, ascending infections involve the tube only early in gestation, before the decidua capsularis makes contact with the opposing uterine wall. We have seen only one placenta of a patient with a history of ruptured membranes for 4 weeks who, in addition to marked *E. coli* chorioamnionitis, had developed sepsis from acute unilateral salpingitis at 32 weeks' gestation. The inference in this patient was that the salpingitis developed after the chorioamnionitis, also by ascending means. Edwards and colleagues (1978) studied 178 patients with gonorrhea during pregnancy (2.75% of the pregnancies cared

for), and reviewed the literature. They found chorioamnionitis in 26% (5% in controls). Premature rupture of membranes occurred significantly more often (63% versus 29%), a point that was denied by Amstey (1982).

Infections with **group B streptococci** (GBS) are important and frequent complications of the perinatal period, and we now differentiate between early- and late-onset neonatal infections because of their significant differences in outcome. This streptococcus is recognized to be one of the most virulent organisms during the perinatal period. Sepsis, pneumonia, and meningitis are common sequelae of this infection (Baker, 1977), and the organism emerged as the number two cause of neonatal meningitis (Anonymous, 1977a). Prematurity and premature rupture of membranes are strongly correlated with group B streptococcal infections. The diagnosis is often difficult unless it is actively pursued. Occult streptococcal infection is an important cause of fetal asphyxia, and stillbirths frequently occur with unruptured membranes (Naeye & Peters, 1978; Peavy & Chalhoub, 1983). This important topic has been reviewed in some detail by Nizet and Rubens (2000) with special attention to the recently identified virulence factors. Pritzlaff et al. (2001) describe specific toxins of the streptococcal variants in a molecular publication and find a novel specific hemolysin and cytokinin and in yet another publication of these investigators (Doran et al., 2002a) the pathogenicity to the lung of various mutants is described. This organism has apparently specific toxicity to epithelial and also endothelial cells.

Novak and Platt (1985) described the placentas of 22 cases of early-onset group B streptococcal sepsis. They found that chorioamnionitis was present in 64%, 27% of patients had funisitis, and in 41% of these patients gram-positive organisms were found in the amnionic fluid. Importantly, though, some placentas showed no pathologic changes or had only villous edema. The authors were disappointed that, excepting neutropenia, the placental findings did not correlate well with fetal outcome. They also emphasized that the extensive colonization of amnion and the leukocytic response argued strongly against late acquisition of the organism by the fetus during fetal descent. They reviewed other studies that gave similar incidence figures and concluded that an important part of the fetal response is related to the specific enzymatic types of the individual organisms. In a study of autopsy files, de Paepe et al. (2004) found that GBS infection was diagnosed in 4.9% of neonatal autopsies (61 of 1236) and was the cause of death in 58 cases. Chorioamnionitis was found in 67% of preterm babies and only 33% of term infants. They concluded that "feto-placental inflammation is a poor indicator of perinatal GBS infection." Importantly, when meconium is present, this apparently enhances the susceptibility of the neonate. Eidelman et al. (2002) found that meconium enhanced

growth of streptococci in amniotic fluid, whereas *E. coli* growth was inhibited.

Altshuler (1984) stated, "There is no inflammation in the placentas of at least 75 percent of newborns in whom group B  $\beta$ -hemolytic streptococcus has been cultured." Our experience also indicates that many placentas of streptococcus-infected babies, even those with neonatal sepsis, have no inflammation. Only very careful search for bacteria will identify the cocci on the amnion. Vigorita and Parmley (1979), on the other hand, described focal abscesses underneath the amnion, areas of epithelial necrosis, and found an accumulation of bacterial colonies in a relevant case. Although we have also seen such abscesses, we have wondered if double infection may have been the cause, as this observation differs so much from previous reports.

Group B streptococci may actively grow in amniotic fluid alone. Abbasi and colleagues (1987) showed that virulent strains of streptococci grew as well in amniotic fluid as in optimal bacterial culture media, although some differences were found among various strains. The authors believed that this point is clinically significant. But when the clinical manifestations of those patients in whom amniotic contamination was proved are compared with those without positive cultures, no differences of clinical risk factors were ascertained (Silver et al., 1990). The differentiation and designation of the many different streptococcal bacteria may not be widely appreciated. Table 20.1 summarizes their designation and features.

Numerous studies have addressed the need for early diagnosis and rapid therapy of perinatal group B streptococcal infection. The most modern studies employ a

DNA probe for rapid detection (Yancey et al., 1993), in part because previous methods (enzyme-linked immunosorbent assay and Gram stain) were inefficient for screening tests (Hagay et al., 1993). Thus there is by no means agreement just how best to screen for the colonization, or how to deal with it when colonization is recognized. Gibbs and Blanco (1981) investigated 48 patients with bacteremia, 31 of which resulted from group B organisms. Endometritis and chorioamnionitis were the most commonly diagnosed clinical features. Although fever was often present, few localizing signs appeared. The authors also discussed effective therapy but some studies have shown that even intrapartum administration of antibiotics often does not prevent neonatal sepsis (Ascher et al., 1993). This has changed in the recent past following introduction of more rigorous protocols. Thus, Schrag et al. (2000) and Wendel et al. (2002) described practical and successful regimens of intrapartum therapy for high-risk patients. Andrews et al. (2000) discovered no organisms that were resistant to penicillin while finding resistance to erythromycin and clindamycin, and Gilson et al. (2000) advocated screening and intrapartum antibiotic therapy with good success. Towers and Briggs (2002) also described the marked decrease in frequency of early-onset disease when chemoprophylaxis is provided.

A prospective study of colonization with this organism was undertaken by Regan et al. (1981). They found a significant increase in PROM and an association with prematurity. That was not the case in the study reported by Amstey (1982), however. Singer and Campagnone (1983) found organisms in the blood of immature stillborns associated with villous edema and mild chorioamnionitis. Two placentas showed acute and chronic villitis, which suggested to them a transplacental (hematogenous) infection. It may well have been a dual infection also. They emphasized the high risk of colonization, particularly during the second trimester of pregnancy. Matorras et al. (1989) showed that maternal colonization (rectal or vaginal) carried a significant risk for PROM. Cervical colonization was especially deleterious. Fetal death from streptococcal sepsis has even been described after intrauterine funipuncture for karyotyping (McColgin et al., 1989).

That this organism does not necessarily arrive in the fetus via hematogenous means, though, was shown by M.A. Pass et al. (1980). They found a severely colonized dichorionic twin A whose co-twin (B) did not have the infection. They believed that twin pregnancies are particularly vulnerable. Doran et al. (2002b), however, described a set of monozygotic (MZ) twins with late-onset disease causing fulminant fatal meningitis in twin A, while twin B recovered completely. The twins had a monochorionic placenta but it was not further described. Forsnes et al. (1998a) described hydrops in one diamniotic/monochorionic (DiMo) twin from whose amniotic

TABLE 20.1. Classification of aerobic streptococci

Group	Designation of species	Blood agar reaction <sup>a</sup>
A	<i>S. pyogenes</i>	$\beta$ -hemolytic
B	<i>S. agalactiae</i>	Usually $\beta$ -hemolytic
C <sup>b</sup>	Several species	$\beta$ -hemolytic
D (enterococci)	<i>S. faecalis</i> , <i>S. faecium</i>	$\alpha$ -, $\beta$ - or nonhemolytic
E (nonenterococci)	<i>S. bovis</i>	$\alpha$ -, or nonhemolytic
F	<i>S. anginosus</i>	Small colony $\beta$ <sup>c</sup>
G <sup>b</sup>	Many species	Usually $\beta$ -hemolytic <sup>c</sup>
Viridans hemolytic species		$\alpha$ -hemolytic
Pneumococci	<i>S. pneumoniae</i>	$\alpha$ -hemolytic

<sup>a</sup>  $\beta$  reaction is clear, complete hemolysis;  $\alpha$  reaction is green discoloration, partial hemolysis.

<sup>b</sup> Groups C and G,  $\beta$ -hemolytic streptococci.

<sup>c</sup> The British classify minute colonies of groups C, F, and G  $\beta$ -hemolytic streptococci and Lancefield-groupable, and capnophilic strains of  $\alpha$ - and nonhemolytic *S. intermedius* and *S. constellatus* as *S. milleri*. The Centers for Disease Control uses the designation *S. anginosus* for minute colonies of  $\beta$ -streptococci and retains the designations *S. intermedius* and *S. constellatus* (C. Davies, personal communication, 1989). Source: Modified from Gibbs & Blanco (1981).

fluid adenovirus was grown. Both twins died at 26 weeks and their cardiac size did not indicate the presence of twin transfusion syndrome. It was assumed that transplacental infection took place in only one twin. Anastomoses were not described. Iams and O'Shaughnessy (1982), who evaluated antenatal versus intrapartum screening, found no advantage in the former method, whereas Pass et al. (1982) correlated infection with puerperal fever and the finding of frequent chorioamnionitis in cases of perinatal infection. The attack rate in their study was two in 1000 deliveries. They recommended intrapartum antibiotic prophylaxis, as did Boyer and Gotoff (1986). Strickland et al. (1990) also suggested a frequency of two early-onset infections in 1000 births and found intrapartum screening for this infection to be cost-effective because of the severe handicaps that can result. Thomsen and colleagues (1987) found that urinary group B streptococcal infection correlated with preterm labor, and they also reported a beneficial effect from penicillin therapy. Dykes et al. (1985) investigated women who gave birth to infected babies. Chronic carriage in the urinary tract, without immunologic response, was therein apparent. Similar findings were reported by Moller et al. (1984). They also found an increased risk of ruptured membranes. Matorras et al. (1989) found that PROM was significantly correlated with vaginal or rectal carrier status. It has also been shown that successive group B streptococcal infection, with early-onset disease of neonates, can occur despite proper antibiotic therapy (Carstensen et al., 1988).

For all these reasons, rapid diagnosis of infection with group B streptococci is urgent, a point addressed in several studies (e.g., Morales et al., 1986; Morales & Lim, 1987). Morales et al. used coagglutination methods for identification; Sandy et al. (1988) tested Gram stains of cervicovaginal swabs; they found it to be an unreliable means for diagnosis. Of alternative methods explored in an editorial, most were considered to be unsatisfactory for routine use (Anonymous, 1986). Latex agglutination tests from swabs may be a useful means of rapid identification (Howe et al., 1987; Stiller et al., 1989). Baker et al. (1988) obtained promising results from immunization of pregnant women. In a large review of the possibility for immunization, Coleman et al. (1992) suggested that such vaccination is attainable and that studies in that direction be pursued; antigens such as cell wall polysaccharides and protein C are the most promising to be investigated.

The effect of this infection can be devastating to the newborn (and fetus), and its onset may be rapid. The neonatal diagnosis, manifestations, and therapy were lucidly discussed by McCracken (1976). Contrary to one's hopes, immediate penicillin therapy to the immature neonate does not prevent early-onset disease, nor does it reduce the excessive mortality (Pyati et al., 1983).

Of interest to the pathologist is the study of Katzenstein et al. (1976). Dissatisfied with the frequency of

autopsy diagnosis of hyaline membrane disease in pregnancies at risk, they used immunofluorescence (on formalin-fixed tissue) to reexamine eight appropriate cases. They identified streptococci in the pulmonary hyaline membranes of five neonatal deaths. These structures were so numerous in one case that they appeared to make up the bulk of the fibrinous membrane. The deaths had previously been attributed to routine hyaline membrane disease at routine autopsy.

Hyde et al. (1989) have shown experimentally that extracts from cultures of this organism may cause isolated portions of umbilical vein wall to contract severely. They suggested that such effects may occur in vivo during intraamniotic infections, and that it may lead to reduced venous return from the placenta, causing fetal damage. Clinical investigations of this phenomenon are now commencing. Fleming et al. (1991) found a correlation of S/D (systolic/diastolic) ratios and biophysical profiles with chorioamnionitis, whereas Leo et al. (1992) did not. It must be pointed out, however, that the latter group did not study the placentas, and other problems exist with the protocol. It is too early to make decisions as to the possible value of predicting chorioamnionitis/funisitis with this methodology.

**Group A  $\beta$ -hemolytic streptococci** pose serious problems for mother and fetus (Swingler et al., 1988). Antenatal acquisition was shown by Monif (1975) in a febrile patient with a tender uterus at 34 weeks' gestation. The membranes were unruptured, and the cervix was closed. A depressed infant was born with leukocytosis, left shift of white blood cells, and positive cord blood culture. Placental histologic study was not undertaken. Other cases were reviewed by Lehtonen et al. (1984). The infection responds readily to penicillin or ampicillin, and the umbilical stump may be a reservoir for the organism. Puerperal infection with this organism, however, may pose serious risks (Silver et al., 1992). Both of their seriously ill patients required hysterectomy, but their pregnancies had ended uneventfully.

Fatal maternal and fetal infection with *Streptococcus pneumoniae* (type III) was reported by Tarpay et al. (1980); that placenta also was not studied. Duff and Gibbs (1983) identified two similar infections with *S. pneumoniae* demonstrable in amniotic fluid. They thought that ascending infection was unlikely because of the stringent pH requirements (pH 6.5 to 8.3) of the organism. They did not identify the source of infection and did not report on the placenta. Andreu et al. (1989), however, reported chorioamnionitis in the placentas of several infants, prenatally infected with this organism and having pneumonia.

*Haemophilus influenzae* was contracted prenatally in a premature infant reported by Barton et al. (1982). It had septicemia and recovered after ampicillin therapy. The membranes had ruptured 15 hours before delivery.

The placenta was not described. Gibson and Williams (1978) observed this infection in a 28-week gestation complicated by leukorrhea, abdominal pain, and fever. The amniotic fluid was opaque and contained the organisms on smears. The placenta had chorioamnionitis and funisitis. The infant died from hyaline membrane disease. There was no pneumonia. A study by Campognone and Singer (1986) of 19 patients with this infection drew attention to the serious nature of this disease. All of their cases had chorioamnionitis, and three had acute villitis in addition. Winn and Egley (1987) added another case with chorioamnionitis and funisitis. The patient had intact membranes. The organisms may be readily identified as gram-negative rods in smears. Rusan and her colleagues (1991) agree that this infection poses serious problems; they undertook a retrospective review and found 13 cases with chorioamnionitis or endometritis over a 10-year span. Of 23 infected neonates, 15 presented with sepsis or pneumonia.

*Diplococcus pneumoniae* (*Streptococcus pneumoniae*) was the cause of neonatal laryngitis in a term infant delivered to a febrile patient with positive amnion and cervical cultures (Hazard et al., 1964). It may here be mentioned that smears of the placental surface have been usefully employed by Nessmann-Emmanuelli et al. (1983) in establishing prenatal infection. Positive smears were obtained in 9% of a high-risk group (63% gram-positive, 17% gram-negative, and 20% mixed). It was especially useful for group B streptococcal and *E. coli* infections.

Gram-negative bacilli, in particular *E. coli*, frequently cause chorioamnionitis. Their association with neonatal meningitis is well known (Kagan et al., 1949; Watson, 1957; McCracken & Sarff, 1974). That this organism, especially the K1 type, is transmitted vertically has been firmly established by the large cooperative study of Sarff et al. (1975). These authors found a strong association with maternal rectal colonization of the organism and likened the acquisition to that of streptococcal infection. The investigators did not examine placentas. Their concept of pathogenesis included lung infection, intestinal infection, sepsis, and meningitis. We believe that the modus of transmission for neonatal meningitis is often through the aspirated amniotic fluid via the middle ear. DeSa (1974) has shown that squames, admixed with pus and organisms, are often found in the middle ears of stillborns and neonatal deaths.

*Salmonella typhi* and other salmonella organisms may cause meningitis of neonates. They may be transmitted vaginally. Pugh and Vakil (1952), Watson (1958), and Scialli and Rarick (1992) reported cases of congenital infection and some fetal deaths, and they also reviewed the literature. Infection by symptomatic women or carriers was also shown by Luder and Tomson (1963), and Freedman et al. (1970). The placenta is usually not mentioned. An exception is the case reported by Awadalla et

al. (1985) of a patient with gastroenteritis at 26 weeks' gestation. A foul-smelling intact gestational sac containing cloudy amniotic fluid was delivered. Blood, stool, cervical specimens, and amniotic fluid yielded the organism. Despite these findings, the authors were of the opinion that transplacental, rather than ascending, infection took place. When Roll et al. (1996) saw a premature neonate die with *Salmonella enteritidis* infection, they cultured the organism from the infant and placenta, but there was no evidence of chorioamnionitis. Seoud et al. (1988) recorded the occurrence of typhoid fever during pregnancy in 13 patients. One infant died with pneumonia. The mothers were treated with chloramphenicol and did well.

Infection with *Shigella sonnei* caused septicemia and enterocolitis in a term infant reported by Kraybill and Controni (1968). Prenatal infection of this infant seemed likely, but the placenta was not studied.

*Clostridium perfringens* infection occasionally complicates pregnancy. Among anaerobic infections, this type has been particularly feared because of the postabortal sepsis and uterine gas gangrene that may be life-threatening for the gravida (Ramsey, 1949). Nash et al. (1963) described a patient at 35 weeks' gestation whose membranes had ruptured for 5 days, a tender uterus, fetal death, and abdominal crepitation from gas infiltration. They carefully described the placenta: It had a greenish amniotic surface and a putrefactive odor. The purulent exudate covered the membranes and fetal placental surface; it contained gram-positive rods. The maternal surface and villous tissue were not involved. A similar case is shown in Figure 20.25. Several reports of abortion due to *C. perfringens* infection have been published that emphasized the severity of this infection and the frequent lethal outcome (Decker & Hall, 1966; Pritchard & Whalley, 1971). Decker and Hall (1966) demonstrated that inflammatory exudate and necrosis of villous tissue may be found in septic cases, and the fetus may be invaded by organisms.

Diphtheroids or corynebacteria are frequent normal vaginal inhabitants and can often be cultured from placental surfaces. They have occasionally been shown to cause chorioamnionitis. Fitter et al. (1979) described a case of funisitis and chorioamnionitis due to *Corynebacterium kutscheri*. It occurred at 26 weeks of pregnancy in a grand multipara who delivered 24 hours after rupture of membranes. Gram-positive organisms were demonstrated and were grown in pure culture from cord, membranes, rectum, nose, throat, eye, and external ear. There was no sepsis in the 980-g premature infant who survived after ampicillin and gentamicin therapy. The placental surface was discolored and had gray-brown plaques. Similar plaques were present on the umbilical cord. The plaques were composed of organisms that also invaded the underlying tissue. Funisitis and chorioamnio-

FIGURE 20.25. Clostridial chorioamnionitis at term. The membranes were friable and meconium-stained. The infant survived with antibiotic therapy. Membrane roll (left) shows intensive deciduitis and chorionitis. Note the umbilical arteritis (center,

right) with a pocket of gram-positive rods underneath the amnion. Touch preparations were strongly positive. H&E  $\times 16$  (left);  $\times 160$  (center);  $\times 640$  (right).

nititis were pronounced. The case proves that not all diphtheroids isolated from the placenta or amniotic fluid are due to vaginal contamination at delivery. In this case, the infection must have occurred prior to membrane rupture.

Altshuler and Hyde (1985, 1988) have drawn attention to the importance of *Fusobacterium necrophorum* and *F. nucleatum* infections as significant complications of pregnancy. These pleomorphic, filamentous, gram-negative, anaerobic organisms were isolated from three of 297 placentas examined for various indications. These authors described in detail the fluorescent antibody identification, chromatography, and usefulness of the Warthin-Starry stain for identification on slides. Brown-Brenn stains were not so useful for demonstrating the bacteria, and in hematoxylin and eosin (H&E) preparations the organisms were even more difficult to identify microscopically. It is also important to note that Bouin's fixative makes their demonstration particularly difficult. Of 92 prematurely delivered placentas, 62 had chorioamnionitis, and of the latter, 11 (18%) had filamentous organisms in the membranes.

In the rat animal model developed by Altshuler and Hyde (1985), inflammation similar to chorioamnionitis was consistently produced. In a subsequent contribution (Altshuler & Hyde, 1988), these investigators reaffirmed the association of fusobacterial infection and prematurity. Among 586 placentas examined, they identified 14 with fusobacteria, and from their literature review, it is evident that as many as 30% of patients with occult chorioamnionitis may be infected with a *Fusobacterium* species. A

typical case of fusobacterial chorioamnionitis is shown in Figure 20.26. It was associated with the scattered villous edema (Fig. 20.27) that Naeye et al. (1983) considered to be so important in causing prenatal hypoxia in association with chorioamnionitis and prematurity. Easterling and Garite (1985) reported three cases of fusobacterial infection and emphasized the importance of this rarely recognized organism as a cause of premature labor, and Romero et al. (1989e) found it commonly in prenatally obtained amniotic fluid with intact membranes. Cox et al. (1988) found bacterial endotoxin in the amniotic fluid of a patient with fusobacterial infection of a preterm delivery, reaffirming the suggestion by Altshuler and Hyde (1988) that these organisms are rich in lipopolysaccharide.

*Bacteroides fragilis* was found to be the cause of ascending infection in five of 15 patients with premature rupture of membranes reported by Evaldson et al. (1982). *Campylobacter (Vibrio) fetus*, a common enteric pathogen in humans and a common cause of venereally transmitted abortion in hoofstock, has been described to cause placentitis, infarcts, and fetal death (Gribble et al., 1981). Their patient had fever for 3 weeks and fetal death at 19 weeks. The amniotic fluid and placental surface were normal, but histologically there were areas of villous necrosis and "acute inflammation in the villous tissue." The organism was isolated from maternal blood, placenta and fetal spleen. These authors reviewed the few other cases reported with pregnancy; when described, the placentas were similar to their case. The route or source of infection was not identified in any of the cases, nor was

FIGURE 20.26. Chorioamnionitis due to fusobacteria in the placenta at 23 weeks' gestation. The placental surface was opaque. Fusobacteria were also found in the fetal lung. At left are Bouin-fixed membranes with inflammation; few indications

exist of the massive bacterial growth seen with the silver stain at right. The dark filaments radiating from the amnionic basement membrane are easily identified as the filamentous organisms. H&E  $\times 160$  (left); GMS,  $\times 240$  (right).

venereal transmission verified. In the case described by Meyer et al. (1997), maternal colitis complicated a 22-week pregnancy, resulting in maternal sepsis, acute villitis, and fetal demise. The organism was identified genetically as well as by Warthin-Starry stain and occurred primarily within the immature villi. Some patients had recurrent abortions. Placental tropism has been suggested to exist in sheep. The earlier literature of infection with this organism was reviewed by White (1967).

Chorioamnionitis due to *Streptobacillus moniliformis*, the cause of rat-bite fever, was reported by Faro et al. (1980). The patient had cervical cerclage for repeated abortions, and with unruptured membranes, amniocente-

sis yielded pus and gram-negative rods. The placenta had a fetid odor. The patient's house was infested with rats. The organism also causes the Haverhill (milk) fever.

Gibbs et al. (1987) isolated the gram-variable organism *Gardnerella* (*Hemophilus*, *Corynebacterium*) *vaginalis* from 28% of 86 patients who had intraamniotic infection. Because controls had a similar frequency of isolation (21%), the authors suggested that this common vaginal organism is part of a microbial spectrum that does not cause PROM. We have isolated it occasionally from maternal and neonatal blood; it causes mild disease, but severe chorioamnionitis, premature delivery, and demise were reported by Pinar et al. (1998). Their description is

FIGURE 20.27. Villi of placenta in Figure 20.26, showing scattered villous edema. H&E  $\times 160$ .

of further interest in that it depicted the turquoise staining of the umbilical cord secondary to amniotic injection of indigo carmine. Hillier et al. (1988), in a case-control study of chorioamnionitis, isolated *G. vaginalis* in 26% and *Ureaplasma urealyticum* in 47% of cases of prematurely delivered infants. They suggested that these organisms are etiologically important.

Tularemia is an uncommon disease, but the responsible organism (*Francisella tularensis*) had once been described as infecting placenta and fetus (Lide, 1947). The placenta of the macerated fetus showed granulomatous lesions with frequent central necrosis, and similar granulomas were found in the fetus. The patient had become infected while preparing rabbits for eating.

Brucellosis is caused by a variety of organisms belonging to the genus *Brucella*. Malta and Bang fevers, in humans, are due to infection with these organisms, but a wide variety of animal diseases are frequently caused by host-specific species of these organisms (Moore & Schnur-berger, 1981). Among the animal diseases, abortion and placentitis are prominent findings. The placental lesions are frequently characteristic (Molello et al., 1963) and have been experimentally studied in goat by Anderson and his colleagues (1986a,b). Human infection with several of the *Brucella* species has been well documented. The infection may be fatal or lead to protracted disease; often it is self-limited, and the organism appears to be acquired from contact with animals or their products, especially raw milk and unpasteurized cheese (Anonymous, 1983b). Although human abortions have been described as being due to *Brucella abortus*, and the organism has been isolated from the fetus (Carpenter & Boak, 1931), it is an uncommon event. In cattle, the organisms are much enriched in placental cotyledons and allantoic fluid, and in mice this infection has provided an important model (Tobias et al., 1993). Meador and Deyoe (1989) depicted large numbers of these bacteria in the trophoblast of infected bovine placentas. Sarram et al. (1974) isolated *Brucella melitensis* from the placenta of abortion in a highly endemic area, and they suggested a causal relation to the abortion. The placentas were not described. The topic was completely reviewed by Porreco and Haverkamp (1974). They found little evidence of an increased abortion rate with this infection and cited only a few cases with positive isolation from the placenta or fetus. The patient they described had verified infection from fresh goat cheese during the 32nd week of gestation. She was treated with kanamycin and delivered a healthy infant at term. The placenta was normal. No characteristic lesions have been described in the human placenta with this disease. Salpingitis has often been reported with brucellosis, and sexual transmission was suggested in several studies (see Ruben et al., 1991). Mofleh et al. (1996) stated that, in endemic regions, infection commonly occurs from animals and their placentas.

## Leprosy

Leprosy is due to *Mycobacterium leprae*. It is now relatively uncommon in the United States, but pregnancy-complicating leprosy has been investigated on many occasions. It has been reported that vertical transmission either usually is uncommon or does not occur, although Duncan et al. (1983) described two young children (12 and 17 months of age) with leprosy. Whether these children acquired the disease transplacentally or shortly after birth remains unknown. The authors examined sections of the placenta and failed to identify acid-fast bacilli. When they made concentrates of the 10 most "bacilliferous" patients' placentas, they found only scanty organisms or cell debris.

Maurus (1978) found no organisms in one placenta and gave up searching for organisms in the placenta following a report by King and Marks (1958) that said they were unable to identify placental organisms in treated leprosy. This statement contrasts with earlier reports, summarized by Duncan (1985), in which frequent abortion with bacterial isolation of organisms from placenta and cord blood was alleged.

For this reason, the detailed study of the human placenta in leprosy by Duncan et al. (1984) is of great value. In their review of the literature, there was one reported placenta with a granulomatous lepromatous lesion in villi; *M. leprae* was present in 66 of 172 placentas studied in the past. Duncan and colleagues (1984) reported a detailed investigation of 81 placentas from leprosy women. No lepromatous lesions were detected histologically in the placentas by electron microscopy or immunologic study. Homogenates of placentas from two patients with active lepromatous leprosy yielded a few acid-fast bacilli. The previously recognized relatively small size of placentas in leprosy (Duncan, 1980) was reaffirmed. This "hypoplasia," however, was now held to be due to smaller placental cell sizes (rather than cell numbers) and not to an altered immune status. Patients with leprosy have depressed T-cell reactivity that is allegedly worse during pregnancy. For unknown reasons, these mothers excrete reduced amounts of estriol during pregnancy (Duncan & Oakey, 1982).

Nine-banded armadillos suffer leprosy frequently, and they can be infected with the human organism. When Job et al. (1987) studied the placentas of three pregnant nine-banded armadillos, they found acid-fast organisms in decidua, trophoblast, and villous cores, as well as in the spleens of some fetuses. Although focal villous necrosis was found, no granulomas were seen in the placentas. One animal had thrombosed cord vessels. In light of the occasional finding of organisms in placentas from leprosy women, and because of some degree of similarity between armadillo and human placentas, vertical transmission remains a possibility, even though it may be uncommon.

## Tuberculosis

In contrast to leprosy, congenital tuberculosis has been repeatedly demonstrated to occur, despite the fact that generalized tuberculosis is a frequent cause of sterility. In some cases there is doubt as to the timing of infection. Neonatal disease may have been acquired postpartum from milk or sputum of an infected mother. No epidemiologic doubt, however, exists about the disease in the macerated stillborn with the extrauterine pregnancy described by Nokes et al. (1957). This 23-cm crown-rump (CR) fetus, removed from an abdominal implantation, had multiple caseating pulmonary nodules and acid-fast bacilli in the liver, spleen, and kidneys. The placenta had many hard, white plaques that represented tubercles that contained acid-fast organisms. The patient had a partially tubally implanted pregnancy with tuberculous salpingitis, and miliary tuberculosis existed in most organs. The authors reviewed briefly 68 previously reported cases of extrauterine pregnancies complicated by tuberculosis.

Beitzke (1935) established criteria for the acceptance of congenital tuberculosis, which is now a rare and preventable disease of infants. These criteria included evidence of hematogenous infection via the umbilical vein. Beitzke also emphasized the need of separating the infant from the mother at birth. Nemir and O'Hare (1985) reviewed diagnostic criteria, reported the longest follow-up of a severely infected child, and gathered more than 200 cases from the literature. Their own case was criticized by Corral (1986) as not fulfilling all of the established criteria. The discussion further elaborated on the difficulties of distinguishing truly transplacentally acquired tuberculosis from infection transmitted by inhalation of infected amniotic fluid and from neonatal disease acquired nosocomially.

The placenta has rarely been examined in putative cases of congenital tuberculosis. Schmorl and Kockel (1894) examined three patients who died with tuberculosis during pregnancy. The placentas appeared grossly normal. The fetuses were near term; all three associated placentas contained typical but rare granulomas with giant cells in the villous tissue. In two fetuses, tuberculous lesions were also found; the placental membranes were uniformly negative. Schmorl and Geipel (1904) found nine additional cases of placental tuberculosis among 20 new specimens. For some of these specimens, more than 2000 sections had to be prepared before tubercles were found. The authors insisted that acid-fast stains must be made, lest early lesions be overlooked. Even so, identification of acid-fast organisms required a prolonged search. Bacilli were frequently found in fetal vessels, intervillous fibrin, and septa. Warthin (1907) provided additional detailed descriptions of placental tuberculosis, with numerous tubercles and acid-fast bacilli identified. He found that the decidua contained areas of necrosis but no

giant cells; there were many intervillous and villous granulomas, and the chorion was involved only sparsely. In a previous case, he also made thousands of sections to verify tuberculous infection. His initial opinion that the syncytium was resistant to infection was subsequently modified because he saw necrosis of trophoblast.

Boesaart (1959) also found tubercles in the placenta of an infected patient whose infant remained well. We saw a placenta membranacea at 35 weeks' gestation from a patient with tuberculous peritonitis. The placental floor had several tuberculous granulomas. The neonate was well and was treated prophylactically (Kaplan et al., 1980). In the same report we demonstrated numerous acid-fast bacilli in the therapeutically aborted villous tissue of a patient who had cavitary tuberculosis for which she was taking appropriate medication. There were neither necrosis nor a granulomatous reaction in this endometrium. Finding the organisms was unexpected. In other cases we have identified acute granulomas (consisting mostly of neutrophils) adjacent to villi and destroying the trophoblast and isolated giant cells in stem villi but without inflammation. We have also been impressed with the extensive and unusual necrosis at the decidua basalis and capsularis in patients with disseminated tuberculosis during pregnancy. The areas appeared bright yellow macroscopically and had a "cheesy" complexion microscopically, similar to what one expects in large granulomas.

## Listeriosis

Listeriosis is caused by a gram-positive bacillus that is occasionally confused with diphtheroids. The disease occurs in a wide variety of mammals and birds, as well as in humans (Dennis, 1968). The literature suggests that the human disease is underdiagnosed (Bowmer et al., 1973). Most adults successfully eliminate the causative organism *Listeria monocytogenes*. Immunodeficiency of adults (Nieman & Lorber, 1980; Wetli et al., 1983), various chronic disease states (Boucher et al., 1984), and characteristically pregnancy may be complicated by significant disease (Gantz et al., 1975). Transmission from mother's milk has been recorded in neonates (Svabic-Vlahovic et al., 1988). Nosocomial infection occurs in nurseries (Nelson et al., 1985), and direct contact with infected animals has also caused infection (Anonymous, 1980). Southwick and Purich (1996) have reviewed the complex microbiology with this organism. Several serologic subtypes exist and specific antibodies are useful for diagnosis in otherwise difficult cases (Roberts, 1997).

Food-borne acquisition of the organism is the most common mode of infection (Gill, 1988; Lamont et al., 1988; Jones, 1990). Numerous epidemics have been reported, and the source of bacteria has been defined in some (Anonymous, 1985). Some of these epidemics have originated from pasteurized milk (D.W. Fleming et al.,

1985), Mexican-style cheese (Linnan et al., 1988), cabbage contaminated by sheep feces and made into coleslaw (Schlech et al., 1983), poorly cooked sausage and chicken (Schwartz et al., 1988), pâté (37 of 73 examined contained the organisms; Morris & Ribeiro, 1989), and other sources. At times, the precise source of an infection could not be defined, despite intensive search (Filice et al., 1978), but a gastrointestinal route appears to be the most likely mode of infection (Breer & Schopfer, 1988). The organism may survive moderate heat, and it thrives in chilled food (Kerr et al., 1988; Gilbert et al., 1989). Guidelines have thus been established for the food industry in order to avoid wide dissemination of this ubiquitous agent to susceptible people (Update, 1988).

The implication that livestock is the cause of transmission of this infection has been challenged, as the organism also occurs in the stool of many normal people and in the soil (Low & Donachie, 1989). Ortel (1975) investigated stools from a large population of normal people after a devastating outbreak occurred in Halle during 1968. Pregnant patients had a 24% rate of contamination (6.5% after delivery), meatpackers 3.6%, and nurse-midwives 9%; finally, the personnel of a laboratory had a 91.6% (!) rate of carriage.

The organism is a danger principally to pregnant women, newborns, and immunocompromised individuals. A 60% perinatal mortality has been ascribed to this infection (Barresi, 1980). We have seen congenital listeriosis in the offspring of a microbiology laboratory technician, suggesting that special vigilance is needed when such personnel are pregnant. Fortunately, the neonate was promptly treated and survived. In infants, listeriosis is known as granulomatosis infantiseptica. "Granulomatosis" is a misnomer because the visible lesions are truly abscesses, not granulomas (Seeliger, 1955). An autopsy report of seven children with perinatal listeriosis indicated that grossly visible microabscesses are relatively uncommon (Klatt et al., 1986). During an outbreak in Los Angeles, which originated from infected cheese, maternal pyrexia and a high index of suspicion were the most essential factors for the early diagnosis (Boucher & Yonekura, 1986). Neonatal meningitis is a serious complication of fetal infection with this organism (Ahlfors et al., 1977; Visintine et al., 1977; Laugier et al., 1978). A rash is often present in the neonate, and gastric aspirates as well as Gram stains (and culture) of skin rashes are helpful for identifying the organism (Halliday & Hirata, 1979). One case of nonimmune fetal hydrops has been attributed to listeriosis; the placenta and stillborn fetus had numerous abscesses (Gembruch et al., 1987). The diagnosis is easily established from cultures, when the infection is suspected. Berche et al. (1990) found that anti-listeriolysin O titers quickly develop after infection, and that they are useful for diagnosis. Despite the infrequency of listeriosis in Saudi Arabia, Boukhari et al.

(1999) described a term neonate with meningitis who was successfully treated, the first case in that country with early-onset disease. Benshushan et al. (2002) reviewed charts of neonates from a 10-year time span in Israel and found 11 pregnant patients with listeriosis in mother and infant. In the five placental examinations available, all had chorioamnionitis and abscesses. Plaza and Gilbert-Barness (2001) described a stillborn intrauterine growth restriction (IUGR) infant with listeriosis and superbly illustrated the placental lesions.

The placenta in listeriosis has the following characteristic lesions: villous abscesses, villous necrosis, necrotizing villitis, and an abundance of bacterial growth on the amnionic surface, usually accompanied by chorioamnionitis. Case reports with good descriptions of these lesions have been provided by Olding and Philipson (1960), Driscoll et al. (1962), Soma (1979), Roberts (1997) and many other pathologists. Yamazaki et al. (1977) found abscesses, chorioamnionitis, and funisitis in a stillborn with proved granulomatosis infantiseptica, but they were unable to demonstrate the organisms in the placenta. They referred to other authors with a similar experience. The development of unusual macroabscesses in congenital listeriosis was described by Steele and Jacobs (1979), and Topalovski et al. (1993) thought that the diagnosis could be made solely from a placental examination. They depicted the macroabscesses in the placenta and suggested that silver impregnation is a better means to demonstrate the organisms than a Gram stain. The diagnosis of listeriosis complicating pregnancy is important because prompt therapy with ampicillin rapidly cures the maternal and fetal infections. There is also good evidence that listeriosis is a common cause of abortion in France (Lallemant et al., 1992), and produces similar pathologic lesions. Forsnes et al. (1998b) observed an interesting diamniotic/dichorionic twin pregnancy in which the "higher" twin B had died in utero from listeriosis (culture proven), with twin A remaining healthy and delivered at 34 weeks. Areas of avascular villi and chorioamnionitis were found in the placenta of twin B. Another dichorionic twin gestation with congenital listeriosis comes from Beinder et al. (1999). Here, again, twin A was healthy but twin B died from the disease.

Aside from the usually opaque surface of the placenta, which is occasionally described as greenish, there are often typical abscesses visible in cross sections of the fresh placenta (Figs. 20.28 and 20.29). When smears of these yellowish lesions are stained with Gram solution, the organisms are often readily apparent. Microscopically, the abscess frequently has a central area of necrosis and is composed of a massive PMNL infiltration (Fig. 20.30). The chorioamnionitis is usually severe and often extends into the villous tissue; the amnion commonly contains a large number of organisms. There is no doubt that some of them have proliferated during cold storage

FIGURE 20.28. Numerous placental abscesses (white nodules at arrows) due to *Listeria* infection. Premature infant; immediate therapy with survival.

FIGURE 20.29. *Listeria* abscess in the placenta underneath the discolored chorionic plate at 37 weeks' gestation. Maternal fever was immediately diagnosed as due to listeriosis from the smears of the abscess. Ampicillin therapy of the neonate cured the infant who had a diffuse rash at birth.

FIGURE 20.30. *Listeria* abscess in an immature placenta of stillborn twins. There is much necrosis of villi, fibrin deposition, and infiltration with PMNLs. Numerous organisms were found on Gram stain. H&E  $\times 60$  (left);  $\times 240$  (right).

of the placenta prior to examination (Fig. 20.31). The amniotic colonization is so prominent in utero, however, that amniocentesis for the differential diagnosis of febrile patients has been advocated (Petrilli et al., 1980).

When listeriosis is recognized during pregnancy and adequately treated, the placental abscesses undergo scarring. They are then sometimes still recognizable histologically as a former abscess. One must assume that abscesses in the fetus may have a similar fate. Effective therapy during pregnancy has been described by Zervoudakis and Cederqvist (1977) and A.D. Fleming et al. (1985). The latter authors presented another case and described meconium staining and chorioamnionitis. Koh et al. (1980) also saw meconium discharge and found many placental abscesses in a newborn who was severely ill; the infant recovered after ampicillin therapy, which had been commenced prenatally. A similar sporadic occurrence was related by Barresi (1980). The organisms were present in gastric aspirate and on body surfaces. Placental abscesses were present. In another case, treated at 13 weeks' gestation, the placenta and infant were normal when the patient delivered at term (Cruikshank & Warenski, 1989). Identical lesions of placenta and fetus have been described in nonhuman primates (McClure & Strozier, 1975).

Recurrence of listeriosis during subsequent pregnancies has occasionally been described (Rappaport et al., 1960; Dungal, 1961; Ruffolo et al., 1962). Such events and

FIGURE 20.31. Listeriosis of the placenta in a stillborn. There is extensive subchorial infiltration with leukocytes, edema of membranes, and massive bacterial growth in amnion. H&E  $\times 160$ . Inset: Gram stain.  $\times 640$ .

the unexplained reason for the unusual frequency of severe listeriosis during pregnancy and in newborns have raised questions about the pathogenesis of this disease. Flamm (1959) experimented with rabbits and was of the opinion that septic transplacental infection causes the placental and fetal infection. This opinion is partly supported by the findings of typical abscesses in the placenta and the occasional finding of organisms within intact amniotic sacs. The presence of organisms in the vagina and in stool and the typically severe chorioamnionitis, however, suggest that an ascending mode of infection additionally occurs. Perhaps the placental abscesses form after fetal septicemia has taken place, similar to the abscesses in the fetus. Whether one or both of these modes of infection is the predominant way of fetal infection with listerial organisms is currently not known.

The susceptibility of immunodeficient and pregnant patients may result from their altered T-cell function. Schaffner et al. (1983) addressed this question experimentally by treating mice with cyclosporin A and cortisone, and by infecting nude mice. Their conclusion was that *Listeria* infection is biphasic: "Bacterial multiplication is controlled by nonspecific defense mechanisms in the early phase, and by acquired T-cell-dependent immunity in the second." This question was further explored in the work of Redline and Lu (1987), who found that local, decidual immune response regulated infection of the fetoplacental unit. They suggested an analogy to the non-rejection of the placental graft in regard to this immunologic interaction of *Listeria* and the decidua. In later studies, Redline et al. (1988) found that hormonal induction of deciduomas allows bacterial proliferation in the uterus, but that this endocrine manipulation does not influence the infection of peripheral organs of mice. It was also true when the mice were preimmunized. The investigators then studied the composition of the immune cells in the decidua and found that "increased bacterial titers were correlated with an inability of macrophages and T lymphocytes to reach [the] tissue *Listeria* [organisms] in discrete regions of deciduoma-bearing uteri." They further suggested that an antifetal (placental) immune response of the host was hindered by the same decidual mechanism that allows uncontrolled listerial growth locally (Redline & Lu, 1988). These findings suggested that the lack of recurrent listeriosis transmission by 74 women who had once delivered an infected child (Degen et al., 1970) is not the result of immunization. Bortolussi et al. (1989) found in rat experiments that neonatal interferon deficiency may be responsible for the susceptibility of infants.

Another organism that was reported to have caused the formation of placental abscesses is *Burkholderia pseudomallei*, the gram-negative bacillus causing **meliodosis** (Abbink et al., 2001). The mother had been treated with antibiotics for ulcerative colitis and a placenta previa

necessitated cesarean section. The neonate had sepsis and the organism was subsequently cultured from the cervix.

### *Actinomyces*

Only three cases of placental inflammation due to this gram-positive anaerobic organism have been reported (Zakut et al., 1987; Abadi & Abadi, 1996). The infection observed by the latter authors occurred in an afebrile patient at 25 weeks' gestation of a dichorionic twin pregnancy with premature labor. Upon membrane rupture, foul-smelling fluid emerged. Both placentas had marked chorioamnionitis and histologically characteristic organisms. Zakut et al. (1987) had reported two cases with massive invasion by actinomycetes and necrotizing placentitis.

### *Mycoplasma Hominis and Ureaplasma Urealyticum*

Mycoplasmas are a well-recognized group of pathogens of many animals. They cause infections of the urogenital tract, are responsible for respiratory and joint diseases, and are a frequent cause of epidemics in laboratory animal colonies (Tully & Whitcomb, 1979). Two organisms, *Mycoplasma hominis* and *Ureaplasma urealyticum* (also known as the "T strain" because the colonies are so tiny) are known urogenital pathogens for humans (Cassel & Cole, 1981); other *Mycoplasma* species affect different organ systems. *M. hominis* is a known cause of PID, febrile conditions during the postpartum period (Naessens et al., 1989), and possibly urinary tract infections. *U. urealyticum* (as well as *Chlamydia trachomatis*) is known to cause nongonococcal urethritis in men (Shepard, 1970; Taylor-Robinson & McCormack, 1980). The organism attaches itself to spermatozoa and may thus more readily penetrate the endocervical mucous barrier (see Fig. 20.24). It is also likely that combined infection with these two organisms is a cause of mucopurulent cervicitis in women (Paavonen et al., 1986). The available evidence suggests that these organisms are sexually transmitted (McCormack et al., 1972). Sterility in women is often secondary to PID, and much direct evidence exists that *U. urealyticum* infection of fallopian tubes is an important cause (e.g., Friberg, 1978). On the other hand, Gump et al. (1984) found that there is no relation between involuntary infertility and *Mycoplasma* infection. Yoon et al. (1998) showed the significant inflammatory reaction that follows infection with ureaplasma.

Kundsin et al. (1967) first suggested that infection with the T strain of *Mycoplasma* may cause chorioamnionitis and repeated abortion. They observed this new strain in cultures from decidua and aborted fetal membranes of a patient who had had four previous unsuccessful pregnan-

cies. The fetal lung contained aspirated pus. Microorganisms were not identified histologically in the inflamed tissues. Additional specimens gave similar results. These observations suggested that this new strain (*U. urealyticum*) may be the cause of repetitive abortions, as well as of sterility. Premature rupture of membranes and premature delivery have recently been associated with both *Mycoplasma* and *U. urealyticum* (Perni et al., 2004). A case similar to that described by these investigators is depicted in Figure 20.32; it is a patient with four previous abortions. Severe chorioamnionitis in this abortus is evident from the opacity of the fetal surface. Subsequent treatment with antibiotics of this patient and her husband resulted in a healthy term pregnancy (Quinn et al., 1983).

Since the initial description of placental infection with *Mycoplasma*, there have been numerous clinical and pathologic studies that aimed to define the roles of these pathogens in reproductive failure of women, specifically attempting to relate them to PROM and chorioamnionitis. Some conflicting results have been obtained. The studies are hampered by the facts that these organisms have specific culture requirements and cannot be identified by routine microscopic examination of tissues. Prenatal infection of fetal tissues has been demonstrated microbiologically in many studies, but positive antepartum cultures do not predict outcome effectively (Carey et al., 1991). Furthermore, erythromycin treatment of infected women does not apparently prevent premature delivery (Eschenbach et al., 1991). Both organisms are a cause of neonatal meningitis (Waites et al., 1988); *M. hominis* has been the cause of neonatal lung abscess (Sacker et al., 1970), and *U. urealyticum* infection has been associated with chronic neonatal lung disease (Cassell et al., 1988; Sanchez & Regan, 1988; Wang et al., 1988).

Madan et al. (1988, 1989) made detailed microbiologic studies of autopsy and placental material; they found that “genital *Mycoplasma* were isolated from 36 cases (8.3%), and acute chorioamnionitis and funisitis were present significantly more often in cases with genital mycoplasmas.” In their detailed study of perinatal deaths, including isolation of various pathogens from placenta and neonatal lung, they came to similar conclusions. One of their stillborns had myocardial calcifications, and some not only had aspirated pus in the lung but also an interstitial chronic inflammatory response, suggesting prolonged exposure to this mycoplasmal antigen. In this decisive pathologic study of perinatal infection with this organism, the authors were much impressed with the attending villous edema in the placenta.

The disease caused by these organisms is similar to that of other acute infections, except for the absence of demonstrable bacteria. The chorioamnionitis is similar as well. There have been some other suggestions that mycoplasmal infection causes villous alterations. Kundsinn et al. (1967) found “unusual sclerosis of villi”; and Romano et al. (1971), who described aspiration bronchopneumonia in an aborted 19-week fetus with isolation of T-strain organisms, described degenerative changes of villous vessels, thrombosis, and villous edema. The illustration accompanying their article, however, depicted normal architecture. This study, as many others, was hampered by our current inability to demonstrate the organism microscopically in tissue sections. In the future it will require special techniques, such as study with immunofluorescence.

The relation of *Mycoplasma* to PROM, premature labor, and chorioamnionitis is still debated; Romero et al. (1989c,d; Romero, 1989) have critically reviewed 12 published studies to assess this relation. They criticized several of them as being indecisive and poorly designed. Their

FIGURE 20.32. Placenta of spontaneous abortion due to *Ureaplasma urealyticum* infection. The patient had had four previous abortions with similar morphology. Note the creamy pus underneath amnionic surface, and fresh marginal hemorrhage.

opinions are that the association of cultured organisms and PROM “does not prove a cause-and-effect relationship,” and when all studies were analyzed in detail, “it seems unlikely that genital colonization with *Mycoplasma* species without a failure of the host defense (fetal and/or maternal) leads to preterm delivery.” This report was criticized by Kundsinn and Horne (1989), and the reply must be read to appreciate the controversies, especially with respect to effective therapy.

In a prospective cohort study of 6500 women, no association of *U. urealyticum* infection with premature labor was found by Nugent et al. (1988). Pathologic and microbiologic studies on neonates from patients with and without chorioamnionitis by Quinn et al. (1987) established a strong correlation between *U. urealyticum* colonization and chorioamnionitis. Kundsinn et al. (1996) found that prenatal infection with this organism increases significantly the longer the membranes have ruptured. They emphasized that eradication of the infection in a gravida should be attempted. Gauthier et al. (1994) felt that isolation of the organism would not lead automatically lead to delivery, and they treated women successfully with erythromycin. When maternal antibody response was taken into consideration, Gibbs et al. (1986) found a strong correlation of a pathogenic role of *M. hominis* infection. Considering the frequently mixed nature of infection, the high prevalence of some of these organisms, and the differences in the composition of the populations studied, it is presently impossible to come to a clear-cut decision. Our impression is that the genital mycoplasmas are pathogenic genital organisms, and that they are a frequent cause of chorioamnionitis and premature birth. In fact, several studies have shown that they are the principal organisms isolated from the placental surface and amniotic fluid of patients with PROM.

### *Chlamydia Trachomatis and C. Psittaci*

The genus *Chlamydia* has several species (Peeling & Brunham, 1996). Of these, *Chlamydia psittaci* causes parrot fever (psittacosis), and *Chlamydia trachomatis* is responsible for the most common sexually transmitted disease in the United States (see also Gaydos et al., 1998; Peipert, 2003). It also causes trachoma, lymphogranuloma venereum, nongonococcal urethritis in men, and the diseases in women that will next be discussed. *Chlamydia pneumoniae* and *C. pecora* are now considered to be subdivisions of *C. psittaci* and have not yet been assigned as being gestational pathogens. It is estimated that between 10% and 20% of sexually active men and women are infected with one of these organisms (Saxer, 1989; Caul et al., 1997; Miller, 2005). Ryan et al. (1990) surveyed a large population of women by cervical culture and found that 21.08% were positive. They recommended routine culture for *Chlamydia*. Approximately half the infants born to infected mothers develop ophthalmia neonato-

rum (“inclusion body blenorrhoea”). Others develop pneumonitis. It is estimated that 3% to 4% of neonates have ophthalmia, and 1% to 2% have pneumonitis from infection with this organism (Harrison et al., 1978; Harrison, 1985).

The bacterium-like intracellular microbe can be visualized in the cytoplasm of infected cells by direct immunofluorescence study. *Chlamydia* has also been isolated from neonates, even from the pneumonia of stillborns infected through intact membranes (Thorp et al., 1989). Other than by culture, the infection can be diagnosed in infected tissues and amniotic fluid with the immunoperoxidase technique, as employed by Shurbaji et al. (1988), and by DNA sequences following polymerase chain reaction (PCR) amplification (Pao et al., 1991). The direct immunofluorescence technique has a sensitivity of approximately 89% (Binns et al., 1988), and fine-tuning allows some additional improvement (Pastorek et al., 1988). Livengood et al. (1988) investigated various staining methods and emphasized the diagnostic importance of having experience when reading the slides. An enzyme immunoassay was advocated by Binns et al. (1988) as being highly sensitive and therefore a good diagnostic test. Reports on the prevalence of the disease must be interpreted with these limitations in mind. But new, simple, and effective methods for detection (e.g., polymerase and ligase chain reactions) have been added to the armamentarium of epidemiologists (Pasternack et al., 1996; Andrews et al., 1997; Locksmith, 1997) that should much improve diagnosis and results from surveys. Thus, PCR from self-obtained samples of the introitus yielded excellent results (Wiesenfeld et al., 1996).

*Chlamydia trachomatis* infection of the cervix, where it causes mucopurulent cervicitis (Brunham et al., 1984, illustrated in color by Peipert, 2003), is also relatively easily demonstrated by the use of the direct fluorescence method (Graber et al., 1985). Brunham et al. (1984) provided impressive color photographs of the stained organisms. *C. trachomatis* is responsible for a significant number of cases of acute salpingitis (Magnusson et al., 1986), and it also causes chronic salpingitis and sterility (Guderian & Trobough, 1986; Moss et al., 1986). The effect of a *C. trachomatis* infection on pregnancy is still controversial. Sweet et al. (1987) reported that PROM was more likely to occur when infection had caused a maternal antibody response, but statistical significance was not reached. Alger et al. (1988) found that the organism was isolated from 44% of patients with PROM but only in 16% of controls. There are suggestions that PROM and perhaps chorioamnionitis are linked to this infection, but much more direct evidence needs to be marshaled before such a conclusion can be affirmed. The organism has not been isolated from the placenta, but has been demonstrated in amniotic fluid, and in the eye and nasopharynx of neonates (Thomas et al., 1990). It has also not yet been demonstrated conclusively to be a direct cause of

chorioamnionitis, except in rat models (Rettig & Altschuler, 1981). Ryan and his colleagues (1990), however, accumulated data on the infection in pregnancy that suggested premature rupture of membranes to be much more likely when the infection was not treated. Other investigators support the notion that chlamydial infection in pregnancy should be treated with antibiotics (Forster et al., 1991; Crombleholme et al., 1990).

*Chlamydia psittaci* infection is rarely recognized as a cause of human abortion, although this infection commonly causes abortions in sheep and other domestic species. Initial infection in sheep is followed by a 30% abortion rate that later declines to 5% when the flock is thoroughly infected (Gunson, et al., 1983). Reports by Johnson et al. (1985) and Wong et al. (1985) indicated that sheep farmers and their wives have a high exposure to this pathogen. A pregnant wife of a farmer became infected and aborted at 28 weeks' gestation. Acute intervillitis was found in the grossly normal-appearing placenta. Syncytiotrophoblastic inclusions were present that showed numerous organisms by ultrastructural study and positive immunofluorescence. The fetus was also infected with organisms recovered from various organs. We have summarized the experience with such an infection (Hyde & Benirschke, 1997; Jorgensen, 1997). This abortion occurred following a febrile episode in a woman who had assisted with lambing. The sheep were later found to be chronically infected with this organism. Characteristically, the patient's DIC ceased after abortion of the infected placenta. In one instance, at least, the pregnant patient succumbed from the disease. The placenta had massive intervillous leukocyte accumulations, villous necroses, and the typical presence of masses of chlamydial organisms that appear to preferentially proliferate in the cytoplasm of the syncytiotrophoblast (Fig. 20.33A–D). Since that report another experience with abortion in pigs due to this agent has been published (Thoma et al., 1997).

## Bacterial Vaginosis

Bacterial vaginosis has been defined by Westrom et al. (1985) as the "replacement of the lactobacilli of the vagina by characteristic groups of bacteria accompanied by changed properties of the vaginal fluid." The other bacterial species include *Bacteroides*, *Gardnerella vaginalis*, *Mycoplasma hominis*, *U. urealyticum*, and perhaps others. A relation to PROM and amnion sac infection has been reported to exist (Gravett et al., 1986). Many authors since have suggested that bacterial vaginosis is a common cause of intraamniotic infection and premature birth (Silver et al., 1989; Hillier et al., 1995; Newton et al., 1997). Consideration of this entity, however, is beyond the scope of this chapter; suffice it to say that current opinion is that systemic antibiotic therapy is required and effective (Hauth et al., 1995; Joesoef et al., 1995; McGregor &

French, 1996). An extensive review has been provided by Martius and Eschenbach (1990) that considered the relation of vaginosis to chorioamnionitis, and numerous clinical publications have also considered this topic. A relation to preterm labor was shown by Subtil et al. (2002) and a meta-analysis by Leitich et al. (2003) showed it to be "a strong risk factor for preterm delivery and spontaneous abortion." Therapeutic trials of antibacterial treatment have been effective in reducing preterm births (Ugwumadu et al., 2003).

## Syphilis

Infection with *Treponema pallidum* may occur at any time during pregnancy. The organism may pass to the fetus through the placenta during all stages of maternal syphilis infection. The responsible organism is a 4 to 10µm long, 0.5µm wide spirochete. According to Grossman (1977), "Most frequently, dissemination is associated with a placentitis arising from hematogenous spread of the spirochetes between the first and second stages of infection of the mother." The commonly held notion that the placenta is impermeable to spirochetes before the 20th week of pregnancy, because of the thickness of Langhans' cytotrophoblast layer (Fiumara, 1975), can no longer be accepted. Braunstein (1978) described a spontaneous abortus (12.8-cm CR length, approximately 4.5 months' gestation) with an abundance of spirochetes in the liver and other organs and marked placental changes. We had shown, by immunofluorescence and electron microscopic studies, that spirochetes can be demonstrated in fetuses as early as at 9 to 10 weeks' gestation (Harter & Benirschke, 1976). One reason why prior studies had failed to identify fetal syphilis is because the expression of the disease's features depends on the fetus's ability to react with antibody production to the spirochetal antigen. Histopathologic changes cannot be seen before that developmental time, and the disease is thus not diagnosed. Ohyama et al. (1990) have since demonstrated spirochetes in syphilitic placentas by the immunoperoxidase technique, and Nathan et al. (1997) also isolated spirochetes from early gestations and subsequently successfully treated the fetuses. Although spirochetes may be difficult to identify, a variety of new techniques are now available. The study of congenital syphilis by Guarner et al. (1999) describes histochemical means by which to demonstrate an abundance of spirochetal remnants in this disease, aside from complete spirochetes, thus making diagnosis considerably easier.

The relation of infection to disease was first clearly elucidated by Silverstein (1962) and Silverstein and Lukes (1962). They found congenital syphilis with attendant fetal plasma cell infiltration and reasoned that the inflammatory response was the cause of illness. Another reason for lack of recognition of early fetal infections is that it is

FIGURE 20.33. A: Acute intervillitis (abscess) with villous destruction in *Chlamydia psittaci* infection. B: Cluster of organisms in syncytial cytoplasm at arrowheads. C: Immunofluorescent localization of antigen. D: Electron microscopic (EM)

demonstration of syncytial organisms. (A,B: H&E  $\times 100$ ,  $\times 400$ ; C: immunofluorescence  $\times 400$ ; D: EM  $\times 1500$ ) arrow at organism. (Source: Modified from Hyde & Benirschke, 1997.)

often difficult to demonstrate spirochetes histologically. Fetuses from such infections are often macerated, and radiographic study of long bones, often diagnostic of the infection, is frequently neglected. The disease may also appear as hydrops fetalis (Barton et al., 1992). The treponemes in macerated fetuses are most abundant in the liver; they are rare in the placenta and umbilical cord. Wendel et al. (1989, 1991) have shown that in gestations with fetal death from syphilis, darkfield examination of amniotic fluid always readily allows demonstration of treponemes. In addition to the conventional silver stains, it has been demonstrated that spirochetes may be stained with immunofluorescence in formalin-fixed tissue (Hunter et al., 1984). Thus Epstein and King (1985) demonstrated spirochetes in macerated liver tissue by immunofluorescence. Nevertheless, improved Warthin-Starry silver stains are probably the best means of identifying spirochetes in tissues (Kerr, 1938). It has now been established also that the organism can be identified in macerated fetuses with the Warthin-Starry stain (Young & Crocker, 1994).

A classic paper of the neonatal pathology in congenital syphilis was written by Oppenheimer and Hardy (1971). They confined their report to 16 neonatal deaths and did not consider the 31 macerated fetuses they saw during the same time. Hepatosplenomegaly was found in all, but after penicillin therapy spirochetes were not demonstrable with the Levaditi stain. The report does not include a consideration of placental lesions. Judge (1988) also provided an excellent review of congenital syphilis, with emphasis on the stage of pregnancy when the disease was acquired.

Many morphologic changes are found in the placenta and umbilical cord with congenital syphilis (Russell & Altshuler, 1974; Horn et al., 1992). By and large, the more severely the fetus is affected, the greater are the pathologic changes in the placenta. A macerated fetus with congenital syphilis may have a massively enlarged placenta with numerous pathologic features; a general increase in placental weight has been demonstrated by Malan et al. (1990). Most authors who have studied the placenta of congenital syphilis have concluded that there are no absolutely characteristic pathologic findings, but bulky villi and some other changes to be discussed should raise the suspicion. When suspicion of fetal syphilis exists, silver preparations for spirochetes are indicated. They may ultimately prove that lesions are due to syphilis when other means such as serology and radiographs of the fetus are not available. It must be cautioned, however, that the stains are not always easy to execute and that incomplete treatment with antibiotics may prevent identification of spirochetes. Fojaco et al. (1989) have claimed that necrotizing funisitis is a specific lesion of congenital syphilis and Knowles and Frost (1989) have expressed a similar view. Discussion of this fallacy is included in the

next section of this chapter. Because much of the informative literature on placental syphilis comes from an era when the other causes of banal types of chorioamnionitis and funisitis were not recognized, the early literature must be interpreted with caution.

When congenital syphilis was suspected in the past, physicians made scrapings of the umbilical venous intima for darkfield examination; and in the discussion of congenital syphilis by Ricci et al. (1989), beautiful silver preparations of this type were illustrated. They also showed the plasma cell villitis in such a case. Hörmann (1954) has reviewed this and other aspects of syphilis in great detail. Baniecki (1928) is one of many authors who sought treponemes in umbilical cords. He found inflammation in five of 14 living infants with syphilis; 12 of 17 stillborns had such inflammation, and five of 40 nonluteic infants had umbilical phlebitis. During the same year, Kaufmann (1928) found no placental lesions in two thirds of children with positive spirochetal infection. Beckmann and Zimmer (1931) made another detailed study of umbilical cords in syphilis. They had 420 cases, of which 392 were at term gestation, including nine stillborns; 28 were premature, including five stillborns. They found inflammation in 18.3% (77 cases; 25 only mild). Of these cases, only three infants had congenital syphilis. Conversely, 13 infants with congenital syphilis had no inflammation. They concluded that funisitis was not characteristic of syphilis but rather was a nonspecific inflammation that was perhaps caused "mechanically." Organisms are also readily identified in amniotic fluid (Wendel et al., 1989, 1991). In some cases of funisitis due to spirochetal infection we found the organisms only peripheral to the exudate and the necrosis, employing the Warthin-Starry stain.

The villous tissue has somewhat more characteristic changes with congenital syphilis. In Braunstein's (1978) 4 months' gestation fetus, the placenta had enlarged villi with endothelial and fibroblastic proliferation. Few mononuclear cells were present. The cellularity of the villi demonstrated in his photomicrographs, however, is impressive and is similar to that shown in Figure 20.34. McCord (1934) had described these features of villous "crowding" and enlargement of the placenta. Russell and Altshuler (1974) were also impressed with the placental enlargement, a feature already commented on by Hörmann (1954), who had referred to a case with a placental weight of 2500 g accompanied by a fetus weighing 2600 g. Russell and Altshuler's diagnostic features included relative villous immaturity, decidual plasma cell infiltration, perivascular fibrous tissue proliferation, and alterations of capillary endothelium. They also found plasma cell infiltrations in the enlarged villi of syphilitic placentas, a finding made repeatedly by us. These changes are all nonspecific. The nature of the infiltrating inflammatory cells within villi has been controversial. Most recently, they

FIGURE 20.34. Plasma cell infiltration of decidua basalis in a placenta of 28 weeks' gestation and an infant afflicted with typical congenital syphilis. The placenta was large 580 gm. H&E  $\times 160$ .

were characterized by Kapur et al. (2004) and found to be largely (or exclusively?) of maternal origin. CD3 lymphocytes predominated in that study. Gummas or granulomas have never been reported in the placenta, but

FIGURE 20.36. Perivascular plasma cell infiltration of chorion in congenital syphilis at 30 weeks' gestation. Mild chorioamnionitis is also present. H&E  $\times 160$ .

Hörmann depicted villous abscesses that had also been seen in earlier studies. In our experience, the villous enlargement is often striking and there are frequent decidual infiltrations with plasma cells; foci of decidual necrosis are common (Fig. 20.35). Abscesses or villous necrosis is frequent in severe infections and chorioamnionitis may be present, but it is also often absent. When it is found, it may include plasma cells, which is an otherwise unusual finding in banal chorioamnionitis (Fig. 20.36). Spirochetes can be found, but often it requires a

FIGURE 20.35. Villi of placenta in congenital syphilis (same case as in Figure 20.38). Villi are hypercellular, infiltrated with mononuclear cells. Note the focal necrosis and vascular obliteration. H&E  $\times 240$ .

prolonged search (Fig. 20.37). Moreover, and regrettably, the art of staining spirochetes in tissues is gradually being forgotten by histologists. There is a reported decrease of estriol production by the placenta in syphilis (Parker & Wendel, 1988), perhaps due to a possible decrease in fetal adrenal androgen precursors, rather than to a placental inability to aromatize androgens.

## Necrotizing Funisitis

The term **subacute necrotizing funisitis** was introduced by Navarro and Blanc (1974) in a report of 16 cases. In the earlier literature this condition had been referred to as “phlegmonous funisitis” (see Hörmann, 1954). It is an infrequent and unusual type of a more chronic inflammation of the umbilical cord in which even calcification of the old exudate may occur. Calcifications of the umbilical cord had only rarely been reported before the descriptions by Navarro and Blanc. Eight of their cases were stillborn infants. With the exception of two isolations of *Candida* species, no pathogen was identified. Syphilis and other specific agents were carefully excluded by serology in that study. The umbilical cords of these infants had severe inflammation deposited in “successive waves.” It was present in a ring-like fashion around the umbilical cord vessels. The exudate was often degenerated and had become calcific. Mural thrombosis was present in several vessels. Two infants had an uncommon presence of plasma cells in their umbilical cord. The nature of the exudate indicated that it is a chronic infection, as did similar inflammatory changes in the lungs of several stillborns. Other signs of chronic infection were found in the stillbirths, and they occurred during the neonatal life of survivors. Chorioamnionitis with frequent surface necrosis was invariably additionally present. In the opinion of Navarro and Blanc, the funisitis differed in severity and chronicity from the usual type of funisitis found in the amnionic sac infection syndrome. Miyano et al. (1998)

suggested that it represents the end of the infectious process, where only immune perturbations still exist.

Perrin and Bel (1965) had previously described three cases of cord calcification, one of which, however, may have originated in a hematoma. In one of these cases, there was difficulty in clamping the cord at delivery. An interesting aspect of this inflammation was the “neovascularization” of the exudate, with the origin of these capillaries being unknown. Schiff et al. (1976) described calcification of all three vessels in the cord and had even visualized it sonographically before birth. As in other cases, the calcifications followed the cord vessels, but they stopped before entering the abdomen of the infant. This observation is important, as it further clarifies the pathogenesis of chorioamnionitis and funisitis. It indicates the presence of antigen within the amnionic sac and negates the opinion that the umbilical vasculitis results from a systemic infection. No inflammation was described in their case, but the fetal growth restriction was thought to be secondary to the restriction of blood flow. Gille (1977) described a similar case and drew attention to the fact that granulation tissue was present in the vessels. The patient was a premature infant who did well. The exudate accompanied the vessels for the length of the cord, and a fresh thrombus was present within the vein. The accompanying photographs showed an impressive and uncommon amount of inflammation and “organization,” which is otherwise rare in the placental vasculature. Knowles and Frost (1989) have added a case report of necrotizing funisitis in congenital syphilis with organisms plentiful in this lesion but sparse elsewhere.

Numerous cases of chronic, necrotizing funisitis have been seen by us. Some had calcifications, but others did not. In our view, they represent different stages in the evolution of funisitis. Figure 20.38 shows a cross section of umbilical cord in an immature placenta with necrotizing funisitis. Figure 20.39 shows the concentric rings of white exudate in a growth-retarded infant at 31 weeks; in contrast to the previous case, here the inflammatory reaction totally surrounds the vessels. In Figure 20.40, a radiograph shows the peripheral calcification that has formed in the old exudate. Numerous plasma cells were found in the inflammatory debris, but electron microscopic search for organisms was unrewarding. The mother had had a febrile illness during the first trimester, but otherwise mother and infant were entirely normal. In other cases, herpes virus II antigen could be localized to such cords with specific antibodies (Robb et al., 1986b).

Craver and Baldwin (1992) reviewed 60 cases of this necrotizing funisitis, 45 of which had clinical information. This is clearly the largest case collection of this lesion. It occurred in 0.1% of deliveries more than 20 weeks' gestation. Growth restriction (28%), stillbirths (18%), and necrotizing enterocolitis (22%) were prominently associated problems. These investigators did not find any single agent

FIGURE 20.38. Umbilical cord at 31 weeks' gestation with chronic inflammatory exudate (necrotizing funisitis). The exudate is concentrically deposited around the vessels; much old exudate is necrotic and beginning to calcify. A partially organized mural thrombus is present in the umbilical vein. The patient had rupture of the membranes for more than 12 hours, a circumvallate placenta, and massive chorioamnionitis. von Gieson.  $\times 12$ .

or maternal condition that caused chronic funisitis. Calcification was present in 47% of their cases and chorioamnionitis in 98%. The investigators suggested that a diffusible toxin in the amniotic cavity might cause this lesion because of its similarity to an Ouchterlony immunodiffusion plate. As stated earlier, Fojaco et al. (1989) suggested that necrotizing funisitis "permits a presumptive diagnosis of congenital syphilis at birth." They referred to the gross appearance as a "barber-pole cord" and found 16 cases of this association with congenital syphilis. All their cases of necrotizing funisitis were in luetic pregnancies, and spirochetes were found in four of 10 patients. Fojaco and her colleagues stated that information in the early literature suggests that necrotizing funisitis is diagnostic of syphilis. In fact, however, Hörmann (1954) had extensively studied syphilis and funisitis, and he did not find an absolute relation between these conditions. It is true that funisitis often occurs in syphilis, but not so regularly as suggested. Hörmann and other authors have also often found necrotizing funisitis in nonsyphilitic pregnancies. This point was well made by Craver and Baldwin (1992), with whom we agree. In some umbilical cords with

necrotizing funisitis, we have identified herpes antigen, to be discussed below. Thus, necrotizing funisitis is a chronic, severe inflammation of the cord, frequently associated with calcification, and caused by immune reaction to presumably several different antigens. Likewise, Jacques and Qureshi (1992) found this not to be a strong association, when they studied 45 cases. Like other investigators, they found *Candida*, *Streptococci*, and other bacteria to be responsible. The necrotizing funisitis is merely the manner by which the umbilical cord can express its chronic inflammatory damage, not being able to remove the debris efficiently that accumulates with chronic exudation. The connective tissue cells of the umbilical cord often degenerate completely with this reaction.

## Other Spirochetal Diseases

**Leptospirosis**, an infection due to one of several species of *Leptospira*, has rarely been reported in pregnancy. Coghlan and Bain (1969) have gathered the few reports of abortion that were presumed to result from this infec-

FIGURE 20.39. Concentric rings of perivascular exudate in necrotizing funisitis. There was marked chorioamnionitis in this 31-week pregnancy.

FIGURE 20.40. Radiographic appearance of calcific rings in a cord with necrotizing funisitis. A term, normal infant was delivered. There was no history of maternal problems except a febrile illness during the first trimester. (Courtesy of Dr. R.R. Oldham, Nashville, Tennessee.)

tion; they described the pregnancy of a patient who was infected with *L. canicola*, acquired from a pig. The mother delivered a macerated fetus. Organisms were not recovered from the fetus or from the placenta. Moreover, there were no histopathologic lesions. Abortion due to leptospirosis is said to be a common disease in China, with organisms having been recovered from the affected fetuses.

*Borrelia*, the spirochetal organism that causes relapsing fever, has been isolated from the blood of a febrile mother and her newborn infant who died shortly after birth (Fuchs & Oyama, 1969). The placenta was not described. The infection follows the bite of an infected tick and the disease is geographically widespread (e.g., Oregon: case just cited; Israel: Yagupsky & Moses, 1985). Shirts et al. (1983) reported a nonfatal case of congenital borreliosis in a febrile patient from Colorado. The spirochetes were depicted in the neonate's blood smear, placental villous capillaries, and umbilical artery. Placental lesions were not described.

**Lyme disease** (erythema migrans) is an emerging borreliosis of epidemic proportion in the northeastern United States (Athreya, 1989; Eichenfield, 1989; Lastavica et al., 1989; Steere, 1989). This infection, caused by *Borrelia burgdorferi*, has been encountered in other parts of the United States and Europe as well. Transplacental infection was reported in Wisconsin by Schlesinger et al. (1985) and in Utah by MacDonald et al. (1987). In the macerated stillborn of the latter case, the placenta was not enlarged and had "rare plasma cells in isolated villi." The specimen was grossly unremarkable. Spirochetes were identified in the fetus and placenta by special stains. The placental histology showed such excess of erythrocyte precursors (in the fetal circulation) that it could easily have been mistaken for erythroblastosis fetalis. In these two cases, the fetuses had congenital anomalies. Hemminki and Kyrrönen (1989) found an overrepresentation of gastrointestinal atresias in offspring from animal caretakers and forestry and agricultural workers. They suggested that

infection with *B. burgdorferi* may be an etiologic factor. The review of Steere (1989), however, suggested that there is no causal relation between this infection and anomalies. The same assertion was made by Strobino et al. (1993), who undertook a prospective study and found neither a definite increase of fetal anomalies nor adverse pregnancy outcomes.

Abramowsky et al. (1991) found nontreponemal spirochetes primarily in the intestines of four spontaneously aborted fetuses with chorioamnionitis, severe chronic villitis, and villous vasculitis in some. It was possible to rule out *Treponema*, *Borrelia*, *Leptospira*, and *Campylobacter*, and the precise nature of this organism remains to be determined. Infections with *Ehrlichia* have also been delineated, and are discussed below.

## Fungus Infections

*Candida albicans* infection of the vagina is common during pregnancy. Oriel and colleagues (1972) estimated that 26% of women harbored yeast: *C. albicans* in 81%; *Torulopsis (Candida) glabrata* in 16%. The use of oral contraceptives increased the frequency. Peeters et al. (1972) reported similar results. They opined that an increased use of antibiotics, contraceptives, and trichomonacides may be responsible for this frequency. Bret and Coupe (1958) demonstrated that neonatal fungal infection (mostly candidiasis) can be traced to maternal vaginal infection in most cases. The organisms usually then disappear spontaneously for unknown reasons.

Prenatal infection of placenta, cord, and fetus has been reported in hundreds of cases since its first description (Benirschke & Raphael, 1958; Whyte et al., 1982; Qureshi et al., 1998). Figure 20.41 illustrates a classical case. The patient was a gravida VI, para I, who had had five consecutive abortions. The pregnancy terminated at 25 weeks with severe chorioamnionitis. The umbilical cord had

FIGURE 20.41. Umbilical cord from a patient with congenital candidiasis at 25 weeks' gestation. Note the numerous small, white plaques (arrows), representing abscesses ("granulomas"). Gravidia VI, para I, abortus V.

numerous tiny plaques of white-yellow color. Histologically, these nodules consisted of infiltrates with acute inflammatory cells underneath areas of epithelial necrosis (Fig. 20.42). When one scrapes these small lesions and stains with periodic acid-Schiff (PAS) or silver methods, fungi are immediately recognized (Fig. 20.43). Hematoxylin and eosin (H&E) stains, on the other hand, hide the hyphae effectively. But fungal hyphae are also readily demonstrated with silver stains when they may be very difficult to identify in H&E preparations. Touch preparations from scraping cord lesions are diagnostic and thus helpful for neonatal therapy. Relative to the severity of the chorioamnionitis, the funisitis is generally only slight and it is often remarkably focal. The umbilical cord finding of surface granules with inflammatory cells and

fungi is characteristic of congenital candidiasis. Although *C. albicans* is the most common candidal organism, infection with *C. parapsilosis*, a common skin inhabitant, has also been reported (Kellogg et al., 1974). We have seen two cases of infection with *C. tropicalis*, and Nichols et al. (1995), who also reviewed the sparse literature, described a 25-week premature with this infection. The fetus had massive pneumonia and there was marked chorioamnionitis but no funisitis. The mother had an IUD in place. Other than for the lack of hyphae, the histologic findings of our case were generally similar (Fig. 20.44). In an immunosuppressed (bone marrow transplant) patient with diamniotic/dichorionic (DiDi) twins, vaginal bleeding led to amniocentesis and recovery of budding yeast, *Candida lusitanae*. Three weeks' of amphotericin therapy

FIGURE 20.42. Candidiasis of umbilical cord. The lesions shown in Figure 20.41 are accumulations of inflammatory cells, debris, and hyphal organisms (arrows in PAS stain) of *Candida albicans*. Epithelial necrosis is striking at top H&E  $\times 60$  (top);  $\times 240$  (bottom).

apparently resolved the chorioamnionitis, although the placenta was not described (DiLorenzo et al., 1997).

A remarkable feature of congenital candidiasis is the frequency of its occurrence with unruptured membranes. We had postulated a silent, healed rupture in our original report. Our subsequent experience was that the organisms may readily penetrate the intact membranes. Why the placental infection is so uncommon, in comparison with the frequency of the vaginal infection, is unknown. It had been speculated that it results from fetal immunodeficiency, but findings of good plasma cell response to the congenital pulmonary infection negates this hypothesis (Hood et al., 1985). More likely is the efficiency of the endocervical mucus plug in preventing ascension. Neonatal candidiasis may be widespread, with skin rash,

dark red skin appearance, pneumonia (Emanuel et al., 1962), meningitis (Levin et al., 1978), sepsis, and frequent intestinal contamination (Taschdjian & Kozinn, 1957). It may cause death but has also been treated successfully on several occasions. Abortions have also been due to *Candida* infection (Buchanan & Sworn, 1979; Smith et al., 1988). We have seen elevations of neonatal WBC counts to 80,000 in congenital infection of a premature infant. There had been rupture of membranes for 3 days.

A well-studied case showed convincing evidence of antenatal septicemia (Bittencourt et al., 1984). In this case, a large fungal invasion into an umbilical vein was shown; moreover, there were many fetal and villous candidal lesions. The latter showed focal necrosis, chronic villitis, and intervillous abscesses. Congenital infection

FIGURE 20.44. Subamniotic cluster of *Candida parapsilosis* in an infant with cutaneous congenital candidiasis (blisters) after prolonged rupture of membranes. The infant did well. Note the absence of hyphae and the intact amniotic epithelium. At other sites, chorioamnionitis was prominent. H&E  $\times 600$ .

has been associated with a retained IUD on several occasions (Schweid & Hopkins, 1968; Ho & Aterman, 1970; Bittencourt et al., 1984; Spaun & Klünder, 1986; Smith et al., 1988; Elliott, 1989; Qureshi et al., 1998). Delaplane et al. (1983) believed that, in their case, the fungus may have been introduced by amniocentesis. Whyte et al. (1982) suggested that at least 30 cases had been reported, and they added 18 of their own. At least 10 additional cases can be added to this list, bringing the total to well over 50 congenital candidal infections, and Pradeepkumar et al. (1998) added five additional typical cases. Bader (1966) reported its occurrence in an anencephalus and depicted the extent of placental involvement. Rhatigan (1968) and Franciosi and Jarzynski (1970) each added a case. Nagata et al. (1981) described a fatal case of pulmonary mycosis and cited some cases from the Japanese literature. Johnson et al. (1981a) reported two cases and gave suggestions for therapy. Delprado et al. (1982) provided excellent illustrations in their report of three cases. They highlighted the association with unruptured membranes and a retained IUD. Shalev et al. (1994) delivered amphotericin transcervically when fungi were cultured from amniocentesis fluid. Rode et al. (2000) also administered amphotericin when, in serial amniocenteses for unexplained hydramnios, the organism was demonstrated and cultured. The neonate died from disseminated infection and the placenta was characteristic. Pera and associates (2002) deduced from chart review that neonatal candidiasis (*C. albicans* and *C. parapsilosis*) was more common in women receiving antibiotics and dexamethasone in pregnancy.

The case report by Levin et al. (1978) is of particular interest. It involved a set of DiMo twins delivered vaginally at approximately 30 weeks' gestation. The mother was febrile. The amniotomy of twin A resulted in meconium-stained fluid, but this infant did not have fungal infection at autopsy. Twin B, whose membranes had ruptured 9 days prior to delivery and whose amniotic sac was found to be dry at delivery, had cerebral candidiasis. In the placenta, a focus of candidal hyphae was found

near the insertion of the umbilical cord from twin B, and chorioamnionitis was more severe.

A case of *Torulopsis (Candida) glabrata* infection of placenta and fetus in a patient with sickle cell anemia, was illustrated by Sander et al. (1983). They assumed that the maternal immune compromise may have rendered this infection more possible. The only previously described case was in a patient with a retained IUD. This widely distributed yeast has now been placed in the *Candida* genus; it lacks hyphae. In the two reported cases there was chorioamnionitis, but the umbilical cords had no lesions. In Sander's case, the patient had cerclage for repeated abortions; the stillborn twins had a fungal aspiration pneumonia. Infection had occurred before rupture of membranes, and marked deciduitis was present. The most remarkable feature of the lesion in the umbilical cord are the peripheral nodules with invading fungi. These nodules contain fungi but are compressed Wharton's jelly, perhaps from digestion of the mucopolysaccharides by the yeast. Few WBC are present in these nodules. Other comprehensive reviews are those by Johnson et al. (1981a), Gerberding et al. (1989), and Schwartz and Reef (1990).

Approximately 65 pregnant patients with **coccidioidomycosis** had been reported when VanBergen et al. (1976) reported a fatal case. The placenta had numerous infarcts with spherules of *Coccidioides immitis*, accompanied by inflammation, necrosis, and fibrin deposits. Figure 20.45 shows a cross section of a placenta with coccidioidomycosis. Figure 20.46 is a representative microscopic appearance of the lesions and the organisms. An acute inflammatory response around the fungal spherules is common, as is extensive fibrin deposition. Smale and Waechter (1970), in an analysis of 15 cases with disseminated infection, mentioned three with placental involvement and one presumed fetal infection. Most commonly, the organism remains confined to the placenta, where it produces infarctive necroses. This picture was first described by Vaughan and Ramirez (1951), who saw 33 cases of coccidioidomycosis complicating pregnancy.

FIGURE 20.45. Section of mature placenta from a mother with coccidioidal meningitis. The coccidioidomycosis lesions are the white infarct and the punctate fibrin deposits. The mother was treated with amphotericin B. The neonate was normal.

FIGURE 20.46. Microscopic view of coccidioidomycosis of the placenta (case in Fig. 20.45). Left: Note the spherule in the X-cell deposit with fibrin and an acute inflammatory reaction. Right: Several large spherules are engulfed in macrophages (right). H&E  $\times 250$  (left);  $\times 640$  (right).

Only one had lesions in the placenta. They were infarctive, necrotic lesions with “purulent filled centers, full of spherules.” The premature infant delivered to that mother died at the age of 6 months but was free of the disease. The other infants also did not contract the infection transplacentally. Shafai (1978) described disseminated infection in a set of premature twins whose mother died soon after giving birth. They found no lesions in the placenta but still assumed that transplacental infection must have occurred. Bernstein et al. (1981) described another presumptive congenital infection, but they did not describe the placenta. Spark (1981) has critically reviewed all cases of congenital coccidioidomycosis and came to the conclusion that transplacental dissemination was unlikely for any of them. The mode of neonatal infection, he believed, was inhalation of infected material (“decidua”) during delivery.

We have seen massive placental involvement with *Coccidioides* lesions unaccompanied by neonatal illness (McCaffree et al., 1978). In one patient in whom the disease was treated with amphotericin B during the entire gestation, the fetus was normal and the placenta merely showed old infarcts and fibrin deposits, without stainable organisms. Peterson et al. (1989) also described a patient with coccidioidal meningitis treated with amphotericin during two pregnancies in whose placentas there were no organisms. Walker et al. (1992) described maternal reactivation of coccidioidomycosis in pregnancy, positive neonatal cord titers, but a negative placenta. A pregnant patient with lymphadenopathy due to *Paracoccidioides brasiliensis* was described by Slevogt et al. (2004). The patient was treated successfully and a healthy infant was born.

**Cryptococcosis** of the placenta was found by Kida et al. (1989) in a patient with acquired immunodeficiency syndrome (AIDS). It had not invaded villi, and the infant did not develop lesions. The mother developed widespread cryptococcosis. Through the courtesy of Dr. G. Altshuler, we examined placental sections with cryptococcal abscesses of a patient with systemic lupus erythematosus (SLE). She suffered cryptococcal meningitis, presumably because of steroid therapy for SLE. In the intervillous spaces of the immature placenta there were large colonies of cryptococcal organisms; inflammation was scant and no invasion of the villi was found. The neonate (850g) died and had no evidence of disease (Molnar-Nadasdy et al., 1994). We have also seen the slides of a patient who had been treated with ketoconazole for pulmonary **blastomycosis** 4 years earlier (Dr. E.G. Chadwick, Chicago, personal communication). The patient had been free of apparent disease but was initially infertile. A healthy term infant was eventually delivered. The placenta then appeared grossly peculiar as it had a nodular consistency, and numerous granulomas as well as chronic villitis at the maternal floor. Organisms were not identified. It remains unknown whether the lesions were due to endometrial blastomycosis or whether this is merely a case of villitis of unknown etiology (VUE).

## Virus Infections and Villitides

### Cytomegalovirus Infection

Congenital cytomegalovirus (CMV) infection is a common disease. Yow (1989) stated that 3000 to 4000 infants are born in the United States each year with

symptomatic disease, and a large number of children suffer late-onset manifestations of the infection, including hearing loss, blindness, and retardation. Stagno et al. (1986) found that 1.6% of seronegative women of high-income groups converted CMV titers during pregnancy, whereas 3.7% of low-income group women did so. The writer of an editorial (Anonymous, 1989c) has found that the rate of transmission to the fetus after recent maternal infection is between 20% and 50%. Moreover, infection during the first half of pregnancy is more destructive to the fetus and it has now been found that infants also infected with HIV have a greater propensity to suffer CMV infection (Doyle et al., 1996). Symptomatic fetal infection can also occur from an immune mother when a new strain of virus is acquired (Boppana et al., 2001). Nigro et al. (1999) found discordant expression of CMV infection in dizygotic twins (one had hydropic change), and that the edema disappeared when the fetus was treated with hyperimmune globulin.

It is also now recognized that the virus is often acquired by sexual contact (Chretien et al., 1977). The widespread nature of this infection was first appreciated by Weller (1971), who had emphasized its protean clinical manifestations. Many virus infections are accompanied by severe inflammation of the placental villi ("villitis"). An excellent review of these lesions is found in the contribution by Altshuler and Russell (1975). Schwartz and his colleagues (1992) have characterized the inflammatory response in this villous infection. They found marked "hyperplasia of fetal-derived placental macrophages...lymphocytic villitis...characterized by positive staining with T-cell antibodies." Plasma cells staining for immunoglobulin G (IgG) and IgM secretion were present in the second trimester, but no IgA positivity was found. Van den Veyver et al. (1998) showed that the virus is readily identified in amniotic fluid, blood, pleural fluid, and tissues by employing PCR and showed a high frequency in samples of high-risk infants.

Infection with CMV is a major cause of chronic villitis. The fetal and neonatal disease has many manifestations, ranging from hydrops fetalis (Quagliarello et al., 1978; Fadel & Riedrich, 1988; Mazon et al., 1994), obstructive uropathy (Symonds & Driscoll, 1974), meconium peritonitis (Pletcher et al., 1991), macerated stillbirth, and cerebral palsy, to minimal hearing loss (Saigal et al., 1982b) or severe CNS destruction (Schimmel et al., 2001). Moreover, some of these manifestations may be ascertained only years later (R.F. Pass et al., 1980; Williamson et al., 1982, 1990). Details of congenital CMV infection have been reported on many occasions (Embil et al., 1970; Krech et al., 1971). A very typical case of intrauterine CMV infection was described in detail as a Cabot case (Modlin et al., 2003).

Ahlfors and colleagues (1988) reviewed the literature of the infection in twins and reported two of their own cases that were discordant for manifestations of CMV

infection. They postulated that monochorionic MZ twins were more likely to be concordant for CMV infection, but lamented that the information on placental and genetic status is too often missing from case reports to draw definitive conclusions. It was their suggestion that fetal (as well as maternal) immunologic response may be of importance in the expression of the prenatally acquired infection. They ruled out, from knowing the location of the twin placentas, that a CMV endocervicitis caused ascending fetal infection.

Congenital infection is perhaps also occasionally acquired from infected endometrium. The presence of CMV in endometrial glands was demonstrated in five of 59 spontaneous abortions by Dehner and Askin (1975). The CMV inclusions have also been found in endocervix (Wenckebach & Curry, 1976). The virus has often been cultured from seminal fluid (Lang & Kummer, 1972) and from amniotic fluid (Weiner and Grose, 1990). Stagno et al. (1982) showed that fetal infection is more serious when it occurs during a primary maternal infection than when it follows recurrent maternal disease. These cases are reasons to consider the benefit of a vaccine (Medearis, 1982). Neonates with this infection may excrete virus for years. They thus become a major source for infection of pregnant mothers and toddlers in day-care centers (Pass et al., 1987). In twin pregnancies, CMV infections have been seen in both twins (Saigal et al., 1982a) but occasionally also in only one twin (Eachempati & Woods, 1976; Stagno et al., 1982).

Fetal intracranial calcifications have been seen sonographically (Ghidini et al., 1989), and neonatal perivascular echogenic signals were demonstrated in their basal ganglia (Teele et al., 1988); the involvement of vessels is a hallmark of this infection. It has been suggested that it may be the cause of cerebral microgyria and other lesions (Dias et al., 1984). Other sonographic manifestations have been transient hydrops (Mazon et al., 1994), abnormal triple-screen results and hyperechoic bowl (Peters et al., 1995), hydrocephaly, and growth retardation (Lipitz et al., 1997). Viral isolates can be obtained from amniotic fluid and fetal blood samples (Hagay et al., 1996). The virus may also be identified serologically, by immunofluorescence, PCR of DNA samples, or in situ hybridization (Ozono et al., 1997).

Fetal infection is undoubtedly most often acquired during primary maternal infection from maternal viremia and by the passage of virions through the destroyed trophoblast. This ability of CMV to infect and destroy the trophoblast has been shown in placental explants by Amirhessami-Aghili et al. (1987), and Chan et al. (2002) found this damage to be mediated by TNF- $\alpha$ . Interestingly, Pizzato et al. (2003) found by in vitro infection of cells that CMV infection downregulates the human leukocyte antigen (HLA)-G<sub>1</sub> expression. Despite this placental infection, no uniform **macroscopic** findings can identify CMV infection of the placenta; thus the selection

FIGURE 20.47. Congenital cytomegalovirus infection. Marked chronic villitis, composed almost entirely of plasma cells, is evident, as is focal necrosis of the trophoblast and capillary walls. The specimen is from a term gestation, and the mother reportedly had porphyria. H&E  $\times 650$ .

of histologic material is difficult, although surface vessels are at times thrombosed and should arouse suspicion (Fig. 20.47). Small placentas with growth-restricted fetuses are common and thromboses may exist. A significant problem in understanding this infection is that some known prenatal infections (positive culture from amniotic fluid) may be followed by normal outcome (Weiner & Grose, 1990). We have also seen many cases of unsuspected CMV infection histologically when the placenta was sectioned for other reasons. For instance, in one case of maternal porphyria, typical CMV inclusions were found in the placenta and the neonate had hepatitis. The maternal disease was a manifestation of a primary infection with this virus and was misinterpreted as porphyria. In another case of a spontaneous abortion at 15 weeks' gestation with an unremarkable macerated fetus, there were widespread cytomegalic cells in the lung, spleen, skeletal muscle, and placenta. The mother had only had a minor "sore throat" 1 week prior. Remarkably, the placenta had extensive destructive villitis. Ultimately, either the virus has to be cultured, or inclusion body cells have to be identified. Although the classical histologic features

are not mistakable, they are often so widely scattered through the villous tissue that only extreme scrutiny of many sections allows the diagnosis from placental sections.

The **histologic** hallmark of CMV infection in the placenta are chronic lymphoplasmacytic villitis (Fig. 20.48), thrombosis of villous capillaries often with adjacent hemosiderin deposits, necrosis of villous tissue and trophoblast (Fig. 20.49), fibrosis of villous stroma (Fig. 20.50), and inclusion-bearing cytomegalic cells (Fig. 20.51). The inclusion bodies may be characteristic nuclear "owl-eye" cells, but are often also of cytoplasmic nature. They are commonly seen in villous capillary endothelium but are also found in the stromal cells of villi. Garcia et al. (1989), who provided an excellent study of placental changes in CMV infection, found owl-eye cells in decidua and amnion as well. They employed the fluorescent antibody technique for diagnosis (see also McCaffree & Altshuler, 1979) and suggested that some types of gross morphologic abnormalities are frequent. Mostoufi-Zadeh et al. (1984) depicted owl-eye cells in the epithelium of the umbilical cord. Saito et al. (1977) described an abortion

FIGURE 20.48. Destructive villitis (large arrowhead) in congenital cytomegalovirus (CMV) infection. Inclusion bodies, or owl-eye cells (small arrowhead), are also present in this 14 weeks' gestation. H&E  $\times 150$ .

FIGURE 20.49. Evolution of fibrosis of the villi with a CMV infection. Left: A villus has plasma cell infiltration, trophoblast necrosis, vascular obliteration, and early fibrosis. with a large number of villous inclusion bodies typical of CMV infection. They diagnosed it as herpes simplex infection, however. We believe they made an incorrect diagnosis caused by an error in the interpretation of the serologic results. The CMV titers were also rising. Their analysis included an excellent electron microscopic demonstration of the virus packets, typical of a herpes-type virus (see also Donnellan et al., 1966, for electron microscopy). Vasculitis of chorionic vessels (Fig. 20.52) may lead to thrombosis and calcification. Huikeshoven et al. (1982) as well as Grose and Weiner (1990) made the diagnosis of CMV infection by recovering the virus from amniotic fluid at amniocentesis, undoubtedly because of fetal renal

involvement. The placental and neonatal features in the former study were typical of CMV infection. The virus can now be detected in histologic sections by in situ hybridization (Wolber & Lloyd, 1989). Sachdev et al. (1990) have used the hybridization technique to identify CMV infection in cases of chronic villitis. They found typical inclusions in three of eight cases of villitis and were able to diagnose three additional cases of CMV infection because of this technique. Mühlemann and her colleagues (1992) have provided an excellent immunocytochemical study of six CMV-infected placentas. They suggested that histologic features are often inconclusive in this congenital infection and found inclusion bodies in

only one of six cases. Immunocytochemistry, on the other hand, revealed viral antigen in five of the six placentas. The antigen was found to be mostly in the villous stroma, once in the syncytiotrophoblast, and sometimes in endothelial cells as demonstrated by double-staining these cells. Kumazaki et al. (2002b) looked for CMV DNA in 254 placentas and correlated it with maternal serum status. Seronegative mothers had negative placentas; 30.5% of seropositive mothers' placenta had antigen in various locations.

The cellular response to this infection is characteristic. It is mononuclear; during the second half of gestation, it is typically accompanied by fetal plasma cells, but we have seen it as early as at 15 weeks' gestation in the placental villi. Here it is then a question of whether the plasma cells are of fetal or maternal origin. This question has not been satisfactorily answered as yet. Plasma cells are not expected to be produced by fetuses at 13 weeks' gestation. Hybridization studies with Y-chromosome probes in appropriate cases are indicated to rule out maternal B-cell immigration, an important consideration for the understanding of chronic VUE. Mostoufi-Zadeh et al. (1984) opined that the fetal infection is more severe when a plasmacellular, rather than a lymphocytic, response is found in the villi. The plasma cell infiltration and the cytomegalic cells in the placenta were first described by LePage and Schramm (1958) and subsequently by LeLong et al. (1960). Since then, there have been numerous observations substantiating and expanding on these findings (e.g., Rosenstein & Navarrete-Reyna, 1964; Monif & Dische, 1972). Blanc (1961b), in a

thorough review of the placenta of prenatal infections, described the villous necrosis; Quan and Strauss (1962) discussed the differential diagnosis of CMV infection from erythroblastosis.

The findings of many other authors are summarized in our previous review (Benirschke et al., 1974). In that paper we described five cases, one of which is of particular interest. It was a therapeutic abortion at approximately 15 weeks' gestation. The patient had fever of unknown origin and antibody titers to CMV and toxoplasma. A double infection was suspected, but no toxoplasmosis was found in the abortus. At dissection, no macroscopic lesions were seen but viral inclusions were found in many organs histologically (Fig. 20.53). There was only a sparse inflammatory response. The villous infection and focal thrombosis in pulmonary vessels were particularly striking. A case of presumed double infection was described by De Zegher et al. (1988), in which *Toxoplasma* was definitely identified, and saliva and urine cultures yielded CMV. The alleged double infection illustrated by Demian et al. (1973), however, was not correctly identified. Only CMV was shown, the cytoplasmic granules representing virus, not *Toxoplasma* as was presumed.

It has often been asked just when the first fetal plasma cell response to CMV can be seen. This question is not yet resolved, as previously stated. Altshuler and McAdams (1971) clearly identified plasma cell villitis at 19 weeks' gestation, but it may commence as early as at 10 weeks, judging from Altshuler's (1973a) second case, seen at 13 weeks' gestation (Fig. 20.54). The owl-eye inclusions are characteristic of CMV infection, and the diagnosis can be made confidently on that basis alone. When only enlarged cells with cytoplasmic inclusions are present, however, the diagnosis of CMV infection is less secure. Serologic studies, virus isolation, and modern techniques of demonstrating the viral genome by hybridization are then

FIGURE 20.53. Fetal brain at 15 weeks' gestation with a CMV cell at the terminus of the capillary. There is no inflammation or destruction. Placenta had numerous CMV cells. H&E  $\times 150$ . (Source: Benirschke et al., 1974, with permission.)

needed. When different strains of the virus were thus identified with endonuclease cleavage of viral DNA, "no common pattern could be associated with these eight strains (of congenitally acquired virus) in comparison with strains from postnatally infected children" (Grillner et al., 1987). Borisch et al. (1988) successfully identified the antigen in the nucleus and cytoplasm by in situ hybrid-

ization, and Chehab et al. (1989) were able to do so with PCR of the DNA obtained from paraffin-embedded tissues. One can only hope that in the future the nature of such placental lesions, as depicted in Figures 20.55 and 20.56 will be resolved by these methods.

## Herpes Simplex Virus Infection

Transplacental infection with herpes simplex virus (HSV) does occasionally occur. It is more serious for the fetus when primary, rather than recurrent, herpes virus infection occurs during pregnancy (Brown et al., 1987). But transplacental infection is uncommon, presumably because of the protective nature of transplacentally acquired maternal antibodies; most women become immune to HSV before reaching childbearing age (Nahmias et al., 1970). "The major problem in newborn infection then is one of natal transmission of HVH (*Herpesvirus hominis*) through recurrent type 2 infections of the maternal genital tract" (Alford et al., 1975). Why it is that fatal infections occur sometimes in utero, and not at other times, and what the reason is for recurrent and latent infections remain unresolved questions. Ideas about the latency of HSV were discussed in an editorial (Anonymous, 1989b), and a succinct review of the fetal infection with HSV has been provided by Baldwin and Whitley (1990). Johnson et al. (1989) found in a survey of 4201 serum samples that 16.4% of the U.S. population from 15 to 74 years of age was infected with HSV-2.

Herpes virus is silently shed by 2.3% of pregnant women (Wittek et al., 1984), although lower numbers (0.1–0.4%) have also been cited (Witlin et al., 1998). Yen et al. (1965) succinctly described and depicted the cervical and vaginal lesions of herpes virus infection and presented three infants with symptomatic mothers. Two newborns had an apparently congenital infection. Kell et al. (2000) suggested that neonates with disseminated herpes infection have acquired it in utero in 4%, natally in 86%, and postnatally in 10%; thus, prenatal infection

FIGURE 20.56. Same case as in Figure 20.55. Chronic villitis (left) with enlarged cells having some of the qualities of CMV cells. The inclusions are not typical, however. H&E  $\times 160$  (left);  $\times 1600$  (right).

is uncommon. In fact, it has led to intrauterine demise, as in the case described by Barefoot et al. (2002) with extensive facial necrosis demonstrates. Herpes virus has also been detected before delivery (of a healthy child) from aspirated amniotic fluid (Zervoudakis et al., 1980). Herpetic endometritis has been demonstrated with and without an IUD (Abraham, 1978; Schneider et al., 1982), and Altshuler (1974) presented evidence for prenatal infection with an involved placenta (*vide infra*). Another case of presumed ascending infection was presented by Hain et al. (1980). They described the premature birth of a 590-g infant with a rash; there was necrosis in various organs at autopsy. The placenta showed cloudy membranes due to "extensive necrosis of amnion without inflammation." Necrotic areas were also present in chorion, and a lymphoplasmacellular infiltration was evident, as in Altshuler's case. In their case, however, chorionic vessel thrombosis and many inclusion bodies as well as "ground-glass" nuclei were present. The mother had primary herpetic vulvitis 4 weeks before delivery. Hyde and Giacoia (1993) have described an important case of severe, destructive congenital HSV infection, delivered by cesarean section of a cervically infected patient. At those portions of the intact membranes that were closest to the cervix, they found immunologically HSV-positive cells in the subamniotic connective tissue, aside from a mild chronic funisitis. This case strongly supports an ascending infection, occurring even with intact membranes. Peng et al. (1996) also described a serious prenatal infection of a twin fetus, whose twin became infected with scalp lesion resulting after amniotomy for scalp electrode placement. Brown et al. (1997) found that when HSV is acquired during pregnancy near the time of delivery, congenital infection may be a sequel. Postpartum endometritis may also be a consequence of HSV infection (Hollier et al., 1997). Witlin et al. (1998) found only focal villous edema and sclerosis in the placenta of a clearly in utero infection.

The review of Baldwin and Whitley (1990) summarized 71 cases of presumed prenatal herpes virus infection. Many of these cases were not fully studied, and the placentas were examined in only a few. The early reports of fetal infection by Mitchell and McCall (1963), Zavoral et al. (1970), Torphy et al. (1970), and Monif et al. (1985) had no placental study. Witzleben and Driscoll (1965) were the first investigators to describe the placental changes in proved congenital herpes simplex infection, and they reviewed other fatal cases of neonatal herpes infections. The mother in their case suffered a primary disseminated infection 1 month before delivery. The neonate remained well until day 6 and then died from generalized disease. The placenta was grossly unremarkable but had many areas of villous necrosis. It included trophoblast and stroma. An inflammatory reaction was absent, but inclusions were found in the placenta and

fetus. Nakamura et al. (1985) demonstrated immunologic staining and, by electron microscopy, typical herpes particles in stromal cells of villi in a presumably hematogenously transplacental infection. Other cases with prenatal onset are those by Chatterjee et al. (2001) with placentitis, and 15-week monochorionic twins and bland villous necroses (Bedolla & Stanek, 2004).

Other excellent descriptions of the placenta in herpetic infection came from Altshuler (1974, 1984), who summarized the earlier-mentioned case in the context of other placental inflammations. There were no complications in the term pregnancy he described, and no herpetic lesions had been known or noted. The infant developed blisters on day 4, with isolation of HVH. He was treated and discharged but continued having skin lesions. The meconium-stained placenta had many areas of necrotizing deciduitis and amnionitis; chorionic vasculitis and funisitis were attended by superficial amnion necrosis. The exudate contained leukocytic and extensive plasmacellular infiltrates (Fig. 20.57). The villous tissue was not altered, and inclusion bodies were absent, but the prenatal acquisition of the infection is evident from the unusual plasmacellular funisitis, not known in banal infections. S. Hyde (personal communication) has also seen a case of neonatal herpes infection with extensive chronic villitis. In contrast to the usual cases of VUE, however, many villi showed an extensive acute necrosis. He examined the lymphocyte markers in this case, finding that 1% of villous inflammatory cells were CD45 Ro (B cells) marked, but no staining occurred in the necrotic villi; many positive CD45 Ro (T cells) and CD68 markers (macrophages) were present in the affected villi and the chorionic plate.

The role of molecular pathology in the diagnosis of transplacental herpes infection was described by Schwartz and Caldwell (1991). They reported the delivery of a neonate who remained well from a patient with suspicious genital lesions. Previously, HSV had been confirmed by culture. Microscopic sections of the placenta were grossly and microscopically normal. In situ hybridization with a biotinylated DNA probe for HSV was counterstained. Subchorionic tissue (maternal-derived tissue of the decidua capsularis) stained positively for the antigen. It is our opinion that these findings are not specific for herpes antigen but that they reflect the biotin content that was so well later defined in endometrium by Yokoyama et al. (1993). These investigators were aware of the similarity of apparent inclusions in endometrium with those of herpes infection; they showed, however, that these vacuoles contained biotin. Thus, extreme care should be exercised in the interpretation of such immunologic localizations employing biotinylated probes in the immunologic reaction.

Bendon et al. (1987) emphasized deciduitis associated with their two cases of intrauterine HVH infection. One

FIGURE 20.57. Congenital herpes virus infection of placenta. Note necrosis of the amnion, thickening of membranes, and intense plasma cell (arrow) infiltration. H&E  $\times 160$  (left);  $\times 640$  (right). (Courtesy of Dr. G. Altshuler, Oklahoma City, Oklahoma.)

was a stillborn 300-g abortus with macular skin lesions, and the other was a 3200-g neonate with blisters who was treated and survived. The authors were unable to detect antigen in cord or amniotic sac, by immunohistochemical reaction but found it at the decidual base of the placentas. For this reason, they suggested that infection may have been disseminated via neural fibers or through endometrial channels, rather than in an ascending manner. Berger et al. (1986) described a mother with herpetic encephalitis during pregnancy; a meconium-stained placenta and fetal infection occurred, despite acyclovir therapy. Gagnon (1968) recovered virus from the placenta but did not describe the organ. Dublin and Merten (1977) showed the severe cerebral necroses that occurred in discordantly affected DiMo twins at 29 weeks' gestation. They stated that the placenta was affected with hemorrhagic and fibrotic changes.

The differences in severity and types of placental and fetal reactions in prenatal herpes infection suggest that transplacental and ascending infection may both occur. Boué and Loffredo (1970) isolated herpes virus type 2 from abortion material and suggested that this infection may play a causal role in abortion. Naib et al. (1970) studied the outcome of pregnancy in women with herpes infection. When infection occurred during the first 4 months of pregnancy, abortions occurred significantly more frequently, suggesting a causal relation.

Two cases with undisputed congenital herpes infection have been seen by us. One was a stillborn without maternal illness or herpetic lesions. The placenta had necrotizing chorioamnionitis with true blisters (Figs. 20.58 and 20.59). Plasma cells were the most abundant cell type in the exudate. The unusual occurrence of plasma cells at this site cannot be overemphasized. The other case was

FIGURE 20.58. Congenital herpes simplex virus-2 (HSV-2) infection with stillbirth outcome. Note the subamniotic blister filled with plasma cells. Also present are chorionitis and amnion necrosis. H&E  $\times 64$ .

FIGURE 20.59. Congenital HSV-2 infection (same case as Fig. 20.58). The large collection of subamniotic plasma cells is unusual. H&E  $\times 160$ .

reported by Herzen and Benirschke (1977). A cesarean section had been done for breech presentation; the membranes were intact. There was no maternal history of herpetic lesions, nor was the virus cultured from the mother. She had a titer of 1:32 that rose to 1:64 after birth, perhaps an insufficient criterion. The infant had severe disease and died. The placenta was circumvallate and had an unusually adherent amnion, and there were infarcts but no villitis. Inclusion bodies were found in the chorion. Severe plasma cell infiltration was present in the decidua; HSV-2 was isolated from fetal skin vesicles and the placental surface. Because of the absent villitis and the presence of chorioamnionitis, we speculated that it was an ascending infection. That opinion is supported by the absence of genital lesions in a large number of mothers with infected offspring.

This case raised further questions. In addition to the characteristic necrotic lesions found in neonatal herpes deaths (Hass, 1935), the autopsy findings included ocular, renal, and cerebral anomalies. The occasional association of congenital anomalies with HSV infection was discussed by Baldwin and Whitley (1989); some of these anomalies surely are the result of the virus infection. When this

infant died at 21 days of age, he had massive destructive disease of the brain, resembling hydranencephaly. Virus recovery was attempted by culture and electron microscopy. Because of this failure and the proved HSV-2 disease, we searched for antigen by immunohistologic procedures (Robb et al., 1986a). Characteristic staining was found with this technique in a variety of tissues from this infant. We then studied abortion specimens and other conditions with unresolved etiology for the presence of herpes antigens. In some of these cases, herpes viral DNA could be detected by hybridization study. The brain and placenta of the neonatal death just discussed also had a strong staining reaction (Robb et al., 1986b). Although we are aware that this method cannot prove the existence of local residual HSV antigen, it is presumptive evidence for this correlation. In the placenta the antigen was prominently found in a subamniotic location, as were the herpetic lesions. Strong antigen reactivity was seen in other cases as well, such as in necrotizing funisitis and many cases of "maternal floor infarction." Future studies must to be undertaken to interpret these findings. Finally, Altshuler (personal communication, 1992) sent us the placenta of a child with congenital herpes infection whose umbilical cord surface showed only extensive acellular necrosis, without any attending inflammatory response. Herman and Siegel (1994), who described another case of congenital HSV-2 infection, emphasized the many calcifications in the newborn's organs but did not discuss the placenta.

### Varicella (Chickenpox)

Pregnancy complicated by chickenpox is fairly uncommon but it may have serious sequelae for fetus and mother (Katz et al., 1995). Despite the fact that most cases of adult chickenpox occur beyond the reproductive period (Stagno & Whitley, 1985), presumptive transplacental infection has been described several times. In a review of 18 maternal varicella pneumonias, Pickard (1968) noted that only three infants were without the disease; 38 neonatal cases of chickenpox had been described by then, with a 21% mortality. Sauerbrei and Wutzler (2000, 2001) review all of the clinical features and the length of incubation, and demonstrate the devastating nature of the illness when it is acquired in utero. Most interestingly, Bruder et al. (2000) observed a 33-week premature with anterior horn destruction, necrosis of one arm, and intestinal atresias that could be attributed to this viral infection. A chronic, necrotizing lesion was found in the placenta. Four other cases of major CNS lesions come from Mustonen et al. (2001) but without placental study. Purtilo et al. (1977) described numerous placental infarcts, without viral inclusions, in their report of a case of fatal varicella in a pregnant woman and newborn. Balducci and his colleagues (1992) identified in

a prospective study 40 patients with first trimester varicella. Three aborted, one was terminated, and the other 36 patients went to term. One had an omphalocele, and the others were normal. From this information the authors concluded that the risk of the congenital varicella syndrome is small. Enders and her coworkers (1994) did a prospective study of 1373 women with varicella and 366 women who had herpes zoster during the first 36 weeks of gestation. In this cohort, nine cases of congenital varicella syndrome were identified, all occurring when the infection had taken place during the first 20 weeks of gestation. A commentary with additional reports is to be found in the editorial section of the journal (Liesnard et al., 1994). Other reports attest to the uncommon association of fetal disease with varicella pneumonia (Qureshi & Jaques, 1996; Chandra et al., 1998). When fetal disease did occur, as in perhaps three of Qureshi's cases, the placenta showed basal chronic villitis with "occasional multinucleated giant cells." The congenital varicella syndrome of cutaneous scars, limb hypoplasia, chorioretinitis, and cataracts (see Williamson, 1975; Alkalay et al., 1987; Wigglesworth, 1996) was found in only one of 11 infants of women with first-trimester varicella infection studied by Paryani and Arvin (1986). According to these authors, who comprehensively reviewed the topic, infection later in gestation rarely has these fetal sequelae. Magliocco et al. (1992) reported a severely malformed child with numerous destructive lesions that are superbly illustrated. The fetal infection dated from the 12th week of gestation. The placenta showed only old infarcts and calcification. In a 35-week neonate whose placenta we examined, tiny dermal scars, hepatic calcification, chorioretinitis, and CNS involvement were found; the mother had experienced varicella 4 months earlier (Benirschke et al., 1999). At that time, the fetus developed hydrops that subsequently resolved gradually. The placenta had numerous foci of marked VUE with occasional granulomatous appearance. Immunohistochemically and by PCR, varicella (but not HSV) antigen was still present in the many collapsed, occluded villous stem blood vessels. None was found in the inflammatory regions. Many terminal villi had atrophied, primarily those supplied by the occluded stem vessels. This case, and a case of toxoplasmosis, would ordinarily have been diagnosed as VUE, and the point is made in that contribution that new studies need to search more extensively for antigens as possible etiologic agents in the otherwise still disputed nature of VUE. Jones and his colleagues (1994) found only a small risk to the fetus from first trimester varicella infection in their prospective study. Paryani and Arvin (1986) and Brazin et al. (1979) reported that herpes zoster-complicating pregnancy usually has a benign prognosis. The fetus and placenta are typically not affected, although some cases of fetal growth retardation and blindness have occurred. Indeed, Higa et al. (1987), who studied 52 infants of women with varicella

during pregnancy, found that 27 suffered anomalies due to the infection when it occurred before 20 weeks' gestation. The placentas were not described. In their review of zoster infections of pregnancy in women who had had varicella in the past, the frequency of anomalies was small. A comprehensive review of varicella infection in pregnancy and the resulting fetal pathology, especially of the nervous system, has been provided by Grose and Itani (1989). Regrettably, they did not address possible placental pathology of this infection. In fact, the placenta of varicella infection in pregnancy has rarely been described. Garcia (1963), who reported two congenital cases, found scattered "firm areas, rice seed-like." He depicted focal necroses. Garcia likened these lesions to granulomas, with epithelioid cells and a giant cell component. Decidual cells contained inclusion bodies. No specific changes were encountered by Saito et al. (1989). They described giant cell pneumonia in a small, prematurely delivered fetus who probably had varicella infection. Immunohistochemical staining of varicella antigens was present on the giant cells in the neonatal lung, but no such antigen was detected in the placenta. It showed merely mild chorioamnionitis. We saw the placenta of a baby with minimal cutaneous scars, chorioretinitis, and seizures. The mother had suffered varicella infection 4 months earlier; then the fetus developed hydrops and cardiac calcifications. They resolved. The placenta had diffuse foci of severe chronic villitis (without plasma cells) and many stem villous vessels were completely obliterated. Immunohistochemistry identified antigen only to the areas of former endothelium in the obliterated vessels. Giant cells were absent, and no inclusions were present.

#### EPSTEIN-BARR VIRUS

Infection with the Epstein-Barr virus is uncommon during pregnancy. In a few instances, however, congenital infection is believed to have produced congenital anomalies in fetuses. The topic has been reviewed by Ornoy et al. (1982), who studied the induced abortuses of five such pregnancies. They found lesions in all, consisting of deciduitis, villitis with lymphoplasmacellular infiltration, trophoblastic necrosis, and endothelial damage to capillaries. Myocarditis was seen in two fetuses. The cases are circumstantial in that the virus was not shown to be present, but lesions as described are otherwise uncommon at that gestational age. Thus at present one must assume that the virus can affect placenta and fetus. Transplacental transfer of the Epstein-Barr virus to the fetus has rarely been proved. In the few cases where it was shown (Joncas et al., 1981), the placenta was not described. The child described by these authors died from apparently simultaneous CMV infection.

#### Smallpox, Vaccinia, Alastrim, and Parvovirus B19

Fetal infection with smallpox virus has often been depicted in early obstetrics texts. This virus can readily pass the placenta and cause fetal death and abortion.

Prior to the eradication of smallpox, fetal and placental *vaccinia* occurred occasionally, primarily with primary vaccinations. Wentworth (1966) examined 65 placentas of women who were vaccinated during pregnancy; those mothers did not have an increased abortion rate. Histologic examination and the search for virus inclusions were negative.

Intrauterine infection was well described by Wielenga et al. (1961). The neonate died within a short time and had extensive skin lesions. There were numerous areas of villous and membrane necrosis, and a leukocytic response was present. The lesions were similar to a case we have seen (Fig. 20.60) in which there were extensive necrosis of trophoblast, intervillous fibrin deposits, and focal calcification, but no plasma cells were found. Killpack (1963) also found necrotic foci, "resembling miliary tubercles," and found scanty eosinophilic inclusions. Other descriptions came from Hood and McKinnon (1963) and Naidoo and Hirsch (1963). Garcia (1963) reported macerated stillborns affected with cutaneous *alastrim* (variola minor). Similar granulomatous areas of necrosis were depicted in the placentas accompanying these two fetuses. Guarnieri bodies were present in the decidua.

Infection with *parvovirus B19* is covered in Chapter 16. It is an apparently frequent cause of fetal anemia because of the preferential infection of erythrocyte precursors by this virus. Hartwick et al. (1989) have shown parvovirus B19 in a dot-blot hybridization study of a 9 weeks' gestation fetus. Considerable vascular endothelial damage was present in the embryo and placenta. In a portion of one umbilical artery the endothelium and muscle were partially destroyed, and in main stem vessels perivascular lymphocytic infiltration was seen. The lymphocytic infil-

tration was composed of cells belonging to the cytotoxic or suppressor T-cell variety. There is a provocative discussion of the origin of these inflammatory cells that bears relevance to the topic of "villitis of unknown origin" (vide infra). Despite the fact that, heretofore, the embryo was not believed to be capable of mounting an immunologic response at this stage of development, the authors gave cogent reasons for assuming that the T cells they identified were not of maternal origin. Interestingly, inclusions were absent in the red blood cell precursors of this embryo but were found in skeletal muscle cells. In an important study of presumed parvovirus B19 infection of the fetus, de Krijger et al. (1998) showed that the presence of putative inclusion bodies is not diagnostic of this infection. They uncovered many such inclusions as artifacts, and asserted that confirmation by PCR is mandatory. There is now excellent evidence that clinical outcome is correlated with the degree of trophoblastic apoptosis (Jordan & Butchko, 2002). These authors showed that the B19 receptor (globoside-containing) is present not only on red cells precursors but also on trophoblast, and that gestations with poor fetal outcome had a much greater degree of trophoblastic apoptosis than those with better results. The difficulty of making the correct diagnosis, especially in nonhydropic fetuses, is highlighted in a paper by Tolfvenstam et al. (2001). Only three of nine DNA-positive cases had erythroid inclusions; this led them to suggest that many more unresolved stillborn infants would have a diagnosis assigned if DNA study were added to the autopsy protocol. An additional problem in the diagnosis of parvovirus B19 diagnosis is the development, temporally different, of two distinct antibodies—linear and conformational (Jordan, 2002).

FIGURE 20.60. *Vaccinia* during pregnancy. Many villi are necrotic, and an intense inflammatory reaction is seen around their remnants. Note the focal calcification of the necrotic area at bottom

right. H&E  $\times 160$ . (Courtesy of Dr. B. Ivemark, Stockholm, Sweden.)

Samra et al. (1989) reviewed all reports on parvovirus infection of the fetus and concluded that the virus passes the placenta readily. They described a stillborn, hydropic fetus in whose placenta there were villous necrosis and calcifications. Infection with different species of parvoviruses has been shown to cause a wide spectrum of diseases in different animals, including congenital anomalies. The subject has been reviewed in detail by Margolis and Kilham (1975), who make reference to human conditions.

## ENTEROVIRUSES

Transplacental *poliomyelitis* infection has been described, and the virus was isolated from the placenta in some of these cases (Barsky & Beale, 1957). No pathologic lesions of the placenta are known.

Infection with **enterocytopathogenic human orphan (ECHO)** and **Coxsackie** viruses occurs commonly during the neonatal period and may have serious consequences in neonates. When infection occurs during pregnancy, the fetus is usually spared, perhaps protected by maternal antibody transfer (Amstey et al., 1988). Amstey et al. also perfused two placentas with a mixture of viruses and found them not to transfer. Nevertheless, transplacental passage and fetal infection have occasionally been shown for ECHO viruses (Hughes et al., 1972; Modlin, 1986; C. Davis, personal communication, 1985), and for Coxsackie B virus (Kibrick & Benirschke, 1958; Sauerbrei et al., 2000). There is also speculation that such prenatal infection may be a cause of juvenile diabetes. The placentas of the few cases proved to have caused prenatal Coxsackie virus infection have shown occasional meconium staining, but other meaningful changes were usually absent. Fetal hydrops secondary to myocarditis has occurred with Coxsackie virus infection; placental lesions were not apparent in that abortus (Benirschke et al., 1986). Garcia et al. (1990) described three perinatal deaths from ECHO 33 and 27 infections with isolation of virus from placentas and fetal tissues. They described villitis and intervillitis in the placentas that may best be likened to VUE (vide infra). The same authors expanded on these findings in 1991. Interestingly, the viruses did not affect the fetus, while they were isolated from the placentas, many of which had typical chronic villitis. Some also suffered mural thromboses and vascular lesions in the umbilical cord. The electron microscopy is not convincing, but is also not expected to contribute in these RNA virus infections.

Batcup et al. (1985) reported villous necrosis and severe intervillitis in the placenta of a patient who had Coxsackie virus A9 meningitis at 33 weeks' gestation. A stillborn, macerated fetus was delivered 5 days later, and the virus was recovered from the placenta. Moreover, there were mild myocarditis and early meningitis in the fetus. Remarkably, the placenta had massive intervillous fibrin deposits, much as one sees in the *gitterinfarkts*, discussed in Chapter 9. Villous stem vessels had mural thrombi, and many aspects of the placenta showed features that are usually designated as VUE (vide infra). It is difficult to believe that the extensive placental alterations depicted in their report, could have arisen within this short time span, but further observations to investigate this possibility are clearly mandated.

Ogilvie and Tearne (1980) described three abortions during episodes of infection with Coxsackie A16 virus (hand, foot, and mouth disease) and recovered the virus from one placenta. The pathologic features of the placenta, however, were not discussed.

## INFLUENZA, MUMPS, RABIES

Transplacental **influenza A2** (Hong Kong) infection was reported by Yawn et al. (1971). The virus was recovered from the fetus and amni-

onic fluid in the fatally ill gravida. Fetal tissues and placenta were found to be structurally normal. In an abortus delivered during the febrile period of parainfluenza-1 virus infection, Lavergne et al. (1969) observed a normal placenta. McGregor et al. (1984) recovered influenza A/Bangkok virus from maternal secretions and amniotic fluid of an acutely ill patient who appeared to have the amniotic fluid infection syndrome. The pregnancy continued, and a normal birth ensued. The placenta was not described, but transplacental infection was inferred. Conover and Roessmann (1990) reported the autopsy findings of a malformed infant in whose brain influenza virus was identified immunohistochemically. The placenta was not described.

Fetal **mumps** virus infection may occur, and it has been suggested that some congenital anomalies are due to this agent. Virus has been recovered from the placenta, but no histopathologic change has been described (Yamauchi et al., 1974). Herbst et al. (1970) found only ultrastructural changes in the placenta of a patient with mumps. Severe villous necrosis, simulating that of herpes simplex virus, was found in three cases of intrauterine mumps infection described by Garcia et al. (1980). They also reviewed the sparse and contradictory literature. Small cytoplasmic inclusion bodies were depicted in the decidua.

Transplacental **rabies** infection is not known to occur in women. Spence et al. (1975) observed two normal fetuses after maternal rabies complicated pregnancy. The placenta was not described.

## Hepatitis

Transplacental infection with hepatitis viruses has been reported; the topic was reviewed by Altshuler and Russell (1975) and Snyderman (1985). Because hepatitis A viremia is short and a carrier state does not occur, fetal infection with this virus is rare but is well documented. Leikin et al. (1996) described fetal ascites and subsequent meconium peritonitis in a fetus whose mother became infected at 20 weeks' gestation. The placenta was not described; other cases of fetal ascites are on record, and McDuffie and Bader (1999) attributed meconium peritonitis to transplacental infection. Asymptomatic hepatitis B infection, however, was found to occur in 0.66% of a low-risk population (Christian & Duff, 1989). Two studies have shown that the antigen passes the placenta (Wang & Zhu, 2000; Xu et al., 2001), and the latter publication traces the virus by fluorescence microscopy. Transmission of hepatitis C virus from chronically infected mothers to fetuses occurs but appears to be uncommon (Thaler et al., 1991; Wejstal et al., 1992; Silverman et al., 1993; Hunt et al., 1997). Gibb et al. (2000), in their review of 441 mother-child pairs, estimated the transmission rate as 6.7% and suggested that it was enhanced in HIV infection. Placentas from such cases of vertical transmission have not been described in the literature, but the ones we have seen have been entirely normal. Vertical transmission of the newly delineated hepatitis G virus has also been reported (Feucht et al., 1996; Inaba, 1997) without placental study. Lin et al. (1996) proposed that transplacental blood contamination may occur during labor.

In contrast to hepatitis A, the high carrier state of hepatitis B virus in adults is a potential hazard to many fetuses. It is generally agreed, however, that this virus is usually acquired enterically during birth or thereafter;

FIGURE 20.61. Placenta with hepatitis B. Pregnancy was interrupted at 20 weeks' gestation. Hofbauer cells are filled with bilirubin (arrows), but there was no inflammation. H&E  $\times 240$  (left, center);  $\times 640$  (right), red filter.

nevertheless, the transplacental acquisition of hepatitis B virus has occasionally been verified (Fawaz et al., 1975; Mulligan & Stiehm, 1994). Mitsuda et al. (1989) found positive cord blood once in 10 patients but showed that the antigen was present in colostrum of eight patients using the sensitive PCR method. Prospective studies of aborted fetuses from virus-carrying mothers showed that four of 48 fetuses (8%) were thus infected (Li et al., 1986).

The placenta has rarely been examined by pathologists. Altshuler and Russell (1975) stated that the placenta shows "relative immaturity." Buchholz et al. (1974) described the placenta of an infected infant delivered by cesarean section as showing "placental insufficiency." Studies with direct and indirect immunofluorescence indicated the presence of antigen, confined to the basement membranes of the (infantile part) of cells. The authors were uncertain that the placental insufficiency was caused by the infection.

Lucifora et al. (1988) studied the placentas of three asymptomatic hepatitis B surface antigen (HBsAg) carriers with immunohistochemistry. All showed strong reactivity of the Hofbauer cells and villous endothelium, but no pathologic changes were noted. Lucifora et al. (1990) then detected the hepatitis B core antigen (HBcAg) histochemically in all placentas of symptom-free carriers. It was again primarily localized in trophoblast and Hofbauer cells, but also found in fetal endothelium and fibroblasts. They suggested minor pathologic changes (edema, congestion) but are not convincing. We described the placentas of two patients with active hepatitis (Khudr & Benirschke, 1972). The only abnormal finding was the presence of large amounts of bilirubin in Hofbauer cells and chorionic membrane macrophages. There was neither degeneration nor inflammation. The pigment bleached

readily when slides were exposed to light, apparently similar to that of meconium macrophages. We have seen the placenta and fetus of a patient who had a therapeutic abortion for hepatitis B. The patient was still icteric when the procedure was done. The fetus, umbilical cord, and membranes were entirely unstained and normal; however, the villous tissues were the color of marmalade, a deep yellow-green. Histologically, numerous deeply bilirubin-stained macrophages were present as villous Hofbauer cells (Fig. 20.61). Some syncytial trophoblastic cells and the membranes had relatively few stained cells. Focal syncytial cell necrosis was present, but there was no inflammation or obvious villous necrosis. There was intense enteritis of the fetus, with meconium deposits and eosinophilic leukocyte infiltration in the submucosa. Several intestinal ulcers were present, and in some areas the bowel was nearly perforated. We assumed that the fetus may have become infected by swallowing amniotic fluid. The case further indicates that bilirubin may traverse the placental barrier but that it then becomes trapped by villous Hofbauer cells.

### Rubella (German Measles) and Other Viral Infections

The fetal rubella syndrome exemplifies transplacental fetal virus infection, but because of vaccination, rubella is now uncommon. Banatvala and Brown (2004) report an updated survey of the global infection rate and summarize the most recent diagnostic tools available. A variety of characteristic anomalies are produced in the fetus when infection occurs early, and the precise mechanism by which the degenerative changes responsible for the fetal rubella syndrome, such as cataracts, are generated has been a matter of intense investigation in the past.

Many investigators have detected the virus in the placenta, amniotic fluid, and abortus by virologic means (Alford et al., 1964; Thompson & Tobin, 1970; Catalano et al., 1971). When they isolated the virus from products of conception, Monif et al. (1965) suggested that many macerated fetuses died from placental, rather than fetal, infection. Töndury (1951, 1952a,b, 1964), in numerous contributions, has championed the idea that the fetal damage resulted from embolism of virus-damaged fetal (placental) endothelial cells. Others have suggested that the damage is due to chromosomal breakage.

Endothelial damage in villi of infected products of conception was confirmed in the large study conducted by Driscoll (1969) and by the finding of “endangitis obliterans” in about 40% of the stem villous vessels of infected cases seen by Horn and Becker (1992) and Horn et al. (1993). Driscoll further described sclerosing villous inflammation, which she interpreted to possibly be responsible for the growth retardation. Töndury and Smith (1966) observed focal trophoblastic necrosis and elaborated on their idea of extensive damage to the villous capillary endothelium in early embryos with rubella infection (Fig. 20.62). Selzer (1963, 1964) described basophilic inclusion bodies, but they have not been reported in other descriptions of placental lesions. Similar lesions have been described in a report of 45 cases interrupted because of gestational rubella infection (Ornoy et al., 1973). They discovered some placental lesions in all cases that resulted in malformed fetuses. Decidual perivascular round cell infiltration was prominent; in villi of early gestations, necrosis and fibrosis were found, and swollen Hofbauer cells were prominent. Vascular inflammation was also a prominent finding, similar to that reported earlier. These authors described inclusions in trophoblast and villous stroma but did not depict them, and other authors (Horn and Becker, 1992; Horn et al., 1993) were unable to identify inclusion bodies. It must be pointed out also that the endothelial abnormalities described are neither diagnostic nor present in all cases of virologically confirmed cases of rubella. Moreover, some of these changes are also observed in stillbirths unrelated to virus infections; thus, a degree of skepticism is needed in their interpretation.

The attenuated strain of rubella vaccine virus has been isolated from placentas and fetuses, but villous lesions have not been observed (Phillips et al., 1970; Vaheri et al., 1972). Only Larson et al. (1971) described “histologic changes in placenta or decidua consistent with rubella infection.” The fetuses were normal, and apparently only decidual changes were detected.

### Rubeola (Measles)

Measles in pregnancy has been very uncommon and its consequences have been described only rarely. There is,

FIGURE 20.62. Sections of immature placenta from rubella-infected fetus. Note the mural thrombosis and nucleated red blood cells (NRBCs) in surface vessel (top) and round cell infiltration of villi (bottom).

however, an extensive database from the 1951 Greenland and the United States epidemics as to the effects of measles on pregnancy. The infection is apparently not teratogenic, and a significantly increased fetal mortality may relate primarily to fever. Access to this literature is provided by Stein and Greenspoon (1991). Placental disease has now been described, but congenital measles apparently does not exist (Eberhart-Phillips et al., 1993). The only report with identification of the antigen in the placenta is the case of Moroi et al. (1991). Their patient suffered fetal demise at 25 weeks after an acute infection, and the virus was detected in the decidua and syncytiotrophoblast by immunohistochemistry. It was not found in the fetus. The placenta was firm and infiltrated with an excessive amount of fibrin and mononuclear cells. Stein and Greenspoon (1991) described three cases: one had an unexplained intrauterine fetal demise (true knot of cord, 30% placental infarct), and the other two did well. Placental lesions were not described, and fetal infection

was not apparent. However, Ohyama et al. (2001) described in detail the placenta and clinical findings of a monochorionic set of twins in which one was a macerated stillborn and the other survived without evidence of measles. The placenta of the stillborn had extensive fibrin deposits, and measles virus was definitively shown to be present in trophoblast (by electron microscopy and immunologically). The mother had become infected at 19 weeks and one twin died at 32 weeks. There were large surface inter-twin anastomoses present. It remains uncertain whether the fetus died from measles infection or because of MZ-twin vascular problems; nevertheless, the presence of inclusion bodies and their demonstration as virus in trophoblast is not doubted.

### Human Immunodeficiency Virus Infection

Infection of the fetus with the human immunodeficiency virus (HIV) has frequently been reported (Berrebi et al., 1987; European Collaborative 1988; Sperling et al., 1989), but the exact time and mode of this vertical transmission is disputed. Moreover, perhaps because this transmission occurs often at the time of delivery, the treatment of HIV-positive mothers with azidothymidine (AZT) has led to a marked reduction of neonatal HIV infection. Pascual et al. (2000) found no virus transmission in early gestation; but other reports have differed. Therefore, the detailed review by Miller et al. (2000) is most helpful. It weighs the pros and cons of studies of this controversial topic; it discusses whether the immunologic stains of placental tissue are powerful enough to demonstrate the virus and, importantly, whether coexisting chorioamnionitis enhances virus transfer. But one result is universal: HIV infection of the placenta (if it occurs at all) leaves no specific lesions that can be diagnosed without equivocation. Indeed, experimental infection of trophoblast or placental lobules in vitro is usually impossible. The prevalence of HIV infection was studied in an obstetrical population by Barton et al. (1989). They found antibodies only in patients with risk factors (7.1%), whereas those without risk factors were negative. AIDS has occurred in some of the offspring, and the vertical transmission rate of HIV is estimated to be 24% (European Collaborative Study, 1988). Nevertheless, Katz and Wilfert (1989) were uncertain that the infection occurred transplacentally rather than during delivery. Their editorial discussed at length the reports of neonatal AIDS presented in the same journal issue. Fetal deaths and prematurity have been seen in women infected with HIV, but many of these patients had other problems that may have been responsible (Gloeb et al., 1988). Nevertheless, maternal HIV-1 infection is associated with prematurity and endometritis, whereas fetal growth retardation was not observed in the study conducted by Temmerman et al. (1994). These authors were also unable to identify histopathologic

abnormalities in the placentas. Monozygotic twins discordant for HIV infection and with a single placenta were reported by Menez-Bautista et al. (1986). The MZ twins had presumably been exposed to the agent only during fetal life. Alger et al. (1993) found no adverse effect upon pregnancy performance in women who are infected with HIV and showed that an HIV embryopathy does not exist.

The virus has been isolated from amniotic fluid (Mundy et al., 1987) and perhaps from the placenta (Hill et al., 1987). In the latter report, HIV was obtained from placenta but not from lochia, the infant, and cord blood. The infant was well; an electron micrograph of an infected T cell accompanied the report, presumably infected with virus from this placenta's culture, but the authors suggested that the isolation may reflect maternal blood infection. The report was criticized by Peuchmaur et al. (1989), who, subsequent to this report, failed to isolate HIV from placental samples. Greenspoon and Settlege (1989) also believed that the virus of this placenta was more likely contained within the maternal blood of the placenta; the child has remained well, now age 3 years. Since those reports, Soeiro et al. (1992) identified HIV-1 in 30% of fetal material from first trimester abortuses by PCR of HIV nucleic acid. Yet only one of eight infected abortuses showed positive in situ hybridization signals.

Brady et al. (1989) used immunoperoxidase stains on placentas of HIV-infected patients. They found positive staining, particularly in Hofbauer cells, and suggested that this presence of viral protein in placental macrophages might present a reservoir for perinatal infection. A morphologic study of the placentas of 49 HIV-infected patients was undertaken by Jauniaux et al. (1988). The light-microscopic findings were unremarkable. No significant alterations were seen, and the lesions were nonspecific. An ultrastructural study showed "retrovirus-like particles" in the syncytiotrophoblast of one induced abortus's placenta. Five other mature placentas showed isolated virus particles. They were similar to the C-type particles described formerly in many human placentas. Lewis et al. (1990) have demonstrated the presence of HIV by immunocytochemistry and in situ hybridization in maternal decidual leukocytes, trophoblast, Hofbauer cells, and embryonic blood cell precursors of aborted specimens (Fig. 20.63). Although the specific CD4 receptors were not identified on the trophoblastic surface, the authors referred to experiments with trophoblast culture that have demonstrated CD4 presence. It was suggested that transmission (around 30%) occurs directly, without transfer of maternal leukocytes being a prerequisite, as had been postulated. On the other hand, in a sizable prospective study of 44 patients with viremia, Ehrnst et al. (1991) found no transplacental HIV transmission to the 27 infants born. In only one of seven placentas was the virus identified. Andiman et al. (1990) similarly had a

FIGURE 20.63. Eight weeks' gestation villi of HIV-1 infected mother. Specimen was hybridized with  $^{35}\text{S}$ -labeled probe. Syncytium, Langhans' cells, and Hofbauer cells are labeled. Hematoxylin  $\times 312$ . (Courtesy of Dr. S.H. Lewis, formerly of New York, New York.)

low vertical transmission rate but also did not examine the placentas. That placental explants can support growth of HIV was shown by Amirhessami-Aghili and Spector (1991). They cultured first-trimester villous tissue, infected it, and demonstrated the presence of the CD4 and HIV antigens; surprisingly, hCG and progesterone production rose in infected cultures. When Katz et al. (1997) sought markers for formalin-fixed placental localization of HIV, the nucleic acid was seen in syncytiotrophoblast by  $^{35}\text{S}$  RNA in situ hybridization. The histopathologic findings, however, were unimpressive, with minor (nonspecific?) inflammatory reactions that are not truly diagnostic of infection. We have also not been able to detect histopathologic placental changes in patients with the infection. It has also been pointed out that unusual tumors metastatic to the placenta may signal HIV infection. Pollack et al. (1993) described a patient who had abdominal delivery for fetal distress. The grossly normal placenta (it had white granular areas on the maternal surface) had intervillous infiltrates by "sheets of small noncohesive, round tumor cells." This was diagnosed as non-Hodgkin's lymphoma. The mother developed further signs of AIDS, but the infant remained normal.

Kalter et al. (1973) had found **C-type particles** in four of six normal human placentas at the junction of syncytiotrophoblast and basement membrane. Their "budding" was more common in premature placentas. Other investigators have shown cross-reactivity of these particles to certain retroviruses (Sawyer et al., 1978; Maeda et al., 1983), and similar structures have been detected in many nonhuman primate placentas (Panem, 1979). C-type particles are nearly ubiquitous viruses, parasites, whose functions are presently unknown. Imamura et al. (1976) detected these RNA-virus-like structures in the placenta

of a patient with lupus but also in normal placentas, albeit in smaller numbers. They also described "tubuloreticular inclusions" in villous endothelium from patients with lupus erythematosus. Similar structures have been induced in Hofbauer cells by maternal interferon therapy in rhesus monkeys (Feldman et al., 1986).

The significance of all of these findings with respect to true viral infections remains uncertain, but congenital HIV infection occurs with certainty (see Goedert et al., 1989). Indeed, the neonatal mortality is significant, and most cases manifest during the first year of life (Scott et al., 1989).

**Dengue** virus transmission to the fetus has been described only a few times, but placental lesions are unknown. Boussemart et al. (2001) described two such neonates and summarized earlier reports. **West Nile Virus** transmission to the fetus has once been described (Alpert et al., 2003). The neonate had chorioretinal damage and CNS abnormalities, but the placenta was not described.

## Toxoplasmosis

Toxoplasmosis is caused by the coccidian *Toxoplasma gondii*, a pan-global parasite of cats and other felids. In cats, a well-explored life cycle exists in the intestinal epithelium. Oocysts are shed in the stools of infected animals. Rodents and other animals ingest these oocysts and acquire the disease. Cats, preying on infected rodents, complete the cycle. The disease is also widespread in domestic animals.

There are several excellent reviews on congenital toxoplasmosis (Kirchhoff & Kräubig, 1966; Frenkel, 1973, 1974; Dubey, 1977; Dubey & Beattie, 1988; Sever et al.,

1988; Freij & Sever, 1996; Montoya & Liesenfeld, 2004). Frenkel (1971) presented a particularly good consideration of all aspects of this disease. The human infection is acquired in adults by two means: (1) contamination with oocysts from feces of infected cats; and (2) ingestion of cysts and tachyzoites in raw, infected meat—largely pork and mutton (Kean et al., 1969). Pregnant women should not eat undercooked or raw meat, and they should also avoid having contact with “wild” (i.e., hunting) cats. Heating to 150°F kills the organism. Cats raised solely on commercial diets are not infected; cats that hunt and are given raw meat may become infected. Emptying their litter box daily to prevent drying and dust-producing feces is recommended (Kimball et al., 1974). A thoughtful review of these aspects has been written by Swartzberg and Remington (1975). Of the Parisian human adult population, 84% have antibodies because of the frequency of raw meat consumption in France.

Transplacental toxoplasmosis is not uncommon. It has been well described to cause severe destructive disease in the offspring who are infected during early gestation. Minor degrees of damage are incurred when infection develops later in pregnancy. Chorioretinitis, encephalitis with hydrocephaly, and other organ involvement may nevertheless cause crippling disease. Wilson and Remington (1980) estimated that the lifetime support for the 3300 children born annually in the United States with toxoplasmosis is the staggering sum of over \$200 million.

It is generally assumed that almost all, if not all, congenital *Toxoplasma* infections occur when a woman has her primary infection during pregnancy. Few reports exist that congenital toxoplasmosis occurs in successive pregnancies. It has also been assumed that the presence of maternal antibodies prevents fetal infection. That this is not so was shown by the important case detailed by Forther et al. (1991). They found a toxoplasma cyst in an abortion specimen from an immune patient who had contact with an infected cat that caused acute toxoplasmosis in her brother. Feldman (1963) has doubted that recurrent infection ever occurs. Desmonts and Couvreur (1974) have provided the most conclusive prospective study of toxoplasmosis in pregnancy. Almost 45% of Parisian women with primary infection during pregnancy had infants with congenital toxoplasmosis. The rate of infection increased with the gestational trimesters (17%, 25%, and 65%, respectively). Fetal destruction was the most severe during early, rather than late, gestation. The authors were skeptical that toxoplasmosis causes abortion and denied the occurrence of repeated congenital toxoplasmosis. Others have found *Toxoplasma* organisms in the placenta and uterus of infected, macerated fetuses (Mellgren et al., 1952) or have isolated it from spontaneously aborted products of conception (Remington et al., 1964; Forth et al., 1991). Stray-Pedersen and Lorentzen-Styr

(1977) studied endometrial biopsies of women with habitual abortion. Six of 96 women had tachyzoites in endometrium and menstrual blood, demonstrated by fluorescent antibody studies, but none was isolated in mouse inoculations. Treatment of these women abolished the organisms.

Because it is often difficult to positively identify the organism in routinely stained placental material, the method by which the organism is verified in tissues is of great importance. It is easiest to demonstrate toxoplasma by placing ground tissue samples into the peritoneal cavity of young mice or into appropriate tissue culture cell lines (Kaufman & Maloney, 1962). Handling this organism, however, is often avoided because of the hazards of infection. Immunologic means are generally preferred, although the results are often dubious. For positive identification in tissues, Dallenbach and Piekarski (1960) have advocated the fluorescence antibody technique. A similar methodology was used by Foulon et al. (1990a) in identifying the antigen from tissue cultures infected with chorionic villus sampling (CVS) specimens. The electron microscopic appearance of *Toxoplasma* cysts (“pseudocysts”) is characteristic and has been well shown by Callaway et al. (1968). Detailed considerations of modern diagnostic tests for toxoplasmosis have been given in a review of all aspects of this disease by Koskiniemi et al. (1989). Savva and Hollman (1990) reviewed the PCR methodology that allows unequivocal detection of the toxoplasma DNA (see also Hohlfield et al., 1994; Fricker-Hidalgo et al., 1998). The problems of prenatal diagnosis were considered by Foulon et al. (1990b), who had much success with amniotic fluid culture and funipuncture.

The organism has been isolated from amniotic fluid and placentas of infected pregnancies (Stray-Pedersen, 1980; Teutsch et al., 1980). The diagnosis of congenital infection was later made by fetal blood sampling, which led to beneficial prenatal therapy in some cases (Desmonts et al., 1985; Daffos et al., 1988). Foulon et al. (1999) found that fetal infection was best made with amniotic fluid PCR and culture, rather than by cordocentesis. Couvreur et al. (1976) described congenital toxoplasmosis in 14 twins. In two of these pairs, only one twin was affected. Although it is stated that these twins were dizygotic, one of the two had a DiMo placenta, and they thus must have been identical twins. The authors reviewed previous reports of discordant dizygotic (DZ) twins, whereas all MZ twins had been similarly affected. Cox et al. (1987) also reported two discordant twins when they assayed fetal blood during pregnancy for antibodies.

Evidence of congenital disease is at times difficult to find. It may require a long follow-up. Thus, the MZ twins reported by Glasser and Delta (1965) were judged to be normal at birth. Their placenta had many cysts in the membranes but no other pathologic features. The chil-

dren first became symptomatic at 7 months of age. Another set of twins, described by Miller et al. (1971), also had late onset, and toxoplasmosis was not suspected until hydrocephaly developed. The mother had eaten ground beef during the pregnancy, the presumed source of infection. Late onset of symptomatology was further explored by Koppe et al. (1986), who showed that in children with congenital toxoplasmosis “new lesions continue to appear well after the age of 5 years, and the impairment can be severe.” In other cases of apparent fetal well-being despite maternal infection during pregnancy, the maternal therapy may have prevented fetal disease (e.g., Hammer & Wegmann, 1966).

Placental infection with *Toxoplasma* has been well documented. It is presumably always produced by organisms circulating in the maternal blood, although the isolation of cysts from endometrium in chronic aborters makes direct infection from the endometrium possible (Werner et al., 1963). Altshuler (1973b), who described a fatal case with placental study, bemoaned that the placenta is not studied more often in this disease and suggested rapid means for identification of the organism. The case he studied was typical. The infant had hydranencephaly, a frequent feature of this disease (Larsen, 1977), hepatosplenomegaly, and hydrops. Hydrops in congenital toxoplasmosis has been described repeatedly. Typical cysts were present in the subamniotic/chorionic tissues, and

they were unaccompanied by inflammation. It is only when the cysts rupture that a local plasmacellular reaction and necrosis take place. Altshuler found a marked increase in villous Hofbauer cells, erythroblasts in the fetal circulation, and vascular proliferation in placental villi. He also depicted a lymphocytic-plasmacellular villitis (Fig. 20.64).

Similar villitis, including necrosis and villous *Toxoplasma* cysts, were found by Elliott (1970) in the placenta of a 3-month macerated abortus. He described the placenta as being “shaggy.” Becket and Flynn (1953) found the placenta in toxoplasmosis to be as pale as it is in cases of erythroblastosis. They depicted the cysts in villi in both of their cases. Driscoll noted that in most of her cases marked plasmacellular deciduitis was a pronounced feature (Benirschke & Driscoll, 1967). Excellent illustrations of cysts within villi, occurring apparently even within trophoblast, were provided by Werner et al. (1963). They considered it to be the result of transmission from infected endometrium. Edwina Popek (1992) described granulomatous villitis in an 18-week stillbirth with intensive chronic villitis; she also reviewed the literature on placental toxoplasma infection in this contribution. Popek found organisms in every section of her case and was able to stain them immunologically. Nevertheless, careful study identified the organisms without additional aid. There were no plasma cells in the villi.

sclerosis of the villi. H&E  $\times 125$  (left);  $\times 240$  (right). (Courtesy of Dr. G. Khodr, San Antonio, Texas, and Dr. J. Hustin, Loverval, Belgium.)

FIGURE 20.65. *Toxoplasma* cysts in amnion/chorion of a child with congenital infection and hydrocephaly at 31 weeks' gestation. Inset: Enlargement of a cyst. H&E  $\times 640$ . Inset: H&E  $\times 1200$  (Case courtesy of Dr. Jean Hustin, Lovervall, Belgium.)

Although the cysts depicted by these authors are classical, care must be taken with the interpretation of *Toxoplasma* cysts in other publications. In consultation, we have seen several cases where cysts had been suspected; they were, however, degenerating syncytium. The photographs shown by Sarto et al. (1982) of syncytial nuclei in "endomitosis" simulate *Toxoplasma* cysts. They must not be mistaken for the organism. Janssen et al. (1970) have discussed these difficulties and urged that these problems must be borne in mind when toxoplasmosis is diagnosed from slides. As difficult as cyst identification is, the diagnosis of tachyzoites in histologic sections is impossible. Without fluorescent antibody staining or smears of infected tissue, they usually cannot be recognized with certainty. Dr. Jean Hustin (Belgium) has made available to us a case of a primary infection at 24 weeks' gestation that was treated with spiramycin. Despite this therapy, the fetus developed hydrocephaly and was aborted at 31 weeks. Numerous cysts were found in the chorion (Fig. 20.65), and plasmacellular infiltration, with necrosis and fibrosis, was found in villi. This maternal therapy is thus ineffective in combating the infection.

In toxoplasmosis, as in CMV infection, thrombosis of chorionic vessels occurs (see Fig. 20.67). The thrombi and vessel walls may be calcified, even vessels of the umbilical cord have been thus calcified (Khodr & Matossian, 1978). Pathologists are frequently challenged to provide a specific diagnosis when chronic villitis is found. They must then find cysts, proceed with antibody staining (Fig. 20.66), or, best, isolate the organism by injecting tissue homogenate into the peritoneal cavity of mice. Tissue culture methods of identification may also be used. Occasionally one may find cysts only in the umbilical cord, perhaps because they stand out better (Benirschke et al., 1999). But when calcified vessels of the placenta remain unexplained, especially when some chronic inflammation of villi is also encoun-

tered, a detailed search for toxoplasma cysts needs to be undertaken.

The questions of whether recurrent toxoplasmosis occurs and with what frequency are not resolved. Kimball et al. (1971) conducted a prospective study of 5000 obstetrical patients and came to the conclusion that abortion is significantly associated with antibodies to *Toxoplasma*, but in none of their 260 abortion specimens could they show the organism. Moreover, habitual abortion was not due to toxoplasmosis in the mother. Feldman (1963) thought that recurrent toxoplasmosis does not occur. Others are dubious or believe that recurrent infection is most likely associated with immunosuppression. Langer (1963a,b) first suggested that toxoplasmosis may be a cause of spontaneous abortion. He inoculated mice with material from 70 repeat aborters and isolated organisms from 23 of them. However, he also obtained organisms

FIGURE 20.66. Villus in congenital toxoplasmosis, anti-toxoplasma antibody staining (brown).

FIGURE 20.67. Placenta of a stillborn with hydranencephaly and other destructive features due to toxoplasmosis. Note the calcified venous thrombus at (arrows). (Courtesy of Dr. G. Khodr, San Antonio, Texas.)

from nine control specimens. Only 19 of the 23 patients had a positive serologic reaction. He isolated *Toxoplasma* from the brain of two successive abortuses. He also described another case with probable toxoplasmosis. In several cases, however, he required several passages for identification, an important aspect of his work.

Garcia (1968) observed a similar patient. This woman delivered a severely affected child who died within a day. Aside from many areas of typical destruction, organisms were shown to exist in several organs. The placenta had many cysts and villitis with conglutination of villi. Cysts were also found around the umbilical vein. A second pregnancy ended with a macerated abortus, also with typical histopathologic changes. Again, *Toxoplasma* organisms were identified; they were also present within the decidua, but they were much less well depicted there. Thus, some doubt of recurrent disease lingers. The suspicions that transplacental toxoplasma transmission may be enhanced in HIV-infected patients have not been supported by the study of Minkoff et al. (1997).

## Kala-Azar

This visceral leishmaniasis is due to *Leishmania major* infection. It is endemic in parts of Africa, and placentas from infected pregnancies have rarely been observed, even though congenital infection is known to occur occasionally. Eltoum et al. (1992) described such a case, a 5 months abortus, as well as a transplacental infection. In the placenta of the abortus, numerous villous vessels were thrombosed and contained typical organisms, amastigotes, within and outside of macrophages. The organisms were confirmed by electron microscopy. There was no inflammation and only focal trophoblastic degeneration was observed.

## Chagas' Disease

Chagas' disease (American trypanosomiasis) is caused by infection with *Trypanosoma cruzi*, an organism that is transmitted by the bite of an infected triatomid, the "kissing bug." The disease is largely limited to Brazil, Paraguay, Chile, and Argentina, but rare cases (also of organism and vector) have come from Mexico and the United States (Woody & Woody, 1974). Chagas' disease produces a wide variety of symptoms and is characterized by a frequently long latent period. Best known are myocarditis and esophagitis, but encephalitis, hepatosplenomegaly, and many other manifestations are well recorded. It is an important and frequent disease in northeastern Brazil. The disease is also known in Venezuela, from which the first congenitally acquired cases were described (Gavaller, 1953). Since then, numerous instances of congenital Chagas' disease have been published. Most have been from Salvador (Bahia, Brazil), but a mild transplacental infection in a Mexican patient was detailed by Gilson et al. (1995). The latter authors pointed out that with currently greater mobility of people, the infection should be more commonly suspected.

The extensive Brazilian literature on congenital and placental Chagas' disease has been reviewed in English by Bittencourt (1976), who is the major contributor to our knowledge of this disease in newborns. Her paper also described in detail the placental pathology. The (maternal) disease was often first identified by the autopsy of stillborn infants, whose organs contained large numbers of the organisms. When parasitemia exists in the mother, the trypanosomes gain access from the intervillous space by traversing the trophoblast as trypomastigotes. This step may occur during an acute infection but is most common in the chronic phase of the disease. In the villi, the organisms change character, becoming amastigotes, and remain

FIGURE 20.68. Chronic, destructive villitis due to Chagas' disease. Although many organisms are present, they cannot be seen at this magnification. The villi at top right are agglutinated;

they have long been fibrosed and are functionless. H&E  $\times 250$ . (Courtesy of Dr. Achil a Lisboa Bittencourt, Bahia, Brazil.)

phagocytosed by Hofbauer cells. When they are released from these cells, they enter the fetal circulation as trypomastigotes. Not all placentas with Hofbauer cell infection cause congenital disease in the fetus. Most of the placentas studied by Bittencourt showed a massive parasitic load, chronic destructive villitis, and intervillous accumulation of fibrin and inflammatory cells (Fig. 20.68). Fibrosis and an occasional villous granuloma-like reaction were also seen. The amnionic epithelium and

Hofbauer cells were the commonest place for amastigotes to be located, although in one case a massive accumulation was found in the syncytium (Fig. 20.69). In a later contribution, Bittencourt et al. (1981) beautifully depicted the amnionic amastigote infection, and showed that the umbilical cord also had surface and internal amastigote aggregates; she speculated that an important route of amnionic epithelial infection may be from infected fetal lung. The chorion also occasionally contained organisms.

FIGURE 20.69. Placenta of a mother with Chagas' disease, showing amastigotes in the syncytiotrophoblast. This newborn was without overt disease, even though the placenta was infected during the acute phase of the maternal disease. H&E  $\times 400$ . (Courtesy of Dr. Achil a Lisboa Bittencourt, Bahia, Brazil.)

The placentas of many affected fetuses were markedly enlarged, pale, and disrupted. Drut and Araujo (2000) depicted unusually large cells in villous stroma and determined their hyperdiploid DNA content. Mezzano et al. (2005) described reduced expression of placental alkaline phosphatase in infected and in diabetic placentas and suggested a causal relation with the presence of trypanosomes in trophoblast. Perhaps, so they speculated, diabetic patients may be more susceptible. Mjihdi et al. (2002) induced placental and fetal lesions in experimental studies of mice using this organism, and Shippey et al. (2005) used trophoblast cell cultures and perfused cotyledons to investigate early infection with trypanosomes. The former mode of infection was more successful.

#### BABESIOSIS, TRICHOMONIASIS, RICKETTSIA, AND EHRLICHIA

Transplacental **babesiosis** has been described, but the placenta was not studied (Esernio-Jenssen et al., 1987). The mother had been bitten by a tick 1 week before delivery; the infant was treated successfully. The organism, *Babesia microti*, was identified in 5% of the child's red blood cells.

**Trichomoniasis** of the vagina, caused by *Trichomonas vaginalis*, frequently complicates pregnancy and is the most common sexually transmitted disease according to Stine (1993), and it has been suggested that it is a cause of premature delivery, especially because it may be associated with bacterial vaginosis (James et al., 1992; Cotch et al., 1997; Boon et al., 2002). Mason and Brown (1980), who studied 70 infected parturients and a control group of patients, found that there was no relation of premature delivery and vaginal trichomoniasis. Cotch et al. (1997) examined a large population of women. They ascertained that vaginal trichomoniasis in the middle trimester is associated with preterm delivery and low birth weight. They corrected for associated infections but were unable to correlate PROM with this trichomoniasis. These authors and Graves and Gardner (1993) considered the probable pathogenicity of this organism upon the endocervical canal and placental membranes. Neonatal infection of respiratory passages and pneumonia, presumably acquired at delivery, have been reported in a few newborns (Al-Salihi et al., 1974; McLaren et al., 1983; Smith et al., 2002; Hoffman et al., 2003). They were delivered vaginally; the placentas were not described. The organisms are difficult to identify histologically, and they would most likely be overlooked in routine examinations (see Lossick & Kent, 1991). Fetal and placental inflammatory lesions have been well delineated in bovine abortions due to a related flagellate (Rhyan et al., 1988), but detailed placental studies in humans have not been reported. They are desperately needed, as the light-microscopic examination of tissue sections is incapable of detecting this organism. Fortunately, new methods for identification have become available such as fluorescent DNA in situ hybridization (Muresu et al., 1994), and the sequence of the trichomonas adhesive protein has been identified (Rappelli et al., 1995). But it needs to be reemphasized that trichomoniasis is one of the most common (if not the most common) sexually transmitted diseases, and it has major sequelae that are in need of more decisive study (Soper, 2004).

**Rickettsial** disease (Rocky Mountain spotted fever) occurred during the pregnancy of a patient described by Markley et al. (1998). After chloramphenicol therapy the patient recovered; the placenta and infant were normal.

**Ehrlichiosis** is an infection with placental transmission identified in horses (Long et al., 1995). The infection causes abortion in sheep, cattle, and horses, and several different species of organisms have been delineated. There is one report of neonatal infection in humans, by

Horowitz et al. (1998). The mother was infected, living in a tick-infested environment, and responded to doxycycline therapy. The neonate became clinically ill at age 7 days and had massive infection of granulocytes with the agent referred to as "human granulocytic ehrlichiosis." The placenta had not been examined, but circumstances suggested to the authors a prenatal, transplacental infection.

## Malaria

Infection with one of the four species of malaria plasmodia is the commonest infectious disease in the world, but truly congenital infection has been described only rarely. Naeye (1988b) made the point that it is important to differentiate between malaria in endemic regions and malaria in areas where the disease is sporadic. The former have continuously new antigen presentation and different, enhanced immune reactions. He believed that this point may be important in the outcome of the disease and its possible transmission to the fetus. But the mechanism of fetal/neonatal infection is still uncertain, despite the prevalence of malaria.

Most authors have found that pregnancy substantially increases the severity of malaria. The disease is associated with premature births, and it reduces the weight of the fetus and placenta (references in Bruce-Chwatt, 1966; Wyler, 1983). There is also some evidence that malaria-infected erythrocytes may be "sequestered" in the intervillous space of pregnant patients (Bray & Sinden, 1979). This sequestration was explained by the expression of intercellular adhesion molecule-1 (ICAM-1) on monocytes in "chronic malaria infection" (Sugiyama et al., 2001). Muthusamy et al. (2004) showed that infected red cells adhere to trophoblast by a "low-sulfated chondroitin sulfate proteoglycan receptor." This attachment, so Crocker et al. (2004) suggested, leads to syncytiotrophoblastic degeneration, possibly thus relating to deficient fetal growth (see Nosten et al., 1999). The organisms have often been identified in the blood of the intervillous space (e.g., Jelliffe, 1968) and may be retained there because of the "sequestration" even after apparently adequate therapy (Procop et al., 2001). It is also stated that the placenta may be "diagnostically black at parturition" owing to malaria pigment (Anonymous, 1983c). This pigment ("haemozoin") has been quantitated by Sullivan et al. (2000), but its quantity was unrelated to fetal outcome. In a study that used polarization microscopy, Romagosa et al. (2004) have shown that this modality is superior in detecting the parasites, as well as the pigment, so long as the tissues were fixed in buffered formalin. Mount et al. (2004) showed that the impairment of humoral immunity to malaria surface antigens in pregnancy is occasionally the result of HIV infection, thus explaining the enhanced susceptibility in pregnancy to malaria.

Congenital infection with malarial organisms occurred in only one twin reported by Tanner and Hewlett (1935) and Balabat et al. (1995). The latter authors asserted that only 300 cases of congenital malaria have been described, and only five were in twin pregnancies. They also suggested that transplacental infection occurred most likely during delivery. Following an epidemic, Wickramasuriya (1935) described six cases of congenital malaria. He believed that congenital infection is much more common than was believed prior to his report. It included a review of previous statements that denied or assumed congenital infection to occur. The patients in his study were severely infected, and several died undelivered with fetus in utero. Parasites were found in umbilical cord blood of one patient, and in the brain and spleen of two. Five fetuses had malaria-pigmented spleens, and one placenta had many infarcts and an abruptio. Other reports of congenital malaria have been reviewed in case reports by Woods et al. (1974) and Thompson et al. (1977). A frequently cited report of Quinn et al. (1982) described four children who had their first febrile episode at 3 to 4 weeks of age. Their mothers had come to Seattle, Washington, from abroad, and the new infection is unlikely to have occurred in Seattle. The mothers had been febrile during labor or before; the placentas were not studied, and the mechanism of fetal infection is only surmised. It was suggested that perhaps antibodies or other proteins suppressed fever before the children finally became ill. In general, perhaps because of transferred immunity, symptomatic disease becomes evident only after several weeks in the neonate, as in the four infants just described. The disease is virtually never recognized at birth or it may be very difficult to diagnose (Hewson et al., 2003). That the transmission was prenatal (or occurred during deliv-

ery) in some of these cases is evidenced by reports of neonatal malaria in patients returning from abroad to the United States and delivering their infants here. Organisms have definitively identified in umbilical cord blood but is said to be more common when the fetus has had an opportunity to make IgM antibodies (Xi et al., 2003).

When it is stated in the literature, however, that the “placenta was infected,” this usually refers to the demonstration of organisms in blood smears made from the placenta. Such organisms could have originated from the intervillous space, as was well demonstrated by the photograph in the studies by Miller and Telford (1997a,b) upon which Lane (1997) and Edwards (1997) commented. Histologic studies have usually not been done, or have been reported only infrequently. One such report, including ultrastructural study, came from Gabon (Walter et al., 1982). These investigators found placental parasites in smears from 33% of cases in an unselected population collected in an endemic area. Infected erythrocytes were frequent in the intervillous space, and there was an accumulation of associated macrophages (Fig. 20.70). An increased amount of intervillous fibrin was present; thickening of trophoblastic lamina was interpreted as possibly representing the results of an immune reaction. The authors suggested that syncytial damage may have occurred, and they found ample malaria pigment (a hemoglobin breakdown product) in fibrinoid, macrophages, and “free” in the intervillous space. In the authors’ opinion, plasmodia cross the placenta infrequently, and in their study the event was not demonstrable. This opinion is different from that of Naeye (1988b), who quoted Reinhardt as having found parasites in the fetus as frequently as in 55% of cases.

FIGURE 20.70. Malaria infected placenta with focus of syncytiotrophoblastic necrosis and pigment (hemozoin) at green arrows. Malaria parasites at red arrows.

The discrepancy is not resolved. The workers who have looked at the placentas histologically have not identified organisms in the fetal circulation. This is also our observation, based on studies of infected Vietnamese patients who have delivered at our hospital. Our present view is that the plasmodium does not cross by itself. When transplacental infection does occur, the parasites are probably transferred within red blood cells. Although maternal to fetal transfer of red blood cells is rare, it does occasionally happen (see Chapter 17). This concept accords with the original observations made by Wickramasuriya (1935) as well. He demonstrated organisms in some stillborns and in the umbilical cord blood of one fetus. His patients had unusually severe pregnancy complications, several having died before delivery. These complications may well have contributed to the enhanced transfer of infected red blood cells. Ordi et al. (1998) examined the placentas of a large cohort of patients in Tanzania and detected "massive chronic intervillitis" in 6.27% of their patients. Of 1179 placentas studied, 415 showed parasites as evidence of active infection, 475 had malaria pigment without parasites, 289 had no evidence of infection, and 74 had massive intervillitis. At least 75% of the intervillous space was involved with infiltration of mainly "monocytes and histiocytes" (CD68- and CD45-positive cells), and frequent fibrin deposits were also observed. Pigment was identified by polarized light study. Four cases had fetal vascular thromboses. The report has an extensive discussion of intervillitis of different origins, but fetal infection was not addressed by these authors (see also Chapter 21). The nature of the intervillous inflammatory cells was studied in greater detail by Ordi et al. (2001) in the same population. It was found that natural killer (NK) cells are conspicuously absent among the cells. Nebuloni et al. (2001) commented on this observation and presented a malaria patient with massive "intervillitis" (vide infra) and further identified the cell type (CD68, CD45RO+, few CD20+).

*Coxiella burnetii* is the organism that causes Q-fever, a zoonosis commonly contracted from domestic animals. Congenital infection with intrauterine fetal death was reported by Friedland et al. (1994). The placenta had a 40% involvement with severe necrotizing villitis with many organisms in the villi. Raoult and Stein (1994) reported another case and reviewed other cases from the abortion literature.

#### OTHER PARASITIC INFECTIONS

Kain and Keystone (1988) reported a patient with recurrent hydatid disease (*Echinococcus granulosus*) during pregnancy. A normal child was born; the placenta was not described. Invasion of the embryo by *Enterobius vermicularis* was described by Mendoza et al. (1987). They depicted a 2-cm embryo, with placenta, and showed the worm to reside within the abdomen of the embryo. The pregnancy was surgically aborted because of the presence of a dead embryo. There was no

inflammatory reaction in the embryo or placenta. When Cort (1921) reviewed the topic of fetal worm infestation, he found only indisputable evidence for transmission of **hookworm** and *Schistosoma japonicum*. In dogs, sheep, and other animals, prenatal transmission of lung worm is well known. Sutherland et al. (1965) depicted placental infection with *Schistosoma haematobium* from a normal delivery. The organisms were located within decidua and villi, but no inflammatory reaction was described. In an addendum, additional cases were discovered. Several other references were made to a case of placental infection with different species of schistosomes. Thus, Bittencourt et al. (1980) found placental infection with *Schistosoma mansoni* in four cases. The gross morphology of the placenta showed no characteristic features, but microscopically granulomas around Schistosome eggs were present in fibrin and villi; occasional worms were also present and are illustrated. Although all four fetuses died, they had no evidence of infection by the worms. Presumably the rarity of this description relates to the paucity of placental studies. Pregnant women also suffer occasionally from disseminated **strongyloidiasis**, but we are not aware of a report of placental pathology in this disease.

### Villitis of Unknown Etiology

Chronic villitis occurs frequently. Rüschoff et al. (1985) found it in 6.6% of 1240 placentas studied, whereas Altshuler (personal communication, 1993) estimated a frequency of 5% to 10% in consecutive placentas. Labarere et al. (1989, 1990), who referred to it as "villitis of unestablished origin" reviewed the incidence and found it to vary in studies from 6% to 33.8%. Villitis of unknown etiology (VUE) is especially frequent in the villi that are near the maternal floor of the placenta, and we have found it to be more commonly in placenta accreta at the implantation site (Fig. 20.71). At times, the etiology is apparent from the history (rubella) or the pathologic features (CMV infection). At other times, despite much effort, no specific etiology is elicited, often even when there are severe clinical abnormalities and autopsies are performed on the neonate. The entity has been termed **villitis of unknown etiology** since its original description (Gershon & Strauss, 1961; Benirschke & Altshuler, 1971; Altshuler, 1973c) and is now a well-recognized entity for placental pathologists. It remains a significant challenge to perinatal pathologists because of its frequency, its high recurrence rate, and the associated poor pregnancy outcome. Sporadic cases such as one we saw with maternal granulomatous disease do not assure a causal relation. No conclusive information on the etiology of VUE has been gained since it was first mentioned by Gershon and Strauss (1961). It is unfortunate that these authors misused the term *placental insufficiency* in this context, a designation to which we do not subscribe. In the literal sense, that term should be used only to represent a pathophysiologic state; it is not synonymous with specific morphologic abnormalities. In our view, few other well-defined lesions of the placenta exist (e.g., maternal floor infarct) for which a fetal or maternal cause cannot be assigned; the term *placental insufficiency* subtly implies that there

FIGURE 20.71. Focal villitis of unknown etiology (VUE) in anchoring villi at implantation site of a placenta percreta. The villi are attached to the connective tissue scar of previous cesarean section. H&E  $\times 160$ .

is an intrinsic defect in placental function or its development. We believe the concept of placental insufficiency to be misleading and one that diverts attention from the search of pathogenetic mechanisms.

The pathologic findings of VUE have often been depicted since the initial emphasis on this entity's recognition (Benirschke & Altshuler, 1971), but there is evidence that the interpathologist diagnostic error of this diagnosis is considerable (Khong et al., 1993). The constituent lesions have a wide spectrum, from occasional villous involvement to extreme involvement wherein all villi have some pathologic reaction (Russell, 1980). Altshuler (1973c, 1984) summarized the salient features of VUE as follows: proliferative villitis; necrotizing villitis; granulomatous, cicatricial, reparative, evanescent villitis; fetal vasculopathy; avascular villi; placental dysmaturity; increase in nucleated red blood cells; hemosiderin; hemorrhagic vasculitis; necrotizing deciduitis; basal villitis; chorangiosis; and ischemia or infarction. All of these abnormalities may be found in cases of placental VUE, or only some of them may be present.

The similarity to known infectious causes of villitis, such as seen with CMV and rubella, is striking. Even though no infectious cause has been delineated for VUE, this entity is discussed here because of its presumed relation to congenital infection. It may well be proved in the future that VUE is not a single or uniform lesion, independent of host immune factors, but that it is composed of several etiologically distinct variants. It is a challenge for future investigation that has recently been taken up by several investigators.

One should also note that degenerative lesions, somewhat simulating VUE, occur peripheral to infarcts (sub-infarctive villous degenerations). These lesions are not to be confused with typical VUE as here discussed. VUE is often associated with fetal growth restriction. Altshuler (1984) saw it in 33% of such cases, Dollmann and Schmitz-Moormann (1972) described it in their patient with recurrent abortions, and others found similar effects (Russell et al., 1980; Labarrere et al., 1982; Salafia et al., 1988). Rüschoff et al. (1985) described the placentas of VUE as "stiff," but a specific macroscopic delineation of VUE has not yet been possible. The placentas are occasionally smaller and have more fibrin content, but no other change allows macroscopic identification.

The frequency of VUE varies with the nature of the investigation, that is, the selection of the material. In general, one may expect VUE in approximately 5% to 8% of consecutively studied placentas. When those of complicated pregnancies, growth-restricted infants, or fetal deaths are studied, the incidence is much higher.

There is little doubt that VUE eliminates a considerable amount of placental parenchyma from nutrient transfer. Fetal growth restriction is thus not surprising. One must emphasize, however, that there is no absolute relation between the severity of VUE and the severity of fetal growth restriction. Attempts to show a relation to elevated fetal IgM levels have not been successful (Mortimer et al., 1985), nor have numerous attempts to identify specific organisms with a variety of serologic, cultural, or structural tools. When neonates survive even severe VUE, they have no detectable illness, and those who die show no lesions at autopsy.

Of greatest interest to us is the frequently recurrent nature of this lesion, so well described in the contribution by Dollmann and Schmitz-Moormann (1972). They saw a patient with two growth-restricted infants followed by three abortions, all with VUE as probable cause. They found that, in some instances, there was a marked intervillous accumulation of macrophages (intervillositis). These cells they determined to be of maternal origin, whereas most of the intravillous inflammatory cells could not be typed with sex chromatin but were thought to be of fetal origin. Jacques and Qureshi (1993) observed six cases of chronic intervillositis and determined the cells to be primarily histiocytes. They were unable to rule out

FIGURE 20.72. Placenta of 36 weeks' gestation still-born with VUE. It was the second of three successive such events. Note the intense intervillousitis with histiocytes and lymphocytes, villous infiltration, villous necroses, and vascular obliteration. H&E  $\times 250$ .

infection, found an association with increased fibrin deposition, and identified some other pathologic features. Although the lesion had a poor prognosis, they were unable to define it more precisely or to identify an etiology. They favored an immunologic determination and next examined it in twin gestations (1994), as did Doss et al. (1995), who suggested a relation to recurrent abortion (see Chapter 21). Discordant involvement of twins was found in both DZ as well as MZ twins, and growth restriction was associated, as was also the case in Kaplan's description (2003) of a set of discordant MZ twins. They pointed out that both viral and immunologic hypotheses for the etiology of VUE are difficult to support when VUE affects the placental portion of only one of mono-chorionic MZ twins. The suggestion relating to VUE and for the adherence and possible penetration of maternal lymphocytes/monocytes to syncytial cells comes from the in vitro studies by Xiao et al. (1997). They showed that inflammatory cytokines of various types increases the avidity of monocyte-binding to syncytium through activation of surface ICAM-1. An immunologic pathogenesis of VUE with maternal cells infiltrating the villi has long been championed by Labarrere and his colleagues (1991). They had earlier first characterized the lesion of chronic intervillitis (Labarrere & Mullen, 1987) and now demonstrated the presence of tissue factor (an initiator of thrombosis through activation of factor VII) in normal villous stroma. In VUE, one often finds minor thromboses in villous capillaries and larger stem vessels. These investigators assume that these originated secondary to focal inflammation, thus releasing cytokines from locally activated helper T cells and macrophages. They envisaged that such reaction would locally engender thrombosis. Further discussion of intervillitis is to be found at the end of this section.

Another of the few attempts at determining the precise nature of the inflammatory cells in villitis is that of Hart-

wick et al. (1989) in a case of fetal parvovirus B19 infection. They found the cells to have a T-cell derivation and provided some support for the fetal origin in this admittedly different disease. Although most of the inflammation in VUE is apparently histiocytic/lymphocytic, plasma cells (B-cell derived) occur as well but much less commonly. We have reason to believe that, in CMV infection, the plasma cells are fetal in origin. Histologic considerations had led us also to believe that in many cases the inflammatory cells of VUE are of fetal origin, but recent studies now indicate that in many instances the majority of the infiltrating cells are maternal cells. In addition, it is apparent that frequently the major inflammatory component is located within the anchoring villi. Also, they are often associated with maternal plasma cell infiltration of the decidua basalis. Indeed, chronic villitis may be *limited* to anchoring villi. Here, the cellular components have a maternal origin, and a dual derivation of the histiocytes, therefore, cannot be excluded. Labarrere et al. (1982) and Russell (1980) have also emphasized the frequent decidual involvement with lymphocytic inflammation and have suggested that VUE may have a relation to chronic endometritis. Whether the recurrent VUE in a patient with recurrent herpes gestationis described by Baxi et al. (1991) has a causal relation will remain unknown until more cases are studied.

The possibility of chronic brucellosis was entertained in a patient of ours with three consecutive pregnancy failures and histologic VUE (Figs. 20.72 and 20.73). Detailed study, however, was negative. In a later pregnancy, the progress was monitored with estriol levels, and when they declined, an elective cesarean section was performed. The growth-restricted infant did well and has remained healthy during the 15 years since this occurrence. The placenta was so severely involved with villitis that one wonders how this infant could have been born alive (Figs. 20.74 and 20.75). The lesion of the first preg-

FIGURE 20.73. Same case of VUE as in Figure 20.72. The villous destruction and cellular infiltration are pronounced; occasional plasma cells are present. H&E  $\times 640$ .

FIGURE 20.74. Placenta of the third pregnancy of a patient with recurrent losses and VUE (as in Figs. 20.72 and 20.73). Patient was also hypothyroid and on medication for this problem. When the amniotic fluid lecithin/sphingomyelin (L/S) ratio became more than 3:1, a cesarean section was done producing a viable fetus. Ten years later, the infant was well. Despite the extensive necrosis and inflammation, this infant weighed 2500 g at 37 weeks. The placenta was 510 g and had massive VUE with destruction of villi and trophoblast. H&E  $\times 250$ .

FIGURE 20.75. Same case as in Figure 20.74. Note the degeneration of the villous vessels. There is no trophoblast necrosis at this site, so the inflammatory cells are likely of fetal origin. H&E  $\times 250$ .

FIGURE 20.76. This placenta comes from the first still-born (at 37 weeks' gestation) of the patient with recurrent VUE (Figs. 20.72–20.75). There is even more necrosis and inflammation of villi than in the other pregnancies depicted. H&E  $\times 100$ .

nancy was identical (Fig. 20.76). The severity and destructive nature of VUE is further exemplified in Figure 20.77, a stillborn, growth-restricted fetus. In yet another case, it was our opinion that the increased frequency of late decelerations during monitoring was caused by the placental lesions shown in Figure 20.78 (Benirschke, 1975). These inexplicable areas of villitis were scattered throughout the placenta. In the case of a severely compromised newborn, the placenta had many vascular occlusions and surface thrombi (Figs. 20.79 to 20.82). No virus infection was diagnosed. This picture is substantially different from the hemorrhagic endovasculitis (HEV) of Sander et al. (1986), which was discussed in Chapter 13.

The precise etiology of VUE is thus still unknown. In fact, we do not even know whether this is a uniform disease or one that, when it is better understood, falls into several etiologic categories. Altshuler and Hyde (1996) drew attention to the possible interaction of cytokines and ensuing fetal growth restriction. Infants can, however,

survive even severe placental villitis without showing subsequent impairment. Their long-term outcome requires much additional investigation. Three principal suggestions have been made with respect to the possible etiology of VUE:

1. It is an infectious (perhaps viral) disease, and due to an as yet unrecognized agent. That this concept has merit derives from the great histologic similarity of VUE to rubella and other known virus disorders that affect the placenta. Moreover, the discovery of parvovirus B19 infection and the similarity of placental response suggest that a viral agent must be sought in future studies. Furthermore, some of the common RNA viruses (Coxsackie, ECHO) are extremely difficult to recognize histologically or by electron microscopy. They also may cause few symptoms in the mother and may not be detected. The report by Garcia et al. (1991) brings this possibility into focus as well.

FIGURE 20.77. Villitis of unknown etiology in a still-born fetus. The intense infiltration with lymphocytes, plasma cells, and histiocytes is widespread. Mineralization of the villous basement membrane is seen at bottom right. Several histiocytic giant cells are present in the central villus, whose trophoblast is degenerating focally. Vessels are obliterated. H&E  $\times 640$ .

FIGURE 20.78. Mild chronic villitis in a 39-week pregnancy with good outcome. Late decelerations during labor were believed to be secondary to VUE. H&E  $\times 250$ .

FIGURE 20.79. Severe chronic villitis in a premature infant with meconium aspiration. Extensive areas of villous destruction and inflammation are seen. H&E  $\times 64$ .

FIGURE 20.80. Same case as in Figure 20.79, showing the subtrophoblastic accumulation of lymphocytic infiltrate and villous necrosis. There were also chorionic vessel thrombi in this placenta. CMV and herpes infections were ruled out. H&E  $\times 250$ .

FIGURE 20.81. Same case as in Figures 20.79 and 20.80, again showing subtrophoblastic inflammatory cells and obliteration of villous stem vessel. H&E  $\times 640$ .

FIGURE 20.82. Same case as in Figures 20.79 to 20.81, showing an old thrombosis of a chorionic surface vessel in VUE. H&E  $\times 64$ .

2. It is an immune reaction akin to placental “rejection” or even the graft-versus-host disease. Several investigators have raised this possibility, in particular because of the histiocytic predominance of the inflammatory reaction and the frequently recurrent episodes. At present, no new studies have conclusively shown or rejected this possibility. It is necessary to have more information on the “normal” fetomaternal immune interactions before this hypothesis can be rejected or affirmed. Moreover, professional immunologists need to be encouraged to become involved in the study of putative fetal antigen recognition. Redline and Abramowsky (1984) have commented on the possibility of the immune hypothesis. They found a 60% reproductive loss in patients with recurrent chronic villitis in contrast to a 37% loss in nonrecurrent villitis (Redline & Abramowsky, 1985). They suggested that VUE is much more common than heretofore believed; perhaps as many as 4% to 10% of placentas have some degree of VUE. They also suggested that “immunologic and structural abnormalities (uterine) in the host may play a role in its pathogenesis.” Several of their patients had autoimmune diseases. Redline and Patterson (1993) found, with X-specific markers in male conceptuses’ placentas, that approximately 60% of the infiltrating immunocytes of VUE represent maternal CD3 positive T-cells that have infiltrated from the intervillous space. This has now been proven. In studies conducted with a male fetus who succumbed in utero from this placental alteration was studied by colleagues of ours. They were able to show the fetal cells to lack the Y-chromosome marker conclusively, whereas it was present in all other villous and trophoblastic cells. The infiltrating cells were T cells and macrophages by immunocytochemistry, and of female gender. The reason for this response is presently unknown but is speculated upon in the contribution by Redline and Patterson. Essentially similar findings were made in the study by Kapur et al. (2004) and they found that essentially similar infiltrates of maternal origin characterized VUE as well as syphilitic villitis. One of our recent cases of VUE that led to fetal demise was also solely due to maternal infiltrates, as shown by Y-marker study. Greco and colleagues (1992) had also investigated the nature of villous stromal cells in VUE, syphilis, and CMV infection with a battery of antibodies and in situ hybridization. They concluded that these infiltrating elements had often markedly different phenotypes and that this was somewhat dependent on the nature of the underlying disease. They expressed an inability to decide about a possible immune reaction portrayed by this villitis (e.g., maternal cell invasion), but pointed out that “the expression of certain cellular markers for villous stromal cells is identical in both CMV and nonspecific villitis.” For a review on the topic of placental nonrejection, see Hunt (1998). Labarrere et al. (1991) have championed this concept for

years, and much of their investigations are there summarized. From their evaluation of placentas derived from in vitro fertilizations, Styer et al. (2003) proposed that VUE is twice as common with donor eggs than native eggs and inferred an immunologic mechanism. This was confirmed more recently by Perni et al. (2005).

3. The disease has a relation to preeclampsia and infarcts. Most of the patients we have seen do not have signs of pregnancy toxemia, and the “villitis” that is associated with preeclampsia is different. It has much less inflammation and is mostly degenerative in nature and found adjacent to typical infarcts. Therefore, we prefer to reject this hypothesis.

Since the original description by Labarrere and Mullen (1987) that defined the entity, a large study of **chronic intervillitis** was undertaken by Boyd and Redline (2000). They studied 21 patients and showed it to be a major cause of IUGR, spontaneous abortion, and fetal death (77%). The recurrence rate was high (67%), and three patients were found to have fetal chromosomal errors. Moreover, there was much intervillous fibrin deposition and some placentas had infarcts. Autoimmune and allergic processes of different kinds were found in 52% of their patients. The cells composing this intervillous infiltrate were of the TH1-type response and included activated macrophages as well as a smattering of other cells. Although this condition is not very common, it does represent an important aspect of fetal demise and IUGR. The authors emphasized that malaria needs to be excluded, as was earlier suggested. This can only be done by careful search for intervillous erythrocytic parasites and hemozoin deposits. A representative example of chronic intervillitis is shown in Figures 20.83 to 20.85. The severely IUGR fetus of this gestation was stillborn at about 17 weeks’ gestation and the mother had one earlier abortion and one normal child. There was excessive fibrin deposition in the entire placenta and massive infiltration of the intervillous space by macrophages (CD68 cells). There was no chronic villitis, however, and there was no significant X-cell proliferation as is seen in maternal floor infarction (MFI). The mother had no history or symptoms of autoimmune or allergic diseases. Interestingly, one large maternal vessel of the decidua basalis was thrombosed.

Chronic intervillitis and VUE are sometimes combined, but in our experience this is not really common and we consider the two histologic entities to be different. At this time, the only certain and common finding is that VUE is not the result of infection with common, known pathogens. No virus or other agent has been consistently identified. Moreover, the children who are born from such pregnancies, many of whom are small for gestational age (SGA), develop normally. The efforts of

FIGURE 20.83. Low-power microphotograph of a typical case of chronic intervillositis. The entire placenta had this much fibrin deposition and collections of intervillous macrophages (dark blue). The intrauterine growth restriction (IUGR) fetus was stillborn but structurally normal.

several laboratories to identify the origin and nature of the inflammatory infiltrate suggest that a majority of the infiltrating cells is of maternal origin. Whether this is tantamount to an immune “rejection” phenomenon mounted by the mother against the placenta needs further investigation. The fact that the surviving infants of VUE placentas remain well and that the disease frequently recurs in families point in that direction. A recent com-

prehensive review of the frequency and relationship to IUGR and fetal demise has come from Becroft et al. (2005).

Likewise, chronic intervillositis has no definitive causal mechanism identified to date. It also may represent different end points of disease, such as malaria and maternal allergic conditions. Much more work is needed to unravel the complexity of these entities.

FIGURE 20.84. Chronic intervillositis at higher magnification with fibrin deposits and disuse infiltration of chronic inflammatory cells in the intervillous space.

FIGURE 20.85. Still higher magnification of chronic intervillositis showing the chronic inflammatory cells (mostly activated macrophages), little villous erosion, and fibrin deposits.

# Abortion, Placentas of Trisomies, and Immunologic Considerations of Recurrent Reproductive Failure

For the present discussion, an abortion or miscarriage is designated a conceptus that is expelled before the 20th week of gestation. That is important to state at the outset, as the pathologic features of failed pregnancies differ markedly in specimens obtained later in gestation. In the United States, terminations before 20 weeks constitute abortions; later gestations are premature deliveries. A pregnancy of 20 weeks is legally at the dividing line; it is a gestation with an “embryo” (that may be treated as a surgical specimen); later it is a “fetus,” whose examination constitutes an autopsy. The terminology employed in publications and statistics differs widely and it is not the same in different countries. For instance, Vogel in Germany (1969, 1992) considered an abortion to be an expelled fetus of less than 1000 g. He differentiated between embryonic and fetal (15–28 weeks) abortion. In many countries, legal viability is considered to be attained only at 28 weeks of gestation, when the fetus has attained approximately 1000 g in weight; but that is not so in the United States. Byrne et al. (1985), in a study of early fetal deaths, considered all specimens of less than 28 weeks’ gestation. For these reasons it is difficult to place the studies of Vogel (1969, 1992) into context with current terminology. Hutchon (1998) reviewed the complex terminology of this topic and proposed (with concurrence of a British study group on terminology) that the term **abortion** be replaced with **miscarriage**, for all types under discussion. Most truly spontaneous abortions occur before 12 weeks of gestation and a majority is due to chromosomal errors in the conceptus. Relatively few really spontaneous abortions occur in the period from 12 to 20 week’s gestation. Thereafter, between 20 and 30 weeks, another type of premature spontaneous termination becomes prevalent, that which is primarily due to ascending infection with chorioamnionitis. Infection is relatively uncommon before 20 weeks. These are fundamentally different processes with also vastly different pathologic findings.

Terms other than **spontaneous abortion** (involuntary) have been employed, and these have often confused the general abortion issue: “therapeutic abortion” (TAB; electively terminated), “missed” (retained for more than 8 weeks after embryonic death), “criminal” (illegally instrumented), “habitual,” and “recurrent” abortions, and other terms designate specific entities. Not all of these definitions are universally accepted, and there is cogent argument that the term “missed abortion” should be abandoned (Pridjian & Moawad, 1989). It is best to clarify the specific nomenclature before one compares data from different institutions or countries. A useful method for categorization of abortion specimens was provided by Fujikura et al. (1966). They divided specimens into groups with and without embryos, those with ruptured and unruptured sacs, and included the degree of the completeness of the specimen. In their experience, 22% were classified as incomplete, and most (35.8%) had a normal embryo or fetus. An embryo may be considered to be a specimen with a crown–rump (CR) length of up to 30 mm (less than 9 weeks), and a fetus may be considered an unborn conceptus greater than 30 mm CR (Moore, 1982, 1994). When only incomplete specimens are available, it has been most practical to determine fetal age from measurements of fetal foot length. Other extensive considerations of classification and specimen examination are laid out in detail by Kalousek et al. (1990). Hern (1984) correlated various fetal measurements with gestational age in 1000 specimens and provided excellent tables from which reasonably exact age determination is possible. “Threatened abortions” are represented by those clinical cases in which vaginal bleeding occurs in the first trimester. Weiss et al. (2004) have reviewed a large study of this phenomenon and found that the amount of bleeding corresponds to different gestational entities such as pre-eclampsia, spontaneous abortion, abruptio, etc.

Spontaneous abortions are common. Despite this frequency, patients often do not understand its nature, and, especially when recurrent abortions occur, they find little

comfort from consulting their physician. For that reason, Cohen (2005) has produced an excellent volume that comprises nearly all that needs to be known about the topic, especially for the parturient. The exact frequency with which pregnancy failure occurs spontaneously has been debated and our understanding of its pathogenesis has undergone remarkable changes in recent years. Its chromosomal causes are nicely reviewed by Cohen (2002), and Clouston et al. (2002) have examined the chromosomal errors in 438 human blastocysts. Of these, 3% were polyploidy (mostly tetraploid), 29% were diploid/tetraploid mosaics, and 68% were diploid and included a variety of trisomies. Trauma is no longer considered to be a common cause of abortion. Hertig and Sheldon (1943) found only one set of twins whose abortion was probably caused by external trauma among the 1000 miscarriages they studied. "Internal trauma" was incriminated in 22 cases. Published figures on the incidence of abortion depend largely on the method of sampling a population. When prospective studies of complete populations are done so as to include also all those pregnancies that give few or no clinical symptoms of pregnancy, it is found that nearly 50% of conceptions terminate in abortion spontaneously. For example, Miller et al. (1980) collected urine of 197 women who were wishing to conceive. They began the collection at ovulation to obtain the earliest evidence of pregnancy and investigated 623 menstrual cycles. Their diagnosis of pregnancy was made with sensitive radioimmunoassays for  $\beta$ -human chorionic gonadotropin ( $\beta$ -hCG). There were 152 conceptions, with a pregnancy loss of 43%; but only 14 of the abortions were recognized clinically as being pregnancies. The other 50 patients merely had a rise of urinary hCG level from which implantation was inferred. McLean (1987) reviewed other studies that arrived at similar figures. They cited that approximately 50% of implanted pregnancies aborted spontaneously, and most of them were clinically unrecognized. Additionally, there are probably conceptuses that vanish even before implantation. Wilcox et al. (1988) identified 31% spontaneous abortions of 707 cycles collected from 221 women. In a subsequent evaluation of early abortions, Wilcox et al. (1999) determined from hormone studies that optimal implantation occurs between days 8 and 10 after ovulation. Of 189 pregnancies, 75% went at least 6 weeks past last menses, 25% ended in early losses. Conversely, Regan and Rai (2000) indicated that 78% of fertilized ova fail to result in a live birth. They analyzed all aspects of miscarriage, especially recurrent abortion, and suggested that in the latter category, 50% occur by chance. They dedicated much space to a consideration of the antiphospholipid syndromes. Mills et al. (1988) found that diabetic women in good clinical control of their diabetes may expect similar rates of abortion and cited an incidence of 16% of clinically recognized gestations. Hertz-Picciotto and Samuels

(1988) have criticized some of these results and gathered the following figures from four studies:

No. of losses		No. of recognized pregnancies	Risk of loss in recognized pregnancies
Subclinical	Clinical		
43	18	154	11.7
7	11	85	12.9
50	14	102	13.7
67	6	41	14.6

Most spontaneous abortions occur before 12 weeks of pregnancy, and chromosomal errors are their most prominent cause but the exact mechanism of the abortion event is still disputed. A recent review by Jauniaux and Burton (2005) suggested that oxidative stress may constitute an important aspect of spontaneous abortions. They argued that because trophoblastic ingrowth of maternal vessels is reduced in spontaneous abortion specimens, an earlier true perfusion of the intervillous space occurs that then results in trophoblastic damage. Numerous other factors are also evaluated in their comprehensive review. In a study of amniocentesis results over 20 years of women age 35 or more, Caron et al. (1999) found that 1.79% had chromosomal errors, with trisomies and structural rearrangements prominent findings. Stern and Coulam (1992) found in a study of recurrent abortions that the reduction in sonographic size of the "fetal pole" and differences in fetal heart rate activity at 6 weeks allowed great accuracy in anticipating an abortion. The hypoplasia of the placenta, so often observed and that presumably correlates with the decreased hCG secretion and hence progesterone support of the decidua, is an accepted possibility. A specific inquiry into the small gestational sac (sonographically) and other gestational parameters was undertaken by Dickey et al. (1992). They found small gestational sacs more often in chromosomally normal abortuses. It has recently been suggested that "illegal" blood flow into the intervillous space at an early gestational age may equally be of importance in causing spontaneous abortions (e.g., Jauniaux & Burton, 2005). Schaaps and Hustin (1988) and Hustin et al. (1988) had earlier reviewed the interesting evidence of early trophoblast invasion. From their findings they concluded that massive trophoblastic infiltration of uteroplacental arteries essentially occludes these vessels before 12 weeks' gestation. This trophoblastic proliferation, they suggested, permits only plasma filtrate to circulate in the intervillous space, at least in early gestation. It is apparently for this reason that chorionic villus sampling (CVS) specimens are usually bloodless. Sonographic and pathologic evidence suggest on the other hand that, in spontaneous abortuses, blood circulates in the intervillous space before the interruption of pregnancy. It is thus speculated that this may come about as the result of inadequate tropho-

blastic proliferation into the decidual arteries and that it affects normal nidation.

Increasing maternal age considerably increases the risk of spontaneous abortion, especially after the age of 35 (Stein, 1985), and it correlates with an enhanced risk of fetal trisomies. No such association could be made with respect to paternal age (Hatch et al., 1990). Moreover, Neuber et al. (1993) found that the frequency of monosomy X and of triploidy decreases with advancing maternal age. When triploids are observed in abortuses of older women, they tend to be more often the result of digyny, that is, maternal failure of producing a haploid gamete. Although this advanced maternal age phenomenon is clearly demonstrable from statistics and has been suggested to be the result of inadequate pairing at meiosis ("non-congression") by Hodges et al. (2002), the **actual age** of the oocyte, often suggested to be a causal mechanism especially in the frequency of Down syndrome, has been studied only once in humans. Simpson et al. (2002) did such a study of women in whose pregnancies the timing of conception could be deduced reasonably well. They found "no association between ageing gametes and major birth defects, including Down's syndrome." These and other studies have led to an inquiry into whether it is the nucleus or the oocyte cytoplasm that may be "at fault" in disturbed pregnancies. These are further discussed below (see Recurrent or Habitual Abortion).

Abortions due to chromosomal nondisjunction were lucidly detailed by Magenis (1988), who summarized especially well the paternal versus maternal nondisjunctional events in trisomies and X monosomy. Also, numerous investigators have commented on the apparent excess of male conceptuses among abortion specimens (reviewed by Shettles, 1964). Contradictory reports have been examined by Kellokumpu-Lehtinen and Pelliniemi (1984). They studied the sex ratio of 551 induced abortions by histologic examination of gonads or by sex chromatin. Early embryos had a sex ratio of 1.64, which became 1.17 in later fetal stages, presumably because of losses in early gestation. There is no convincing explanation for the disproportionately high loss of male embryos. Embryos also are often improperly sexed by pathologists. It has been our experience that male gender is often inaccurately assigned because of misinterpretation of the normally large clitoris in young female embryos. Kirby et al. (1967) have suggested immunologic reasons for the excess male wastage.

Clendenin and Benirschke (1963) and Carr (1965) were the first investigators to establish that spontaneous abortions principally result from chromosomal errors of the conceptus. Subsequent investigations from many countries have confirmed and extended these observations. Boué and Boué (1969) reported that 70% of spontaneous abortions occurring during the first 6 weeks of pregnancy had chromosomal errors, and 50% during the

first 10 weeks. Trisomies constituted 56% of the errors, triploidy 18%, monosomy X 15%, and the remainder were double trisomies, tetraploidies, and individual chromosomal errors, such as rings, translocations, and mosaicism. Hassold et al. (1980), in a detailed study of 1000 spontaneous abortions, found 44.5% trisomies, 24.2% monosomy X, and 15.1% triploidy. Kajii et al. (1980) found 53% of their specimens to be chromosomally aberrant. Other studies, largely from cultured material, have produced approximately similar results (Kuliev, 1971; Creasy et al., 1976). Eiben and colleagues (1990) studied 750 spontaneous abortions with direct chromosome preparations (as opposed to preparations made from cultured cells). Roughly similar error rates were detected, but it was striking that there was a considerable excess of females in chromosomally normal abortions (sex ratio 0.71). The use of postmortem villus sampling after the specimen is delivered was advocated by Johnson et al. (1990). They not only found it to be more successful than skin biopsy and amniocentesis, but also discovered an unusually high error rate.

The pathologist is occasionally asked to provide material for chromosomal study from fetuses and placentas. In our experience, this is best done from embryonic tissue or from the chorionic surface when an embryo is not available. Although general sterile techniques are desirable when obtaining the material, Boué used tap-water-washed specimens with good results. Absolute sterility may not be needed, but it is preferable. When sampling the placenta, it is best to cleanse the fetal surface, peel the amnion away, and then to obtain chorionic tissue with sterile instruments, ideally to include some chorionic surface vessels. Geisler and Gropp (1967) have provided more detailed instructions for the explantation of this material.

## Anatomic Findings

The evaluation of specimens from spontaneously aborted conceptions has greatly changed. The so-called *Windei* (blighted ovum) of early authors, the "pathologic ovum" (with its many subgroups), and many other designations used in the past have now become obsolete. Likewise, terms such as *nodular*, *cylindrical*, *stunted*, and *disorganized embryo* have little specific use in describing the nature of the embryonic abnormality (Fig. 21.1). For a better understanding of the pathogenesis of the many defects in aborted specimens, it is necessary to know their chromosomal constitution. It may not be reasonable to undertake complex cytogenetic studies of spontaneous abortion specimens on a routine basis because of the expense and because it adds little for management. This is disputed, however, by Wolf and Horger (1995), who presented cogent argument for such investigations.

FIGURE 21.1. Cylindrical embryo of a spontaneous abortion at 9 weeks' gestation. Embryo is also growth-restricted (should be 2.5 cm) and hemorrhagic. It was undergoing autolysis on microscopic study; abortion is undoubtedly due to a chromosomal error.

Understanding the principles may be sufficient, but what to sample remains a personal choice. An excellent pictorial guide for the study of abortions is to be found in Kalousek et al. (1990). Salafia and her colleagues (1993) undertook a study to ascertain how the histopathologic findings can be used in making the diagnosis of chromosomally caused abortions. They devised scoring criteria and concluded that an intact fetal circulation, villous infarcts, decidual arteriopathy, and chronic "intervillositis" argued against cytogenetic error as the cause of an abortion (see also Doss et al., 1995). New methodology is evolving that will make it feasible to describe the genetic defects more accurately, such as DNA studies, the polymerase chain reaction (PCR), fluorescent in situ hybridization (FISH) of whole cells (e.g., Hogge et al., 1996; D'Alton et al., 1997; Bischoff et al., 1998; Clouston et al., 2002), and delineation of translocations by spectral color staining of chromosomes. Some of these tests are feasible even using fixed and selected individual cells from paraffin-embedded tissues (for reviews see Antonarakis, 1989; Kovacs et al., 1989; Kuchinka et al., 1995). The placental material also lends itself for paternity diagnosis (Strom et al., 1996). Horn and his colleagues (1991) suggested that abortion material be examined with a lens, so as to identify hydropic swelling and hypoplasia; histologically, few additional findings of importance are made.

Because hydropic villi are such a frequent finding in many placentas of spontaneous abortions, the differential diagnosis from moles and partial moles is often required and may present difficulty. To do so, we have advocated a much wider use of flow cytometry, the most rapid means for the delineation of diploidy and triploidy. The ploidy ( $2n$  versus  $3n$ ) of aborted specimens, particularly triploid "partial moles," are thus being differentiated from "true"

(complete) hydatidiform moles much more quickly (see Chapter 22). We also recommend that a mini-autopsy be performed on embryos when they are present, as its findings are often startling. Despite the frequent maceration of these embryos, an autopsy is easily done when running water over the dissected specimen is employed during the dissection. This allows easy identification of the presence of major structures. For comparison of gross and microscopic specimens, two excellent atlases by Chi et al. (1992) and Keeling (1994) are useful. How problematic it is to differentiate histologically between partial moles and placentas of spontaneous abortuses is well illustrated by the observation of Rakheja et al. (2004). Their abortion specimen had typical scalloping and syncytial "inclusions" that are usually seen primarily in partial hydatidiform moles. The karyotype of this specimen, however, was 46,XY, del 18q.

The youngest described abnormal specimens originated from the systematic studies of early human implantations. Hertig et al. (1959) summarized their extensive search for early conceptuses, which they conducted in 210 women. They described 34 early ova, 10 of which were abnormal. Histologic abnormalities included multinucleated blastomeres, necrotic blastomeres, lack of cavitation, hemorrhage, and deficient trophoblastic proliferation. These studies were done, however, before cytogenetic study was feasible. Harrison et al. (1966) depicted an abnormal 13-day ovum with unbranched villi and abnormal amnionic budding.

Most of the descriptions of aborted specimens come from systematic studies of spontaneous abortion. Kaeser (1949) presented an extensive study of the frequency, nature, and pathologic features of abortions, highlighting the "hydatidiform degeneration" of villi (Fig. 21.2). Huber et al. (1957) found in 76% of their specimens that the embryo was abnormal; 40% of the specimens had hydatid changes of villi. Sadovsky and Laufer (1961) emphasized the extensive decidual hemorrhage that is often regarded as being one cause of early abortions, especially those with intact villi (Fig. 21.3). Eckman and Carrow (1962) described the presence of extensive villous stromal collagenization as a prominent feature of their abortion specimens and found 29% to possess hydatid changes. The fibrosis of villi was considered to be secondary by Abaci and Aterman (1968), who studied 237 abortion specimens. They found changes of hydatidiform mole in 41.3% and subchorionic hematomas (Breus' mole) in 20.2% (Fig. 21.4).

The hydropic degeneration (hydatid change) of villi is a recurrent finding in all studies of abortion specimens (Fig. 21.5). This feature was reviewed by Ladefoged (1980), who compared 100 spontaneously aborted specimens with 160 therapeutic abortions. Whereas hydropic change was noted in as many as 81% of instrumented specimens (representing probably the normally edema-

FIGURE 21.2. Spontaneous abortion at approximately 8 weeks' gestation. Note the opened sac at right with the nodular embryo (open arrow). The hypoplastic placenta with focal marked villous edema ("hydatid degeneration") is seen at the left (arrows). Decidua basalis is hemorrhagic.

FIGURE 21.3. Spontaneous abortion with a fragmented, macerated embryo (arrow). It would previously have been described as a "hematoma mole" (carneous mole). The specimen exhibits a common feature of many early abortions: The amnion is prematurely attached to the chorionic sac.

FIGURE 21.4. Breus' subchorionic tuberos hematoma in a missed abortion at 6 months' gestation. Note the large hematoma to the right of the macerated fetus.

FIGURE 21.5. Hydatidiform swelling of a villus in a spontaneous abortion. Microcystic spaces develop in the distended villus. Note the trophoblastic hypoplasia and focal necrosis. H&E  $\times 160$ .

tous appearance of these villi), in only 6.9% was the hydatid change excessive, in contrast to the 41% found in spontaneously aborted specimens. Jurkovic and Muzelak (1970) observed focal hydatid changes in 21% of legal abortions, and in 2% it was diffusely distributed. Fibrosis was seen in 4.4%; other, nonspecific changes were less frequently identified. These authors emphasized that the frequency of pathologic findings demands more careful scrutiny of these specimens than is usually done. Abortions with hydatid changes had significantly more aneuploidies, as identified by flow cytometry, than was the case in nonhydropic abortuses (Fukunaga et al., 1993). A study of van Lijnschoten et al. (1994) sought to differentiate histologic features of induced from spontaneous abortions. The spontaneous abortuses had smaller villi with some hyalinization and fewer vessels. Moreover, the trophoblast was less hyperplastic. Because many villi are degenerating in specimens from spontaneous abortion, there is often much finely granular mineralization (calcification) along the trophoblastic basement membrane. We presume that it is accumulated because the usually avid calcium transport of trophoblast continues even after villous circulation has ceased.

Fujikura et al. (1971) also compared spontaneous with induced abortion specimens. They pointed out that the hydropic changes found in normal (induced) abortuses is primarily a feature of villi in the chorion laeve, where the villi are expected to undergo degenerative changes. Thus, the sampling site is of importance when such specimens are compared. In their analysis, the number of villi also did not differ in the two groups, and therefore reduced villous growth cannot be held responsible for abortion. The first ultrastructural studies of aborted specimens were presented by Herbst and Multier (1971). They depicted microvillous hypoplasia, lacunar spaces, and enlarged endoplasmic reticulum of the syncytium, as well as villous fibrosis. No specific and constant changes were described that characterized abortion specimens. The newer techniques to demonstrate programmed cell death (apoptosis) were employed to study placentas from patients with labor and in sectioned placentas by Thiet et al. (1995), and they were also used by Miller et al. (1996) and Lea et al. (1997b) to compare spontaneous and induced abortions. Although DNA laddering was observed in all specimens, there was no significant difference between the groups. Apoptosis occurs normally in trophoblast and stromal cells of the human placenta and it increases with gestational age (Smith et al., 1997a, 2000). It is also known, however, that apoptosis is much increased in the syncytiotrophoblast of placentas associated with intrauterine growth restriction (IUGR) (Smith et al., 1997b). Whether this is the result of hypoxia or a reason for the IUGR needs to be ascertained in the future; a beginning was made in the review by Jauniaux and Burton (2005).

All of the placental alterations described so far are relatively nonspecific. They are also not uniformly present, and many (e.g., the hydatid changes) may be the sequelae of embryonic death. The reason for the preponderance of hydatid change in aborted specimens is not fully understood. It is generally believed that, following fetal death, the trophoblast continues to transport water from the intervillous space into the villi, whence it cannot be removed by an absent fetal circulation; hence the villi enlarge. This explanation is probably too facile for a complex process, especially because fibrotic villi with intact trophoblastic cover also exist.

The comparison of chromosomally abnormal with euploid abortion material produced more insights. Singh and Carr (1967) made the first efforts to identify morphologic features of the aborted specimens and related them to cytogenetic findings, but Philippe (1986), collaborating with Boué (Philippe & Boué, 1969), has probably investigated this issue in more detail than most pathologists. These authors' observations and those by some other investigators (Honoré et al., 1976; Ornoy et al., 1981; Byrne et al., 1985; Göcke et al., 1985) allowed some subdivision of abortion specimens into major categories. Indeed, some of these investigators have gone so far as to suggest that many pathologic changes are so characteristic that they enable chromosomal diagnosis from the morphologic findings of the villous tissue alone. Others could not find a good correlation between cytogenetic findings and morphology (Rehder et al., 1989; Horn et al., 1991). Redline et al. (1998) examined the proliferative extent of trophoblast (and some other features) in specimens from spontaneous abortions that were also successfully karyotyped. An increase in trophoblastic proliferation was seen in trisomic abortuses, especially in trisomy 7 and 15. Much the same applies to molar or abortion material with significant hydatid change.

A group of investigators from Europe and Australia has analyzed the potential error in the diagnosis of molar (hydatid) specimens made by several observers (Howat et al., 1993). They took 50 molar abortion specimens of different types and sent them for independent assessment to seven colleagues, two with a special interest in gynecologic pathology. Interested readers can find the details in the article, but suffice it to say here that the experts and regular diagnostic pathologists were unable to specifically label a given microscopic appearance with confidence. Especially, they were not able to reliably distinguish complete moles from partial moles, and partial hydatidiform moles could not be reliably differentiated from non-molar abortion material. The authors found that reliable histopathologic criteria do not exist for this differential diagnosis. We agree with this interpretation of their pathologic findings. Indeed, Rehder and her colleagues (1989) were unable to differentiate structural findings of aneuploid abortuses from those of euploid material. It is

true that, generally, the placentas of spontaneous abortions are abnormally small and too thin. When examined by dissecting microscopy, their villous ramification is decreased and hydropic degeneration is visible in some (Honoré et al., 1989; Shepard et al., 1989b). More extensive data provided by Shepard et al. (1989c) showed that placentas of trisomy 18 fetuses were smaller, and some trisomy 13 placentas had low weights. In the placentas with triploidy, the placental weights correlated, in part at least, with their chromosomal contribution. In conformity with the findings of Jacobs et al. (1982), those triploids whose extra chromosome set was acquired from the mother were smaller, and when two paternal sets were present, the placentas were larger or hydropic. One might have postulated that anembryonic but nonmolar spontaneous abortion specimens have a genetic similarity to complete hydatidiform moles. A specific study directed to elucidate this point came from Henderson et al. (1991), who studied 14 such specimens with locus-specific minisatellite probes and showed that these anembryonic placentas possessed both maternal and paternal genomes. They were thus not androgenetic as are the hydatidiform moles. A succinct appraisal of the current dilemma in the differential diagnosis of general abortion material for histopathologists was provided by Fox (1993). He reviewed all the relevant publications and concluded that precise histopathologic classification is a "valueless exercise." Cytogenetic study and flow cytometry are now needed for more precision.

## Summary of Placental Findings in Chromosomally Defined Abortions

### Trisomies

For historical reasons only, the usage trisomy C, D, E, and so on is employed here. Because usually the exact chromosome involved in the trisomy is not immediately identified, we employ this grouping as merely indicating that these elements belong to the major subgroups of chromosomes so designated.

### Trisomy E (16–18)

Trisomy 16 is one of the commonest cytogenetic anomalies found in spontaneous abortion material (Fig. 21.6). In general, the embryo is absent and the chorionic cavity is empty and small. Anembryonic gestations may be confused with other abnormal gestational products, and it is for that reason that, as mentioned earlier, Henderson et al. (1991) had examined the genetic makeup of anembryonic specimens. Trisomy 16 was one of the results. Importantly, these embryo-deficient abortuses had maternal and paternal genetic reasons for the extra chromosome. Most trisomy 16 abortuses constitute the typical blighted ovum, the *Windei* of the German literature. The villous growth is reduced, the trophoblast is hypoplastic, and the villi are usually avascular and some are hydropic (Vernof et al., 1992). Enlarged cytotrophoblastic giant cells (see

FIGURE 21.6. Trisomy 16, the commonest trisomy of spontaneous abortions. Giemsa-banded karyotype. (Courtesy of Dr. M. Bogart, Honolulu.)

FIGURE 21.7. Spontaneous abortus at 17 weeks of 41-year-old woman, trisomy 13 (cleft lip, polydactyly, renal cysts). Scalloping of villi and trophoblastic inclusions. H&E  $\times 250$ .

below) are found in the stroma of up to 30% of villi. Discrepancies of trisomy 16 are frequent in cytogenetic assessment of villi and amniotic fluid. Mosaicism is common. This topic was extensively reviewed by Benn (1998) but without further consideration of placental morphology. Sebire et al. (2000) found in ongoing gestations with trisomy 18 increased trophoblastic proliferation by using a specific antibody to the Ki-67 antigen, and they deduced from this an increased cell turnover.

#### *Trisomy C (6–12)*

Abortions with this genotype have a variable morphology, and the placenta is less mature than expected for gestational age. Giant villous trophoblast cells are found in 40%.

#### *Trisomy D (13–15)*

This chromosome anomaly exhibits variable placental maturation and reduced villous vasculature, and is also

reported to contain giant cytotrophoblast in 50% of villi. In our review, this is uncommon, however. Occasionally, markedly hydropic villi exist, and scalloping as well as trophoblastic inclusions may occur (Fig. 21.7). Although these changes are not invariable, they may be similar to what is often believed to be typical for partial moles (Fig. 21.8). The embryo frequently has facial and other anomalies.

#### *Other Trisomies and Related Errors*

There are even fewer characteristic patterns of the placentas of other trisomies; Zerres et al. (1988), however, described hydatid swelling of villi in four cases of trisomy 22. The villi also had vascularization. One of their cases was terminated at 36 weeks' gestation; it had fewer villous abnormalities. Honoré et al. (1974) described significant molar changes, including atypical trophoblastic proliferation in the placenta of trisomy 2, and trisomy 22 was found in the placenta of a severely growth-restricted infant by Stioui et al. (1989). Roberts et al. (2000) sug-

FIGURE 21.8. Partial hydatidiform mole in triploidy (69,XXX). Most villi have hydatid enlargement but are attached to a chorionic sac. A chorionic cavity would not be expected in a true mole.

FIGURE 21.9. Partial molar degeneration in triploidy (69,XXY). Many villi are not hydropic.

gested that trisomy 21 placentas had more frequently two-layered trophoblastic surface, and more capillaries and nucleated red blood cells (NRBCs). In trisomy 18 and 13, more basophilic “stippling” (calcification) was found along the basement membrane. It may also be of interest to note that the first microarray study of placentas has been done. Gross et al. (2002) used samples of trisomy 21 placentas and controls for this analysis, and found that there is overexpression of two expressed sequence tags in this study when compared with normal controls. Rakheja et al. (2004) described scalloping of villi and “pseudoinclusions” of trophoblast in an abortus with a long arm deletion of chromosome 18.

Tetrasomy 12 is a well-recognized chromosomal error with usually lethal anomalies (e.g., Shivashankar et al., 1988). In a typical case we saw with similar malformations and neonatal demise to those in the case described in detail by these authors, the placenta was essentially normal. Because of associated preeclampsia there were

infarcts but neither placenta (450 g) nor neonate (3390 g) were growth-restricted. The villi were normally constructed, and the cord was 37 cm in length. In neonatal lymphocyte cultures the abnormal cells were quickly replaced by a population of 46,XX cells, whereas early fibroblast cultures were tetrasomic. Later cultures, again, began to be overgrown by 46,XX cells.

## Polyploidies

### *Triploidy*

The triploidy genotype is discussed in greater detail in the discussion of partial moles in Chapter 22. Macroscopically, the placentas of triploids are frequently at least partially molar (Figs. 21.8 and 21.9), but this depends largely on the origin of the extra set of chromosomes. It is the general finding that, when an extra **paternal** set is present, the placenta has molar change and a severely

FIGURE 21.10. Triploid abortus with macrocystic villous hydropic change at bottom left (C) intermixed with small villi above. This picture is typical of a partial mole. Numerous trophoblastic inclusions are seen at arrows and at right. They come about by infolding, as seen at the white arrow. H&E  $\times 64$  (left);  $\times 240$  (right).

FIGURE 21.11. Two enlarged villi in a triploid abortus. One (left) is hypercellular, with faintly visible remnants of former fetal vessels; the other is hydropic. H&E  $\times 160$ .

abnormal or absent embryo; when an extra **maternal** set is involved, then the embryo is better formed, has some characteristic anomalous features such as digital fusion, and the placenta is less molar or not at all hydropic. Also, the embryos, when present, are too small for the expected age. Some villi have microscopic cavities (lacunae) (Fig. 21.10), and others may be broken or they are compacted, with an increased cellularity (Fig. 21.11); the trophoblast is variably hypoplastic or moderately proliferated. There is characteristic “infolding” (scalloping) of trophoblast into the villi, with trophoblastic nests occurring seemingly isolated in the villous stroma (Fig. 21.10). A Breus’ mole is occasionally found with triploid abortuses as well, although this is commoner in monosomy X. It is important for the pathologist to recognize that the villous edema disappears quickly when the specimen is stored. Numerous abnormalities, such as fusion of some digits or toes, have been described in the fetus of triploid conceptuses (Rehder & Gropp, 1971; Ornoy et al., 1978; Moen et al., 1984), but frequently the embryos are nodular and degenerating (Geisler et al., 1972). They may have a single umbilical artery (Kulazenko & Kulazenko, 1976), as is the case with many other spontaneous abortus specimens. Triploid fetuses rarely survive as long as the 10-month-old child described by Sherard et al. (1986). As expected, the extra set of chromosomes in that patient was of maternal origin. Digyny is much commoner in triploids than is diandry (McFadden et al., 1994) and was also present in the 2500-g triploid fetus who survived for 20 days (Puvabanditsin et al., 2004). The latter reviewed previous reports of live births, suggested a frequency of triploidy of 2%, and termination occurring usually before 24 weeks. Triploidy has even been described in an embryo produced by in vitro fertilization (Rosenbusch et al., 1997).

### *Tetraploidy*

Tetraploid abortuses have an empty cavity and voluminous, poorly vascularized villi. They frequently have severe

decidual and villous hemorrhages, and their villi are invariably somewhat cystic. A specimen that we have recently seen had massive hydatid change, but, perhaps because one half of the placenta was supplying a normal diploid female neonate, many villi had normal, perfused blood vessels. We conjecture that this may have been a twin gestation. There is one report, however, of a liveborn tetraploid male at 37 weeks’ gestation (Nakamura et al., 2003). The newborn weighed 1728g, had numerous congenital anomalies, and died shortly after birth. The placenta was small and not hydropic.

### **Monosomy X**

Frequently, only a cord remnant is found in a cavity that is small for gestational age (Fig. 21.12). There are well-developed villous vessels. Intervillous thrombi of the so-called Breus’ mole type are often present (Fig. 21.13). Occasionally, these specimens have a form of amnion nodosum (Fig. 21.14) that may be accompanied by hemosiderin deposits in the membranes. But often they appear to be relatively normal; there are no cystic villi, only villous fibrosis may exist. The embryo may have nuchal hygroma and severe hydrops (Fig. 21.15). Mostello et al. (1989) have reported spontaneous resolution of hygroma and hydrops in serial sonograms. Microscopic examination of the ovaries shows that they are nearly normal up to the second trimester; thereafter, they become depopulated of germinal cells. Of parenthetic interest is the recent study by Barr and Oman-Ganes (2002) that seeks to explain the cause of hydrops in Turner syndrome and the fetuses’ frequent demise in mid-gestation. They examined in great detail the various hypotheses that had been advanced and concluded that hydrops may be related to or due to the myocardial hypoplasia, which they consider to be a primary defect.

The giant cytotrophoblastic cells in villi, discussed above, were initially described by Philippe and Boué (1969). Honoré et al. (1976) suggested that they were

FIGURE 21.12. Monosomy X abortus, with only a cord remnant (arrowhead) present. A small yolk sac remnant is also found. The defects in the chorionic membranes are from cytogenetic sampling. This site is convenient for tissue culture material.

derived from internally delaminating cytotrophoblast. Ornoy et al. (1981) were more cautious in their interpretation of the origin of this cell type but apparently leaned toward the view that the cells are swollen (edematous) stromal cells; they suggested that the origin be clarified by ultrastructural study. We also believe that most of these cells are enlarged Hofbauer cells (Fig. 21.16).

Philippe (1986) suggested that a hallmark of many chromosomally aborted specimens is their growth restriction. Byrne et al. (1985) provided the most comprehensive correlation of fetal phenotype with chromosomal findings. Other studies of fetal morphology in spontaneous abortuses have been published by Bruyere et al. (1987) and Kalousek (1987). The latter investigator correlated chromosomal findings with embryonic phenotype. Ornoy et al. (1981) and Novak et al. (1988) found fre-

quent inflammatory changes of the membranes and villi in their studies, changes not found by us or other investigators, and they are probably unrelated to the chromosomal aberrations. Shepard et al. (1989a) undertook a 20-year analysis of aborted specimens and found that 19% of fetuses had a localized defect. Neural tube defects existed in 3.6%, and recognizable abnormal phenotypes due to chromosomal errors were present in 2.7%. They encountered amnionic bands in four specimens, renal agenesis in two, and facial clefts in 30 of 214 abnormal embryos.

#### INDUCED ABORTIONS

Pregnancies may be terminated legally ("therapeutic" or "induced" abortion) or illegally ("criminal" abortion). There is little difference between the two from a pathologist's point of view, except that the latter

FIGURE 21.13. Breus' mole (subchorionic tuberosus hematoma). No embryo is present. This finding is frequent in monosomy X.

FIGURE 21.14. Microscopic appearance of Figure 21.14. There is old subchorionic, intervillous thrombus in pockets of bulging membranes. The amnion is focally defective and has attached debris. It has been considered as amnion nodosum, but the debris is not squames, as there is no embryo. Often seen with monosomy X. H&E x40.

FIGURE 21.15. Two abortuses with monosomy X. The left embryo (10 weeks) has pronounced hygroma; that on the right is edematous and has hygroma as well. Note the hypoplastic placenta.

FIGURE 21.16. Villus with cytotrophoblastic giant cells in a spontaneous abortion. The much-enlarged cells in the villous core represent enlarged Hofbauer cells, although a suggestion of cytotrophoblast proliferation is seen (arrow). Cystic lacunae are developing in the villus. H&E  $\times 400$ .

FIGURE 21.17. Yolk sac at 5 weeks' gestation, intermixed with primitive villi (left) from a therapeutic abortion. H&E  $\times 64$ .

type is frequently followed by a uterine infection. Induced abortion has been a common cause of maternal mortality in the past, but since the legalization of abortion approximately one fourth of pregnancies in the United States are terminated. The safety of the procedure has increased dramatically, with a markedly reduced maternal mortality (approximately 1.5 in 100,000). A succinct review of legal abortion and its history was provided in an editorial (Anonymous, 1989). Induced abortions are performed by dilatation and curettage (D&C), the use of prostaglandins (with or without the use of cervical laminaria), intraamniotic injection of hypertonic saline or urea solutions, or other means (Palomaki & Little, 1972). The pathologic findings in the aborted fetal/placental specimen differ somewhat for each procedure. The study of therapeutic abortion material is often helpful for an understanding of the normal placental relations. A superb electron microscopic study was thus performed on a previllous ovum, 11 days old, one that had recently implanted (Knoth & Larsen, 1972). In such material, the pathologist may also find microscopic structures with which he or she is not familiar, particularly the early yolk sac. This normal feature of early gestation is shown in Figures 21.17 to 21.19. It is the probable initial site of  $\alpha$ -fetoprotein (AFP) production and hematopoiesis, and may serve in early fetal nutrition (Lockett, 1972). When the pathologist examines histologic material from abortions, often the question is raised about the time of fetal demise. To determine this more accurately, Jacques et al. (2003) studied 36 placentas of known interval between the injection of KCl into the fetus and placental morphology. They concluded that these findings "cannot be used to accurately predict time of death."

When D&C or suction curettage is performed, instrumentation of the cervix and uterus have occasionally led to misplacement of fetal tissues as well as to sporadic uterine perforation (Kaali et al., 1989). Ayers et al. (1971) reported a 3-cm paracervical bony mass containing a fetal skeleton. The original suction curettage had been done 3 months earlier, when the mother was 10 weeks pregnant. (She had suffered symptoms of pulmonary embolism.) Placental and various other fetal tissues were present, including bone. Incompletely removed fetal tissues have been incriminated in causing infertility, as in the 11 cases of residual fetal bones reported by Moon et al. (1997). Dawood and Jarrett (1982) reported uterine retention of fetal bones for 6 years; the authors suggested that this material acted similar to an intrauterine device (IUD), perhaps by inducing endometrial synechiae. Melius and colleagues (1991) found bones in the uterus 13 years and 14 months after abortion. A similar case is shown in Figure 21.20. We have seen a case with maternal death following TAB at 20 weeks' gestation. The uterus was inadvertently perforated and massive intraabdominal hemorrhage occurred. The patient survived for 2 days and died with disseminated intravascular coagulation (DIC) and adult respiratory distress syndrome. Pulmonary emboli contained deported placental villi

FIGURE 21.18. Yolk sac at 6 weeks' gestation with chorionic membrane, carrying a fetal vessel (below). Note the large sinusoids in the yolk sac epithelium filled with erythropoietic cells. H&E  $\times 240$ .

enmeshed in fibrin coagulum (Fig. 21.21). Similarly deported villi are shown to be located in uterine veins (Fig. 21.22) in a patient whose uterus was removed when, during an abortion procedure, the uterus was perforated. Uterine perforations were the topic of a review by Darney et al. (1990). They suggested that errors in estimating the gestational age were common in such cases. Lawson et al. (1990) reviewed fatal pulmonary embolism after legal abortion. They found that 45 patients among 231 maternal deaths were caused by embolism with air, clot, or amniotic fluid. Disseminated intravascular coagulation occurred in 11 patients. But even in spontaneous deliveries, unexpected transport of tissues can take place. Thus, Baergen et al. (1997) found embolization of cerebellar material into lung and placental vessels in

FIGURE 21.19. Same case as in Figure 21.18, yolk sac at 6 weeks' abortion. The tissue is rich in glycogen and has glandular spaces. Endodermal epithelium is inside (above). H&E  $\times 640$ .

FIGURE 21.20. Retained, necrotic fetal bony lamellae in inactive endometrium that also shows mild chronic endometritis. They are remains of an abortion that took place several years ago. These fragments presumably acted as a contraceptive device; they were removed in 1987, and full term delivery ensued in 1989. H&E  $\times 60$ . (Courtesy of Dr. W. Tench, San Diego.)

FIGURE 21.21. Deported villi in uterine vein; this happened during therapeutic abortion curettage. H&E  $\times 160$ .

FIGURE 21.22. Pulmonary embolus following a therapeutic abortion complicated by fatal uterine perforation, abdominal hemorrhage, and disseminated intravascular coagulation. Immature villi are engulfed in a fibrin coagulum. H&E  $\times 160$  (left);  $\times 240$  (right).

FIGURE 21.23. Macroscopic appearance of an immature placenta from a saline-induced abortion. Note the subchorionic hemorrhage and fibrin deposit, and pallor of the placenta. The superficial villi are necrotic; fetal blood is hemolyzed.

a spontaneous delivery at term and reviewed the sparse literature of similar events.

When bougies are used for termination of midtrimester pregnancies, the placentas were found to be entirely normal (Manabe et al., 1971). Suter et al. (1970) found that suction curettage in infected pregnancies was more difficult to complete; the reason was a presumably more adherent placenta.

There are severe placental changes when pregnancies are terminated with intrauterine installation of hypertonic saline, as extensive fetal ion fluxes occur promptly (Anderson & Turnbull, 1968; Frigoletto & Pokoly, 1971). When these are also reflected in the maternal circulation because of accidental injection into the maternal sinusoids, maternal hypernatremia and deaths have ensued (Schulman et al., 1971; Gustavii, 1972). Clostridial infection is another feared complication (Sehgal et al., 1972). Saline-induced terminations are now rarely done; they are performed without general anesthesia. Associated pathologic changes include amnion necrosis and fluid accumulation underneath the amnion. Most importantly, there are coagulation of intervillous blood and focal necrosis underneath the chorionic plate.

These changes were well illustrated in the study of Christie et al. (1966). A placenta from such a termination is shown in Figure 21.23. It has the characteristic band of hemorrhagic necrosis and coagulation underneath the chorionic plate. The villous tissue is typically pale owing to hemolysis of fetal blood. Another detailed study of the placental changes in saline terminations was reported in the dissertation of Gustavii (1973; see also Gustavii & Brunk, 1972). Other authors who have examined the effect of saline installation into the amniotic cavity are Bengtsson and Stormby (1962) and Jaffin et al. (1962). Gustavii found that saline installation into the extramembranous space quickly stripped the membranes from the uterine wall and led to marked sodium fluxes into the amniotic fluid. It caused decidual necrosis and lysis, whereas the trophoblast remained normal. Gustavii regarded the decidua as the "target" in the procedure. Steinberg et al. (1972) observed a febrile reaction after saline termination in about 20% of cases. From negative placental cultures, they deduced that it was rarely caused by infection.

Hospital admissions for septic abortion have decreased significantly since abortion became legal (Stewart & Goldstein, 1971; Seward et al., 1973). In the large Yugoslavian experience with legal abortion (D&C or suction), the maternal mortality was 0.02% and the morbidity 4.29% (Jurukovski, 1969). Similar reports have come from other countries. Kubatova and Trnka (1967) histologically examined the specimens of 100 legal abortions and found that myometrial admixture was more common in D&C (22%) than in suction curettage. Decidual necrosis and inflammation were common, but the villous tissue was usually normal.

The intentional termination of early pregnancies allows an insight into embryogenesis. Nishimura et al. (1968) thus studied the phenotype of 1213 "undamaged" fetuses from therapeutic terminations undertaken by D&C for psychosocial reasons. Fetal death had occurred in 2.39%, most commonly in women with genital bleeding and of slightly older age. The investigators found macroscopic anomalies in 1.15% of these embryos. It is also important to note that no hydatidiform moles were encountered by these investigators in this survey, even though this disease is so much more common in Japan than in this country. This

indicates to us that early moles are not recognized as such; only in their later evolution are the hydropic changes developed that makes the diagnosis feasible. Singh and Carr (1968) also described fetal specimens having anomalies but normal karyotypes; most common were omphaloceles. Several large studies have been undertaken to assess the karyotypes of legally aborted embryos. For instance, Sasaki et al. (1967) examined the chromosomes of 140 such abortion specimens, terminated at an average gestational age of 9.6 weeks of pregnancy. Of the 140 specimens, 133 were normal, three were mosaic, and four had other chromosomal errors (5%). The investigators additionally cited other published surveys. Yamamoto and Watanabe (1979) found a 6.4% incidence of chromosomal errors among 1661 legal abortions before the 12th week of gestation. Of interest again is the therein reported absence of hydatidiform moles, despite the prevalence of moles.

Jewett (1973) reported maternal deaths when saline had been instilled illicitly, and Monrozier (1971), who studied 426 "criminal" abortions, found that 55 (13%) had serious complications, including uterine hemorrhages, perforations, DIC, and life-threatening infections.

FIGURE 21.24. Placental surface in urea termination at 19 weeks' gestation. The large chorionic, fetal vessel is thrombosed, there is much edema in the membranes, and underneath the chorionic plate is a dense accumulation of fibrin, blood clot and some polymorphonuclear leukocytes. H&E  $\times 40$ .

FIGURE 21.25. Placental site from curettings of an incomplete spontaneous abortion. There are foci of decidual necrosis, lymphocyte and macrophage infiltration, and fibrin deposition throughout this former placental implantation site. H&E  $\times 64$ .

In placentas of septic abortions, Studdiford and Douglas (1956) found acute villitis, intervillitis, and bacterial colonies filling the fetal villous capillaries. Because they had elicited no inflammatory reaction in some of the cases, the colonies doubtless grew postmortem, although sepsis must have preceded the deaths.

Segal et al. (1976) studied the placental changes associated with infusion of hypertonic urea solution. They examined 52 placentas and found subchorionic fibrin deposits (similar to those of saline infusion) and swollen Hofbauer cells. These authors indicated that no placental changes occur with hypertonic glucose instillation. It should be cautioned, however, that swollen Hofbauer cells have also been observed in the usual abortions and may thus be nonspecific activation of these macrophages (Matsubara et al., 1998). In our experience, the changes seen in the subchorionic space following urea termination are usually much less severe than when hypertonic saline solutions are used. Accumulations of polymorphonuclear leukocytes are frequent in the subchorionic space as well but not in the fetal vasculature. In other cases there is chorionic vascular obliteration and much the same subchorionic thrombosis as is seen with hypertonic saline (Fig. 21.24). A detailed study of these changes was reported by Babaknia and colleagues (1979).

## Incomplete Abortion

Pathologists are often expected to make the definitive diagnosis of intrauterine pregnancy from curettings of women who are presumed to have sustained an abortion. When villi or syncytiotrophoblast are seen, the diagnosis is obvious, but frequently these elements are not present in the decidual debris that is intermixed with fibrin and hemorrhagic material. The diagnosis of pregnancy is then more difficult and depends on the pathologist's ability to differentiate degenerating decidual changes (which could result from an ectopic pregnancy) from those of intrauterine implantation sites. The decidua basalis at the placental implantation site undergoes characteristic morphologic changes that should be identified in curet-

tings, even in the absence of villi and syncytium, and that serve as a diagnostic clue. These changes include infiltration with fibrin, alterations of decidual blood vessels (physiologic changes; see Chapter 9), and most characteristically, the decidua basalis contains X cells (extravillous trophoblast) at the implantation site. These cells are usually easily recognized in spontaneous abortions, and their presence establishes the presence of placentation at this site. They are larger than decidual cells, do not possess the silver-impregnable cell borders of decidua, have an amphophilic cytoplasm, and are mostly uninucleate. They stain with cytokeratin and antibodies to major basic protein (MPB). In addition, there are frequently some decidual degeneration and inflammatory cell infiltration. The principal microscopic indicators of a placental site are shown in Figures 21.25 and 21.26.

Lichtig et al. (1988) described the vascular component of this decidual change. They believed that it is a pathologic change, and thus they differ from the many authors who have considered the vascular invasion by extravillous trophoblast as physiological. They cited these authors but still preferred a different interpretation. What is important in their contribution is that they addressed the dilemma often faced by the practicing pathologist, and they provided valuable and practical suggestions for the differential diagnosis.

The term **placental polyp** is occasionally applied. It refers to the residuum of placental tissue, either from abortion or, more often, following term pregnancy. A placental polyp is frequently embedded in degenerating blood clot. Its cause may have been a placenta accreta or incompletely aborted placental tissue. Placental remnants can now also be accurately identified by sonography (Tal et al., 1997). This condition is more fully discussed in Chapter 10.

FIGURE 21.26. Placental site of spontaneous abortion, curettings. Note the infiltration with fibrinoid and large placental site giant cells. They are X cells (intermediate trophoblast) and have

infiltrated and altered the blood vessel wall at right. Despite the absence of villi and syncytium, this histologic picture suffices for the diagnosis of placental site. H&E  $\times 260$ .

## Placenta in Chorionic Villus Sampling

Alvarez (1966) first used placental biopsy for differential diagnosis of hydatidiform mole and later for assessment of villous morphology in erythroblastosis, syphilis, and other disorders. Chorionic villus sampling (CVS) was subsequently used to determine fetal sex (Anonymous, 1975), and Kazy et al. (1982) applied chorionic villus sampling to determine fetal genetic disorders. Chorionic villus sampling is now widely used for the prenatal diagnosis of chromosomal and genetic disorders and is undertaken during the first trimester. Some clinicians prefer this method because it allows access to the fetal genotype before performing an amniocentesis is feasible. Chieri and Aldini (1989) used CVS also during the second trimester, and encountered one abortion in 220 patients. Others have preferred early amniocentesis with generally good results (for discussion see Eiben et al., 1997). Similarly, Daniel et al. (1998) found that early amniocentesis is safe and a good alternative to CVS.

Although CVS is generally a safe procedure, it has occasionally caused placental complications, including fetal bleeding (Shulman et al., 1990). Cashner et al. (1987) suggested that great difficulties exist in the precise risk evaluation from CVS because of the general risk of spontaneous abortion in this gestational age group. With a live fetus from an 8- to 12-week gestation, the risk of spontaneous abortion was 2% in their analysis, and it was greater in older women, who are more likely to be sampled. Lippman et al. (1984) estimated the associated spontaneous abortion rates, and were not convinced that CVS is a significant cause of fetal loss. The complications of CVS were followed by sonographic surveillance in 714 patients

studied by Wade and Young (1989). They had a 4.1% “unintended” abortion rate by 20 weeks’ gestation, and it was higher when repeated catheter insertion was necessary. Subchorionic bleeding was witnessed in one patient, with abortion following in 48 hours. Late abortions were “more likely to have in utero death or premature rupture of the membranes.” During CVS, Pozniak et al. (1988) noted sonographically the rapid development of a retro-membranous hematoma that formed from a venous lake. Its expansion ceased spontaneously. Facial hemorrhages in the fetus were demonstrated by fetoscopy during CVS by Quintero et al. (1993).

Occasional cases of septic abortion have followed CVS. Brambati and Varotto (1985), who found bacterial cultures from the cervix of CVS patients to be positive in a large percentage of cases, performed 700 CVS procedures and found acute infection twice. Barela et al. (1986) reported septic shock and renal failure 4 days after CVS at 11.5 weeks’ gestation. Associated endomyometritis ultimately necessitated hysterectomy. Muggah et al. (1987) found degenerated villi with transcervical CVS at 73 days’ gestation. Chorionic villus sampling was repeated 4 days later. The patient experienced fever that disappeared at 12 weeks’ gestation. She miscarried at 16 weeks and was treated for septic shock. Coliform organisms were cultured from the placenta and fetal parts but not from amniotic fluid. Marini et al. (1988) reported septic abortion 10 weeks following CVS. The placenta (at 20 weeks) showed acute chorioamnionitis, but it is doubtful that this event was causally related to the CVS.

In general, CVS does not usually have serious placental sequelae. When we have examined the placentas of patients who have had CVS during the first trimester, no abnormal

findings were apparent. Similar results came from a large multicenter study of 2278 CVS procedures; the findings were compared with the results of amniocentesis in 617 patients. There was only a 0.8% increase of fetal loss in the CVS group (Rhoads et al., 1989). Concern has been expressed over the finding that limb-reduction defects may follow CVS (Firth et al., 1991; Burton et al., 1992). Letters to the editor (1991) in *Lancet* have subsequently examined the issue. In some of these letters, "organized thrombi" were found in fetal stem vessels (Scott, 1991); a vascular etiology was also suggested by Burton et al. (1992). Other reports of a correlation of fetal age at CVS and limb defects comes from Firth et al. (1994) and a collaborative American study (Olney et al., 1994; see also Botto et al., 1996). It is currently felt that the relation may exist principally in the gestationally earlier CVS that has been practiced in Europe, although contrary opinions have been reported (Froster & Jackson, 1996). No limb-reduction defects were identified in the large series by Williams et al. (1992) when CVS was done after 9 weeks.

Most concern about prenatal diagnosis relates to discrepancies of chromosomal findings among results obtained from CVS, amniocentesis, and fetal blood culture. Often the cause is real mosaicism and even chimerism; at other times, pseudomosaicism exists. The differentiation between mosaicism and other causes is important and may be difficult. It was readily accomplished by Falik-Borenstein et al. (1994) because of the presence of XX and XY+9 cells, but they were confined to the placenta and probably represented a vanished twin from superovulation. Some authors have attributed this to the usage of the Chang tissue culture medium (Krawczun et al., 1989); contamination with maternal tissue is another possible cause. The finding of mosaic cell lines has caused much concern in the fetal prenatal assessment, and discrepant results are not always easy to explain. They may reflect the differing origin of cells from the inner cell mass (fetus) or its shell (placental trophoblast), as well as non-disjunctive events taking place in the sometimes prolonged tissue culture. It is essential to understand the handling of the materials from this procedure. Chromosome preparations are feasible from the **direct** analysis of cells that happen to be in division (largely cytotrophoblast) or from cells cultured for several days, representing primarily the connective tissue compartment of the villi. The former cells derive from the "shell" of the blastocyst and, as we will see, mosaic preimplantation embryos have now been identified; these trophoblast cells may not accurately reflect the **fetal** cytogenetic constitution. We have presented elsewhere (Chapter 11) what is known of the derivation of the connective tissue of villi. They are clearly **fetal** cells, rather than **placental** elements, as the placental connective tissue derives from the epiblast of embryo, not the trophoblastic shell (Enders & King, 1988; Bianchi et al., 1993). Thus, one must know which cells are found to be chromosomally abnormal when CVS is done in order

to infer probable fetal genotype. Griffin et al. (1997) analyzed the topic appropriately. They analyzed 691 spontaneous abortions by long-term culture, and 177 with additional short-term mitotic study. Success rates were 82% and 76%, respectively. They believed also that the cultures have had a significant maternal (decidual) contamination, because many more 46,XX cells were found than expected. They caution that results need careful interpretation. An additional aspect of this complex array of prenatal diagnostic measures is that one must be aware of "imprinting" occurring on fetal and placental tissues, and that numerous cases of uniparental disomy are now known to complicate confined placental mosaicism. Imprinting, that is, the transcriptional silencing of a portion of one parental genome, is a reality affecting placentation and many disease states (Tycko, 1994). Presumably it is accomplished by DNA methylation of specific genes (Zuccotti & Monk, 1996). Good evidence has been accumulated that some paternal genes are silenced during embryonic development, whereas maternal genes are silenced in placental development (paternal imprinting). It is an important feature in understanding triploidy and the development of partial hydatidiform moles. The genetic consequences and possible phylogenetic advantages of parental imprinting have been critically examined by Wilkins and Haig (2003), although not from a placentation point of view. Uniparental disomy (UPD), that is, the presence of two chromosomes from one parent, is an occasional finding in growth-restricted newborns (Moore et al., 1997) and appears to be linked to confined placental mosaicism (Bennett et al., 1992). It is postulated to take its origin from a trisomic conceptus with the loss of one trisomic chromosome during cell division, and this may be an additional cause of abortion. A systematic search for UPD in spontaneous abortions by Shaffer et al. (1998) failed to identify any cases.

One of the most interesting cases in this respect has been the finding of trisomy 16 confined to villi, with the ultimate finding of a normal fetal karyotype. Verp et al. (1989) reported such a case; there was a grossly and histologically normal placenta, but it was associated with a growth-restricted fetus. They also referred to a report with a normal stillborn fetus described earlier. These investigators cautioned that the presence of a fetus with an otherwise lethal karyotype in CVS should alert one to the possible confinement of aneuploidy to the placenta. Perhaps the aneuploid placenta functioned less efficiently than a normal organ would. This might have produced the fetal growth restriction they observed. Another interesting case addresses a similar problem. Nonmosaic trisomy 16 was observed by CVS in a pregnancy associated with an apparently normal fetus by Tharapel et al. (1989). Fetus and placenta were found to be normal 46,XX at delivery, but a placental nodule had 46,XX/47,XX,+16 mosaicism. It was inferred that this represented a vanished twin gestation. Regrettably, a histologic study of the nodule was not

undertaken. A similar case of pure trisomy 16 in placenta and normal 46,XY fetus was observed by Vernof et al. (1992) in a severely preeclamptic woman. The neonate was growth restricted but normal. At other times, placenta and fetus were found chromosomally and structurally normal after a nonmosaic trisomy 16 diagnosis from CVS (Sundberg & Smidt-Jensen, 1991). In the large study reported by Rhoads et al. (1989), 1.8% of the samples were correctly diagnosed as being aneuploid. Reports of two specimens (tetraploidy and trisomy 22) were later proved to be false. A study by Stavropoulos et al. (1998) described a molecular study using FISH in a fetus with trisomy 16 placental mosaicism. Cultured placental stroma showed disomy and trisomy 16; amnion was disomic, whereas high levels of trisomy 16 were found in trophoblast and chorion. Only disomy was present in fetal kidney, brain, lung, and cord blood. Remarkably, 26% of fetal oocytes were trisomic, and uniparental maternal disomy was found in fetal lung and adrenal gland. This remarkable finding has profound implications for our future understanding of CVS results and prenatal diagnosis in general.

Not all aneuploidies are due to meiotic errors. Kalousek and Dill (1983) have produced the first good evidence that chromosomal mosaicism is often confined to the placenta (confined placental mosaicism, CPM); they have expanded this concept in many subsequent contributions to the literature. Handyside (1996) reviewed the evidence now accumulating that many preimplantation embryos have a mosaic chromosomal constitution, caused by mitotic non-disjunction. In a relevant review, Kalousek and Barrett (1994; Kalousek, 2001) found it most likely that, in many cases, the embryo had originally been trisomic as well. Regrettably, there is not yet much direct correlation with placental phenotype (e.g., pathologic features) in the various types of CPM that have been described. DeLozier-Blanchet et al. (1993) suggested that the chromosomally abnormal areas of villous biopsies show structural pathologic features, but have not yet elaborated further. It would appear, however, that CPM is found more frequently in unexplained stillbirths. Its elucidation has certainly made the interpretation of some chromosomal errors in CVS more difficult. Phillips et al. (1996) found that approximately 10% of gestations with CPM have fetal cytogenetic abnormalities. As indicated earlier, Falik-Borenstein et al. (1994) found two cell lines in CVS, and because of their different sex chromosomes (46,XX and 47,XT,+9) interpreted this as confined placental chimerism. In a study of CPM of growth-restricted fetuses and placentas, Wilkins-Haug et al. (1995) found it three times more commonly with IUGR. All neonates had normal blood karyotypes, their placentas were smaller but not histologically abnormal. Breed et al. (1986) found a deletion of chromosome 16 in a CVS specimen but a normal fetal karyotype. The chorionic tissue was later found to be mosaic. Brandenburg et al. (1996) found nonmosaic trisomy 16 in CVS (euploid

fetuses) and found all pregnancies to have bad outcomes. Verjaal et al. (1987) reported six discrepant results and cited many other such inconsistencies from the literature. Schulze et al. (1987) found two cases of CVS with mosaic trisomic cells in which the aborted fetuses were euploid, and Vernof et al. (1992) had another. Cheung et al. (1987) suggested that direct preparations of extended chromosomes be made from multiple villi in order to ascertain mosaicism that is confined to the placenta. Some investigators have argued that such mosaicism, detected at CVS and amniotic fluid study, should be followed by fetal blood karyotyping. They have suggested that it usually would reveal fetal euploidy, but Kaffe et al. (1988) confirmed the mosaicism found earlier in amniotic fluid cells. Thus, mosaicism is not always confined to the placenta. It is of interest here that Kalousek and McGillivray (1987) found that all surviving fetuses with trisomy 13 and trisomy 18 had placental karyotype mosaicism. Subsequently, this finding was extended to terminated pregnancies with these trisomies (Kalousek et al., 1989). The mosaicism was confined to cytotrophoblast and was not found in villous stroma, chorion, or amnion. Moreover, no such mosaicism was found in fetuses with trisomy 21. The suggestion is that trisomies with mosaic (aneuploid/diploid) placentas have a better chance of reaching maturity than those with truly trisomic placentas. A large review of the San Francisco experience with CVS comes from Goldberg and Wohlferd (1997). They found an incidence of 1.3%, and in 20% it was confirmed in the fetus, but neonatal outcome was normal for all fetuses with mosaic placentas.

Villous tissue is useful for structural and genetic studies. Besley et al. (1988) diagnosed Gaucher's disease (and trisomy 21) from deficiency of  $\beta$ -glucosidase in aspirated villi. We had the opportunity to examine tissues of a fetus that was diagnosed by amniotic fluid analysis as having Hunter's syndrome (mucopolysaccharidosis II, iduronate sulfatase deficiency). Although some inclusions were present in the liver, the spinal cord showed striking abnormalities. Ultrastructural analysis of the placenta was normal. Further discussion of the identification of fetal storage disorders with CVS is found in Chapter 18.

Cytogenetic analysis is also now feasible from trophoblast shed into the cervical canal. These are collected by cytobrush (Kingdom et al., 1995) or by irrigation (Bahado-Singh et al., 1995). The cells recovered are mainly syncytiotrophoblast from which DNA can be recovered or on which FISH can be done for specific chromosomes. Adinolfi et al. (1993) diagnosed trisomy 18 in nucleated cells from cervical flushes.

Fetal cells may enter the maternal circulation in sufficient numbers to allow chromosomal diagnosis by aspiration of maternal blood. Lo et al. (1990) identified Y-specific sequences, but Holzgreve et al. (1990) as well as Gänshirt-Ahlert et al. (1992) were not convinced. Kao et al. (1992) were more successful in positively identifying Y-chromo-

some-specific genes; Elias et al. (1992) used hybridization with chromosome 21-specific probes to identify fetal trisomy 21, and Sekizawa et al. (1996) were able to determine fetal RhD genotype from a single NRBC so recovered. The fetal cells in the maternal circulation were tentatively identified by Suzumori et al. (1992) as being red blood cells contaminating the maternal blood. This new method is still under study to enhance a less invasive fetal diagnosis. It relies on sorting fetal cells with flow cytometry, using antibodies and studying the DNA after the use of PCR. Enrichment of the sample is variably handled, but magnetic sorting seems to be the least destructive method for the cells (e.g., van Wijk et al., 1996). Others (Takabayashi et al., 1995) used micromanipulators successfully for isolation of fetal NRBCs from maternal blood. A symposium held to address these issues should be consulted for details (Simpson and Elias, 1994). Fetal chromosome determination from these cells, employing FISH for five different chromosomes, has been elegantly demonstrated by Bischoff et al. (1998). The most current studies employ circulating DNA in maternal blood from which Y-sequences from male fetuses can be recovered (Lo et al., 1997). Although one might think that this signal comes from perhaps degrading and deported syncytial cells, Smid et al. (1997) found the amount of free fetal DNA to decrease with advancing gestation, and suggested its derivation from NRBCs. Fetal RhD typing from free DNA in maternal plasma was demonstrated in the report by Gautier et al. (2005), but Moise in an editorial of the same journal emphasized that it is not routinely used in the United States, although it is commonly done in Europe.

## Trisomic Placentas

There are few specific findings that truly characterize a delivered placenta with trisomy, but many types of abnormality have been found sporadically. Thus, the incidence

of single umbilical artery (SUA) is higher. Hecht (1963) reported five cases of trisomy 18 and found that the associated placentas were unusually small. Histologically, one of his specimens showed markedly increased fibrin deposits, syncytial knotting, and infarcts. Similar findings were reported by Matayoshi et al. (1977). Rochelson and colleagues (1990) studied the placentas of 18 trisomic fetuses with quantitative morphometry, using appropriate controls. Doppler analysis of umbilical arterial blood flow had been performed in 10 of them. They found that the placentas had a "significant reduction in small muscular artery count and small muscular artery/villus ratio," which correlated with abnormal Doppler waveforms. A quantitative study of normal and chromosomally abnormal placentas between 18 and 23 weeks' gestation was reported by Kuhlmann et al. (1990). They found no differences in fetal and placental weights but a significant decrease in small muscular arteries and total vessel counts was seen in the aneuploids. Aside from smaller size, we have noted an increase in syncytial knots in trisomy 18 (Fig. 21.27), increased cellularity of villous stroma (Fig. 21.28), or vascular abnormalities. The latter were either old occlusions or fresh thromboses of surface and umbilical cord vessels (see Fig. 21.30). Villitis of unknown etiology (VUE; Chapter 20) was found in another case, but its relation to trisomy 18 may be spurious. In one case of trisomy 18 associated with many abnormalities of fetal development, the small placenta had numerous cysts scattered throughout. They were composed of large villi with cisternae (see Fig. 21.31). Although this appearance was very different from that of the partial moles in triploidy, this morphology certainly is not characteristic for or diagnostic of trisomy 18. In trisomy 13, the placenta is also frequently smaller and more often has SUA; the villi are frequently dysmature and sometimes had trophoblastic inclusions (Figs. 21.29 and 21.32). We have the impression that the villi may also have deficient capillarization. The relation of SUA to

FIGURE 21.27. Villi of immature placenta (28 weeks' gestation) of a growth-restricted (370-g) stillborn fetus with trisomy 18. There is markedly increased syncytial knotting despite the absence of preeclampsia. Villi lack fetal vessels because of fetal demise, but many have hyalinized centers. H&E  $\times 64$ .

FIGURE 21.28. Other areas of the trisomy 18 premature placenta shown in Figure 21.27. Note the marked increase in villous stromal cells. H&E  $\times 160$ .

chromosome errors has been explored by Saller et al. (1990) in 109 chromosomally abnormal pregnancies, with 53 cords identified. Six single umbilical arteries were found (two of nine trisomy 18; two of six with trisomy 13; two in other cytogenetic errors). Quantitative studies, especially combined with assessment of SUA, have not been done. Trisomy 21 is not accompanied by characteristic pathologic changes in the placenta. Kouvalainen and Österlund (1967) found a somewhat enlarged placental weight in trisomy 21 and suggested that it may “be a reflection of an immunologic reaction of the mother against her incompatible fetus.” Qureshi et al. (1994) found an increased number of irregular villi (“dysmature

villi”) and some villous hypovascularity in trisomy 21 placentas.

#### CHEMICAL MARKERS AND TRISOMY

Steier et al. (1986) evaluated the amount of hCG in the blood and uterine contents of women with legal abortions, spontaneous abortions, and ectopic pregnancies. They found identical values in the first group, but in the other two groups the uterine levels were significantly higher than those obtained from the peripheral circulation. When Bogart et al. (1987) measured hCG, the  $\alpha$ -subunit levels of hCG, and AFP in serum of pregnancies with chromosomally normal and abnormal conceptuses, they found that 56% of the abnormal gestations had elevated gonadotropin levels beyond 18 weeks’ gestation (1.35% of normals). Elevated  $\alpha$ -subunit levels were found in 28% of abnormal pregnancies

FIGURE 21.29. Other areas of the trisomy 18 premature placenta shown in Figure 21.28. Note the marked increase in villous stromal cells. H&E  $\times 160$ .

FIGURE 21.30. Umbilical vessels of a placenta with trisomy 18, showing thrombosis, hemorrhage into the vascular wall, and irregular thickening of the vessel wall. H&E  $\times 60$ .

FIGURE 21.31. Cross sections through placenta of trisomy 18 stillbirth. The cysts are composed of enlarged villi; the fetus had numerous anomalies, aside from growth retardation.

FIGURE 21.32. Placental villi in trisomy 13 at 27 weeks' gestation. Villi are irregularly matured. Some are edematous, with capillary ectasia, and others are excessively small with deficient vascularization. H&E  $\times 160$ .

FIGURE 21.33. Fetal demise due to a tight, true knot in the umbilical cord, followed by abortion at 10 weeks' gestation.

and in none of the normals. The authors then suggested that these findings may be useful for screening procedures; they are now universally undertaken. In a later study, Bogart et al. (1989) examined maternal sera for these hormones in earlier pregnancies and found that aneuploid fetuses did not deviate from the normal controls, and their earlier findings were confirmed. There is still no satisfactory explanation for these and other deranged chemical markers, such as free  $\beta$ -hCG and dimeric inhibin A (Wenstrom et al., 1997). The importance of adequate monitoring was highlighted by the danger of overlooking an ectopic abortion when a therapeutic abortion is undertaken; three fatal cases of this complication were reported by Li and Smialek (1993).

### Other Findings

There are many other causes of spontaneous abortion than the genetic abnormalities just described. Among these there are amnionic adhesions (Chapter 11), infections (Chapter 20), knots in the umbilical cord (Fig. 21.33) and excessive umbilical cord twists (Chapter 12). The pathologist is urged to undertake microscopic study of even macerated fetuses. Frequently unexpected features are found, for example, cytomegalovirus infection that cannot be anticipated from the history or gross morphology. Fetal and maternal deaths are more likely to occur in women using IUDs, especially the formerly used Dalkon Shield (Cates et al., 1976). We have found in the placenta of a spontaneous abortion specimen large numbers of Hofbauer cells whose cytoplasm contained granular accumulations that resembled Russell bodies, but they were not plasma cells (Fig. 21.34). Their presence remains an unresolved mystery.

## Recurrent or Habitual Abortion

Habitual abortion has been variously defined. Wall and Hertig (1948) considered it a "condition in which a woman had two or more consecutive abortions." They examined 100 such patients and observed that the same pathologic findings were made in 58% of their cases. Of them, 43% were considered to result from ovular factors and 15% from other maternal factors. A comprehensive review of this topic has been made by Gant (1989). He lamented not only that this entity has been differently defined but also that other aspects of nomenclature hinder precise analysis. Stirrat (1990a), in an extensive analysis of recurrent abortion, felt that the definition should be three or more spontaneous abortions because after two mishaps the chance of successful pregnancy was 80%. As indicated earlier, some recent insights have been gained into oocyte maturation and possible reasons for recurrent spontaneous abortions. For instance, because of the labo-

FIGURE 21.34. Villi of a spontaneous abortion with accumulation of a large number of granular, proteinaceous Hofbauer cell inclusions, whose origin remained obscure. H&E  $\times 160$  (left);  $\times 600$  (right).

rious efforts involved in routine karyotyping, Daniely et al. (1998) have shown that by genomic hybridization study, they were able to detect trisomies, translocations, and monosomies; 48% of their samples from recurrent abortions were abnormal. In a later study, however, the same group used cytogenetics and banding for this purpose and found 29% chromosomal errors (Carp et al., 2001). They then studied the mothers and found an increased frequency of aneuploid cell that suggested to them “mitotic instability” that remained unexplained (Daniely et al., 2001). An interesting editorial by Lockwood (2000) reviews much additional investigation (e.g., cannabis metabolism in spontaneous abortion) and draws attention to a study by Zhang et al. (1999). These investigators transferred the germinal vesicles of oocytes from older women into enucleated eggs of younger age and found that the maturation proceeded more successfully than when no transfer was done. Related studies of chromosomes obtained from in vitro fertilization studies by Simon et al. (1998) had shown that those obtained from older patients had more chromosomal errors. These are probably some of the reasons for the recently more widely practiced preimplantation genetics, which seeks to avoid implanting chromosomally abnormal embryos or those afflicted with single gene mutations. The topic has been reviewed by Sermon et al. (2004) and Sampson et al. (2004); it is beyond the scope of this chapter. The prenatal diagnosis of X-linked diseases by the study of male cells from maternal blood is currently under active study (Costa et al., 2002; Bérout et al., 2003; Kilpatrick et al., 2004).

Several distinct types of recurrent abortion exist, the known etiologies vary widely, and many causes are either poorly understood or overrated (Stirrat, 1990b). Infectious causes are discussed in Chapter 20; chronic debilitating disease, for example, lupus erythematosus, maternal heart disease, endocrine disorders, and nephritis, are discussed in Chapter 19; recurrent villitis of unknown etiology (VUE; Chapter 20), and maternal floor infarction (MFI; Chapter 9), constitute another group. The relation of substance abuse to spontaneous abortion and to abruptio placentae is difficult to evaluate, especially the possible contribution of maternal smoking. Many patients who smoke or use various toxic substances additionally consume alcohol, have various infections, and are prone to suffer misuse and trauma. Although they probably do not make up a large segment of repetitive abortions, they form a substantial aspect of polemics in medicine. Direct studies are few; most are epidemiologic correlations that seem to establish a connection between these agencies and abortion (Ness et al., 1999). Studies suggest that increased levels of tumor necrosis factor (TNF) may play an etiologic role (Mallmann et al., 1991; Shaarawy and Nagui, 1997). Lea et al. (1997a), however, found that recurrent abortions are characterized by a decrease in the expres-

sion of TNF- $\alpha$  in syncytiotrophoblast, in contrast to its normal expression in random spontaneous abortion specimens. Doss and colleagues (1995) reported on 10 cases of recurrent abortions with massive, repetitive chronic intervillitis and excess fibrin deposits. Chronic villitis was present in some, but not all, of these placentas. The intervillous cellular infiltrate consisted of predominantly leukocyte common antigen (LCA) and CD68-positive cells, suggesting an immunologic origin of the abortive event.

Parental chromosome aberrations and some immunologic errors associated with placentation are other well-studied causes of recurrent abortion and they need special consideration here. Occasionally, a balanced chromosomal translocations of one parent has been the cause of habitual abortion. Granat et al. (1981) described a 22/22 translocation in a man whose wife had had six consecutive abortions. All of the specimens had been early, partially necrotic, and incomplete missed abortions. As is usual, the presumably aneuploid conceptuses were not studied chromosomally. The authors reviewed previous studies of similar case material but with different cytogenetic errors. Their experience led them to urge physicians that, in couples with recurrent abortions, the mother *and* her husband be examined cytogenetically. Simpson et al. (1989), who studied 342 women and 297 men with more than one first-trimester miscarriage, found that parental translocations were not a common cause of recurrent spontaneous abortions. Such chromosomal errors were more frequent only when anomalies and other reproductive failures were combined. Smith and Gaha (1990) found an appreciable incidence of translocation carriers in a large study of recurrent abortion families. There were 15 balanced reciprocal translocations and 9 Robertsonian fusions in that population. Table 21.1 reviews some of the large cytogenetic studies of recurrent abortions. There are

TABLE 21.1. Cytogenetic studies of recurrent abortions

Source	Year	No. of families	Error rate (%)	Types of errors
Rosenmann et al.	1977	12	38.4	Variants
Mennuti et al.	1978	34	14.7	Translocations (T)
Heritage et al.	1978	37	8.1	2 T; 1 XXX
Neu et al.	1979	30	3.3	Translocation

Portnoi et al.	1988	1,142	4.8	T, I, others
Hussain et al.	2000	193	7.7	11 T, 2 inversion 2 mosaic
Hogge et al.	2003	517 (28 no growth)	6.2	Not specified, inherited

a number of reasons why studies of this kind are difficult to compare: The methods of analysis differ, the interpretation of chromosomal "variants" is problematic, and aneuploidy is usually only inferred to be the reason for spontaneous abortion as the aborted specimen is virtually never karyotyped. Some recurrent abortions then are caused by parental chromosomal errors; others are due to increasing maternal age with its increased chance of aneuploidy. The morphology of the specimens does not differ from those of other spontaneous abortions. The pathologist can make a contribution to a better understanding of the etiology by requesting cytogenetic evaluation of aborted specimens from recurrent aborters. Lanasa et al. (2001) examined six families with unexplained recurrent abortions, and of these, four had a "highly skewed X inactivation pattern" with selective loss of male conceptions. A novel insight into unexplained recurrent abortions was gained by the study of Lissak et al. (1999). They studied 41 patients with recurrent losses and found in both anembryonic and embryonic gestational specimens a high prevalence of nucleotide substitution (methylenetetrahydrofolate reductase nucleotide 677—cytosine to thymine). Although I (K.B.) have been skeptical of the causative relationship of this enzymatic defect and fetal demise, a recent case makes me reconsider this possibility. This patient with tetrahydrofolate reductase deficiency produced an extremely premature and growth-restricted infant who soon succumbed. Remarkably, the placental surface had large thrombi for which no other explanation could be found. Moreover, one thrombus had central calcifications, testifying to its age.

There is not only considerable disagreement as to whether immunologic disturbances cause abortion, there is even more controversy as to the management of such mothers. Because autoimmune diseases, such as lupus erythematosus, have such a deleterious effect on pregnancy (Scott et al., 1987), it has been suggested that an immunologic mechanism may also be responsible for rejection of the fetal genotype. These considerations could involve specific antibodies, whose actions may be evident in arterial lesions; but such has not often been shown to be the case with the usual habitual abortions. That there are changes in a variety of immune parameters with pregnancy, and perhaps especially with abortions, has been shown by MacLean et al. (1991), who described alterations in T-cell counts (down), WBC (up), mitogen response (up), and interleukin-2 receptors (marked increase in abortion). Parazzini and colleagues (1991) studied 220 women with recurrent abortion and found lupus anticoagulant in 17 and none in the controls. Increased anticardiolipins were present in 19, and they suggested that in at least a portion of such patients immunologic causes may be operative. They did not describe the associated placentas. Kwak et al. (1992) made similar

observations but warned that "what constitutes an autoimmune abnormality in women with recurrent spontaneous abortion is not yet defined or agreed on." Bahar et al. (1993) studied 103 patients with unexplained recurrent abortions in Kuwait and found anticardiolipin antibodies significantly more frequently in this population. It must be noted, however, that antiphospholipid antibodies normally rise in pregnancy, even with in vitro fertilization (Rai & Regan, 1997), and that other studies (Gleicher, 1997) have failed to confirm a definite causal relation to abortion. Bizzaro et al. (2005) have evaluated the prevalence of antiphospholipid and other antibodies in patients with systemic lupus erythematosus (SLE) and in recurrent miscarriages. Their results suggested that elevated anti-annexin V constitutes a definite risk in recurrent pregnancy losses. Other investigators have studied a possible relation of activated protein C resistance to abortion, finding none (Balasch et al., 1997). The complexity of this problem, **thrombophilia**, and the lack of our understanding of fetal/maternal immunologic interactions is further discussed extensively in letters to the editor (1992) of the *New England Journal of Medicine* that address the case-control study of Infante-Rivard et al. (1992). It can also be illustrated by the existence of several large texts that attempt to summarize relevant data (Edwards et al., 1975; Beer & Billingham, 1976; Wegmann et al., 1983; Gill et al., 1987). Despite the large body of investigative data, there are still many areas of uncertainty. It would be inappropriate to itemize all of these findings in a text of placental pathology. Central to the problem is our deficient understanding of the failure by the mother to reject the placental graft. The physiology of this adaptation has been a topic of intense study for many years, and resolution of this paradox is yet to occur. Of the many approaches, the following main positions have been investigated:

1. The mother does not "recognize" the placenta as a foreign genotype perhaps because the trophoblast does not present histocompatibility antigens. Recent studies have examined the differences in major histocompatibility complex (MHC) antigen structure with identification of the human leukocyte antigen (HLA)-G, expressed by young human trophoblast (Kovats et al., 1990; review by Yokoyama, 1997). A complex interaction exists with decidual natural killer (NK) cells that is under investigation and may provide the answer to the nonrejection of placental trophoblast. Suffice it to say that recurrent abortion is not influenced by HLA presentation (Eroglu et al., 1992; see also Hill et al., 1995). From studies of monkey histocompatibility antigens Knapp et al. (1996) concluded that sharing of class I MHC antigens significantly (72%) predicted pregnancy losses.

2. Maternal immune recognition (and rejection) may be intact but thwarted by local (decidual) regulators. The

presence of large numbers of NK cells in the decidua is currently unexplained.

3. Maternal immune cells, normally endowed with properties to reject allogeneic grafts (T-lymphocytes, macrophages) cannot reach the target (because of decidual barriers). Michel et al. (1989) have suggested that the decidual "granular cells" contained smaller granules in repetitive abortion material. For further consideration, see Chapter 9.

Cogent evidence has been provided by immunologic studies that placentation proceeds more advantageously when fetus and mother have maximal histocompatibility differences. It is admitted, however, that inbred lines of mice, having no such dissimilarity, have successful gestations. This species, however, does not possess HLA-G. These studies showed that the circulation of maternal blocking antibodies to paternal (placenta present) antigens prevent rejection. These antibodies can be assayed; they are present in normal pregnancies. Other antibodies (against fetal leukocytes, for instance) can also be detected in maternal sera. That fetal proteins interact with maternal lymphocytes in vitro (suppressing their proliferation) has long been recognized (Olding et al., 1974). Whether this interaction has sequelae in vivo is undecided. Proteins from embryos ("early pregnancy factor") have been shown to modulate immunosuppressive properties (Bose et al., 1989). Most recently, extensive studies on 300 couples with recurrent abortion and 30 control women have shown that a large proportion of the former possess factors in their circulation that are directly toxic to trophoblast and/or embryonic tissues. These authors suggested that this newly recognized cause of recurrent abortion may "involve the 18kd, heat-labile, T-lymphocyte cytokinin interferon gamma" (Hill et al., 1992). The delicate balance between fetal antigens and maternal recognition is further discussed in the comments by Reid (1998), especially with reference to unusual infections that are more common during pregnancy.

Vincent et al. (1998) demonstrated that women with recurrent miscarriage generate increased amounts of thrombin. They found in a study of 86 women with history of recurrent abortion that the thrombin-antithrombin (ATA) complexes were significantly raised and concluded that "thrombosis . . . plays a pivotal role in recurrent miscarriage." Debus and colleagues (1998) investigated the relation of the common factor V Leiden mutation to congenital porencephaly. The resistance to anticoagulation by activated protein C is usually the result of an Arg-to-Gln point mutation in the factor V gene. They found that of 24 patients, 13 had genetic risk factors for thrombosis: Leiden, three; protein C deficiency type I, six; increased lipoprotein a (Lpa), three; protein S deficiency, one. Other papers suggesting a strong relation of thrombophilia to recurrent abortion were reviewed by Younis

(1998). Suffice it to state at this time that hypercoagulability of various inherited types is presumably responsible in a major way for recurrent miscarriage and for fetal thrombotic states. These are only now being investigated with greater efficiency, and the future is likely to bring many new insights.

Because of the desperate wish for children, parents with habitual abortions have tried many immunologic therapeutic interventions, including transfusion and immunization with paternal cells (e.g., Mowbray et al., 1985; McIntyre et al., 1986; Cauchi et al., 1987). Fraser et al. (1993) who reviewed the topic in some detail felt that immunization for recurrent pregnancy loss should be abandoned. Treatment with polyvalent intravenous immunoglobulin has been advocated with some seemingly good result by Mueller-Eckhardt et al. (1991), and intravenous infusion of trophoblast plasma membranes isolated from term placentas was undertaken by Johnson et al. (1988). Some of the many studies have been summarized in the cited reference texts and by Stirrat (1990b). In an effort to circumvent possible cryptic endometrial herpes virus infection, Kundsinn et al. (1987) have used acyclovir to treat women with habitual abortions. It was moderately successful in the small number of cases treated.

Other than the placentas of patients with lupus erythematosus, those of habitual aborters have no distinctive pathologic features. Most emphatically, they do not possess histologic changes of rejection, as seen in other transplanted tissues. Salafia and Burns (1989) have found decidual vasculitis in some such specimens and suggested that it may signal pregnancy loss on an immunologic basis. Still, it is sobering to read that, despite all these new insights, the study of Plouffe et al. (1992) failed to show any improvement of outcome with varied therapy when they compared recurrent abortions in two widely separated time spans (1968–1977 and 1987–1991). Aksel (1992) who reviewed all aspects of reproductive immunologic disease is also cautious in advocating immunotherapy for recurrent abortion.

# Molar Pregnancies

## Hydatidiform Moles and Partial Moles

The term **gestational trophoblastic neoplasia** (GTN) has become popular in recent years, although it comprises entities that are clearly not neoplastic, such as triploid “partial” moles. Others commonly now refer to these entities as gestational trophoblastic disease (GTD). Driscoll (1981), in an excellent review of the morphology of these diseases, strongly favored abandonment of the time-honored term **hydatidiform mole**. Fox (1989) has added fuel to the fire by suggesting the following: “Is it, in fact, justifiable to continue distinguishing complete from partial moles in routine histopathologic practice?” He based this opinion primarily on the exceptional finding of a single case of choriocarcinoma said to have followed a partial hydatidiform mole (PHM) (Looi & Sivaneratnam, 1981). Persisting trophoblastic disease has also been described by Rice et al. (1990). Fox (1997), in analyzing the histologic differences between complete hydatidiform mole (CHM) and PHM, concluded that a degree of subjectivity accompanies these decisions, an opinion with which we strongly agree. Malinowski et al. (1995) go even further by suggesting a continuum to exist from molar degeneration to choriocarcinoma when they suggested the existence of the “sad fetus syndrome,” the association of a fetus with molar or neoplastic conditions. This view is not ours, however. After all, choriocarcinoma is also an occasional sequela of an apparently “normal” gestation, as Fox readily conceded in which there may have been a choriocarcinomatous cell line *ab initio*.

This chapter discusses the typical hydatidiform mole (the CHM), syncytial endometritis, invasive moles (chorioadenoma destruens), “benign metastasizing mole,” the PHM with or without fetus, and ectopic moles. Their terminology is often confusing and imprecisely used, but we do not favor abandonment of the term **hydatidiform mole**. Rather, we implore that it be used more precisely. Choriocarcinoma is discussed in Chapter 23.

Hydatidiform moles are excessively edematous immature placentas, characterized by massive fluid accumulation within the villous parenchyma; this fluid characteristically leads to the formation of microcysts (cisternae or lacunae) within the villi. In general, there is also an absence of fetal blood vessels. When all villi are thus changed, we speak of a “true” or “complete” mole. When only some villi are involved macroscopically, with large portions of the placenta being grossly more or less normal, then the process is called a “partial” mole. The distinction is often difficult, and strict morphologic guidelines are not easily established. This definition rests, however, on the **macroscopic** features alone. It can be supported by subsequent study or not; the gross description defines the denominational entity. To confuse even more, the distinction is often blurred at early gestational ages, during the evolution of the altered placenta. Because choriocarcinoma (chorionepithelioma) so frequently follows the occurrence of a complete hydatidiform mole, all of these entities are now often encompassed by the term **gestational trophoblastic disease**. Several comprehensive books have discussed this group of placental diseases (Smalbraak, 1957; Holland & Hreshchyshyn, 1967; Park, 1971; Goldstein & Berkowitz, 1982; Szulman & Buchsbaum, 1987; as well as the November 1997 issue of *General Diagnostic Pathology*). These volumes discuss the evolution of our understanding of the genetic derivation of moles, the frequently confusing terminology, the clinical features, and the therapy of these entities.

## Hydatidiform Moles

The CHM is a diffusely edematous and enlarged placenta in which the macroscopically enlarged villi generally lack blood vessels and have cistern-like fluid-filled cavities. The villi are connected to one another by thin strands of connective tissue, the former mainstem villi. Intervillous thrombi occur frequently. Although there is usually no embryo or identifiable chorionic cavity in CHM, a few

exceptions have been described (Baergen et al., 1996). The CHM may also occasionally coexist with a normal twin and even triplet pregnancy, but this does not make it a "partial mole." It can be differentiated genetically as well as macroscopically.

The PHM, which is discussed below in greater detail, is macroscopically composed of normal and distended villi, and it is also more often associated with an embryo or remnants thereof. The trophoblast of complete moles is usually, but not always, more abundant than it is in PHM and in normal placentas. In the CHM there is also frequently much nuclear pleomorphism and anaplasia. These cellular abnormalities have given rise to several grading classifications, some of which have endeavored to assign prognostic values. Thus, a hydatidiform mole of grade V was considered to have a greater malignant potential than one to which a grade II designation was attached. Hydatidiform moles usually occur as uterine pregnancies, but they are occasionally also present as ectopics in the fallopian tube (Depypere et al., 1993) and ovary. The trophoblast of moles invades the uterus, much like it does in a placenta increta. When hydatid villi and their trophoblast invade the uterus and destroy a portion of it in the process, then this entity is designated an invasive mole or a chorioadenoma destruens.

Moles have occasionally been observed to occur repetitively, and Parazzini et al. (1991) found that this was much more likely to be the case in patients with CHM. Sand et al. (1984), who reviewed this literature, suggested that it occurred in 0.60% to 2.57% of patients. There were no differences in outcome. Hsu et al. (1963) described five cases of two moles in the same patient; one patient suffered three moles. Johnson (1966) observed a patient with four consecutive moles. We have seen a young African-American woman who had three consecutive complete moles; the last developed into a fatal choriocarcinoma. It is of further interest that this patient conceived these moles with two different husbands. Kronfol et al. (1969) described five patients with repetitive moles and commented on the greater frequency of the condition in the Lebanese population. Patek and Johnson (1978) and Endres (1961) each had a patient with five consecutive hydatidiform moles and no children. Wu (1973) observed a patient with nine consecutive molar pregnancies. Remarkably, all of the moles in the last case lacked Barr bodies, and one was karyotyped as being 46,XY. Although the author speculated on a paternal cause for this repetitive event, normal paternal and maternal karyotypes were found. Semen analysis was refused. Ambrani et al. (1980) reported familial moles in three family trees, but the possible genetic cause was not determined. Parazzini et al. (1984) found two sisters, one with three CHMs and the other with one. La Vecchia et al. (1982) described monozygotic twins, each with molar pregnancy. Most recently, Slim et al. (2005) have analyzed familial moles genetically. They studied a

family in which five women had seven moles, three miscarriages, and three children. Their conclusion was that a previously linked locus to 19q13.4 was not responsible and that other factors modulate the occurrence of moles. An important genetic study of the origin of two choriocarcinomas was undertaken by Osada et al. (1991). They examined the restriction fragment length (RFL) polymorphism of the moles and preceding pregnancies in two patients. In one family the choriocarcinoma could be traced to a previous complete, androgenetic hydatidiform mole, not the two normal pregnancies. In the other patient, however, the tumor derived from the third of three normal pregnancies and carried both parental chromosomal markers. The publication does not provide details whether one or the other genome had a better prognosis. The few similar reports in the literature are referred to by these authors. Since then, Seoud et al. (1995) evaluated the familial recurrent moles (13 moles in the pedigree) of two sisters with moles and found a high degree of unusual lymphocyte antigen histocompatibility. Studies of this kind should probably now be employed to better understand the genetic reasons for molar gestations and to correlate choriocarcinoma with putative precursors. Such an effort is especially important when long time spans separate pregnancy and tumor, or when primary choriocarcinomas of presumably nongestational types are observed, for example, the cervical lesion reported by Ben-Chetrit et al. (1990). We have seen a placenta of a near-term gestation with surviving, normal female infant and a sharp division between a molar portion and normal placental tissue (Fig. 22.1). Flow cytometry on the molar portion showed it to be uniformly tetraploid, and the normal tissue was diploid. DNA was isolated from paraffin-embedded tissue and polymerase chain reaction (PCR) studies were then undertaken. Employing five different markers, all RFLs were uniform, assuring with highest probability the identical genotype of the tissues. There was one chorionic sac and no second cavity or embryonic remnant. Remarkably, many hydatid, tetraploid villi had fetal blood vessels, some atrophied, and others well circulated by the living infant. We interpreted this specimen as having one of two possible origins. Either a focus of placental tissue underwent polyploidization (unlikely), or a monozygotic, monochorionic twin developed as tetraploid fetus (and died), leaving behind the mole. Meanwhile, the other twin's circulation kept perfusing some of the molar villous tissue. Although the gross impression was initially of a partial mole, the studies ruled this out, as did the presence of a normal surviving infant. Follow-up study showed no untoward sequelae (Benirschke et al., 2000). Higashino et al. (1999) described triplets, two normal fetuses (46,XX and 46,XY) and normal placentas and a typical androgenetic mole (46,XY), that were followed by persistent trophoblastic disease. They were totally separate placentas, however, in contrast to the case described by us.

FIGURE 22.1. A: Sharp division of molar (top) and normal placental tissue (bottom) in presumed monozygotic (MZ) twin. Molar tissue is tetraploid, diploid female infant survived. B: Focal intermingling of molar with normal villi. C: Molar vesicle

with atrophying blood vessel. D: Molar villus with intact, perfused fetal blood vessel. Note tetraploid connective tissue of mole. H&E  $\times 16$  (A),  $\times 16$  (B),  $\times 64$  (C),  $\times 160$  (D).

The natural history of recurrent molar disease was discussed by Federschneider et al. (1980) in their presentation of seven patients. They also reviewed the literature and stated that their recurrent cases were more malignant and more often required treatment for residual disease than nonrecurrent moles (see also Rice et al., 1989). Mor-Joseph and his colleagues (1985) reported four recurrent moles following three spontaneous abortions. The moles occurred after clomiphene therapy, as was previously described by Schneider and Waxman (1972). These experiences support the finding by Parazzini et al. (1985) that moles are significantly more common with increasing numbers of spontaneous abortion. An interesting case with three recurrent CHMs was described by Fisher et al. (2000a). All three were biparental (not androgenetic), yet CHMs; moreover, the male partners were two different individuals and two moles were XX, one was XY. This finding has implications for possible in vitro fertilization (IVF) efforts in patients with recurrent moles. Helwani et al. (1999) had also described CHM with biparental origin in the seven (!) moles from two Lebanese sisters. The authors suggested the existence of an autosomal-recessive gene that was responsible. In a subsequent publication, Moglabey et al. (1999) studied members of these two families and identified an aberrant gene on 19q. Most interestingly, Sensi et al. (2000) found in an unrelated Italian family with recurrent moles of biparental nature (!) an abnormality of 19q in two sisters. Fisher et al. (2004b) reviewed the entire topic of recurrent moles (152 pregnancies) and stated that the sequelae were similar to the usual CHMs. It is thought that this abnormal gene is involved in imprinting and thus suppresses the usual influence of the maternal gene, causing enhanced expression of the paternal allele. In this way, a molar phenotype would be expressed even though the mole was biparental. Not only is the genetic derivation of complete moles unusual (most have only paternal chromosomes, that is, are "androgenetic"), but there is great variation in the prevalence of moles in different populations. Asian women, especially Japanese and Filipinas, suffer a much-increased frequency of molar pregnancies. It is further remarkable that hydatidiform moles have been observed only in human pregnancies; only one other primate has exhibited this pathology despite extensive breeding records. This was a mole occurring in a chimpanzee reported by Debyser et al. (1993). This *Pan troglodytes*, while pregnant, died from massive genital hemorrhage and ovarian torsion. The entire uterus was filled with a PHM that had commonly accepted histologic features. Its DNA content was hyperdiploid, possibly triploid, and a degenerated fetus was present. There are rare reports of moles in cows (Folger, 1934), and Drieux and Thiéry (1948) reviewed rare cases described in a cat and dog. These are truly exceptional circumstances and their analogy to human CHM is uncertain. This was the case

until Meinecke et al. (2002) presented their specimen of a typical hydatidiform mole in cattle that was associated with a stillborn male calf. They also reviewed the few previously reported cases of moles in animals. For the first time it was conclusively shown that the 60,XX molar tissue was indeed androgenetic and the co-twin calf was 60,XY. There were rare chimeric cells in the two tissues that derived most likely from the formerly present placental anastomoses, but the term (that includes freemartin) is strictly speaking incorrect, as the normal fetus was male. Apparently there were no sequelae to the cow that delivered the twins. Choriocarcinoma is also exceptionally uncommon in animals, although it has been reported in a rhesus monkeys (Chapter 23).

### Incidence

The exact incidence of hydatidiform moles varies in different populations and it is impossible to ascertain it exactly. An estimate of 1 per 2000 pregnancies is generally cited for the United States (Hertig, 1950). When Grimes (1984) undertook an extensive epidemiologic study of many different populations he found an CHM incidence of 1 in 1000 pregnancies for the general U.S. population. Etiologic factors were not obtained from his investigation. In part, the inability to ascertain a precise incidence is due to the probable confusion of CHM with PHMs, the presumed triploid conceptuses. Undoubtedly also, PHMs have often been counted as CHMs (the presumed androgenetic moles), especially when one reviews the early literature. We know from personal experience that this is still the case. The methodologic problems in ascertaining a true incidence have been dealt with particularly well by Buckley (1987), and the later contribution by di Cintio et al. (1997) is relevant. In their review of the epidemiology of gestational trophoblastic disease they found that the incidence in the U.S. is 108/100,000 pregnancies, whereas in Northern Italy it was only 62/100,000. In Indonesia it was 993/100,000, whereas in China it was 667/100,000 pregnancies. There is then little doubt that vast differences in frequency of CHM and other GTDs exist; CHM is especially common in the populations of Hawaii, the Philippines, and Japan. Table 22.1 summarizes incidence figures derived from several relevant studies. Other tables may be found in these publications and in the books cited. Several authors have provided additional reviews of early incidence figures that add little important information. There is thus a general agreement that the incidence of moles is, at least partially, racially influenced. This phenomenon is not completely explicable by the higher parity and older age of Asian gravidas (Iverson et al., 1959). Das (1938) found moles more commonly in the Indian than the Caucasian population. In an inquiry that distinguishes environmental from racial causes, Natoli and Rashad (1972) observed

TABLE 22.1. Incidence of complete hydatidiform moles in various populations

Country	Author	Year	Time span of the study	Incidence/term gestation
India	Das	1938	108,951 gestations	1: 502
Mexico	Márquez-Monter	1963	1961 gestations	1: 200
Hong Kong	Chun et al.	1964	1953–1961 gestations	1: 242
Sweden	Ringertz	1970	1958–1965 gestations	1: 1560
Singapore	Teoh	1971	1963–1965 gestations	1: 823
Israel	Matalon	1972	1950–1965 gestations	1: 1300
Hawaii	Natoli	1972	1950–1970 gestations	1: 977
Paraguay	Rolon	1977	1960–1969 gestations	1: 4369
Paraguay	Rolon et al.	1990	1970–1982 gestations	1: 3906
Netherlands	Franke	1983a	1978–1980 gestations	1: 2270
Italy	Mazzanti	1986	1979–1982 gestations	1: 1510
England	Bagshawe	1986	1973–1983 gestations	1: 1000 to 1.54:1000

moles much more often in the Japanese and Hawaiian stock, than in Chinese and Caucasian residents of Hawaii; many other examples of racial influences can be found in the cited publications. It must also be recognized that postmenopausal women are not necessarily free from the possibility of conceiving a molar gestation. Over 100 cases of moles past age 50 have been described, and Garcia et al. (2004), who reviewed the topic, even found a 61-year-old woman with this disease. She recovered after evacuation.

These reports all found that the incidence of CHM correlated with race rather than with geography. A review of molar pregnancy suggested also that the traditional clinical picture presented by patients with moles has changed, but that persistent trophoblastic disease has become more common (Soto-Wright et al., 1995). Bracken (1987) undertook a special study of these features and found that the incidence of CHM in Japanese was inexplicably twofold higher than that of Caucasians and Chinese. He stated, “Maternal age is the most consistently demonstrated risk factor; teenagers and, especially, women over age 35 being at increased risk” (see also Bandy et al., 1984).

Maudsley and Robertson (1965), who described the development of a mole in a 52-year-old woman, reviewed the literature of approximately 60 similar cases in older women. Mathieu (1939) made a thorough review of moles and choriocarcinomas and found a 55-year-old woman, emphasizing the dependency on maternal age. Clearly, older maternal age (and somewhat also extremely young age) predisposes to GTDs (di Cintio et al., 1997). The possible influence of the father’s age has also been studied. No relationship was ascertained in most studies, except in that undertaken by La Vecchia et al. (1984), who found a higher incidence in fathers over 45 years, and this predilection was compounded by smoking. Other investigators have not identified smoking as a risk factor. The possible and disputed etiologic role of herbicides is unlikely to be resolved, according to Bracken (1987).

McCorriston (1968) evaluated possible reasons for the higher incidence in particular racial groups of Hawaii and stated that their different food preferences are unlikely etiologic antecedents. This point was further examined in a case-control study from China where no relation to diet was identified by Brinton et al. (1989). Berkowitz et al. (1985a) suggested that vitamin A deficiency may be causally related to molar gestations, and suggested carotene supplements for prevention. There have been no other meaningful concepts that explain the racial differences of CHMs. Indeed, the possibility has been studied that the marked ethnic differences in molar incidence reflect different diets, and possibly other environmental factors might disappear upon immigration to other countries. A key question thus is whether the incidence of CHM in Asians who emigrated to San Francisco and then lived Western lifestyles differs from that of Caucasians. Overstreet (personal communication, 1963) ascertained that, in the immigrant Asian population of San Francisco, the incidence of CHM is 1 per 2000 deliveries, much the same as in Caucasian women. Atrash et al. (1986) similarly ascertained molar pregnancies among 84,318 abortions from different institutions. The incidence of moles was 7.5 per 10,000 pregnancies (1 per 1333). Bracken (1988), however, has criticized this result on methodologic grounds and as being a gross underestimate. Although more moles were found in Chinese, this difference was not significant. African Americans had the same incidence as whites. The only significant correlation occurred with maternal age.

A number of **classifications** of GTDs should be mentioned. The World Health Organization (WHO) recognizes the following scheme (Tavasoli & Devilee, 2003):

Hydatidiform mole  
 Complete mole  
 Partial mole  
 Invasive mole  
 Metastatic mole

### Trophoblastic neoplasms

Choriocarcinoma

Placental site trophoblastic tumor

Epithelioid trophoblastic tumor

### Nonneoplastic, nonmolar trophoblastic lesions

Placental site nodule and plaque

Exaggerated placental site

The International Federation of Gynecology and Obstetrics (FIGO) and the National Institutes of Health (NIH) use different systems for classification, and prognostic scores were assigned by the classification issued from the WHO. These aspects and histologic criteria are well covered by Horn and Bilek (1997).

### Genetics

Ever since Park's early studies (1957), cytogeneticists have known that sex determination of trophoblastic tumors appeared to be impossible. Shorofsky (1960), applying cytometrics, found that nuclei of molar trophoblast had the same parameters as normal trophoblast. Márquez-Monter (1966), using radioautography, showed that the syncytium of molar trophoblast originates from cytotrophoblastic precursors, just as it does in normal villi. With the discovery of the sex chromatin, it became known that most moles possess a Barr body (sex chromatin: the inactivated X chromosome of females) (see Tominaga & Page, 1966; Baggish et al., 1968; Loke, 1969). Early systematic studies by Sasaki et al. (1962) had also shown that most hydatidiform moles possessed an apparently normal female or occasionally male diploid complement. Bourgoïn et al. (1965a,b) also found male and female karyotypes but further observed some aneuploidy in their specimens. They encountered methodologic difficulties in making cell preparations, however. Sajiri Makino and his colleagues in Japan (1964, 1965) ascertained that some apparent hydatidiform moles, now referred to as partial moles, have a triploid chromosomal constitution, an observation that was soon confirmed by Carr (1969). It is now known that triploidy is the karyotype of most PHMs.

The major breakthrough in our understanding of molar pregnancies came when Kajii and Ohama (1977) showed that hydatidiform moles are "androgenetic," that is to say, all molar chromosomes are paternally derived. It is easiest to envisage that this occurs as the result of fertilization of an "empty egg," with subsequent duplication of the haploid spermatozoal complement. That mechanism also explains why moles are almost always 46,XX. If a male-determining spermatozoon with Y chromosome were to fertilize an empty egg, a karyotype of 46,YY would result from such sperm duplication, and this is apparently a lethal cellular condition. It must be mentioned, however, that nobody has shown an "empty egg" as yet in ovaries

or ovulated follicles. Thus, it may be possible that chromosomal or other nuclear abnormalities predispose to the female component's regression. The theoretical aspects of this vexing problem have been discussed at great length by Golubovsky (2003), a paper worth reading as it also attempts to explain twins and chimeras in these products of gestation. Kajii and Ohama karyotyped 20 moles and determined the disposition of the chromosomal Q- and R-band polymorphism. There is sufficient heterogeneity in the normal human chromosome structures that this polymorphism allowed them to ascertain with confidence that, in CHM, these markers were exclusively paternal (Fig. 22.2). These findings were quickly confirmed by Wake et al. (1978a) and Jacobs et al. (1978), and Azuma et al. (1991) showed that the molar mitochondrial DNA has a maternal origin. Many markers are now available for chromosome identification. They extend from the Q and R bands to C bands, shown by fluorescent in situ hybridization (FISH), and they also include the identification of inversions, translocations, and other minor varieties, as shown in Figure 22.2. Since this original description of androgenicity, not only has the concept been amply confirmed, but androgenesis has also been verified by genetic markers, such as homozygosity of polymorphic enzymes (Jacobs et al., 1980) and human leukocyte antigen (HLA) markers (Wake et al., 1978b; Couillin et al., 1985; Goldman-Whol et al., 2001). Interestingly, two of the mothers studied by Kajii and Ohama (1977) had reciprocal translocations of different chromosomes. Similar findings were then made in the later studies of Lawler et al. (1979) and Vejerslev et al. (1987d). This apparent frequency of translocations might initially be assumed to have possible etiologic significance for the creation of an empty egg, but subsequent studies have negated this possibility. Vejerslev et al. (1987d) karyotyped 237 mothers and 217 fathers of CHM as well as 125 mothers and 106 fathers of PHM. "No significant increase in the frequency of translocations . . . was found."

To explain the genesis of moles, it is further hypothesized that molar transformation of the conceptus results from the homozygous concentration of some lethal genes. It is commonly estimated that four or five lethal genes are regularly carried (in the heterozygous state) in normal individuals. When they become homozygous (as they would be in CHM), the duplication of lethal genes causes embryonic death; only the placenta survives, to be transformed into molar vesicles. The notion of an empty egg with fertilization by a 23,X sperm and subsequent chromosomal duplication was supported by the genetic studies of Jacobs et al. (1980). Moreover, experimental investigations in mice indicated that maternal and paternal genomes are essential for normal embryonic and placental development. Paternal genes are apparently especially important for normal placenta formation. It was found that embryos from two female pronuclei (gynogenesis)

FIGURE 22.2. Normal human diploid karyotype, 46,XY, Q-banded (Q = quinacrine). In the normal karyotype, chromosomes may be banded by different techniques. Here, a normal male set is banded with quinacrine stain (Q bands), which allows precise comparison between elements (maternal and paternal). Note that in this male there are differences between the banding pattern of several elements. Various segments do not “match”; they represent normal variations in our chromosomes that are inherited. The following chromosomes differ in this karyotype: No. 1, the right element has additional heterochromatin at the centromere; No. 9, the left element has additional centromeric heterochromatin, and the right chromosome has an inversion; No. 14, there are prominent satellites; No. 15, the right chromosome has a centromeric variant; No. 16, the right chromosome has additional centromeric material; No. 22, the left chromosome has prominent satellites, and the right chromosome has a centromeric variant. It has been possible to show that, in the typical complete hydatidiform mole (CHM), there is only the banding profile of the paternal chromosome set, both elements are exactly alike (Kajii & Ohama, 1977). (Courtesy of Dr. Mark Bogart, Honolulu.)

developed poorly, and particularly their placental membranes were abnormal. The embryos derived from two male pronuclei died very early, but their placentas were reasonably well formed (Surani & Barton, 1983; Barton et al., 1984; Ho et al., 1984). Irregular X-chromosome inactivation inexplicably also occurs in placental membranes of female conceptuses. There is preferential female X-chromosome activity in a variety of cells of the placenta of female fetuses (Tagaki & Sasaki, 1975; Roper et al., 1978; Harrison & Warburton, 1986; Harrison, 1989).

After this definition of androgenesis as the cause of molar development had been clarified, many cytogenetic studies were performed on CHMs and PHMs to further delineate the possible relations of chromosome sets and the possible impact on the prognosis of the various molar conceptions. Tsuji et al. (1981) determined that there is a higher frequency of aneuploidy ( $2n = >46$ ) in the moles from older women, and also in invasive moles and in choriocarcinomas. They suggested that it may have prognostic significance. Jacobs et al. (1978) had also observed an apparently malignant mole with aneuploidy and hypotetraploidy but with a paternal origin of all chromosomes. When trophoblastic cells are separated from molar tissue and then cultured, Habibian and Surti (1987) found that these cells exhibit a 2.8 times greater frequency of polyploidy when compared to normal trophoblast. Chromosomal breakage was also much more common. The X-chromosomal replication pattern of diploid, androgenetic molar cells, however, was normal (Tsukahara &

Kajii, 1985). A useful review may be found in the paper of Lindor et al. (1992). The participation of imprinting and of telomerase activity in moles was reviewed by Li et al. (2002). Castrillo et al. (2001) had shown that the imprinted gene product  $p57^{KIP2}$  is paternally imprinted, and that it was absent or markedly underexpressed in cytotrophoblast and mesenchyme of CHMs because of their paternal derivation, while decidua, PHMs, and normal placentas had good expression. This proves to be a potentially useful additional means of differentiation between the moles, and an immunohistochemical stain has been developed and used successfully (Jun et al., 2003). In a later study, however, Fisher et al. (2004b) showed paradoxical gene expression due to retention of a maternal copy of chromosome 11 (plus two paternal copies) in a case of CHM, thus explaining the rare abnormal expression of this gene in marker studies for  $p57^{KIP2}$ . Fukunaga (2004) found aberrant expression of  $p57^{KIP2}$  in two tetraploid (92,XXYY) moles. This suggests derivation from two sets of chromosomes, paternal and maternal. Saxena et al. (2003) showed that the *IPL* gene (also imprinted) is absent from the syncytium in moles. It is also of interest to note that N.J. Sebire et al. (2004), employing this stain on choriocarcinomas, were unable to infer their origin.

As more moles were investigated genetically, exceptions to the early findings have come to light. The existence of 46,XY moles was then first recognized (Surti et al., 1979; Ohama et al., 1981; Pattillo et al., 1981; Surti

et al., 1982). Fisher and Lawler (1984) found three 46,XY moles and determined that they derived from dispermy. It now appears that about 8% of CHMs are the result of fusion of two male pronuclei following dispermic fertilization (Ford et al., 1986). In addition to the XY moles, occasional heterozygous 46,XX moles were found (approximately 5% to 10% of moles are now known to be heterozygous and androgenetic). Wake et al. (1981) suggested that these moles may have a greater malignant potential. Kajii et al. (1984) studied nine XY moles and compared the clinical outcome with 16 normal XX moles. Their study showed dispermy as the causal mechanism in the XY moles. Three of eight XY moles and five of 15 XX moles had a delayed decrease in human chorionic gonadotropin (hCG) titers. Mutter et al. (1993) were unable to show that an increased risk for metastasis exists in the XY moles that they studied with PCR. They found 7.7% of the moles with metastatic consequence and 9.1% of the metastatic group in their large sample of moles studied possessed a Y chromosome. In the experience of Fisher and Lawler (1984), patients with heterozygous moles needed further treatment of trophoblastic tumor in 31%. In a subsequent study of this important observation, Lawler and Fisher (1987) examined 163 moles, 38 (23%) of which were PMHs and 125 were CHMs. All of the PHM were either triploid or hypertriploid, with most having arisen by dispermic fertilization; they had no untoward sequelae. Of the CHM, whose genetic study was informative, 10% were heterozygous diploid moles. Of these heterozygous moles, 25% required subsequent chemotherapy, in contrast to 17.6% of the CHMs with homozygous constitution, a result that was not statistically significant.

Hitchcock et al. (1991) addressed the difficult differential diagnosis between CHM and PHM when they undertook an important retrospective flow cytometric study of molar specimens diagnosed at the Armed Forces Institute of Pathology (AFIP). Their diagnosis of CHM differed from that of the submitting pathologist in 78%, and in the diagnosis of PHM in 57% of cases. Howat et al. (1993) evaluated the pathologist's ability to reliably distinguish between these conditions and provided specific criteria. The findings of an evaluation of 50 molar pregnancies by seven competent pathologists gave no assurance of a correct diagnosis. Fukunaga et al. (1996) found by employing flow cytometry on paraffin-embedded tissues of 35 hydropic villi that 25 were complete hydatidiform moles, while 10 were hydropic abortions; none were partial moles. Ten hydropic abortions were of maternal and paternal contributions, with two being tetraploid. Two tetraploid moles developed invasive lesions, one a choriocarcinoma. They suggested that tetraploid moles require special follow-up and strongly advocated the use of DNA determination of moles (see also Fukunaga et al., 1993). Lage (1991) deter-

mined that one course of single-agent chemotherapy caused complete remission in all triploid PHMs, and more were required in the two diploid PHM they studied. Later, these authors examined 142 hydropic placentas (Lage et al., 1992) and found 38% CHM, 35% PHM, and 26% hydropic abortuses, the majority of the latter being near diploid; only 11% were triploid. "Persistent tumor" was seen in 33% of CHM and 12% of PHM. Additional insight has been gained through the publications by van de Kaa and her colleagues (1991, 1993, 1997), who are strong advocates for a genetic/ploidy study to objectively differentiate CHM from PHM and hydropic abortuses. Berezowsky et al. (1995) found a high proportion (42%) of nonmolar and molar (47%) conceptuses in their DNA study, while most partial moles (89%) were triploid. They suggested that tetraploid moles derive from diploid conceptions with subsequent polyploidization.

From these studies, then, it appears that it is not yet possible to reliably diagnose the molar pregnancies by hematoxylin and eosin (H&E) histologic study alone, let alone assign a prognosis on the basis of a CHM karyotype. Others have come to the same conclusion and strongly urge cytometry to be part of the evaluation (Conran et al., 1993). The most important decision to be made when encountering a mole is to differentiate between triploidy and diploidy, for which flow cytometry is the most important methodology whose usage should be more widely employed. The patients with PHMs never experienced metastatic disease. Only rarely have such patients required chemotherapy for persistent trophoblast, and we doubt that it was needed in many cases; moreover, the diagnosis may be in error or is poorly supported, as was the case in the patient recorded by Gardner and Lage (1992). Bae and Kim (1999) showed that the possession of telomerase activity of CHM is more likely to eventuate in persistent trophoblastic disease. In recent years, however, pathologists have added new tools to their armamentarium in order to distinguish CHMs from PHMs and hydropic abortuses. This was especially well accomplished by antibody staining for p57.

Although the gross morphology alone of PHM is often persuasive, difficult cases do arise, especially when twin pregnancies are admixed with moles. The existence of confined placental mosaicism (CPM) has been evoked to explain unusual cases. Thus, Sarno et al. (1993) described a partial mole (69,XXX) associated with a surviving diploid premature girl. We saw the placental material from a triploid conceptus born at 33 weeks and who survived for some time without anomalies (C. Kaplan, personal communication). The placenta of this 2050-g boy was a 1000-g placenta with chorangiosis but without hydatid changes. As has been alluded to earlier, because cytogenetic studies are not feasible for all laboratories, it has been strongly advocated that ploidy of moles be determined by the rapid method of flow cytometry

(Anonymous, 1987; Benirschke, 1989). Fisher et al. (1987) showed early on that this technique unequivocally distinguishes the two molar entities. The same method was employed by Hemming et al. (1987), who demonstrated that CHMs more often had hyperdiploid cells. Lage et al. (1988) also produced similarly good results in separating CHMs from PHMs with this method (Fig. 22.3). It is noteworthy that paraffin-embedded material can be used for retrospective flow cytometric studies. Bell et al. (1989, 1998) recommended such studies and PCR for more difficult cases. Moreover, because flow cytometry easily distinguishes diploid complete moles from triploid partial moles, it is important to note that occasional and unexpected findings occur that further mandate employment of this methodology. As an example, Lage et al. (1989) found three tetraploid moles. One of them, a 92,XXXX mole, was a CHM. Another specimen had a complement of 92,XXYY (two paternal and two maternal genomes), and one was diploid/triploid mosaic (69,XXY/90,XXXY).

FIGURE 22.3. DNA histogram of normal placenta (above), a complete mole (center), and a triploid partial mole (below). The vertical axis is the number of cells; the horizontal axis is fluorescence and indicates DNA content. There is a single diploid peak in the normal placenta, a large diploid peak in the CHM with a minor peak at tetraploidy, and a large peak of triploid cells (arrow) in the partial mole. (Source: Lage et al., 1988, with permission.)

After evacuation, none of these moles had recurrent trophoblastic disease. Martin et al. (1989) also determined the ploidy of various moles from paraffin blocks, as in the study of Hitchcock et al. (1991) reviewed above. The outcome for the patients following delivery of the moles was known. It was found that moles with an aneuploid population of cells had a significantly higher incidence of gestational neoplastic sequelae than did those with diploid (euploid) moles. Although these malignant moles also had a higher proliferative index, this was not statistically significant. A retrospective study of 13 complete moles by Bewtra et al. (1997) identified eight (61.5%) as being tetraploid, and diploid moles often had tetraploid cells as well. None developed sequelae and no histologic differences were found in these populations. Tetraploid moles tended to occur in older patients and were accompanied by higher  $\beta$ -hCG levels. Newer technology employs DNA fingerprinting from very small samples to differentiate these conditions (Nobunaga et al., 1990; Ko et al., 1991); also, PCR is advocated for rapid diagnosis (Fisher & Newlands, 1993). Ishii et al. (1998) advocated the use of short tandem repeat-derived DNA polymorphism for the differential diagnosis of twins with moles and partial moles with fetus. Lai et al. (2004) had to reclassify some specimens when they examined moles by fluorescent microsatellite genotyping and ploidy study by in situ hybridization. They found that the diagnosis of CHM was more readily done histologically than that of PHM. Three PHMs developed GTDs, but the authors did not define their nature.

Mixed populations of cells with different karyotypes occur in the occasional exceptional CHM. Takagi et al. (1969) described a triploid/diploid "mosaic" XX mole without providing further relevant information. Ford et al. (1986) found an avascular, androgenetic diploid CHM (608 g) that was mosaic for normally fertilized cells. Interestingly, there was a reciprocal translocation in one population that enhanced the ease of analysis of the chromosomal origins. To explain their finding, the authors suggested that the fusion of dizygotic (DZ) twins was unlikely; they favored an origin from the abnormal fertilization of a single egg. In our interpretation, fusion of two DZ twins (a chimera) remains a strong possibility. The case also argues strongly against the perhaps overly simplistic notion that moles result from fertilization of an empty egg. The authors urged that other diploid moles be examined for possible differentiation of mosaicism/chimerism. Vejerslev et al. (1987a) found two homozygous moles with second cell lines that also suggested twin gestations. Other possible admixtures of fraternal twins, one a mole and the other normal, are discussed below. Vejerslev et al. (1987c) have summarized all unusual karyotypes of CHM, diploid PHM, and the hyperdiploid CHM. In recent studies of our own service, a PHM was found in a specimen whose amniocentesis showed uniform

trisomy 3 and whose aborted fetus had the characteristic features of this trisomy.

Among other exceptional karyotypes there are exist the tetraploid specimens. Vejerslev et al. (1987b) found one tetraploid mole with three paternal contributions and one maternal contribution among 29 molar conceptuses, 24 of which were dispermic triploids. This tetraploid specimen was, in principle, similar to the PHM but did not have the clinical presentation of that entity. Lage et al. (1989) identified three tetraploid moles. One of them, a CHM, had 92,XXXX; the two PHMs had 92,XXYY and 90,XXXY,-11,-13/69,XXY, respectively, reason for these authors to strongly advocate the use of flow cytometry for identification of unusual specimens. It now appears that most diploid moles have also some tetraploid peaks at flow cytometric study; those with diploid genomes occurred in younger women (Bewtra et al., 1997). The newer diagnostic methods of genetic analysis already referred to may be just as rapid in appropriately equipped laboratories, and they are decisive. Saji et al. (1989) showed elegantly by DNA fingerprinting that CHMs have only paternal genes. The advantage of such a study with restriction fragment length polymorphism (RFLP) is that only minute samples are required. When RFLP studies of trophoblast and corresponding fetuses were compared in 50 samples, four pairs showed differences in DNA content (Butler et al., 1988). This unexpected finding has not yet been fully explained, but it is likely to be important.

### Morphology

A “hydatidiform mole is defined as a conceptus, usually devoid of an intact fetus, in which all or many of the chorionic villi show (1) gross nodular swelling culminat-

ing in cyst formation, (2) disintegration of blood vessels, and (3) variable proliferation of trophoblast” (Edmonds, 1959). This must be regarded as the swelling of most or all of the villi in a placenta that may once have been more normal. When moles are diagnosed in the course of a pregnancy, the molar tissue fills most of the uterine cavity (Fig. 22.4). Intervillous coagula are common because of the aberrant intervillous circulation, and it may be associated with vaginal bleeding. Moles occasionally present with the clinical picture of abruptio placentae, according to Sauter (1965). The uterus may be markedly distended and may even rupture, especially when it is stimulated to contract (Lee & Siegel, 1965). Ovarian theca lutein cysts are often present (Fig. 22.4) because of the ovarian overstimulation by the excessive hCG production. Because the ovarian cysts regress spontaneously after evacuation of the mole, the ovaries do not need to be removed when hysterectomy is performed for molar sequelae.

The molar villi are fairly uniformly distended by fluid. McKay et al. (1955a,b) have analyzed this fluid biochemically and found its osmolality to be lower than that of maternal serum. The authors suggested that later gestational trophoblast has different capacities, which they explained as a reason why villi atrophy rather than expand when fetal death occurs in later fetal life. Jauniaux et al. (1998), who also reviewed subsequent studies, compared the content of molar vesicles with nuchal fluid, amniotic fluid, and maternal serum. They found significantly lower urea content and determined that the vesicle fluid  $\alpha$ -fetoprotein was more yolk sac-like, whereas nuchal fluid was more liver-like. When molar tissue is floated in water (Fig. 22.5), the translucent nature of the distended terminal villi is evident. The protein content of the fluid is apparent when such villi are first fixed and then floated (Fig. 22.6). The connections to a possible former chorionic

FIGURE 22.4. Hydatidiform mole in situ. Note the distention of the uterus and bilateral theca lutein cysts of ovaries. The vesicular nature of molar villi is apparent.

FIGURE 22.5. Hydatidiform molar villi photographed under water. Note the bulbous swelling of terminal villi and the slender nature of mainstem villi.

sac also then become evident. The swelling is primarily one of the terminal villi and can be construed to result from the continued water transport by trophoblast. The syncytium has this singular transport function. In the absence of fetal vessels to remove the transported fluid, the villi expand, and enlarged cisternae develop in the villi and vacuoles in the syncytial cytoplasm. The absence of a fetus, the lack of a chorionic cavity, and deficiency of chorionic vasculature are characteristic of CHM. Nevertheless, a few cases with tiny embryos have been described.

Thus, Hertig (1968) depicted a chorionic cavity in the center of an apparently complete mole that was fixed in situ within a uterus (his Figure 196). This chorionic sac contained a deformed, stunted embryo with this mole (his Figure 199). Because an embryo was associated with the specimen, it may be argued in retrospect that the specimen was a PHM. This consideration is invalidated by the case shown in Figure 22.7. In this patient, a tiny embryo was present within a typical hydatidiform mole (the patient's third). This pregnancy was followed by fatal,

disseminated choriocarcinoma. Baergen et al. (1996) showed that a hydatidiform mole (androgenetic) had a "fetal pole" and a gestational sac at early sonography. In fact, Weaver et al. (2000) even showed that the occasional amnion that can thus be found in verified CHM has an androgenetic pattern. Several authors have found that fetal red blood cells and other fetal structures occur in verified CHMs and that the usually avascular villi may possess capillaries early in development (Fisher et al., 1997; Paradinas et al., 1997; Qiao et al., 1997; Zaragoza et al., 1997; Neudeck et al., 2003). Thus, occasional embryos accompany moles, especially perhaps during their earliest development. This is an important point as pathologists often rely solely on microscopic features for the differential diagnosis and these do not necessarily conform to the teaching they received. This point should have been evident from the presence of connective tissue in the villi alone. As was discussed in some detail in Chapter 12, the connective tissue of the placenta has an *embryonic* derivation; it does not come from the trophoblastic shell, as was formerly thought. That the differential diagnosis

FIGURE 22.6. Same villi as in Figure 22.5 but after fixation in Bouin's fixative. The protein has precipitated, making the villi opaque. The connecting stalks are obvious.

FIGURE 22.7. Hydatidiform mole with degenerating embryo. There were no vessels in this “malignant” mole. It was the third consecutive CHM and was followed by fatal choriocarcinoma. The tiny embryo is visible above the 1.0- to 1.5-cm portion of the ruler. The choriocarcinoma of this pregnancy is shown in Chapter 23.

between the three categories—hydropic abortus, PHM, and CHM—is difficult on histologic grounds alone was well demonstrated by Gschwendtner et al. (1998). They studied, retrospectively, their “molar” specimens with ploidy analysis. This was done after the stricter criteria proposed by Paradinas (1994) had been applied. Despite this special care, ploidy study necessitated reclassification in many cases. This aspect has also been studied by Genest (2001). Agreement was found in histology and ploidy results with CHM, and in 79% of PHM and triploidy. Their discussion indicates, however, that completely reliable histologic features do not exist that allow accurate categorization; ploidy study is required, especially in gestationally young specimens.

Moles are now typically removed by suction curettage. Because the specimens are usually markedly disrupted and accompanied by much clot, it is not surprising that possible chorionic sacs and embryos are not found more often. The stalks from which the hydatid villi emanate, however, also indicate that a more normal structure must have preceded the typical CHM configuration. Also, in younger CHMs, there is generally less villous swelling, and the connections to a possible chorionic sac by stem villi are more visible (Fig. 22.8). Kajii et al. (1984), moreover, found that younger moles had smaller, elliptic or club-shaped villi and poorly delineated cisternae, whereas older moles had more globular villi (see also Keep et al., 1996). The latter also had more trophoblastic hyperplasia and fewer remnants of capillaries; no significant morphologic differences were found between XY and XX moles.

It is of historical interest to cite the invasive mole described by Jarotzky and Waldeyer (1868). They observed a chorionic cavity in the center of this typical invasive mole whence all the hydropic villi emanated. One may thus ask: What would a CHM, usually delivered between 15 and 20 weeks’ gestation, have looked like at 6 weeks’

FIGURE 22.8. Hydropic villi of “early” CHM at 10 weeks’ gestation. Note that only some villi are bulbous and that the connecting mainstem villi are still prominent. (Source: Benirschke, 1981, with permission.)

gestation? The answer is unknown, but the observations by Sasaki et al. (1967) and Nishimura et al. (1968) suggested that typical hydatidiform moles might not be recognized in such young developmental age groups. For that reason these investigators examined a large number of therapeutic abortions in Japan and found no CHMs, although many would have been expected in that population. Early CHMs might also contain fetal blood vessels, similar to the occasional embryos that have been seen with CHM just enumerated. Blood vessels in the placenta disappear rapidly after fetal death. Their absence from a CHM does not ensure that there never were villous capillaries. We suggest then that in transitional stages, the differential diagnosis may be difficult to make by morphology alone. It is here that flow cytometry and DNA fingerprinting have become useful adjuncts.

Edmonds (1959) employed the term **transitional mole**. Whether it applied to the transition from a more normal young placenta or to what is now known as a partial mole remains unknown. For these reasons, we prefer not to use this terminology. It would be much better if we identified these abortions as diploid androgenetic, triploid, or diploid-triploid moles, if distinctions are needed. The availability of more precise techniques now demands this precision from pathologists. Cohen et al. (1979) suggested that eight of their 4829 elective first-trimester abortion specimens were molar. In our opinion, however, the criteria for their diagnosis of CHM and their photomicrographs are not convincing.

Microscopically, moles are characterized by swollen villi with apparently empty cisternae. The cisternae result from the dissociation of loose villous connective tissue; transitional stages are frequently observed (Fig. 22.9). Characteristically, there are no blood vessels or recognizable vascular remnants, with the exception of the cases

FIGURE 22.9. Microscopic appearance of the villous surface in CHM. The villous core lacks fetal capillaries; it shows marked edema and early cisterna formation at right. There are many Hofbauer cells. The villous surface has normal epithelium at left and markedly hyperplastic trophoblast on the right. H&E  $\times 100$ .

alluded to above. An abundance of Hofbauer cells is frequent, as it is in PHM. The trophoblastic covering of CHM varies enormously from mole to mole. It may even vary within a mole (Fig. 22.10). Occasionally, the trophoblast is degenerated or enmeshed in fibrin. Hertig and

FIGURE 22.10. Surface of molar villus with greater degree of trophoblastic proliferation than that seen in Figure 22.9. Note the aneuploidy of many syncytial nuclei and the syncytial cisternae (dilated transport vesicles) at top. H&E  $\times 160$ .

Sheldon (1947) paid particular attention to the nature and abundance of trophoblast. Using this feature, they subdivided moles into groups I to VI (later revised to three groups), from benign to malignant, and sought a correlation with subsequent development of choriocarcinoma and other sequelae. Hertig (1950), however, later stated, "It is well nigh impossible to predict accurately which mole will be followed by this most rapidly malignant of all cancers." Although Douglas (1962) affirmed this relation between graded moles and choriocarcinoma, most other pathologists have had difficulty with so rigorously classifying moles, and their results have not allowed a perfect correlation with outcome (Novak, 1950; Hunt et al., 1953; Javey et al., 1979; Genest et al., 1991). A detailed study by Messerli et al. (1987) showed that the classification of moles and related entities had poor correlation among different observers. A quantitative study of nuclear dimensions of trophoblastic cells in CHM by Franke et al. (1985) also failed to use such parameters as predictors of outcome. Benign moles are said to have been followed by pulmonary metastases of choriocarcinoma (e.g., Bonnar & Tennent, 1962), and choriocarcinoma has even followed normal pregnancy and abortion. For these reasons and because clinical follow-up with hCG titers is efficient, this scheme of classifying moles into groups with histologic differences is no longer followed. A variety of histochemical studies on molar villi have added little useful information regarding pathogenesis and prognosis (Bur et al., 1962; Lauslahti, 1969).

Several **ultrastructural studies** of CHM have been undertaken. They also have yielded little additional information to our understanding of the biology of these placental errors. Wynn and Davies (1964) showed especially clearly the spectrum of cells that are transitional between cytotrophoblast and syncytium. They also pointed to the fluid imbibition by the syncytium, which is often clearly seen light microscopically as empty spaces (vacuolation) in syncytial cytoplasm (Fig. 22.10; see also Fig. 22.26). They found a correlation between hCG levels and the abundance of syncytium, but not with that of cytotrophoblast. Essentially similar findings were reported by González-Angulo et al. (1966) and Okudaira and Strauss (1967). Merkow et al. (1971), who studied a mole that progressed to choriocarcinoma, were impressed by the lipid inclusions in the syncytiotrophoblast. Ockelford et al. (1989) undertook a scanning electron microscopic study of 31 CHMs and 12 placentas. They observed peculiar and novel surface organelles in several moles. These structures are absent from normal trophoblast, especially the reticular organization of the surface that betrays the underlying cytoskeletal architecture of villi.

Several studies have attempted to localize various markers and antigens to molar trophoblast. Thus, to better understand possible immunologic interactions with the mother, HLA antigen characterization of moles has been done. Lawler et al. (1974) found HLA antibodies against hus-

band's antigens in women with persistent trophoblastic disease, and Berkowitz et al. (1983a) showed that monoclonal anti-HLA antibodies stained villous stroma but not the trophoblast of CHM. Using the peroxidase antibody technique, Sunderland et al. (1985) showed that class II antigens are not present on molar trophoblast. They detected class I histocompatibility antigens, however, on "proliferating extravillous trophoblast and on villous stromal cells, but not on quiescent villous trophoblast." This finding is similar to those in normal first-trimester placentas. When Yamashita et al. (1979) compared the HLA types of parents with those of the molar tissue, they identified the molar antigen as paternal. Berkowitz et al. (1985b) also detected transferrin receptors in the villous trophoblastic surface, similar to those that occur in normal tissue. These investigators localized trophoblast-leukocyte common antigens on normal and molar villous surfaces (Berkowitz et al., 1983a, 1986). Rh<sub>0</sub>(D) antigens were demonstrated on the malignant trophoblast of a D-negative patient who became sensitized by a choriocarcinoma, which had developed after the delivery of a D-positive child (Fischer et al., 1985). Goto et al. (1980) had previously demonstrated that trophoblast may contain the D antigen, and Tomoda et al. (1981) subsequently suggested that the racial disparity of incidence in gestational neoplastic disease may be secondary to the irregular distribution of the D antigen. Sarkar et al. (1986) found an expression of *c-myc* and *c-ras* oncogenes in early trophoblast, CHM, and malignant trophoblast cell lines. This pattern was absent from an 11-week conceptus. The expression of merosin, a novel basement membrane protein, was found in normal and malignant trophoblast (Leivo et al., 1989). Remarkably, this antigen was present only in intermediate trophoblast (X cells: extravillous trophoblast). It was not in the syncytium or in Langhans' cells. This observation further suggests that the X cells represent a distinct and separate lineage of chorionic cells. Minami et al. (1993) demonstrated with antibody staining methodology that molar trophoblast contains inhibin-activin subunits, after having shown earlier their presence in normal placentas. Certain moieties are found in syncytium and cytotrophoblast, others in extravillous trophoblast. But, like the localization of various other placental hormones to different trophoblastic components (Sasagawa et al., 1987), the immunologic localization does not necessarily prove that these cells are the production sites. Trophoblastic production of hormones was further elucidated by studies of moles. Thus, Sagawa et al. (1997) found leptin production in molar pregnancy. Petit et al. (1996) showed an alteration of the elaboration of G proteins in moles and related it to placental lactogen and hCG production. An excessive production of plasminogen activator inhibitor-1 (PAI-1) was established by Estellés et al. (1996) and related to the increased incidence of PIH in molar gestations. Various other histochemical stains were employed by Olvera et al. (2001) without adding really useful new tools to our armamentarium, however.

The **prenatal diagnosis** of CHM moles is now usually possible with sonography. Ultrasonography identifies the lack of a fetus and displays the multiple echogenic signals, the "speckled" or "snowstorm" appearance of the molar placental tissue. Additionally, in PHMs a fetus may be visualized (Harper & MacVicar, 1963). Despite general knowledge of molar gestations, physicians make the diagnosis infrequently at the first antenatal visit (Ringertz, 1970), probably because in early gestation the villous swelling is only minimal. Other physicians who have made similar observations have also pointed to the frequent difficulty of early diagnosis (e.g., Stroup, 1956). The sonographic differentiation from missed abortions was further refined by the studies of Fine et al. (1989). Gynecologists have had the experience, however, that sonography during early pregnancy fails to make the diagnosis

consistently (e.g., Woodward et al., 1980). Romero et al. (1985), therefore, correlated hCG levels with sonography. They set the hCG level of 82,350 mIU/mL as a diagnostic criterion, in addition to absent heart movement seen by ultrasonography. The diagnostic accuracy of recognizing moles thereby increased from 41.6% to 88.8%. Amniography has also been utilized (Gerber, 1970), as has arteriography (Hendrickse et al., 1964; Borell et al., 1966; Breit & Schedel, 1970). It is of special interest that ultrasonographic examination of first trimester pregnancies that eventuated in CHM did not show alterations that could be used to anticipate molar development (Woodward et al., 1980).

#### OTHER ATTRIBUTES

Maternal hyperthyroidism often accompanies hydatidiform moles (Herzman & Higgins, 1971; Sanchez & Sanchez, 1998), and sometimes it causes pulmonary edema. Both disappear promptly after evacuation. The nature of the thyroid-stimulating agent that is presumably released from the placental tissue is controversial. Some findings have suggested that it is identical to placental hCG (Nisula & Taliafouras, 1980). Amir et al. (1984) conducted a detailed study to identify this agent and concluded that it was unlikely to be hCG, but that it must represent another protein moiety released from the trophoblast of moles. Gunasegaram et al. (1986) suggested that it was a thyroid-stimulating hormone (TSH)-like protein, distinct from the hCG and the luteinizing hormone (LH) that they identified in molar vesicles. Other alterations of enzymes and proteins have been described in molar gestations. Thus  $\alpha$ -fetoprotein is consistently absent in choriocarcinoma patients. It is rarely found in moles and then only in low concentration (Ishiguro, 1975). Yoshimatsu et al. (1987) immunologically examined tissues of various types of abortuses for the presence of  $\alpha$ -fetoprotein. Molar fluid and trophoblast were consistently negative, but the protein was found in villi of PHM. Elevated serum glutamic oxaloacetic transaminase (SGOT) levels, found in some moles by Tobin (1963), were believed to result from cellular degeneration. Borek et al. (1983) suggested that urinary levels of DNA breakdown products after molar evacuation may be a useful adjunctive measure to indicate successful therapy. They found nucleosides and some DNA-derived enzymes to be elevated when active trophoblast remained after therapy. The disappearance especially of  $\beta$ -aminoisobutyric acid from the urine, even in the presence of persisting hCG levels, forecasts a good prognosis. Lee et al. (1981) found that circulating levels of the pregnancy-specific  $\beta_1$ -glycoprotein (SP-1) and placental protein 5 (PP5) were markedly reduced in patients with untreated CHM and choriocarcinoma. They suggested that this measurement was a decisive means for differentiating benign and malignant trophoblast.

The usual means for following patients with CHM is the serial determination of serum hCG levels or its  $\beta$ -subunits. This hormone is concentrated in molar villi, according to the studies of Sciarra (1970). He found mean values of 1524 mIU/mL in the fluid of small vesicles, and 1202 mIU/mL in the larger villi. Normal values of all hormones and secretory products of neoplastic trophoblast have been ably summarized by Clayton et al. (1981). Yedema and colleagues (1993) have constructed a gonadotropin regression curve from 130 patients with no trophoblastic sequelae after the evacuation of a molar pregnancy. They found that 71 of 77 patients with persistent trophoblastic disease could be identified from their elevated hCG levels, and in more than 50% it was possible to achieve this diagnosis within 6 weeks of operation. Khazaeli et al. (1986) suggested that the determination of a ratio between  $\beta$ -hCG and hCG has prognostic significance. The more malignant moles apparently produce significantly more free  $\beta$ -hCG units

(Khazaeli et al., 1989). Ozturk et al. (1988) found that the ratio of  $\beta$ -hCG to hCG fairly reliably distinguishes between normal pregnancy and CHM, and between CHM and choriocarcinoma. Presumably the hCG secretion, known to be of syncytial origin (Yorde et al., 1979; Bonduelle et al., 1988), reflects the increased quantity of syncytium in moles, rather than a qualitative change in its secretion pattern, although abnormal trophoblast appears to produce an excessive amount of  $\beta$ -hCG subunits. The rate of decline in  $\beta$ -hCG levels following delivery of moles was also summarized by Yuen (1983), a study that also included data on prolactin and estradiol secretion. In general, the  $\beta$ -hCG levels fall rapidly to zero within 8 weeks after evacuation. Bagshawe et al. (1986) stated that in 42% of women with CHM serum, hCG was undetectable 56 days after evacuation; none of the patients required chemotherapy. Franke et al. (1983b) determined that the average disappearance time of serum hCG after CHM was 99.3 days, after PHM 58.9 days, and after hydatid degeneration in abortuses 50.7 days. They recommended that, provided there is a continued decrease in the levels, therapy not commence before day 100 after evacuation. Human placental lactogen (hPL) levels correlated poorly with hCG levels of moles and choriocarcinomas; they were generally low (Ehnholm et al., 1967). This finding suggests that chorionepithelium is not the principal source of hPL, and that its cellular source, the X cell, has undergone little proliferation during molar development, which is borne out histologically. The interpretation of enhanced hCG secretion by moles because of increased villous (and hence trophoblastic) surface may be an oversimplification. The suggestion has been made that it relates to the expression of paternal genes. Goshen and Hochberg (1994), commenting on a paper by Feigin et al. (1993) that studied placental hormone secretion, made these interesting comments. They suggested that high hCG values are expected in CHM because of paternal disomy 19 (the hCG locus is on that chromosome); low levels are expected (and found) in triploid PHM with **maternal** contribution of the extra haploid set.

Numerous studies have examined how the **implantation site** of moles might differ from that of normal gestation. The reader is referred to the section on X cells (see Chapter 9). In CHMs the site of implantation often shows exuberant trophoblast and, especially, placental site giant cells. They are mostly X cells (extravillous trophoblast), but syncytiotrophoblast is also present. The amount of trophoblast at the placental site may be confusing, and there may be difficulty in differentiating it from invasive choriocarcinoma. King (1956) paid special attention to the borderline lesions of gestational trophoblastic neoplasia. These lesions encompass (1) residual mole and syncytial endometritis, and (2) invasive mole (chorioadenoma destruens). To minimize the problem of recurrent disease, King advocated routine curettage after removal of a CHM.

**Syncytial endometritis** is not a neoplasm. It represents "a residuum of trophoblastic cells after a normal pregnancy, abortion, or hydatidiform mole" (Novak & Seah, 1954). Strictly speaking, syncytial endometritis does not contain molar villi. Also, there are no solid areas of pure trophoblast that might indicate the presence of choriocarcinoma. The placental floor in syncytial endometritis is composed of trophoblast and this is intermingled with decidual cells, with a few inflammatory cells also admixed. Its cellular composition is highly variable. This lesion is now termed exaggerated placental site. Berkowitz et al. (1982) examined the composition of the maternal floor in 11 CHM cases, specifically looking for deposits of immunoglobulins (Igs) and complement. Immunofluorescent deposits of IgG, IgM, and C3 were confined to the spiral arterioles. The authors thus concluded that CHM

does not evoke “a vigorous host humoral immune response.” In a later study, Kabawat et al. (1985) showed the presence of increased numbers of inflammatory cells at molar implantation sites, especially T cells with predominance of T4<sup>+</sup> cells. They speculated that this infiltrate relates to the development of a delayed hypersensitivity reaction, participating in rejection. In the peripheral circulation of patients with trophoblastic tumors, however, there is a significant reduction of T cells and other immunocytes (Ho et al., 1986). Ho and his colleagues discussed the immunologic significance of these findings.

Because there is no accompanying fetus in CHMs, they also lack the fetal adrenal precursors for estriol formation. They have therefore an extremely low E<sub>3</sub> content (Chamberlain et al., 1968). Incubation studies with dehydroisoandrosterone and other androgenic precursors indicate, however, that moles and choriocarcinoma do possess the ability to convert this steroid to estriol (MacDonald & Siiteri, 1966; Houtzager et al., 1970). From their in vivo studies with the appropriate precursors, Barlow et al. (1967) suggested that the low E<sub>3</sub> production may be useful for differentiating moles from normal early pregnancies.

Moles and partial moles are also frequently associated with preeclampsia. Llewellyn-Jones (1967) related this to uterine size. Eclampsia was seen at 17 weeks in a triploid pregnancy with partial molar transformation of the placenta by Slattery et al. (1993) and by Ramsey et al. (1998) at 14 weeks gestation. The existence of pregnancy-induced hypertension (PIH), however, is not a useful differential diagnostic feature for clinical differentiation between CHM and PHM. Scott (1958) reviewed this subject in context with the frequent PIH that is found in hydrops and hydramnios. He concluded that similar hormonal disturbances must exist to evoke PIH. Fatal eclampsia has occurred with molar pregnancy. Lee (1965) described a mother with a mole and severe PIH at 13 weeks' gestation. Sicuranza and Tisdall (1976) found eclampsia associated with what was apparently a PHM and with a live fetus of 125 g. Their report was similar to the case earlier described by Lloyd (1921). An increase of syncytiotrophoblastic glycogen content was observed by Arkwright et al. (1993) to exist in molar and PIH-related trophoblast. Choriocarcinomatous cells contain the most glycogen. The authors suggested that this accumulation may be a marker of “immaturity” of this cell. We have earlier alluded to the finding of altered PAI-1 expression in mole and its possible relation to PIH (Estellés et al., 1996). The relation to PIH was one of increased syncytial turnover in PIH that was observed by Chua et al. (1991).

### *Deportation*

Molar tissue, as is true of the normal syncytium, may be transported to the lung. This deportation may occur spon-

taneously and during the evacuation of a molar uterus. It may cause acute pulmonary hypertension, edema, and even death. In other cases, such vascular deportation has been associated with disseminated intravascular coagulation (DIC). Benign molar tissue has even been observed to grow in the lung; hence the term **benign metastasizing mole**. This term was coined by Ring (1972), who observed two patients with isolated pulmonary nodules associated with invasive moles. Both lesions pursued a benign course. Leeder (1964) had previously described a molar pregnancy with metastatic molar tissue in lung, vagina, and vulva. All regressed spontaneously. The patient described by Johnson et al. (1979) suffered hemothorax from a pleural mole that improved only after chemotherapy. Meyer (1966) also reported a pulmonary nodule composed of molar tissue. The patient had a typical CHM with considerable trophoblastic pleomorphism. She developed the lung lesion and had persistent uterine trophoblast 7 weeks after delivery of the mole. There was an intense lymphoplasmacellular reaction at the pulmonary site. Reed et al. (1959) reported similar cases, and Bardawil et al. (1957) described a case with spontaneous regression of pulmonary metastases developing months after evacuation of a mole. They considered an immunologic rejection to have been the most likely mechanism for this regression. Mark and Moel (1961) discussed the radiologic differential diagnosis, and Hsu et al. (1962) found that deported molar metastases occurred most commonly in the pudendal tissues. These entities all fall into the broader category of invasive mole. Clinical follow-up and therapy do not differ from those of CHM that remains confined to the uterus. Although deportation of complete molar villous tissue can readily produce radiologic pulmonary lesions, the events described by Cohle and Petty (1985) and Lipp et al. (1962) are more difficult to understand. They found extensive pulmonary capillary plugging by syncytial cells and suggested that it was the cause of fatal embolism.

Syncytium normally reaches the lung of pregnant patients (Schmorl, 1905; Lee et al., 1986; see also discussion by Pool et al., 1987; Chua et al., 1991; see also Chapter 17); presumably this dissemination occurs even more readily in molar gestations (Figs. 22.11 and 22.12). Hankins et al. (1987) studied this problem with pulmonary artery catheters during mole evacuation. They found multinucleated giant cells (probable syncytium) but no villi. Moreover, there was no change in pulmonary arterial pressures or lung perfusion. Tanimura et al. (1985) identified deported trophoblast in pulmonary capillaries in nine of 10 patients who died after abortion or delivery. That this deportation of cells can be massive enough so as to occlude the pulmonary circulation remains to be shown. It is more likely that DIC occurred in these cases, as similar instances have been observed repeatedly (Beyth, 1973; Egley et al., 1975; Orr et al., 1980). Paren-

FIGURE 22.11. Syncytial trophoblast in pulmonary capillaries of maternal death at 16 weeks' gestation. H&E  $\times 100$  (left);  $\times 260$  (right).

thetically, it might be mentioned that intrauterine instillation of hypertonic saline (for attempted pregnancy termination) may be fatal to patients with hydatidiform mole (Frost, 1968). Even normal villi are deported on occasion. Figure 22.13 shows the presence of immature villi, enmeshed in coagulum, within a pulmonary artery. This was discovered at autopsy of a woman who died after traumatic disruption of the uterus during therapeutic abortion.

#### *Chorioadenoma Destruens (Invasive Mole)*

Invasive mole is a malignant neoplasm composed of infiltrating trophoblast and molar villi. The tumor invades the uterus and often the adjacent structures. It overlaps the aforementioned condition of benign metastasizing mole and the pseudotumor, later renamed placental site trophoblastic tumor (discussed in Chapter 23). Invasive mole is differentiated from true choriocarcinoma only by

FIGURE 22.12. Term placenta with syncytial "knots" (arrows) having detached and being swept into the maternal intervillous circulation, whence they reach the maternal lung. H&E  $\times 160$ .

FIGURE 22.13. Pulmonary artery filled with thrombus and immature villi. They were deported during therapeutic abortion, when the uterus was perforated. H&E  $\times 60$ .

the presence of villi scattered among the trophoblast. Its behavior often is also similar to that of choriocarcinoma, and usually it requires similar therapy. Perhaps it is unwise to retain this category. King (1956) placed it into his category of borderline conditions. An invasive mole is nothing more than the molar equivalent of placenta increta, and it may be as destructive. The term was coined by Ewing (1910). King distinguished three types: simple invasive mole, invasive mole with regression, and invasive mole with signs of progression. The terms speak for themselves. The prognosis is conditional on the initial nature of the mole and the efficacy of its primary removal. Figure 22.14 shows a typical case of invasive mole. The molar villi, including exuberant trophoblast, have deeply invaded the myometrium. Often this picture is combined with much more hemorrhage than is demonstrated by this particular case. Invasive moles often present challenging diagnostic and therapeutic problems. The following case illustrates it well.

A 34-year-old gravida III had vaginal bleeding at 3 months; sonographic studies at 14 weeks were suspicious but not diagnostic of mole. An amniogram at 16 weeks showed CHM, which was evacuated by suction after a single dose of methotrexate (5 mg) had been administered. The molar tissue showed much trophoblastic exuberance (Figs. 22.15 and 22.16). Methotrexate was continued for 5 more days, causing the development of oral lesions and leukopenia. The patient had serial hCG titers shown in Figure 22.17. Two pulmonary metastases were diagnosed radiologically, 2.5 months after evacuation. After five additional courses of methotrexate and two courses of actinomycin D therapy, the lung lesions faded. Six months after evacuation, the hCG levels had still not returned to normal. Three additional courses of actinomycin D were given. Arteriography was performed and found to be negative. Hysterectomy was done at this time. Serial slicing of the uterus showed a single hemorrhagic cavity (Fig. 22.18) that contained a small group of degenerated villi (Fig. 22.19), adjacent to which was intramuscular viable trophoblast with positive fluorescence by anti-hCG antibodies. The patient remained well thereafter.

Similar cases abound in the literature. Invasive moles are also known to produce late pulmonary metastases.

Such cases are well illustrated and discussed by Spademan and Tuttle (1964) and many other authors. Conservative therapy was advocated by Rubin (1964) because many of these “tumors” have an innate benign potential. There is even a report of uterine perforation by a destructive mole (Kyodo et al., 1988), but this patient also had an apparently normal fetus. It is not clear from the report, however, whether the mole was a partial molar triploid pregnancy or a twin gestation. Thiele and de Alvarez (1962) described two patients with CHM and metastases.

FIGURE 22.14. Invasive mole (chorioadenoma destruens) in the myometrial wall (below), showing marked trophoblastic hyperplasia. H&E  $\times 40$ .

FIGURE 22.15. Molar villous surface of a patient with the invasive mole shown in Figures 22.16 to 22.18. There is moderate trophoblastic hyperplasia in an otherwise typical CHM. H&E  $\times 100$ .

They reviewed the literature on invasive moles and secondary implants, and Thatcher et al. (1989) described the tubal equivalent of such a lesion. Most tubal pregnancies are accretas and, when they rupture, they resemble placenta percreta. The implantation of trophoblast outside the tube is therefore not surprising. These authors saw secondary peritoneal implants of trophoblast after laparoscopic salpingostomy (see also Cataldo et al., 1990). The nodules were excised and proved to be normal trophoblast; the patient recovered. Ultrastructurally, invasive moles are similar to normal placenta, CHM, and choriocarcinoma (Wynn & Harris, 1967), but the chromosomes of invasive chorionic lesions have rarely been studied. Makino et al. (1963) found invasive moles to have hyperdiploid and aneuploid chromosome numbers more frequently than CHM; choriocarcinoma was even more aneuploid.

#### THERAPY

The treatment of trophoblastic neoplasms has changed drastically with the introduction of methotrexate therapy in 1956 (Li et al., 1956). Li et al. recognized the specific toxicity of this agent to trophoblastic and embryonic cells because of its folic acid-inhibiting quality. It has effects in vitro as well (Sand et al., 1986) and comprises the well-known leucovorin rescue that is often used during therapy. Detailed protocols for the various trophoblastic disorders have been provided in the contributions to the Symposium on Gestational Trophoblastic Neoplasms (Goldstein & Berkowitz, 1981). This area is beyond the scope of this book. As Acosta-Sison (1964) so aptly stated already, there are changing attitudes to the management of moles, and this continues today. Early and complete evacuation is perhaps the most important aspect of successful therapy (Mathieu, 1939). When properly done, the new therapeutic regimens are nearly uniformly effective (Lurain et al., 1983; Schlaerth et al., 1988). Some patients require no therapy, and it has repeatedly been noted that metastatic lesions may disappear spontaneously. There is continued controversy as to the wisdom of prophylactic therapy for all patients with CHM (Goldstein, 1971; Kim et al., 1986). Hertz et al. (1963) showed that rigorous treatment with methotrexate

FIGURE 22.16. Same case as in Figure 22.15; invasive mole. Note the markedly “anaplastic” area of trophoblast. H&E  $\times 100$ .

FIGURE 22.17. Course of a patient who developed pulmonary metastases and invasive mole after evacuation of an intrauterine mole (see text). The mole is shown in Figures 22.15 and 22.16 and the chorioadenoma destruens in Figures 22.18 and 22.19.

FIGURE 22.18. Same patient as in Figures 22.15 to 22.17. The hysterectomy specimen shown here had a small subendometrial hemorrhagic cavity containing molar tissue.

FIGURE 22.19. Invasive mole of the patient in Figures 22.15 to 22.18. Note the largely degenerated villi and trophoblast. H&E  $\times 40$ .

and actinomycin D is generally completely successful when metastases develop. Kashimura et al. (1986) suggested that the recurrence rate of trophoblastic disease is between 5.7% and 26.0%. These investigators followed 420 patients with CHM, 293 of whom were given prophylactic methotrexate (10 mg for 7 days). There was a significant improvement of those receiving therapy (7.5% versus 18.1%), and it was more marked in older patients.

The surveillance of molar cases after evacuation with serial hCG levels is a convenient way to ensure success. It must be reemphasized, however, that the exclusion of PHM cases from therapeutic regimens is mandatory. Such patients are most easily identified with routine flow cytometry on the initial specimen. Hysterectomy is now rarely necessary. Moreover, appropriate chemotherapy is compatible with future fertility (Song et al., 1988). What has been controversial, though, is which pregnancies should be screened for possible GTD sequelae. Because early CHM cannot be diagnosed reliably and because 15% of CHMs and 0.5% of PHMs are followed by neoplasias, M.J. Sebire et al. (2004) have suggested that all pregnancy terminations (for whatever reason) should be screened for possible GTDs.

### *Ectopic Moles*

The occurrence of moles in the fallopian tube and ovary has been described and it includes tubal rupture (Westerhout, 1964); indeed the occurrence of placental site nodules has been reported in the fallopian tube (Muto et al., 1991; Nayer et al., 1996). Data from the older literature are not necessarily convincing, however, because of the possible presence of a PHM among these reports. Pettit (1941) reviewed 42 cases of tubal moles and choriocarcinomas and reported a new case with good outcome. Sze et al. (1988) described a patient who had an intrauterine "molar pregnancy" 2 months after salpingostomy for tubal ectopic pregnancy. The mole was accompanied by a malformed fetus. It was a partial mole, most likely a triploid conceptus. The authors believed this report to be the first description of such a combination of implantations. The case is important because it highlights the care one must exercise when reviewing the topic. Although listed as "molar" pregnancy, the text clearly described it to be a PHM. It is also acknowledged that the excessive levels of hCG in this patient (467,000 mIU/mL) are not helpful in the differential diagnosis between CHM and PHM. Other examples of triploid PHM in the tube abound in the literature, as for instance the case of Montgomery et al. (1993).

On rare occasions, a hydatidiform mole is believed to have originated in the ovary. Jock et al. (1981) described the sixth such reported case and estimated that this condition occurs perhaps only once in 50 million pregnancies. They also reviewed the literature. Their patient, a 27-year-old primigravida, was admitted for evacuation of a sonographically evident intrauterine mole at 12 weeks' gestation. The uterus, however, was found to be empty. The mole was present within a 14-cm ovarian mass. No postoperative chemotherapy was needed. Of interest was the extensive pseudodecidual change found on the omental surface. The case described by Stanhope et al.

(1983) resulted in a benign outcome following local resection. Yenen et al. (1965), who described and illustrated a similar case, removed the uterus. In retrospect, this surgery seems to have been unnecessary.

### *Partial Hydatidiform Mole*

Macroscopically, the usual CHM has an almost uniform distribution of hydatid villi, the placenta is much enlarged and remnants of fetal capillaries or other embryonic remnants are exceptionally rare. There are, however, molar specimens in which only a portion of the placenta is hydropically altered, the so-called PHM. These moles are also more often associated with fetuses. Atkin and Klinger (1962) were the first to correlate triploidy with this type of molar change. Sporadic reports followed (Schlegel et al., 1966). It was Carr (1971), however, who first established that "85% of triploid and hypertriploid embryos showed hydatidiform degeneration or mole." Subsequently, Vassilakos et al. (1977) drew sharp attention to the entity that we now know as PHM. They clearly distinguished it from the CHM. In a series of 811 spontaneous and 1097 induced abortions, they found 75 placentas with gross villous swelling, most of which showed chromosomal anomalies, primarily triploidy and trisomy 16. None had marked trophoblastic dysplasia, and all had a good outcome. The diagnosis of PHM is not always correctly established by pathologic criteria, as the studies with flow cytometry and DNA fingerprinting have shown (see Takahashi et al., 1990). Therefore, one must be cautious in interpreting the data from many series that have been published in the past. Moreover, there are numerous exceptional cases, mosaics, and chimeras, and also theoretical considerations of the unusual centrosome behavior of triploids that warrant better explanations for these errors of fertilization. They are cogently discussed in a large contribution by Golubovsky (2003) that needs to be studied in detail. He states, "Dispermic zygotes, in contrast to digynic ones, are characterized by (a) cytogenetic phenomenon described here as postzygotic diploidization of triploids (PDT)," and he then produces examples that would explain the mixoploids and other unusual findings that have been reported in the past. One such aberrant case was studied by Zhang et al. (2000). A normal male fetus (46,XY) was associated with a placenta that was admixed (diploid/triploid) in whose hydropic villi fetal blood was circulating. Genetic study showed that this was not a chimera, as both diploid and triploid markers were identical. Makrydimas et al. (2002) also described an unusual mole. This term female singleton gestation also had a placenta with diffusely intermixed hydropic villi. Amazingly, the genetic study showed that all cells had a monospermic origin, and the neonate was diploid and biparental, but the hydatid villi were androgenetic and monospermic. The authors referred to this as confined placental mosaicism.

Vassilakos and Kajii (1976) coined the phrase “hydatidiform mole, two entities.” This observation was immediately confirmed, and PHM is now well established as a distinct entity. Szulman and Surti (1978a,b) have made many contributions to delineate this placental abnormality. All but three of their initial 12 cases had an associated fetus. There was often a striking elevation of hCG levels, but these levels dropped rapidly after delivery. These authors emphatically stated that there is no transition between mole types and that the older term *transitional mole* is inappropriate. One of their cases of PHM with 46,XX and fetal parts is of interest. Its true nature remains unknown, but it served to caution that these designations are not watertight syndromes. It should be pointed out that not all triploid conceptuses have elevated hCG titers. Fejgin et al. (1992) suggested that placental insufficiency may be one cause of such low levels, and Morrish et al. (1992) felt that PHMs have an impaired facility of hormone production in response to stimulants.

The **morphology of PHM** is variable, and it is also dependent on the genotype. The villi of PHM are much more irregularly swollen than those of CHM, and many normal villi may intervene among grossly molar tissue. Cisternae may be present but they are also generally less common than is true for CHM. The more important feature for the differential diagnosis is the very frequent presence of villous capillary remnants (Fig. 22.20). Many of these contain fetal red blood cells, even though the fetus may have died or was not recognized in the specimen received. There is generally much less, and usually only focal, trophoblastic hyperplasia. The villous covering is frequently scalloped, and villous inclusions of trophoblast (tangentially cut surfaces) are common (Fig. 22.21). Most investigators have suggested that these trophoblastic inclusions are found only in triploids, but that is somewhat contrary to our experience. We find trophoblastic

inclusions occasionally even in normal immature placentas and certainly in other chromosomally abnormal abortuses (see also Novak et al., 1988, and Chapter 21). Therefore, we do not use this criterion as an important feature for the diagnosis of PHM. These inclusions are sometimes quite large and have been beautifully demonstrated in color pictures by Kliman and Segel (2003). They suggested that the included trophoblast derives by cytotrophoblast absorption and provided a theoretical model. A particularly useful review contribution by Sebire et al. (2002a) describes the morphologic characteristics of the two types of moles and hydatid changes in abortion specimens. Although the authors suggested that the differential diagnosis of the nature of the lesion can usually be made by morphologic criteria alone, the use of ancillary techniques in questionable cases is advocated (Genest, 2001). Szulman et al. (1981) reviewed cytogenetically verified triploid abortuses and found that 86% of them had placentas that could be classified as PHM. Their fetuses tended to have died by the eighth week of pregnancy, but uterine retention was commonly longer than for other chromosomally aberrant conceptuses.

Szulman and Surti (1982) estimated from a hospital population that CHM occurs in 1 of 1330 pregnancies and PHM in 1 of 1730 pregnancies. All types of triploidy arise in approximately 1% of recognized human pregnancies for as yet unknown reasons. Berkowitz et al. (1995) recognized that it occurred more often in women with irregular cycles and oral contraceptive usage, and that dietary factors played no role in the etiology of PHM. Jacobs et al. (1982) reported that most triploids are due to the fertilization with two paternal genomes (dispermy). Only 1% to 3% eventuate in a molar pregnancy (Lawler et al., 1979). The analysis of 106 triploid specimens by Jacobs et al. (1982) is especially interesting. The extra haploid set of chromosomes was of paternal origin (androgenetic)

FIGURE 22.20. Histologic appearance of villi of triploid partial hydatidiform mole (PHM) at 12 weeks' gestation. Note the irregular size of the villi and the minimal amount of trophoblast. Remnants of atrophying fetal capillaries are present (arrows). There is early cisterna formation of villi between arrows and prominent infolding (scalloping) of villi. H&E  $\times 65$ .

FIGURE 22.21. Partial (triploid) hydatidiform mole with extensive edema and prominent infolding (scalloping) of the minimally hyperplastic trophoblast. This infolding leads to the

histologic appearance of trophoblast islands within edematous villi. There is much syncytial cysterna dilatation at right. H&E  $\times 60$  (left);  $\times 120$  (center);  $\times 260$  (right).

in 51 cases; it was maternally derived (gynogenetic) in 15. The former gestations lasted longer (122 days) than the latter (74 days). This difference may explain, in part, why paternally derived triploid conceptuses are concentrated among the PHMs, as it takes time for grossly visible villous swelling to come about. The studies of Uchida and Freeman (1985) gave similar results. There is evidence that molar villous swelling only gradually takes place and makes early sonographic diagnosis, for instance, difficult (Jauniaux et al., 1997). For that reason, most triploid abortions escape detection unless cytogenetic analysis is done. Ohama and his collaborators (1986) investigated the chromosome status of 56 partial moles. They found

that 46 were triploid, and nine were diploid. The diploid moles lacked trophoblastic hyperplasia and stromal inclusions (Fig. 22.22). Importantly, four of these nine diploid PHMs had chromosomal heteromorphisms. In other words, they were not androgenetic, as is typical for the diploid CHM. Although most partial moles are triploid, a few are not. McFadden et al. (1994) found different origins of the extra set of chromosomes. They identified more cases of digyni rather than the former prevalent diandry. All PHM were diandric triploids, whereas only one of four diandrics developed PHM. Similarly, in a large study by Zaragoza et al. (2000), most PHMs were found to have a diandric origin; but the authors caution

FIGURE 22.22. Possible partial hydatidiform mole with diploid, 46,XX, and homozygous karyotype on C banding. A 720-g, 24 weeks' gestation, female infant with renal dysplasia resulted with neonatal death. The placenta weighed 1460g and had scattered molar vesicles throughout. The umbilical cord was normal, and there was virtually no trophoblastic proliferation. Maternal outcome was good.

that only a small portion of triploid conceptuses eventuates in PHMs, indicating that the mere presence of two paternal genomes is not sufficient for molar development. Of parenthetic interest is that Hasegawa et al. (1999) described a digynic nonmosaic female triploid infant who survived for 46 days. The small immature neonate had numerous congenital anomalies, including the characteristic digital fusions. Of four previous survivors they summarized, only one was diandric. Philipp et al. (2004) studied the embryos of triploids by embryoscopy and showed their early marked developmental abnormalities when associated with partial moles.

The important question arises whether there is a possibly different prognosis for these groups. Davis et al. (1987), who analyzed ploidy by flow cytometry in 35 assumed PHMs, unexpectedly found that six (17%) were triploid and 29 (83%) were diploid. These investigators did not find any complications in the triploid group, but five (17%) of the diploid cases had nonfatal sequelae. Examples of these complications included the need for recurettage and chemotherapy. Teng and Ballon (1984) described three patients with mole and a coexisting fetus. The patients had persistent hCG elevations and two required chemotherapy. This report has been criticized by Szulman and Surti (1985), who considered these cases to be DZ twin gestations and urged that stricter criteria be employed in reporting these conditions.

Some reports have emphasized the existence of pre-eclampsia with PHM, and that ovarian theca lutein cysts may complicate PHM (Lewis & Cefalo, 1979). These cystic changes of molar and partial molar placentas have been recognized sonographically (Harper & MacVicar, 1963; Bendon et al., 1988; Jauniaux et al., 1996). Several investigators have studied hCG levels in CHMs and compared them with those in PHMs. Smith et al. (1984) found that, after evacuation of the uterus, the hCG levels disappeared similarly quickly, but that the levels found immediately after evacuation were significantly higher in CHM. Berkowitz et al. (1989), in a detailed analysis of the various gonadotropin moieties, found the following in maternal serum: CHMs had higher levels of  $\beta$ -hCG than PHMs, but the latter had higher  $\alpha$ -hCG levels; both moles had higher levels of both subunit levels than did comparable normal pregnancies (see also Khazaeli et al., 1986). Markedly elevated  $\alpha$ -fetoprotein levels were present in two patients with PHM and triploidy (Kazazian et al., 1989), something that does not happen in CHM.

The **natural history of PHM** has been evaluated by several authors, especially with emphasis on possible malignant sequelae. Czernobilsky et al. (1982) found no untoward outcome in 25 PHMs. Berkowitz et al. (1983b) followed 81 patients with PHM. Serum hCG levels exceeded 100,000 mIU/mL in only two patients. Eight of their patients (9.9%) developed nonmetastatic trophoblastic disease that was successfully treated with metho-

trexate. In six of eight patients, residual molar tissue was found on curettage; there were no choriocarcinomas. One possible exception in the large experience with partial moles is the case of Looi and Sivanesaratnam (1981). The patient in their study was said to have developed a choriocarcinoma following a partial mole. Kohorn (1986) has questioned the need for this (premature) intervention with chemotherapy. There are very few reports that have verified true trophoblastic neoplasia to occur following partial moles, an important point made in the report by Heifetz and Czaja (1992). Their 69,XXX gestation with fetus had a nodule of what would appear to be choriocarcinoma in situ. But the postpartum course was entirely benign. Szulman et al. (1981) did a retrospective study of 13 PHM patients from Hong Kong. One, a case of invasive (partial) mole, required chemotherapy. In our opinion, the case was one of placenta increta of a triploid specimen, not true trophoblastic neoplasia. Gaber et al. (1986) reported a similar case. PHM may recur (Honoré, 1987; Honoré et al., 1988). We believe that when the diagnosis of triploidy is truly established for a PHM, then a complete evacuation generally cures the patient. Bagshawe and his colleagues (1990) undertook a study of 11 patients whose condition had been originally diagnosed as PHM and whose course was complicated by gestational trophoblastic tumor. DNA analysis led to revision of PHM to CHM in four cases, and two cases had been incorrectly diagnosed as complete moles but were not. These authors suggested that four patients required chemotherapy, although their last pregnancy was a triploid PHM. No proof is provided, however, that these lesions were choriocarcinomas, and it was also not discussed how far the GTD had spread. Little doubt, however, can be expressed when the study of Seckl et al. (2000) is read. They reviewed 3000 patients with partial moles of whom 15 required chemotherapy for persisting GTD; three eventuated in choriocarcinomas. Lawler et al. (1991), who studied 202 molar specimens (51 PHM with 44 triploids; 149 CHM with 105 diploid, one haploid[!], one triploid), saw no need for chemotherapy in any of their PHMs. Other reports should be consulted concerning the persistence of trophoblastic disease after partial moles, such as Rice et al. (1990) and Muto et al. (1991). Forrester and Merz (2003) did a survey of triploidy in a population from Hawaii (1986–1999) and identified 38 cases. Of these, 31 were early fetal deaths; 39% were XXX, 58% XXY, and 3% XYY. The maternal consequences were not detailed and advanced maternal age was found, contrary to earlier reports, but the authors admitted a possible bias for chromosome studies at that age group.

### *Differential Diagnosis*

Distinguishing the various entities discussed here constitutes a continuous challenge for the practicing patholo-

gist. Thus, it must first be stated that completely satisfactory methods do not exist, but some practical steps are possible. The pathologist must recognize that even CHMs may start out as small placentas with an appearance of spontaneous abortuses that possess hydatid changes; they may even have diminutive embryos. Further, partial moles are not all triploid and some chromosomally abnormal (trisomics, not triploid) and aborted specimens may have some cystic, molar villi. How then to proceed?

Our suggestion is to proceed as follows, if the tools are available: If a fetus is present with a mole, examine its fingers for possible fusions (suggesting triploidy with imprinting). Stain the slides with antibodies to the commercially available p57: Normal specimens (abortions) show expression by strong nuclear staining of trophoblast and mesenchymal tissue. Complete moles show no expression, whereas PHMs may show minimal to moderate expression (Jun et al., 2003; Romaguera et al., 2004). If the results are not completely satisfactory, perform flow cytometry for ploidy; this can even be done from paraffin-embedded tissues. Ideally, chromosome preparations are made for complete resolution of the diagnosis; this is most helpful in cases with possible mosaicism or twinning, but it requires fresh tissue and considerable effort.

### *Mesenchymal Dysplasia*

This entity is only marginally related to PHMs, but it needs discussion and bears some connection to partial moles with which it may be confused, especially sonographically. Moscoso et al. (1991) and then Jauniaux et al. (1997) described the entity perhaps first as representing placentas that were markedly enlarged with what appeared to be an excess of mesenchyma, although they then referred to somewhat similar cases from the older literature. A most typical case was described by Ohyama and colleagues (2000) of a 26-year-old Japanese gravida I whose 46,XX fetus died at 34 weeks with growth restriction (1516g). The placenta was large (1050g) and was mostly composed of enlarged villi with a “myxoid stroma” and decreased, occasionally obliterated fetal blood vessels. Thrombi were found in some surface vessels but the trophoblast appeared to be normal and the term **pseudo-partial mole with angiomatous proliferation** was coined. Remarkably, some of the surface vessels were massively enlarged and “noodle-like,” and many were thrombosed. The authors gathered 17 cases of similar nature from the literature and added 15 cases of placentas associated with the Beckwith-Wiedemann syndrome (BWS) because there are significant similarities at least in the placental manifestations (Chapter 24). This is especially true because in some areas there was significant vascular proliferation that bordered on chorangiomas. The vascular abnormalities, also described as “cirroid aneurysms” (Chapter 12), resemble two placentas

described by Zhang and Benirschke (2000; see Fig. 22.27). Their fetal karyotypes were also diploid and similar histologic placental features were then described. Paradinas et al. (2001) identified 15 cases in their database, and cautioned that some had been labeled partial moles, which was incorrect. The same is true of a case described by Matsui et al. (2003) in which the BWS was specifically excluded. The most recent description of a case of mesenchymal dysplasia is by Gibson et al. (2004), also with normal 46,XY karyotype. Prenatally, cysts had been seen in the placenta; the 3250-g infant delivered at 39 weeks, and the placenta weighed 1258g and had numerous cysts, normal villi, and intervillous thrombi. Interestingly, the neonate had a vascular hamartoma of the face and ptosis. The combination of fetal angioma and chorangioma is common; perhaps these placentas then relate mostly to an angiomatous malformation. Their vascular growth factors thus need to be studied. The precise pathogenesis of this seemingly specific placental abnormality needs much further study, especially with a genetic evaluation of the chromosomal region that defines BWS (11p15.5) and its possibly altered methylation status. It should be emphasized, though, that these cases in no way relate to the so-called association of Breus’ mole in PHM as was described by Kim et al. (2002). We believe that their interpretation is correct, namely that the subchorionic tuberosus hematomas, which they found to be composed of mostly maternal blood, were the result of sluggish intervillous blood return and that they antedated fetal demise.

### *Complete Mole and Fetus*

There have been numerous reports of molar pregnancies with associated fetuses, and Malinowski et al. (1995) referred to this as the “sad-fetus syndrome,” implying that there exists a continuum of moles to choriocarcinoma. Care must be exercised in the differential diagnosis of this condition. Although it is often assumed that the coexistence of a fetus with a molar placenta implies the diagnosis of partial mole, DNA analysis negates this often. Thus, Choi-Hong et al. (1995) studied nine pregnancies of this kind and found in eight cases normal placentas with FISH study for X and Y chromosomes; four had Y signals in the normal tissue and X signals in the moles, implying dizygosity and CHM in at least these rare cases. Popek (1994) who studied 10 cases of CHM with a twin fetus indicated the incidence to be 1:10,000 gestations, the majority being triploid specimens. But CHM with a twin fetus does exist and was estimated to be as uncommon as 1:250,000. Such fetuses occasionally survive, and the situation warrants answers to the following precise questions: Are these truly triploid gestations, or are they DZ twins with one being a CHM or a PHM, and the other a normal conceptus (Fig. 22.23)? The differential diagno-

FIGURE 22.23. Mole with “living coexisting fetus.” It is most likely a triploid conceptus: a male fetus, 9-cm crown–rump (CR) length, nearly completely molar change of placenta.

sis of these cases is often uncertain from macroscopic review alone, and frequently it cannot be reconstructed from the published reports. Moreover, is it possible that such gestations will become more common as artificial reproductive technology (ART) is practiced commonly now in older women? The case presented by Wax et al. (2003) suggests this possibility. It was the product of IVF with sperm donation in a 41-year-old woman; and Amr et al. (2000) found a triplet gestation from ART with normal male and female newborns plus a complete, androgenetic mole. Another unsuccessful usage of IVF/ART in a patient with habitual abortion and two triploid conceptuses was related by Bar-Ami et al. (2003). Abnormal ova and sperm as well as fertilization products were identified in this relatively young couple (30 and 29 years). The largest series of CHM with DZ twin comes from Sebire et al. (2002b), who had 77 cases in their registry. (Interestingly, there is a United Kingdom Web site for mole: [www.hmole-chorio.org.uk](http://www.hmole-chorio.org.uk)). According to their data, 60% of women who decided not to terminate the gestation lost the fetus in utero or had a complete pregnancy loss; 19% developed GTDs, not an increased frequency over that of the usual CHMs (16%). The natural history of eight well-documented cases of apparent CHM and coexisting fetus was described by Steller et al. (1994). These authors also analyzed the literature of this topic and found that the presence of a fetus often led to the sonographic (mis)diagnosis of PHM. They performed flow cytometry and found that five of these eight patients developed persistent trophoblastic disease that required chemotherapy. In other cases, the characteristic pattern of fetal anomalies allows identification of triploidy, especially the digital fusions. Not only is there a rich literature on the frequency of triploidy in spontaneous abortuses, but numerous cases have delineated the various anomalies occurring in liveborn infants with triploidy (e.g. Uher

et al., 1963; Beischer et al., 1967; Goecke, 1967; Butler et al., 1969; Schmickel et al., 1971; deGrouchy et al., 1974; Niebuhr, 1974; Fraikor et al., 1980; Graham et al., 1989). In some of these cases, the infant was living (Crooij et al., 1985) and the outcome was otherwise not complicated by trophoblastic sequelae. It is noteworthy that the placenta of some large triploid fetuses has not included hydatid changes. Fetus and placenta are also often growth-retarded, and a single umbilical artery is common. Absent umbilical artery diastolic flow has been reported in them (Sherer et al., 1993). It would be interesting to correlate the phenotypes of placentas with paternal/maternal sets of chromosomal contributions. The present belief is that, with triploidy, two paternal chromosome sets more often lead to PHM than do two maternal sets of chromosomes, which is more characterized by malformed fetuses. Some cases of PHM with fetus have been diploid, with a normal heterozygotic chromosome set (Kubo et al., 1986). Feinberg et al. (1988) reported such a case (46,XX) that was diagnosed sonographically. The fetus was hydropic but did not have any congenital anomalies. Urbanski et al. (1996) reported a normal diploid twin pregnancy associated with a tetraploid hydatidiform mole. Following the spontaneous passage of molar tissue, premature delivery was accomplished by cesarean section; the patient developed no persistent trophoblastic disease. A normal male embryo (25 g) was found associated with a CHM, reported by Al-Takroni et al. (1994). Following delivery the mother developed a choriocarcinoma, successfully treated with methotrexate. In a study of six patients with molar pregnancy and fetus or embryo studied by van de Kaa et al. (1995), two patients developed persistent disease, which led the authors to recommend special vigilance in their follow-up. They employed DNA probes for specific chromosomal regions to make the differential diagnosis and found frequent polyploidy and trophoblas-

tic hyperplasia in the molar components of the placentas. In four of their well-described six cases the 46,XY constitution of the fetuses declared dizygosity.

We described above a relevant case, diagnosed as partially hydropic placenta sonographically. The pregnancy ended with a normal female surviving infant. Approximately half of the enlarged placenta (see Fig. 22.1) was molar and the other half was normal. Flow cytometry indicated tetraploidy of the molar portion, and diploidy of the normal, and PCR done on paraffin-embedded tissue showed similar DNA constitution of the two components; thus, the genomic origin of the two components was the same. The vascular tissue of these tetraploid villi was diploid. Of the two interpretations, we prefer to think that this was a monozygotic twin with tetraploidization of one, followed by fetal demise. The perfusion by one twin's blood vessels would thus not be unusual, as anastomoses between monochorionic twins is common. Assuredly, these were not DZ twins with one being triploid, and this was not a partial mole in the usual sense. Gonadotropin titers remained normal in mother and neonate.

### *Partial Hydatidiform Mole with Twin Gestation*

The occurrence of a macroscopically PHM with a fetus always raises the question of triploidy; alternatively, there is a possibility of a twin pregnancy when not the entire placenta shows hydatidiform changes. The complex topic is discussed in some detail by Vejerslev et al. (1991), who described five pregnancies in a woman who had four consecutive molar pregnancies. The one that was associated with the fetus was a biparental diploid mole, which they considered to constitute a distinct and separate

entity. Most cases turn out to be singleton pregnancies. There are many reports, however, in which one normal placenta and fetus was present with a molar placenta. The assumption is often made that all of the cases are DZ gestations. The fact that some of them were later complicated by choriocarcinoma (Hohe et al., 1971) indicates that at least some of the moles may have been typical CHM. Table 22.2 summarizes the major reports describing such twin gestations, and a typical case is shown in Figures 22.24 to 22.26. Beischer and Fortune (1968) used the sex chromatin method (Barr bodies) to approach the nature of karyotypes in their early studies of this phenomenon. They delineated a number of twin gestations, wherein one was normal and the other molar. Important summaries of large series of moles with coexisting fetuses are those by Beischer (1966) and Vejerslev et al. (1986). They contain several cases of verified twin gestations and can be consulted for details. Nugent and his colleagues (1996) reported on a twin pregnancy, one a normal 46,XX and with a normal placenta, the other 69, XXY with PHM. Selective termination of the triploid fetus at 15 weeks was followed by the development of severe pre-eclampsia that necessitated termination at 19 weeks. They made the point that placental growth and PIH are not prevented by elimination of the triploid embryo. How complex such cases can be is shown in the case reported by us (Benirschke et al., 2000). The placenta was sharply divided into a normal organ (with normal, surviving fetus) and a typical CHM, which, however, had still perfused vessels. DNA analysis showed tetraploidy of the molar connective tissue, but euploidy of the perfusing vessels. This indicated to us that a formerly normal monozygotic (MZ) twin gestation was changed into this con-

TABLE 22.2. Twin pregnancies, one a molar gestation

Author	Year	Fetus	Mole	Outcome

FIGURE 22.24. Twin with mole. The patient was a 24-year-old woman who had had three pregnancies, one ending in abortion. Her course was benign until 32 weeks, when she delivered a 1900-g boy who did well. There was a normal 330-g placenta and separate 780-g complete, Barr body-positive hydatidiform mole (see Fig. 22.25).

FIGURE 22.25. Molar villi of Figure 22.24 show typical, uniform villous swelling.

FIGURE 22.26. Histologic appearance of twin's mole in Figures 22.24 and 22.25. There is moderate trophoblastic hyperplasia and, especially, proliferation of cytotrophoblast, rarely seen in PHM. H&E  $\times 400$ .

FIGURE 22.27. This is another example of a placenta with apparently molar transformation of one third of its villi. The reason for the latter, however, was extensive aneurysmal dilatation with thrombosis and infarction of surface vessels (see text).

figuration by polyploidization of one embryo (who was then lost) but whose placenta had already developed anastomoses to the surviving twin (see Fig. 22.1). Another observation of a placenta with apparently fused molar mass indicates how complex the differential diagnosis may be. Figure 22.27 shows a placenta from a severely growth-restricted fetus (1300 g at 31 weeks' gestation) whose problems were due to extensive aneurysmal distentions with thrombosis of surface vessels ("cirroid aneurysms"). Portions of the villous tissue showed typical molar changes but were genetically found to be of the fetus' origin (Zhang & Benirschke, 2000). Thus, a twin pregnancy was excluded.

# Trophoblastic Neoplasms

Among trophoblastic neoplasms, choriocarcinoma is the most well known. The classification of gestational trophoblastic disease (GTD) has been alluded to in the previous chapter, and Soper et al. (1994), who evaluated 454 tumors according to three classifications, found the prognostic aspects to be fairly similar among these otherwise divergent classifications. Perhaps the clinical staging provided the best prognostication. An excellent and concise review of chorionic tumors has summarized the progress made in understanding these lesions and prescribing therapy for them (Berkowitz & Goldstein, 1996). A checklist for the characterization of trophoblastic malignancies has been provided by Lage (1999), and several other noteworthy reviews among many others are those by Silverberg and Kurman (1992), Baergen (1997), and Baergen and Rutgers (1997). The classification of GTD, recently endorsed by the World Health Organization (WHO) (Tavassoli et al., 2003), is the most widely used and is shown in Table 23.1.

## Choriocarcinoma

Choriocarcinoma is a malignant neoplasm composed exclusively of cytotrophoblast and syncytiotrophoblast. If villi are associated with such invasive tumors, then the lesion is referred to as “invasive mole” or chorioadenoma destruens (Chapter 22). The nature of choriocarcinoma was first correctly identified by Marchand (1895). Teacher’s detailed observations in 1903 followed Marchand’s description. The early history of this tumor, the “deciduoma” as it was first known, has been admirably recounted by Ober and Fass (1961). Until the neoplastic elements of choriocarcinoma were ultimately shown to be derived from the embryonic as opposed to maternal cells, their derivation had been in dispute. Ewing (1910) was the first investigator to differentiate between the various types of trophoblastic neoplasms. He introduced or used terms such as **invasive mole**, **syncytial endometritis**, and **syncy-**

**tioma**. Some of these terms are still in use, even though the latter two have been replaced as greater knowledge of the biology has been accumulating.

In the United States, gestation-related choriocarcinoma is said to occur with a frequency of about 1 per 40,000 pregnancies (Hertig & Mansell, 1956). In their oft-depicted diagram (Fig. 23.1), Hertig and Mansell estimated that the lesion was preceded by a complete hydatidiform mole (CHM) in 50%, an abortion in 25%, a normal pregnancy in 22.5%, and an ectopic pregnancy in 2.5%. There is wide geographic variation in its incidence as it is in that of its precursors. In a study of choriocarcinoma from Japan, five of eight choriocarcinomas followed complete moles, one followed a term pregnancy (the only patient who died), and two followed abortions (Fukunaga & Ushigome, 1993a). All were diploid by flow cytometry.

The tumor consists of solid sheets of cytotrophoblast and syncytium. Choriocarcinoma has the great propensity of vascular invasion (Fig. 23.2) and, consequently, many choriocarcinomas are hemorrhagic and friable (Figs. 23.3 and 23.4). So much blood may be present in some choriocarcinoma metastases that one may have to search long for the tumor cells (Fig. 23.5). Characteristically, broad sheets of cytotrophoblast form the central portion of the tumor, the periphery being syncytium. Nuclear pleomorphism is common, but mitoses are confined to the cytotrophoblast. Wolf and Michalopoulos (1992) studied the distribution of nuclear antigen in normal placentas and trophoblastic tumors. Its presence correlated with mitotic, reproductive activity and, in placentas, it was also confined to the cytotrophoblast, where it was strongly expressed. The same was true in CHM and choriocarcinomas; the cytotrophoblast and extravillous trophoblast (X cells) stained, but not the syncytium. Several studies have shown that many intermediate trophoblastic cells are present in choriocarcinoma, even though they are not the hallmark of the lesion. These are the cells truly intermediate between cytotrophoblast and syncytium and are not

the intermediate trophoblastic cells described in lesions of extravillous trophoblast (vide infra). They are especially readily identified by electron microscopy (Pierce & Midgley, 1963; Wynn & Davies, 1964) (Fig. 23.6). The X cells, the other major line of trophoblastic elements, the extravillous trophoblast, were identified with certainty in choriocarcinoma-like lesions; they are also not a striking feature of hydatidiform moles. Because of its dilated cytoplasmic cisternae, the syncytium of choriocarcinomas is frequently vacuolated. This vacuolation may obscure the true nature of the cells. Much glycogen may also be contained in this tissue (Arkwright et al., 1993). When Crescimanno et al. (1996) cloned BeWo choriocarcinoma cells (human choriocarcinoma cell lines) and identified two separate lines of cells, they found different behavioral expression in these two lines. One was rapidly invasive and produced tumors and metastases in nude mice, and the other did not. The invasive line produced much greater quantities of gelatinase A (and less gelatinase B), and this activity was found to be stimulated by laminin and matrigel. This is a first approach for understanding the com-

FIGURE 23.1. Frequency relations of choriocarcinoma to its various precursors. (Source: Hertig & Mansell, 1956, with permission.)

plexity of invasion of the placenta into the decidua at implantation, as well as for understanding the invasive properties of some trophoblastic tumors, but not others. It is usually difficult to assign a prognosis from the histologic picture of a choriocarcinoma. Some choriocar-

Below are two large cells with irregular nuclei and many more mitochondria. Desmosomes (D) are seen in both. (Source: Wynn & Davies, 1964, with permission.)

cinomas (even metastatic lung lesions) have regressed spontaneously (see Bardawil & Toy, 1959; Rauter, 1968). Deligdisch and her coworkers (1978) suggested that solid tumor nests, with high pleomorphism and mitotic activity, have the worst prognosis. Fibrin deposits at the interface between tumor and host tissues are of good prognostic value. Another feature that bespeaks a better prognosis is a significant cellular “reaction” around the tumor (Elston, 1969). Sebire et al. (2004) have endeavored to use immunohistochemistry staining for p57<sup>KIP2</sup>, a maternally expressed gene *CDKN1C* to differentiate choriocarcinoma derived from moles or nonmolar pregnancies. They found, however, that this marker does not provide a sufficiently accurate means.

To be inclusive it must also be mentioned that nongestational choriocarcinomas have been described on rare occasion. Thus, Liu et al. (2001) presented a gastric choriocarcinoma that was associated with an adenocarcinoma. It secreted large quantities of gonadotropin, which decreased after initially successful therapy. But the tumor recurred, with elevation of gonadotropins, and eventually led to the patient’s demise. Although she had three pregnancies in the past, no connection to these could be established, and the authors considered “dedifferentiation” as a possible mechanism of formation. Interestingly, in their literature review of extrauterine primary choriocarcinomas, the authors found that they are more frequent in the Japanese population.

Choriocarcinoma **metastases** occur most commonly in the lung and in the brain, but many other organs may be involved. The distribution of metastases was well recorded by Ober et al. (1971). That presentation also excelled in the description of the macroscopic lesions and in the

microscopic appearance of choriocarcinoma. Vaginal secondaries and metastases to the cervix occur relatively frequently (Marquez-Monter & Velasco, 1967; Martin et al., 1983). Acosta-Sison (1958), who studied primary metastases in 32 patients, found the lung to be involved in 44% and the vagina in 31%. Eventually, the lungs were the site of metastases in 94% and the vagina in 44%; other organs were much less often involved. A relatively uncommon site is the kidney, although isolated cases have been reported (Jarrett & Pratt-Thomas, 1984; Soper et al., 1988). Some patients have been successfully treated, despite large tumor burdens. A patient whose third hydatidiform mole (Fig. 23.3) proved fatal had extensive metastases in the liver, but she died from an exsanguinating hemorrhage that originated in a duodenal lesion. This location is otherwise a relatively uncommon site of metastasis.

Pulmonary dissemination of molar tissue occurs often, but such vascular tumor deportation may lie dormant for many years. Figures 23.7 to 23.10 illustrate the lung of a patient who died from pulmonary hypertension 4 years after delivery of a hydatidiform mole. Her pulmonary arteries had thrombi and numerous masses of pure trophoblast. Neoplastic tissue was present in many vessels, but it did not completely traverse the vascular wall. There was an intense chronic inflammatory reaction at these sites, suggesting a barrier to invasion (Fig. 23.10). Similar patients have been described by Seckl et al. (1991) but they were successfully treated. The hypertensive effects of tumor embolization to the lung in general have been discussed in detail by Veinot and colleagues (1992), who believed this to be an important and often unrecognized problem.

FIGURE 23.7. Lung sections from a patient with pulmonary hypertension and infarction 4 years after hydatidiform mole. Throughout this lung the arteries were obstructed by choriocarcinoma and thrombi. (Courtesy of Dr. A.T. Hertig. Patient discussed by Bardawil & Toy, 1959.)

FIGURE 23.8. Same patient as in Figure 23.7. Pulmonary artery is filled with solid choriocarcinoma metastasis. There is an inflammatory reaction in the vascular wall at the point of invasion. H&E  $\times 40$ .

FIGURE 23.9. Same patient as in Figures 23.7 and 23.8. A small amount of viable tumor is present at left, the remainder of the artery is filled with thrombus. H&E  $\times 40$ .

FIGURE 23.10. Same patient as Figures 23.7 to 23.9. Choriocarcinoma fills the artery and is enmeshed in thrombus. At points of invasion there is much chronic inflammation, including many plasma cells. No “villous stroma” is produced. H&E  $\times 100$ .

The cellular response to choriocarcinoma has been studied in some detail by Elston (1969). He found variable degrees of lymphocytic, histiocytic, and plasmacellular reactions in response to invading tumor cells and correlated this with outcome. Patients with tumors that had the most intense reaction fared best with chemotherapeutic treatment. Elston also saw in the maternal cellular response an attempt of the host to “reject” the neoplasm. This pulmonary complication of latent vascular tumor growth is apparently not uncommon. Fahrner et al. (1959) described a patient who died with cor pulmonale and endarterial tumor growth 5 years after delivery of a mole. Spiegel (1964) had a similar case and reviewed 10 others from the literature. Excellent preservation of neoplastic tissue resulted from the ability of the neoplasm to grow within blood. Other cases have come from Dyke and Fink (1967); and Bagshawe and Nobel (1966) discussed the various types of pulmonary metastasis in some detail. They paid special attention to the radiologic and cardiac aspects. The latter authors and Evans and Hendrickse (1965) accumulated large series of this intraarterial pulmonary tumor spread. Many of the cases were associated with acute pulmonary hypertension and cor pulmonale.

Diagnostic curettage for the treatment of moles may be the mechanism of dissemination of malignant trophoblast with villous tissue. Indeed, villi are occasionally present in such embolic lesions. Bagshawe (1964) pointed out that the presence of villi in trophoblastic lesions “cannot be taken as a guarantee that it will remain benign indefinitely.” We strongly agree with this statement but recognize the difficulty experienced by the practicing pathologist and the dilemma of diagnostic semantics. Often an absolute diagnosis of chorionic malignancy cannot be made from curettings alone, especially when villi are present. Optimal care requires follow-up with serial gonadotropin titer determinations. Carlson and his colleagues (1984) described a patient who developed fatal pulmonary lesions immediately after normal pregnancy, despite chemotherapy. Bagshawe (1988) is incorrect, however, to state that the pulmonary lesions occur only in London, and that they have not been recognized during life. They are rarely considered, to be sure, unless preceded by a recent CHM.

Choriocarcinoma most commonly follows CHM and invasive moles. Hertig and Mansell (1956) estimated that only 18.5% of CHM terminate with choriocarcinoma. Most patients pursue a benign course once the uterus has been evacuated. As Figure 23.1 shows, choriocarcinoma may also follow normal gestations. The neoplasm has then occasionally been found within otherwise normal placentas and is then designated choriocarcinoma in situ. Thus, Fukunaga et al. (1995, 1996) observed two cases in the placentas of spontaneous abortuses, clearly arising from stem villi. Other cases of choriocarcinoma in situ are described below. Other origins of choriocarcinoma include gonadal teratomas and, rarely, teratomas at other

sites, but they are then not GTDs. It is unusual for choriocarcinoma to arise without a known antecedent neoplasm. Suzuki et al. (1993) were able to determine the origin of their choriocarcinomas with DNA analysis. Two cases followed complete hydatidiform moles and had androgenetic profiles, whereas another had parental DNA and followed a full-term pregnancy. They concluded from nine cases that polymerase chain reaction (PCR) study of the DNA of these tumors allows determination of the androgenetic origin. Seckl et al. (2000) made an important contribution when they studied the outcome of 3000 patients with partial hydatidiform mole (PHM). Having verified the true triploidy in the PHMs studied, they found that 15 had required chemotherapy for persisting trophoblastic disease, and three of these women developed choriocarcinoma. It was the authors’ point to emphasize that PHMs also need serial follow-up in order to prevent this serious consequence.

Choriocarcinoma has no villi, in contrast to **chorioadenoma destruens** (invasive mole), in which villi are present. This arbitrary designation of the two lesions does not signify any significant difference in their biologic behavior, as chorioadenoma destruens may be significantly invasive and destructive (Fig. 23.11). Indeed, the

FIGURE 23.11. Invasive mole (chorioadenoma destruens). Slices of uterus show the invasive, hemorrhagic mass of tissue. It is composed of mostly solid trophoblast with a few villous remnants.

two lesions are behaviorally essentially identical. Choriocarcinomas have also been reported in some experimental animals, but their commonest antecedent, the CHM, has not been observed in nonhuman primate pregnancies. It is unknown if these animal choriocarcinomas have the same unusual genetic background as some of the human gestational choriocarcinomas. There are several large reviews that discuss the major aspects of choriocarcinoma, including its historical perspectives, diagnosis, and treatment (Bagshawe, 1969; Ober et al., 1971; Park, 1971; Goldstein & Berkowitz, 1982; Silverberg & Kurman, 1992).

### Choriocarcinoma In Situ and Choriocarcinoma Coincident with Pregnancy

Driscoll (1963) described an incidental “choriocarcinoma” in the mature, circumvallate placenta of a normal pregnancy (Figs. 23.12 and 23.13). The mother and child did well. A small “infarct”-like lesion was sampled for histology and found to be a typical choriocarcinoma. The tumor invaded adjacent villi but not their vessels. Now that placentas are more often examined routinely, such tumors have been detected more commonly, and are always detected as infarcts on macroscopic study. Perhaps they should now be called placental choriocarcinoma. Brewer and Gerbie (1966) had two cases of choriocarcinoma developing within otherwise normal placentas. These

authors paid special attention to the earliest formation of this proliferative lesion and described the degenerative changes that occur within it. The degenerative process, they thought, may lead to detachment and deportation of tumor fragments. We have seen similar cases, three of which were the cause of massive transplacental fetal hemorrhage, and in one of them hydrops and fetal death (Santamaria et al., 1987) (Fig. 23.14). In another case, the anemic neonate had bled 250 mL into the maternal circulation, but survived. Mother and child had normal postpartum human chorionic gonadotropin (hCG) titers and remained well. The lesion appeared to be an infarct on gross examination and was sampled only because of the neonatal anemia. In yet another patient the mother developed central nervous system (CNS) and pulmonary metastases 1 month after delivery; the neonate had anemia and elevated hCG levels but remained well. In a case published by Lele et al. (1999), the 2 cm × 1.5 cm incidental choriocarcinoma in a mature placenta led to disseminated metastases that were successfully treated. It appeared as a typical infarct but was histologically a typical choriocarcinoma that had invaded adjacent normal villi. Metastatic choriocarcinomas identified during pregnancy have been seen more often. In a description of a pertinent case, Barnes et al. (1982) found 18 cases described before 1970, and reviewed the literature at that time. Their patient, a gravida II (routine spontaneous abortion 13 months earlier and with normal histology), suffered a metastatic choriocarcinoma in brain and lung in the second trimester. The fetus died and was devoid of metastases. The 270-g placenta contained a

FIGURE 23.12. Mature placenta with choriocarcinoma in situ (arrows). This lesion was accidentally discovered and thought to be an infarct macroscopically. The patient did well. H&E × 76. (Source: Driscoll, 1963, with permission.)

FIGURE 23.13. Same case as in Figure 23.12, but a higher power view of the tumorous elements. Note the obvious pleomorphism of tumor cells that surround the central villus. There is more syncytium than is usually present in choriocarcinoma. The dilated cisternae of the syncytium are obvious (bottom, center). H&E  $\times 200$ . (Source: Driscoll, 1963, with permission.)

6  $\times$  6  $\times$  4 cm choriocarcinoma that had not metastasized to the stillborn fetus. Following chemotherapy and irradiation, the woman had two normal pregnancies but suffered a glioblastoma from which she died 7½ years after the original tumor. Fox and Laurini (1988) found two additional cases of placental choriocarcinoma. In one, the fetus was stillborn, but the other did well. The placental lesion had the macroscopic appearance of an infarct. A particularly interesting case is that of Lage and Roberts (1993). Many white nodules in the placenta were diagnosed as choriocarcinoma, and pulmonary metastases ensued that responded to therapy. Placental villi had not

been invaded. The 46,XX neonate remained normal. Further, this publication brings together all of the literature on choriocarcinoma in situ. It may be argued that these histologically identified lesions are not “malignant” but, rather, in the sense used by Huber (1969), represent benign lesions, which he described as “chorionepitheliosis interna.” It may be so, except that not all such cases eventuated without causing metastases. The concept of choriocarcinoma in situ is variably interpreted, and more must be learned from future biologic studies of early lesions. They are probably much more common than recognized and fall, in a way, into the spectrum of confined

FIGURE 23.14. Choriocarcinoma in situ in an otherwise normal placenta. Solid nests of partially anaplastic tumor cells surround degenerating villi; note also the invaded villi (arrow). Fetus was hydropic and stillborn due to transplacental hemorrhage. H&E  $\times 125$ . (Source: Santamaria et al., 1987, with permission.)

placental mosaicism. A relevant case is shown in Figure 23.15. This was a normal placenta, and random section disclosed this unusual villus with multiple layers of trophoblast and several mitoses. It is possible that such a lesion eventuates into a choriocarcinoma. The important case described by Heifetz and Czaja (1992) emphasized this. In their 69,XXX triploid PHM with fetus, a small nodule of truly malignant-appearing trophoblastic growth was found. Despite this, the woman pursued a normal postpartum course; the report also summarized the 10 or so choriocarcinomas in situ reported to 1992. Additional cases with fetomaternal hemorrhage or with a rise of  $\alpha$ -fetoprotein (AFP) levels and benign subsequent course were presented by Duleba et al. (1992) and Ollendorff et al. (1990). Duleba et al., as did several others, treated their patient "expectantly" and showed in photographs that the lesion appeared grossly as an infarct. Ollendorff's patient with elevated maternal serum AFP (MSAFP) and a placental choriocarcinoma had rising hCG titers and developed a pulmonary nodule. The discussion following this paper (Hustin & Jauniaux, 1991) proves that the lesion differed from their chorioangiocarcinoma (vide infra). Jacques et al. (1998) described five cases of intraplacental choriocarcinoma identified in a 5-year period. In two women, pulmonary metastases were present, but none of the fetuses suffered disease, although two were premature and one had anemia. In situ hybridization for Y chromosomes was positive in the two gestations with male fetuses. The lesions had the gross appearances of infarcts. These authors also suggested that this intraplacental neoplasm may be more common than heretofore recognized.

Schopper and Pliess (1949) used the term **chorionepitheliosis** for borderline cases in a lengthy discussion of trophoblastic properties. They were especially concerned with spontaneous cures of alleged choriocarcinomas and with ectopic chorionepitheliomatous growths. They described a woman with a vulvar trophoblastic tumor

that had developed during normal pregnancy. Benson et al. (1962) described massive fetomaternal hemorrhage in a patient who subsequently developed uterine choriocarcinoma with pulmonary metastases. Blackburn (1976) and Feldman (1977) reported similar cases. In four additional patients with small placental choriocarcinomas reported by Brewer and Mazur (1981), disseminated maternal lesions were found. The infants did not have tumors, but three were stillborn.

Hertig and Mansell (1956) indicated that choriocarcinoma follows (in the United States) normal pregnancies in a 1 per 160,000 incidence. It is thus not surprising that choriocarcinoma should also be found occasionally coincident with pregnancy and abortions (Fig. 23.1). Relevant cases are those by Heller and Householder (1952), Driscoll (1983), Miller et al. (1979), and Olive et al. (1984). It is apparent from reviewing these reports that the choriocarcinoma that follows normal term pregnancy has a much poorer prognosis than that which follows CHM. Patients with this complication of pregnancy also have often much earlier metastatic disease (Hutchison et al., 1968; Greene & McCue, 1978; Miller et al., 1979). In occasional cases of neonates with tumors, the placental choriocarcinoma was not detected or the placenta had not been examined. This was the case with cerebral choriocarcinoma metastases that caused death in a 1-month-old child described by Chandra et al. (1990). The mother had no untoward sequelae and delivered another child, with normal placenta.

There are many other reports of choriocarcinoma that occur simultaneously in mother and infant or fetus. Buckell and Owen (1954) described the death of a 7-week-old infant from chorionepitheliomatous metastases; the mother needed a hysterectomy because she suffered postpartum choriocarcinoma. The authors referred to a similar case described by Emery in 1952. Mercer et al. (1958) found a fatal choriocarcinoma in a 3-month-old infant whose mother died from dissemi-

FIGURE 23.15. A single villus within a term placenta, randomly sectioned, shows proliferation of trophoblast with several mitoses and hyperdiploidy, as judged by nuclear size. Perhaps this is the precursor lesion of choriocarcinoma in situ. H&E  $\times 400$ .

nated disease. Another case, fatal for mother and infant, was reported by Daamen and colleagues (1961). Witzleben and Bruninga (1968), who reported a case, suggested that these findings constituted a specific syndrome. In their case, the mother had no obvious disease initially but later died from disseminated choriocarcinoma. Metastatic choriocarcinoma was the cause of fetal death in the report from Kruseman et al. (1977). The hydropic fetus had bled transplacentally. The mother developed metastatic disease and was successfully treated.

### Chorangiocarcinoma

Yet another new tumor type was reported by Jauniaux and colleagues (1988). They called this lesion chorangiocarcinoma. It was described as a “missing link,” but they still believed that “it is a true malignant neoplasm or a voluminous chorangioma covered by extreme trophoblastic hyperplasia” (Hustin & Jauniaux, 1991). The unique lesion they described appeared to be a solitary chorioangioma with extensive trophoblastic hyperplasia at its borders. The authors also concluded that chorangiomas are not hamartomas but true neoplasms. Trask et al. (1994) published a second case of chorangiocarcinoma, a choriocarcinoma in situ with accompanying chorangiosis, occurring in a twin pregnancy. The other twin’s placenta was normal and the mother did well. The lesion appeared to be an infarct macroscopically, as most other similar lesions have been. It introduces the question as to whether one should routinely sample all infarcts for histologic study, a practice that we have thus far avoided. The third case was described by Guschmann et al. (2003), again an incidental finding without deleterious consequences. Even the angiogenetic factors that they studied in this case were normal; they postulated this to be a “collision tumor,” at least as being one possibility for the genesis of the tumor.

### Exaggerated Placental Site: Placental Site Nodule, Placental Site Trophoblastic Tumor, and Epithelioid Trophoblastic Tumor

Kurman et al. (1976) introduced the term **trophoblastic pseudotumor** to designate a trophoblastic lesion they saw in 12 patients that behaved in a benign manner. The lesion tended to occur in young women, usually after pregnancy or abortion. The authors considered this entity to be “an exaggerated form” of the older entity syncytial endometritis. These placental site lesions were usually treated successfully by curettage. The trophoblastic *pseudotumor*, however, also formed occasional hemorrhagic nodules in the myometrium. This entity, we believe, is equivalent to the concept of chorionepitheliosis, which was discussed at

length by Schopper and Pliess (1949). It also probably encompasses the chorioma of Ewing (1910) and perhaps the syncytioma and other vague designations of borderline trophoblastic lesions discussed in the past. These entities are not uncommon but were infrequently reported. As better delineation became available, more cases were described, and a good survey is provided by Baergen and Rutgers (1997). The designation of these lesions depends much on the interpretation by individual pathologists and on the clinical behavior (see Fig. 23.19).

Because of the superficial resemblance to choriocarcinoma, it thus came as no surprise that metastatic consequences were later observed, despite the earlier belief that the trophoblastic pseudotumor was a benign growth. Because several patients with apparently malignant lesions have since been identified, this led Scully and Young (1981) to introduce yet another term, the **placental site trophoblastic tumor** (PSTT), which is characterized by mononuclear extravillous trophoblast that infiltrates within the uterus and its vessels. Only rarely, are villi present. The absence of cytotrophoblastic cell masses and the usual absence of syncytiotrophoblast differentiates the entity from choriocarcinoma. The lesion is largely composed of placental site cells (extravillous trophoblast, or X cells) and blends with placental site nodules and plaques as well as exaggerated placental site (vide infra). Such a lesion is shown in Figures 23.16 to 23.18. Here it is a nodule of trophoblast that had perforated the uterus 18 months after a normal term pregnancy. After hysterectomy, the patient thrived. There were no metastases. Finkler and his colleagues (1988) treated seven patients with PSTTs and included a detailed review. One case followed a CHM, and the others occurred after abortion or premature delivery, in contrast to choriocarcinoma, which more commonly follows a CHM. All but one that followed an abortion pursued a benign course. Despite chemotherapy, this exceptional patient had metastatic disease in pelvic nodes. Although the authors did not publish any photomicrographs, they did describe an unprecedented high mitotic count. This point is particularly noteworthy because placental site cells (X-cells or extravillous trophoblast) are not usually very mitotic.

In the relatively short time since the description of PSTT, a large number of cases have been reported, in spite of the fact that it is the rarest proliferative lesion of trophoblast. An interesting study of this lesion was undertaken by Eckstein et al. (1985), who also reviewed the literature most competently. In their view, differentiation from choriocarcinoma should be easy because the lesion is a “well-circumscribed yellowish mass in which hemorrhage and necrosis are less conspicuous than in choriocarcinoma.” The histology is more like a placental site than like choriocarcinoma. The tumor in the aforementioned patient followed an apparently normal pregnancy but was eventually fatal with widespread metastases. It

FIGURE 23.16. Placental site trophoblastic tumor that had penetrated the uterus 18 months after a normal, term delivery. Hysterectomy alone cured this patient. The “malignant” cells are pleomorphic placental site giant cells (largely X cells). There are no solid sheets of cytotrophoblast and few syncytial cells. There are no mitoses. H&E  $\times 100$ .

FIGURE 23.17. Placental site trophoblastic tumor; same case as in Figure 23.16. H&E  $\times 160$ .

had a diploid DNA content, and biopsies were easily transplanted into nude mice. Unlike other lesions of this type, the tumor cells did not have a high mitotic rate. Fukunaga and Ushigome (1993a,b) reviewed the entire topic comprehensively and added three cases of PSTT to the literature. One of their patients died with widespread metastases. That patient had a term delivery and returned 9 months later with uterine, vaginal, bladder, and lung tumors that resisted chemotherapy. Of the three cases they reported, two recovered, all had diploid flow cytometric DNA values, and all were of pregnancies with female babies. Characteristically, many fewer mitoses were seen in these lesions than in typical choriocarcinomas, and histochemically they showed significantly less hCG production, and more human placental lactogen (hPL) staining despite their epithelioid appearance (Rhoton-Vlasak et al., 1998). As in eight other cases described, their fatal case had associated nephrotic syndrome, a complication not reported in choriocarcinoma. They estimated that perhaps 10% of PSTTs behave in a malignant manner.

Although histologic and clinical features of the tumor, such as tumor stage, advanced age, interval from previous pregnancy of greater than 2 years, previous term pregnancy, clear cytoplasm, tumor necrosis, mitotic rate, and myometrial invasion, have been shown to be of prognostic value, no specific feature or features can predict benign versus malignant behavior (Rutgers et al., 1995, Baergen & Rutgers 1997). Furthermore, high mitotic rates have been identified in patients who ultimately pursued a benign course and low mitotic rates have been seen in patients with metastatic or even fatal disease (Fig. 23.19).

Rosenheim et al. (1980), who described a patient with uterine hemorrhage after abortion, decided that this

diagnosis can be made only on a hysterectomy specimen. The uterus they studied showed an endometrial polyp that was composed of clot, with masses of atypical trophoblast interspersed. Villi had earlier been obtained by curettage from this patient. The tissue was like that of a CHM. The trophoblast invaded 30% of the myometrium. After its removal, the patient experienced full recovery. Nagelberg and Rosen (1985) described other interesting biologic features in a patient following a normal pregnancy. They performed many endocrine studies, because the tumor was accompanied by virilization due to testosterone production, possibly secondary to ovarian theca cell stimulation. It was also relatively resistant to chemotherapy, a characteristic that distinguishes PSTT from choriocarcinoma. After an eventual hysterectomy, the pathologist found a solitary 2-cm mass of tumor cells. This report provided much insight into other endocrine parameters of this condition. The prolonged production of hPL by the X cells of such a lesion was held to be responsible for the erythrocytosis in a patient reported by Brewer et al. (1992). After hysterectomy the symptoms disappeared; the lesion was a 6-cm hemorrhagic mass that infiltrated the myometrium but was primarily composed of X cells. The difficulty of differential diagnosis was also highlighted by Horn et al. (1997). They described a patient in whom a uterine lesion was initially mistaken for a cervical carcinoma. Radical hysterectomy proved to have been unnecessary; indeed, the lesion may merely have been an exaggerated placental site rather than a PSTT. Caution and experience are necessary in the diagnosis before critical therapy is instituted. Another large cervical GTD (presumably a choriocarcinoma) was treated only with chemotherapy and disappeared (Sohn et al., 1996). The only

FIGURE 23.19. Placental site trophoblastic tumor with epithelioid appearance and numerous mitoses. H&E  $\times 400$ .

guides were hormone levels and the postgestational history of the lesion.

Fukunaga and Ushigome (1993a) believed that intermediate forms of these tumors exist. The case described by Hopkins et al. (1985) would thus perhaps still best be considered a choriocarcinoma following normal pregnancy, rather than a placental site tumor. Its histologic composition most conformed to cytotrophoblast and syncytium, rather than to extravillous trophoblast. More precise methods to differentiate among these various lesions are desirable. Horn et al. (1996) presented differential diagnostic criteria for these lesions. Such efforts may be accomplished by the use of histochemistry, as performed by Wells and Bulmer (1988) and Fukunaga and Ushigome (1993a,b). These authors found in one such lesion the existence of a few tumor cells with hCG markers; more cells contained hPL antigen (see also Rhoton-Vlasak et al., 1998). Duncan and Mazur (1989) compared the ultrastructure of one such tumor (following normal pregnancy) with that of nine choriocarcinomas. The findings included an absence of cytotrophoblastic nests in the placental site tumor. The cellularity was composed primarily of intermediate trophoblast (extravillous trophoblast, X cells), with occasional interspersed syncytium. The authors found by immunohistochemistry that some of the neoplastic X cells contained hPL as well as hCG, which is not usually the case in normal cells. The cells in PSTT also stain positively for  $\alpha$ -inhibin, Mel-CAM CD 146, a cell surface adhesion molecule and placental alkaline phosphatase (Shih & Kurman, 1998b).

The most recently described neoplastic lesion of trophoblast is the **epithelioid trophoblastic tumor**. Shih and Kurman (1998b) described 14 cases of this unusual lesion that is characterized by sheets of large mononuclear cells that resemble epithelial carcinoma. The infiltrative neoplasm is thought to derive from a specialized lineage of extravillous trophoblast and has a behavior more similar to that of migratory extravillous trophoblast, such as exist in the chorionic plate and extraplacental membranes. Several patients have had metastases and some died from wide dissemination, but this tumor appears to have a similar behavior and prognosis as the usual type of placental site trophoblastic tumor.

**Syncytial endometritis** is an ancient term that reflects the presence of many trophoblastic giant cells in the floor of the placenta. Others might have used the term **chorion-epitheliosis** to describe this morphology. This lesion is considered to be nonneoplastic and merely an exaggeration of a normal physiologic process. It is common in molar implantations. It has no relation to any inflammatory or infectious lesion, and the term has been abandoned in favor of exaggerated placental site (Tavassoli et al., 2003). In reality, though, it is often impossible to distinguish this lesion from normal placental sites. One must also remember that few normal placental sites ever come to be

observed by pathologists, as they are rarely curetted and death is uncommon at that stage of development (Dallenbach-Hellweg, 1981). Therefore, the pathologist may be unduly alarmed by the appearance of a normal postpartum placental site. A relevant example is shown in Figures 23.20 and 21.21. It came from the curettage of a placental bed in an 8-week gestation and had no adverse consequences. But the exuberance of normal trophoblast at this site is apparent. Figure 23.22 illustrates another exaggerated placental site. A cytogenetic NISH (nonradioactive in situ hybridization) study done by Faul et al. (1994) in cases of exaggerated placental site trophoblast indicated that the often-bizarre nuclei found in these lesions are polyploid or aneuploid, perhaps arising by cell fusion or by endoreduplication of chromosomes. Two cases of chorion-epitheliosis were published by Van Bogaert and Staquet (1977), presumably representing the same entity. The authors also considered the lesion to be a benign proliferation of trophoblastic elements. To clarify the differential diagnosis, these authors developed a scheme for differential diagnosis which has been adapted in Table 23.2.

Yet another lesion of extravillous trophoblast that has been described is the **placental site nodule**, which is a benign, nonneoplastic lesion that may be diagnosed many years after the preceding pregnancy. Nickels et al. (1978) described such a lesion in a 52-year-old woman whose last pregnancy was 20 years earlier. According to them, the lesion was "a normal anatomic event at the placental site after miscarriage or full-term pregnancy." A review of 20 cases of placental site nodules and plaques was undertaken by Young and colleagues (1990), and 40 cases were

FIGURE 23.20. Exaggerated placental site at 8 weeks. The infiltrating cells split myometrial bundles and are composed of uni- or multinuclear extravillous trophoblast. This is a benign, normal placental floor but histologically may easily be confused with a placental site trophoblastic tumor. H&E  $\times 160$ .

FIGURE 23.21. Exaggerated placental site following fetal demise at 8 weeks. Endometrial glands are surrounded by extravillous trophoblast and these are admixed with multinucleated giant cells. H&E  $\times 250$ .

reviewed by Huetter and Gersell (1993). Most of the cells stained with antibodies to hPL and cytokeratin; all lesions were either incidental findings or followed with a benign course. There is now agreement that these nodules represent retained placental sites in which much hyalinization and degenerative change are found. A useful marker for the identification of the proliferating cells is the presence of major basic protein (MBP), and less useful is placental lactogen. Rhoton-Vlasak et al. (1998) found 100% of exaggerated placental site nodules to be positive for MBP, and 78% of PSTTs. Tsang et al. (1993) identified Mallory bodies in two cases, representing high molecular

weight cytokeratins. Shih et al. (1999) were able to differentiate the cells composing these lesions of extravillous trophoblast into distinct types—those presumably arising from the membranous extravillous trophoblast (mild proliferation, smaller, glycogen-rich) and those from the intervillous/placental floor spaces (more eosinophilic, larger, and pleomorphic). We found a nodule like this 5 years after the last pregnancy when a patient had hysterectomy for cervical carcinoma.

It is difficult to define these lesions precisely, especially when the diagnosis depends on tissue obtained at curettage (see also Horn et al., 1996; Horn & Bilek, 1997). A

FIGURE 23.22. Curettings after normal pregnancy. There was postpartum bleeding of this 35-year-old woman who had had eight pregnancies, with two live births. The lesion was interpreted as choriocarcinoma, but the patient had an uneventful course without chemotherapy. It is best interpreted as exaggerated placental site. The cells are placental site giant cells (largely X cells). No solid sheets of cytotrophoblast are present, and there are no mitoses. H&E  $\times 260$ .

TABLE 23.2. Diagnostic differences between trophoblastic pseudotumor and other diseases

Signs	PSTT	Exaggerated placental site	Choriocarcinoma	Mole
Blood vessel invasion	+	–	+	–

Hemorrhage	+/-	–	+	–

PSTT, placental site trophoblastic tumor.

detailed review with illustrations and prognostic predictions has been provided by Baergen and Rutgers (1997), but it remains a difficult topic for most pathologists. The hope of differentiating a potential malignancy among these placental site lesions by an assessment of ploidy or DNA has been disappointing. Most lesions have been diploid or tetraploid, as summarized by Lage and Sheikh (1997). To ascertain whether one could anticipate the development of persistent trophoblastic lesions, de Kaa et al. (1996) performed DNA analyses and cytogenetics. They found this of limited value and also concluded that nuclear pleomorphism of CHM was of no prognostic significance.

Detailed study of genes by comparative genomic hybridization of four archival cases of PSTT undertaken by Hui et al. (2004) has shown chromosomal gain in two cases, no chromosomal losses, and neither gain nor loss in the remaining two cases. Initial results of studies by Shih and Kurman (1998a), who have been most interested in defining these lesions, showed that double immunohistology using Ki-67 and Mel-CAM antibodies allows some differentiation of exaggerated placental site, PSTT, and choriocarcinoma.

Interesting attempts at the differential diagnosis have been published in the intervening years since the last edition of this book. First, in an exhaustive study, Oldt et al. (2002) showed with numerous markers that the cells that compose these gestational trophoblastic neoplasias (GTNs) (other than the choriocarcinoma) have fetal genetic and chromosomal markers; they are thus not maternal neoplasms. Further, all of these 42 tumors studied had heterozygous SNIPS (single nuclear polymorphisms) and were thus different from the androgenetic moles and choriocarcinomas. It has been possible for Shih et al. (2004) to assign some of these lesions to different categories from a study of certain isoforms of the expression patterns of the *p63* gene, and thus to assign putative ancestors among the trophoblast lineages, the

membranous vs. placental extravillous cytotrophoblast. This has led to improved understanding of the otherwise confusing histopathology. In essence, then, this contribution has confirmed their earlier deduction of the specific origin of these lesions (Shih & Kurman, 2001).

## Ultrastructure of Trophoblastic Tumors

Wynn and Davies (1964) studied the fine structure of trophoblastic neoplasms that were transplanted to hamster cheek pouches. They combined their morphologic study with an endocrine assessment; they were unable to demonstrate estrogenic activity. Except for excessive dilatation of syncytial cytoplasmic channels, the tumor resembled early human trophoblast. Larsen et al. (1967) made similar observations and showed that syncytial cells performed phagocytosis. Other electron microscopy (EM) studies were carried out directly on human choriocarcinomas that had not been transplanted (Infrerrera et al., 1967; Knoth et al., 1969a; Arai et al., 1976; Duncan & Mazur, 1989). The various investigators made the same observations. Several of the descriptions included cells that are truly intermediate between cytotrophoblast and syncytium (“transitional” cells) (see Fig. 23.16), which was also shown in the choriocarcinomatous cell lines maintained in vitro by Knoth and colleagues (1969b).

## ANTIGENIC STUDIES OF TROPHOBLASTIC TUMORS

Most choriocarcinomas have at least some paternal genome. Perhaps most (at least those derived from hydatidiform moles) have only paternal chromosomes. It is therefore possible that the tumor’s antigenic determinants may engender immunologic rejection. This assumption was an important explanation for their frequently favorable prognosis. Elston (1969), though, described variably intense cellular reactions to the invading trophoblastic neoplasm and related it to outcome. Observations such as this one have led to the study of immune interactions of the tumors with the host and to the determination of human leukocyte antigens (HLAs) in choriocarcinoma.

Mogensen and Kissmeyer-Nielsen (1968) studied HLA types in mothers, fathers, and their children in conjunction with placenta-associated choriocarcinoma. Despite antigenic differences between father and mother, most of the children were histocompatible with the mother. This compatibility, the authors suggested, made the tumors capable of growing in the uterus, rather than being rejected. Tomoda and his colleagues (1976) investigated HLAs and ABO antigens in patients with gestational trophoblastic neoplasia and their husbands. ABO types had no correlation, but patients with choriocarcinoma were “frequently incompatible” at various HLA types. Nevertheless, patients with choriocarcinoma were more frequently histocompatible with their husbands than those having invasive moles. Rudolph and Thomas (1971) had found significantly different HLAs in the mother and child of a patient who developed choriocarcinoma. The authors thereby refuted the notion that the tumors develop because of a failure of trophoblast to be rejected. Lawler et al. (1971) found that there was no increased histocompatibility between mothers and children in choriocarcinoma cases. There was a suggestion that major incompatibilities of HLA and ABO types protected the mother from disseminated disease. This aspect was further supported by findings of Mogensen and Kissmeyer-Nielsen (1971). Ivaskova and her colleagues (1969) found lym-

phocytotoxic antibodies against HLAs in 12 of 13 patients with choriocarcinoma or moles and speculated that these antigens may be important in tumor rejection. Differences in the population of the HLA<sub>2</sub> membrane attack complex of complement (MAC) did not exist from controls in a French population of choriocarcinoma patients (Amiel & Lebovici, 1970). Ho et al. (1989) found that whites did not share HLAs, whereas Chinese with choriocarcinomas did. Yamashita et al. (1984) performed direct tissue studies to ascertain the possible presence of histocompatibility antigens on choriocarcinoma cells. By this method, normal villi, hydatidiform moles, and two choriocarcinomas did not have any apparent class I and II antigens. Differences in responsiveness to class I and II antigens were concisely reviewed by Nepom (1989).

When ABO blood group antigens were studied in a Lebanese population, families with trophoblastic disease had a normal distribution, as controls (Iliya et al., 1969). Bagshawe et al. (1971) observed that blood group A women married to blood group O husbands have the highest risk of trophoblastic neoplasia; those married to blood group A husbands have the lowest risk. Blood group AB patients have tumors that metastasized widely and were least affected by chemotherapy. The investigators considered that these effects show immunologic modulation of the tumor.

Because Rh(D) antigen is said to be expressed on trophoblastic surfaces, Tomoda et al. (1981) suggested that hydatidiform moles [with Rh(D)] would be rejected by the Rh(d) host (see also Fischer et al., 1985), and that the difference in Rh antigens of Orientals could explain their high incidence of trophoblastic disease. Support for this idea has also come from the early studies by Scott (1962, 1968).

It is not yet certain that biologic trophoblast-specific antigen expression exists. Cheng and Johnson (1988) endeavored to produce antibodies to such possible antigens. When the antibodies were carefully absorbed, these authors found a low incidence (3.6%) of corresponding antibodies in serum samples of infertile women. These investigators suggested that the earlier results of Grimmer and colleagues (1988) were erroneous, those that suggested a possible relation of these antibodies to lupus-like disorders. Srivannaboon (1971) found, in immunologic studies with a trophoblast line, that choriocarcinoma contained an antigen that was not shared by normal trophoblast. The nature of this antigen was not identified.

There have also been attempts to treat gestational trophoblastic neoplasia with immunologic methods. Doniach et al. (1958) immunized a patient with choriocarcinoma by injecting her husband's cells. Hackett and Beech (1961) injected concentrates of the husband's leukocytes intradermally without inciting a reaction. They also employed Freund's adjuvant therapy and noted a gradual diminution in metastatic tumor nodules. Final tumor resolution, however, occurred only after chemotherapy. The conclusion of these authors was that choriocarcinoma is not antigenic in the usual sense. Others have not agreed with this conclusion. Cinader et al. (1961) thought that their patient was successfully treated with leukocytes but were unable to rule out spontaneous remission. Although some spontaneous remissions of choriocarcinoma are well documented (Brewer et al., 1961), this is not a common event and certainly spontaneous remission cannot be reliably anticipated in clinical management. Ewing (1941), in fact, did not accept such lesions that regressed as having been true choriocarcinomas.

The immunologic tolerance of the husband's skin graft was explored in two patients with choriocarcinoma by Robinson et al. (1963), and Mathé et al. (1964) found variable skin graft survival in some patients with choriocarcinoma. There is no doubt that some GTNs elicit a cellular and immunologic response and that this may be related to survival (see Ober, 1969). It is also the presumed explanation for the poorer response to chemotherapeutic agents of the testicular choriocarcinomas in men because they lack foreign antigens. Until the precise mechanism of graft rejection is understood and we know more about the tolerance afforded to normal placental trophoblast, it is useless to engage in further speculation. The reader is referred to the numerous papers from symposia that have dealt with this question (Edwards et al., 1975; Beer & Billingham, 1976; Wegmann & Gill, 1983; Gill et al., 1987).

## EPIDEMIOLOGY OF CHORIOCARCINOMA

As with hydatidiform moles, the frequency of choriocarcinoma is irregularly distributed in different populations. It is also difficult to enumerate precisely because malignant moles are often included with choriocarcinoma. Nevertheless, there are major differences in prevalence. For instance, Ho et al. (1989) found the prevalence of GTN to be lowest in whites (3/100,000 to 6/100,000) and highest in Chinese (68/100,000 to 202/100,000). They studied cellular antigens and found that Chinese had significant HLA sharing; whites did not. This finding suggested to them that genetic and nongenetic factors are of etiologic importance, and that this may also explain the generally better prognosis in whites. Rolon and Lopez (1979) summarized much of the epidemiologic aspects; their data and those of others are summarized in Table 23.3.

The higher incidence of choriocarcinoma in older women is also apparent in most of these studies. Oettle (1961) made the point that, despite the frequency of choriocarcinoma in Bantu women, there is no increased frequency of hydatidiform moles in that population. They believed that the higher incidence of choriocarcinoma in that population may result from higher ages at childbearing. In a study of Lebanese patients, Iliya et al. (1967) hypothesized that consanguinity is an important cause of choriocarcinoma. Parazzini et al. (1988a) adduced some data in favor of specific dietary deficiencies (e.g., vitamin A) in gestational trophoblastic neoplasia; "however, the limitation of available evidence still introduces serious uncertainties in the interpretation of these findings."

## Endocrine Aspects of Gestational Trophoblastic Neoplasia

The most important endocrine consideration of choriocarcinoma is its production of hCG or subunits thereof (see also Chapter 22). Follow-up of patients with CHM and choriocarcinomas is effectively done by assay of this hormone in serum (Delfs, 1959). Urine hCG values above 100,000 IU/24 hours (or serum levels of  $\beta$ -subunits measured by radioimmunoassay) strongly suggest the presence of a hydatidiform mole or malignant GTN. Conventionally, patients are monitored with weekly determination of hCG levels until none is detected for 3 consecutive weeks after the initial treatment of complete moles. In the usual case, hCG becomes undetectable within 8 to 173 days (Yuen et al., 1977). Chorionic gonadotropin is cleared by renal mechanisms, with a half-life of 35 hours (Midgley & Jaffe, 1968). Hammond et al. (1981) suggested that, after the titers have disappeared, hCG should be monitored for 1 year after evacuation of a mole. Even so, late recurrences have been reported and they have frequently occurred despite adherence to this regimen (e.g., Kirk, 1965; Vaughn et al., 1980). The observations by Rotmensch and Cole (2000) in the treatment of possible GTNs on the basis of elevated hCG titers should be appreciated. These authors showed clearly that elevated hCG titers, by themselves, are not a reliable indication of trophoblastic tumors. This is due to the variable nature of antibodies against hCG used commercially and perhaps also to the possible binding of preexisting antibodies to mouse immunoglobulin G (IgG). Inasmuch as this elevation of titers had led to the inappropriate therapy

TABLE 23.3. Frequency of choriocarcinoma and chorioadenoma destruens among number of pregnancies

of 12 patients, they recommended greater scrutiny in the face of such laboratory findings. A possible improvement of monitoring cases with GTN is perhaps feasible with the determination of  $\beta$ -subunits of hCG in urine by radioimmunoassay (Wehmann et al., 1981). Through simultaneous measurements of serum and spinal fluid  $\beta$ -hCG levels, studies suggested that it may be possible to anticipate cerebral metastases (Soma et al., 1980).

Yazaki et al. (1980) compared isoelectric homogeneity of serum hCG in various types of normal and abnormal pregnancies. They found that normal gestations, CHM, and invasive moles had “normal” isoelectric peaks, whereas additional peaks were detected in sera of patients with choriocarcinoma. A variety of studies have shown that the hCG originates from the syncytial component of the choriocarcinoma. When Dawood (1975) measured progesterone levels in patients with choriocarcinoma, he found that it correlated with hCG. He believed that the elevated progesterone levels resulted from its production by the hCG-stimulated ovaries, as many patients experience theca lutein cysts with this neoplasm (Kohorn, 1983), rather than the trophoblast. Lacking appropriate fetal adrenal precursors, estrogen production is sparse in choriocarcinoma patients, and its determination is not useful. It is different in men with choriocarcinoma. They have excessive estrogen production and often suffer gynecomastia (Martin & Carden, 1963), presumably because of Leydig cell stimulation. Follow-up with hPL, MBP, and other trophoblastic proteins has either not been undertaken or has not been useful for therapeutic and management purposes.

Occasionally, choriocarcinoma is associated with excessive androgen production. These rare reports have been competently reviewed by Nagelberg and Rosen (1985). The origin of the androgens is still in dispute, although some in vitro work suggested a trophoblast origin. Searle et al. (1978) measured a placenta-specific  $\beta_1$ -glycoprotein in the serum of patients with GTN and found a moderate elevation in CHM and choriocarcinoma patients—much

less than that of hCG, however. They were not enthusiastic about the use of this marker in the management of patients. Nisbet et al. (1982) localized another placenta protein marker (PP5) to syncytium of placentas and its tumors. Serum levels, however, were not sufficiently elevated for its clinical use.

PSTTs are also associated with increased production of hormones, specifically hCG. Serum levels of hCG, however, are only moderately elevated, usually up to only 10,000 IU, as opposed to the extremely high levels seen in choriocarcinoma. In addition, only about 75% to 80% of patients show any elevation at all (Baergen & Rutgers, 1997).

### Ectopic Choriocarcinomas; Tumors in Men

Aside from the truly gestational choriocarcinoma that most commonly follows a complete hydatidiform mole, choriocarcinoma has occasionally been reported in the fallopian tube, ovary, and other locations. These lesions may then be referred to as heterotopic chorioepithelioma (Nanke, 1959). Nanke, however, discovered such a tumor after hysterectomy was performed for hydatidiform mole, and it is most likely that the CHM was the tumor's antecedent of the cerebral, renal, and pulmonary metastases. The author opined that the tumor arose from deportation of benign trophoblast that subsequently dedifferentiated. He termed it “chorioepitheliosis.” As detailed in Chapter 22, such uncertainties can now be resolved when genetic markers are studied. Three rare cases of choriocarcinoma in tubal pregnancies were the topic of a publication by Horn et al. (1994). All were successfully treated and metastases did not occur.

The primary choriocarcinoma in the lung of a patient without any other lesions, reported by Tanimura et al. (1985), most likely resulted from a prior therapeutic abortion. To support such a proposal, the authors examined the lungs of 10 patients dying after delivery or abortion and found pulmonary trophoblast in nine. Tubal

choriocarcinoma was reported by Madden (1950) following tubal abortion, as did most of the 48 other cases reviewed by the author. Other reports on tubal choriocarcinoma have come from Riggs et al. (1964) and Lurain et al. (1986). A comprehensive review was published by Ober and Maier (1981), who found 93 cases in the entire literature, deemed 58 to be acceptable, and added 18 of their own. These investigators indicated that small tumors are difficult to distinguish from ectopic pregnancy. They found two cases that still contained villi and thus should not be called choriocarcinoma. Some patients were cured by simple hysterectomy, whereas others (94%) responded well to chemotherapy.

Ectopic lesions of extravillous trophoblast have rarely been reported. Baergen et al. (2003) added seven new cases to the previous 12 descriptions in the literature of extrauterine lesions of intermediate trophoblastic proliferation. Follow-up was benign and an origin from ectopic pregnancies was postulated. The fact that trophoblast is so highly susceptible to methotrexate has led to many trials of the medical treatment of ectopic pregnancies with this agent (Ory et al., 1986; Carson et al., 1989). Five of six patients had no further need for therapy; one required subsequent salpingectomy. As described earlier, Barnes et al. (1982) reported the successful treatment of a placental choriocarcinoma, metastatic to the brain and lung. Following two normal pregnancies, however, this was followed by a primary lethal brain glioblastoma 7½ years after the choriocarcinoma, a lesion that was perhaps secondary to irradiation. Creinin et al. (1998) studied the action of methotrexate in early pregnancy and concluded that its main result is the disruption of the change from cytotrophoblast to syncytium—cytotrophoblast syncytialization as they called it.

Some choriocarcinomas occur without known antecedent pregnancy (Acosta-Sison, 1957). Benjamin and Rorat (1978) reported ovarian choriocarcinomas as “primary.” Their patient developed the fatal ovarian (and hepatic) tumor apparently spontaneously. The uterine cavity contained only necrotic debris. The authors found six previous cases similar to theirs in the literature. Turner et al. (1964) reported on a successfully treated patient with an apparently primary ovarian choriocarcinoma. No antecedent or coincident pregnancy was found, although the authors called the tumor gestational. Cunanan et al. (1980) reported an ovarian choriocarcinoma that was associated with a normal uterine pregnancy delivered by hysterotomy several weeks after resection of the mass. The patient did well on chemotherapy; the infant and placenta were normal. This report included a review of 24 additional choriocarcinomas coexisting with pregnancy. In 10, the tumor was found in the placenta, in five it was absent, and in the remaining 10 cases there was a lack of information. Axe et al. (1985) found six similar cases in their Registry of Ovarian Tumors. One of those patients died.

Manivel et al. (1987) reviewed the extensive literature of trophoblastic differentiation from germ cell tumors. This tumor is outside the scope of the present book. Suffice it to say that these investigators paid special attention to the presence of intermediate trophoblast in these germinal tumors. The cells were designated large mononuclear cells with a variety of immunologic characteristics that had led Kurman et al. (1984) to call them intermediate trophoblast. They should now be studied with more specific markers, such as MBP, and the designation “extravillous trophoblast” is more appropriate. Choriocarcinoma may differentiate from primary germ cell tumors of testis and mediastinum, and from teratocarcinomas. Fine et al. (1962) reviewed this topic adequately and reported a fatal case in which the tumor arose in the mediastinum, and paid special attention to the endocrine aspects of the neoplasm.

Wenger et al. (1968) reported a mediastinal choriocarcinoma in a man. This tumor is unusual. They had seen only 17 choriocarcinomas in men at the Mayo Clinic. Chemotherapy is significantly less effective in men than for trophoblastic neoplasms, which has been assumed to be due to the assistance of immunologic rejection mechanisms in the gestational tumor. Soma et al. (1973), who studied the chromosomes of a man with gastric choriocarcinoma, identified fluorescent Y bodies in this hyperdiploid cell line. Fukunaga and Ushigome (1993a) found their eight tumors to be diploid and reviewed the evidence that suggested that chromosomes of these tumors are normally diploid. A primary choriocarcinoma without antecedent lesion was described in the lung of a 51-year-old man (Sullivan, 1989). A pulmonary choriocarcinoma was also reported in a 60-year-old woman (15 years after menopause). Because of her age, it is unlikely that it had derived from a preceding gestation (Pushchak & Farhi, 1987). Pushchak and Farhi speculated that it came from epithelial metaplasia, as she (and the patient of Sullivan) had been heavy smokers.

These cases must all be interpreted with caution, however, especially when one knows of the remarkable patient described by Dougherty et al. (1978): an 86-year-old woman with fatal pulmonary and cerebral metastases whose uterus had choriocarcinoma with degenerated villi. The inference was that the villi and trophoblast had existed since her last pregnancy, 34 years earlier. She had been amenorrheic after that pregnancy. This case is truly exceptional. Another remarkable case is that reported by Lathrop et al. (1978) of a choriocarcinoma that developed 14 years after tubal ligation.

#### THERAPY OF GESTATIONAL TROPHOBLASTIC NEOPLASIA

Aside from the attempts at immunotherapy discussed previously, surgery and chemotherapy are used for the treatment of choriocarcinoma and its precursors. Initially, only surgical excision, perhaps prophylactic

hysterectomy, was available for eradication of residual trophoblast after evacuation of hydatidiform moles. The survival rate after hysterectomy was only 31.9% with uncomplicated choriocarcinoma; when metastases were present, it was 19.2% [Brewer et al., 1963]. Some patients with metastases had spontaneous regression, a surprising observation then. A complete review of various therapeutic modalities, including new chemotherapeutic agents and modern methods of detection, has been provided by Seckl and Newlands (1997). An important aspect of therapy is to determine the best time to commence therapy when a choriocarcinoma is suspected. This can be important, for instance, in the follow-up of patients with choriocarcinoma in situ, accidentally discovered in the placenta. Because such patients are followed by serial determination of hCG levels, knowledge of the disappearance rate of gonadotropin levels following normal delivery is essential. Korhonen et al. (1997) studied this in some detail in six women following normal delivery. From levels of around 35,000 IU/mL at the end of pregnancy, rapid decline leads to virtual elimination (5 IU/mL) by 21 days after delivery, hCG- $\alpha$  having a much more rapid decline than hCG- $\beta$ .

Much more rapid progress was made after the discovery that the folic acid antagonist methotrexate produced beneficial results (Li et al., 1956). The historical developments that followed were succinctly recalled by Hertz (1972) and Li (1972); in a larger thesis, Hertz (1978) provided a complete overview. So effective is methotrexate against proliferating trophoblast that it was even used for therapeutic abortion (Thiersch, 1952) and it is now often employed in the treatment of ectopic pregnancies (Ory et al., 1986). Others have employed this agent to cause the involution of residual trophoblast in abdominal implantations (St. Clair et al., 1969; Rahman et al., 1982). This method of therapy has improved patient survival remarkably (Brewer et al., 1964; Lewis et al., 1966; Goldstein, 1972). Many contributions have been published since these early studies and are aptly summarized in books by Goldstein and Berkowitz (1982) and Szulman and Buchsbaum (1987). Individual reports have established that immunologic interactions occur when metastatic disease is treated chemotherapeutically in incompatible situations (Gallmeier et al., 1970). Even the feared cerebral metastases have a 50% remission rate when treated vigorously with chemotherapy and radiation (Weed & Hammond, 1980).

Despite these excellent results from methotrexate, actinomycin D, and other newer agents, there remains the problem of early diagnosis. This point is important. Delays and repeat chemotherapeutic treatment after a symptom-free interval often result in resistant metastases. Parazzini et al. (1988b) found that patients over age 40, with AB blood group, and with a history of complete mole had an especially poor outlook. Surwit et al. (1984) provided suggestions for aggressive therapy in other categories of poor-prognosis GTDs. Interestingly, students of this disease still disagree as to whether patients with hydatidiform moles should receive prophylactic chemotherapy in an effort to prevent the occurrence of choriocarcinoma. Bagshawe et al. (1969) believed it to be contraindicated. It is the experience of some physicians, however, that such a prophylactic regimen is not only safe but also useful (Homesley et al., 1988). These considerations require a correct, precise diagnosis. We believe that patients with triploid, partial moles should be exempted from this consideration of prophylactic chemotherapy because only very rarely do choriocarcinomas follow such moles. A most readable review of the progress made in the therapy of this tumor comes from Walter Jones (1990), who paid special tribute to Kenneth Bagshawe as having initiated a new age in the therapy of GTN.

Because of the relative frequency (approximately 10%) of neoplastic sequelae when a placental site trophoblastic tumor is diagnosed, hysterectomy is usually advised and is considered the mainstay of treatment. That complete excision may be feasible and followed by normal gestations was shown by Leiserowitz and Wenn (1996). The tumor they saw was typical for a PSTT; it was visible sonographically and, after simple excision, the patient had three pregnancies. Patients are usually treated successfully by surgery when the tumor is confined to the uterus; however, when metastases are present, chemotherapy is advocated.

Unfortunately, the success of chemotherapeutic treatment in choriocarcinoma is not shared by the PSTT. Occasionally, patients with single metastases have been treated successfully with resection of the metastatic lesion, but additional chemotherapy is usually necessary, and even then success is not assured. The overall management of GTDs has been summarized in an American College of Obstetricians and Gynecologists (1993) technical bulletin.

It has often been asked if the multiple chemotherapeutic agents that are used to treat this neoplasm have an adverse effect on ovarian follicles. Several prospective studies have affirmed that normal pregnancy is subsequently possible (Patterson, 1956; van Thiel et al., 1970; Walden & Bagshawe, 1976; Garner et al., 2003). Despite experimental evidence that alkylating agents damage rodent ova, there is no reported increase in congenital anomalies and chromosomal anomalies of future offspring. Occasional life-threatening hemorrhage may occur during the evolution of choriocarcinoma; Pearl and Braga (1992) were able to treat two such patients by local embolization. Roberts and Lurain (1996) reported good success in low-risk GTD with single-agent therapy. All their 92 patients were cured, employing methotrexate, actinomycin D, or a combination of both. Only one patient needed multiple-agent therapy. However, 22 patients also had hysterectomy. The agent Taxol (a derivative of yew tree bark) had potent effect in choriocarcinomatous cell culture and is a future agent for therapy (Marth et al., 1995; Osborne et al., 2005).

### *Choriocarcinoma in Animals*

Although there have been very few reports of true hydatidiform moles in animals, especially nonhuman primates, spontaneous choriocarcinoma has been observed a few times in several species. Lindsey et al. (1969) reported the first spontaneous choriocarcinoma in a rhesus monkey. The primary lesion was in the uterus and there were widespread pulmonary metastases. Pregnancy had been confirmed by rectal palpation, no known abortion had taken place, and the tumor was unequivocally a choriocarcinoma by histologic study. Madarama et al. (1989) found a localized hemorrhagic tumor in the uterus of a DDD (Inbred mouse strain) mouse at age 601 days. Histologically, the pathology was clearly choriocarcinoma with appropriate immunochemical and electron microscopic characteristics. Experimental choriocarcinoma has often been produced in rats (Stein-Werblowsky, 1960; Shintani et al., 1966; Miyamoto, 1971), the nine-banded armadillo (Marin-Padilla & Benirschke, 1963), and the rabbit (Kushima et al., 1967). More recently, Fleetwood et al. (2004) described a placental site trophoblastic tumor in a cynomolgus monkey that had an ovarian origin and behaved in a benign manner. Vascular invasion and few mitoses were identified nevertheless. The tumor was positive for hPL but only few cells reacted with hCG antibodies. Farman et al. (2005) described a choriocarcinoma in a rhesus monkey that had elevated hCG levels.

## Choriocarcinoma in Cell Lines and Genetics

It has long been possible to transplant trophoblastic neoplasms into the cheek pouches of Syrian hamsters (Galton et al., 1963). The transplanted tumor grows to a large size. This experimental system has been useful to determine susceptibility to chemotherapeutic agents and to study tumor biology and its cytogenetics. Immunologic rejection processes could also be studied with this model. Apparently, the cheek pouch is an immunologically "privileged" site, and metastases do not occur in Syrian hamsters unless the neoplasm is transplanted to other sites (Ehrman & Gliserman, 1964). Chromosome numbers of

such transplanted tumors are hyperdiploid ( $2n \approx 80$ ) and they increase with time. This finding coincides with the DNA studies of trophoblastic tumors by Makino et al. (1963) and Goldfarb et al. (1971). The latter investigators found mostly hyperdiploid (often tetraploid) values for choriocarcinomas, chorioadenoma destruens, and some moles, including values obtained for cytotrophoblastic cells (see also Atkin, 1965). Park (1957), who studied the Barr body content of the tumors, found that they were equally aggressive whether coming from a male or female pregnancy. In cytogenetic studies, some choriocarcinomas have been shown to have chromosomal polymorphisms, heterozygosity, and many are aneuploid (Wake et al., 1981; Sheppard et al., 1985). The few other decisive modern chromosome and DNA studies carried out on choriocarcinoma are referred to in Chapter 22. Shih et al. (2002) reported on the creation of cell lines from extravillous trophoblast. They created these lines from PSTTs and CHMs by employing genes from the human papilloma virus. The former line had paternal and maternal genes, the latter only paternal chromosomes. These cells did not establish tumors when injected into nude athymic mice.

Transplantation of choriocarcinoma into rhesus monkey brain was also successful, but not all implantations into the lung yielded tumor growth (Lewis et al., 1968). This finding suggested that immunologic factors are involved in the rejection of such neoplasms. Carr (1979) found that when mouse trophoblast was transplanted into the lungs of mice, it was accepted only by neonatal mice; adults failed to support trophoblast growth. Carr reviewed the well-known deportation of chinchilla trophoblast to the lung of normal gestation. Kato et al. (1982) made the interesting observation that when tissue from 21 hydatidiform moles and 10 invasive moles (chorioadenoma destruens) was transplanted into nude mice or immunosuppressed hamsters, it was not accepted. Only seven of nine cases of choriocarcinoma could be successfully transplanted. Kato et al., therefore, concluded that choriocarcinoma is a true neoplasm, but moles are not. Izhar et al. (1986) observed the development of trophoblast from human teratocarcinoma cell lines.

## Benign Tumors and Chorangiomas

### Angiomas

With rare exceptions, vascular tumors are the only benign tumors of the placenta. Tumors designated chorioangiomas, chorangiomas, fibroangiomyxomas, fibromas, and the many other names that have been applied in the past are essentially similar, relatively common neoplasms of the placenta. Three large reviews have been published that bring together most of the literature. DeCosta et al. (1956) found about 250 case reports and listed all the synonyms applied previously. They also made reference to the frequency of hydramnios and associated fetal angiomas. Fox (1967), who also reviewed the often confusing nomenclature, indicated that Clarke described the first such tumor in 1798. Since then, the review by Siddall (1924) encompassed 130 cases, that by Marchetti (1939) comprised 209 cases, and Fox traced another 127 cases. Fox accounted for 344 published cases and gave incidence figures of 1 in 9000 to 1 in 50,000 placentas. When careful study of placentas is undertaken, the real prevalence may be as high as 1 in 100 pregnancies, according to some authors, although in our experience this number is somewhat excessive. Wallenburg (1971) provided 13 new cases and summarized publications between 1939 and 1970. His reported incidence in consecutively collected placentas was 1 in 117. These authors provided an extensive literature documentation that would be redundant to repeat. Bashiri et al. (2002) found a significant risk of preterm delivery in patients with chorangiomas. Soma et al. (1991) found that the tumor existed in 0.2% of placentas in Japanese women but was more common (2.5–7.6%) in the high-altitude population of Nepal (Soma, 2001). This is similar to the higher frequency of chorioangioma observed in placentas of women living at altitude by Reshetnikova et al. (1996). We have seen chorioangiomas associated with chronic vascular thrombi and elevated nucleated red blood cells (NRBCs) in the fetal circulation. Thus, an hypoxic stimulus is inferred to lead to excessive villous capillary proliferative stimula-

tion. Although still speculative, such angiogenesis may well be regulated by such vascular growth factors as demonstrated to occur in the placenta by Jackson et al. (1994). A more detailed consideration of the placental villous adaptation to hypoxia can be found in the contribution by Kaufmann et al. (1993), and Kadyrov et al. (1998) provided information on how anemic women produce increased placental angiogenesis in early development. The control of angiogenesis is complex, but it is an essential aspect of placentation and regulation during anemia, preeclampsia, and other pathologic states in pregnancy. There are numerous factors now being explored and many have significant impact on the villous vascularization. A detailed review was provided by Sherer and Abulafia (2001) that is too complex, however, for the brief consideration possible in this chapter. Guschmann (2002, 2003) and his colleagues in Berlin (Guschmann et al., 2003a) have described various angiogenesis factors in chorangiomas. It was their experience that high expression of angiopoietin-1 and -2 and their receptors was demonstrated in chorangiomas, whereas vascular endothelial growth factor (VEGF) was uniform with the normal villi, but variability existed. Further remarkable in their series was that 72% of accompanying babies were of female gender, and tumors occurred much more commonly in the first pregnancy. North et al. (2001) studied immunoreactivity for a variety of antigens in chorangiomas and juvenile angiomas. Thus, FcγRII, Lewis Y antigen, merosin, and glucose transporter-1 (GLUT1) were found to be highly expressed in the small placental vessels and angiomas, but not in control blood vessels or those of granulomas etc.

The typical chorioangioma is composed of fetal blood vessels that are usually supported by only scant connective tissue. The tumors often bulge on the fetal surface of the placenta (Fig. 24.1). When they are embedded in the villous tissue, they are located closer to the fetal surface (Fig. 24.2). The vessels comprising this tumor may be capillary or sinusoidal (Fig. 24.3). Frequently, the stromal

FIGURE 24.1. Typical chorioangioma (left), bulging on the fetal surface. Fetus and pregnancy were normal; there is slight circumvallation of the placenta at right.

component is abundant, and the lesion resembles a fibroma (Fig. 24.4). When Wharton's jelly-like material participates in the formation of the tumor, the appearance is that of a myxomatous neoplasm. The latter is particularly frequent when a chorioangioma arises near the base of the umbilical cord (see Chapter 12, Figs. 12.68 and 12.69). In such cases, a mucicarmine stain reveals the presence of mucus (Dunn, 1959). Chorioangiomas are invariably covered by trophoblast; one may envisage them to be the proliferation of fetal capillaries of a villus whose surface thus expands (Figs. 24.5 and 24.6). Ogino and Redline (2000) suggest that chorangiomas derive specifically from stem villi rather than terminal villi. The

tumors often have degenerative changes, calcification, infarcts, and thromboses, which may leave hemosiderin behind (Dunn, 1959). At times, thrombosis and infarction are clinically manifest with cessation of maternal symptomatology, such as the frequent hydramnios that is associated with these lesions. Chazotte et al. (1990) observed such a lesion sonographically in a fetus that also had meconium peritonitis; when the chorangioma shrank there was some improvement of the hydramnios. The 5-cm chorangioma in the 620-g placenta had focal infarcts. Hsieh and Soong (1992) challenged this report and presented a larger lesion with hydrops. It is now also possible to laser-fulgurate the vessels that supply symptomatic chorioangiomas and thus treat the hydrops fetalis at

FIGURE 24.2. Partially infarcted 1-cm chorioangioma underneath the chorionic surface of an otherwise normal, mature placenta. It had a golden-yellow appearance and could easily have been mistaken for an infarct.

FIGURE 24.3. Multiple chorioangiomas in mature placenta, some of capillary type and others of more cavernous type. H&E  $\times 50$ .

FIGURE 24.4. Chorioangioma with primarily fibromatous appearance. It measured 2.5 cm and occurred in a 29 weeks' gestation placenta. The cellularity of this lesion has suggested that such tumors may represent sarcomas. H&E  $\times 170$ .

its root cause. Another modality of therapy, the injection with alcohol, has been suggested by Nicolini et al. (1999). These authors injected 1 mL of absolute alcohol into the veins centrally in two patients' large tumors (5 and 6 cm) whose pregnancy was complicated by hydramnios. It was followed by immediate cessation of blood flow; a second injection was necessary in both patients. Both eventually delivered normal infants; the state of the tumors at delivery, however, was not described. A case similar to this was treated by colleagues in Wisconsin (courtesy of R. Franciosi, 2002) and eventuated with a large placental infarct.

Macroscopically, chorioangiomas may be small and multiple (Fig. 24.7); alternatively, they may constitute large masses that displace villous tissue and bulge on the fetal surface. They are fleshy, dark, often congested, and invariably benign. Previous authors, impressed with mitoses and the great cellularity of some tumors, suggested that occasional chorioangiomas represent sarco-

mas. Metastases and true invasion, however, have never been seen. Cary (1914) considered his case of "sarcoma" to be "well authenticated," but he did not provide photographs. Moreover, mother and infant did not suffer any known deleterious consequences from the  $6.5 \times 4.0 \times 3.0$  cm, focally calcified tumor. Similar observations were made by Mesia et al. (1999), who described an atypical case that was "mitotically active." Despite this feature and their review of the other rare cases described with similar findings, invasion or metastases did not take place. Another unusual case comes from Guschmann et al. (2003b), who described the lesion they found as "chorangiocarcinoma" (the world's third case), even though mother and fetus did well. The possibility of a "collision tumor" and "reactive lesion" were considered but not resolved. Expressions of angiogenic factors were not increased, but the markers for trophoblast were strongly expressed.

The tumors labeled haemangioendothelioblastomas by Williams (1921) were apparently benign. Variability of

FIGURE 24.5. Chorioangioma that was associated with fetal transplacental exsanguination. The congested capillaries of the tumor are evident. The convexity of the tumor is covered by syncytiotrophoblast. H&E  $\times 160$ .

FIGURE 24.6. This chorioangioma displays the feature of overgrown capillaries in an enlarged villus covered by syncytium. H&E  $\times 40$ .

the histologic appearance, often within the same tumor, has confused many authors. Capillary, cavernous, endotheliomatous, fibrosing, and fibromatous tumors have been included in the nomenclature suggested by Schulz-Hetzel (1978). We believe that such precision is unwarranted because the clinical outcome is almost always the same, and it depends more on the size of the mass(es) than on the composition of the tumor(s). One may regard these tumors as hemangiomas or as hamartomas. The latter designation, however, probably is unwarranted as other placental elements (e.g., trophoblast) never participate in their composition. This would be expected if the designation hamartoma were to apply, a point amply discussed by Marchetti (1939). This nomenclature was also examined in some detail by Barry et al. (1951) in a discussion of angiomas of cord and placenta. They ruled out that the lesions represent hamartomas and supported a neoplastic etiology.

It is theoretically possible to differentiate between a neoplasm and malformation-like tumor (hamartoma)

with some precision. Linder and Gartler (1965) found that when they investigated leiomyomas of the uterus using glucose-6-phosphate dehydrogenase (G-6-PD) variants as markers in the frequently (15%) heterozygous African-American population, a single-cell origin was the rule for these neoplasms. The same was found to be true for most other tumors. Congenital tumors such as neurofibromas, on the other hand, had multiple cell derivation. These tumors represent a malformation or hamartoma-like type of lesion. A study of chorioangiomas using this simple technique could be decisive in differentiating hamartoma from "true" neoplasm in females with G-6-PD heterozygosity.

The relation of chorioangioma to hydramnios has been known at least since Siddall's extensive review in 1924. He observed that hydramnios was particularly associated with large tumors, but that the prognosis for the gravida was otherwise excellent. Marchetti (1939), who gathered 209 cases and added eight of his own, drew attention to the much commoner location of chorioangiomas near the fetal surface. He also suggested their subdivision into three types and debated whether it represented a true tumor (he thought not) or a malformation, perhaps a hamartoma. The association with hydramnios was of particular interest to McInroy and Kelsey (1954). They saw a pregnancy from whose amniotic cavity 3400 mL amniotic fluid was withdrawn. The placental tumor weighed 454 g, measured 10.5 cm in greatest dimension, and had its own vascular pedicle. They suggested that the tumor represented "dead space" and was therefore responsible for fluid exudation. Such a large tumor, associated with a stillborn fetus that had cardiomegaly, is shown in Figure 24.8. In an extensive consideration of this tumor, Kühnel (1933) opined that the tumor would have to cause venous obstruction before it could cause hydramnios.

Klaften (1929), who observed a patient with 6000 mL of hydramnios and a 1700-g stillbirth, found a fist-sized tumor bulging on the fetal surface of the placenta. He

FIGURE 24.7. Chorioangiomatosis of the placenta. The nodular, pale lesions represent chorioangiomas, which comprise approximately 50% of the placenta. The lesions could easily have been mistaken for infarcts. The placenta weighed 430 g and was accompanied by a 3200-g infant with cardiomegaly, anemia (hematocrit 40%), and thrombocytopenia at birth. Chromosomes were normal. (Courtesy of Dr. P. Bromburger, Kaiser Hospital, San Diego.)

FIGURE 24.8. Exceptionally large (400 g) chorioangioma shelled out from its placenta. The infant was stillborn and had cardiomegaly.

discounted previous opinions that hydramnios was caused by the enlargement of amnionic surface from the bulging tumor mass. Rather, he believed that the tumor caused increased vascular resistance with transudation ensuing. A different mechanism for fetal hydrops was suggested by the case described in detail by Hirata et al. (1993). They discovered the 8.8-cm placental mass by Doppler and color flow mapping sonographically, and when hydrops developed, fetal blood sampling identified a hematocrit of only 17%. The hydrops improved after intrauterine transfusion. The anemia was attributed to microangiopathic hemolytic anemia, but a Kleihauer-Betke test was not done on maternal blood. This might have shown transplacental bleeding as has been observed in other cases of placental chorangiomas. Large chorangiomas may also affect the fetal circulation directly as was probably the case in the patient with a 7-cm tumor whose premature neonate had periventricular leukomalacia (Harigaya et al., 2002).

Numerous large angiomas have been described (e.g., Lopez and Kristoffersen, 1989). These authors saw a patient with placenta previa at mid-gestation with sonographically recognized tumor. They suggested that placenta previa is one of several recognized complications with chorioangioma. The fetus was growth-restricted (899 g), and the placental tumor weighed 503 g. There are many other reports of large chorioangiomas associated with hydramnios, hydrops fetalis, and fetal death. The placenta may be edematous and large in such cases. For instance, Knoth et al. (1976) found a 1150-g placenta with multiple chorioangiomas throughout the placenta, associated with a 3250-g stillborn fetus. Other cases of fetal hydrops with large chorioangiomas were reported by Mandelbaum et al. (1969), Sweet et al. (1973), and Imakita

et al. (1988). Size alone, however, may not be the decisive factor. In Figure 24.9 we show the 900-g chorangioma ( $14 \times 13 \times 10$  cm) on a 950-g placenta in a neonate with virtually no problems who survived. The umbilical cord was massively edematous (110 g) and the neonate had normal platelet counts, 14 NRBCs/100 white blood cells (WBCs) and mild hepatic enlargement and minimal edema. There had been no hydramnios, and the cesarean section done for breech presentation was the time when the neoplasm was discovered. The large artery supplying this tumor was four-fifths occluded by old thrombus with calcification. This presumably was the reason for the infarction of four fifths of the tumor. The villous tissue was edematous, and there was certainly impending cardiac failure, although the cardiac size was normal. Dorman and Cardwell (1995) were the first authors to present a description of the Ballantyne syndrome with a large chorioangioma. This syndrome (also referred to as maternal hydrops syndrome, pseudotoxemia, triple edema, mirror syndrome) occasionally exists in a variety of conditions, such as non-immune hydrops, moles, teratoma, etc. The patient described by these authors had severe hypertension, proteinuria, and edema with an hydropic fetus due to a  $9 \times 6 \times 8$  cm chorangioma at 19 weeks gestation. After delivery, the placenta was found to have numerous infarcts in addition to the chorangioma. Ideally, such tumors will be treated in utero with laser vascular ablation in future.

The hearts of these newborns are often enlarged. The neonates may also be severely anemic, and we believe that hydrops usually develops because of fetal heart failure (Nuutinen et al., 1988). Similar observations are made when large fetal angiomas or arteriovenous fistulas cause hydrops (Cohen & Sinclair, 1963; Cooper & Bolande, 1965; Daniel & Cassady, 1968; Murray et al., 1969). Cardiomeg-

FIGURE 24.9. A 900-g subchorionic chorangioma with marked edema of the umbilical cord and thrombosis of the nourishing chorionic artery. Four fifths of the tumor was infarcted, and there was villous edema and minimal neonatal cardiac failure. The infant did well.

ally alone was reported with the chorangioma described by Benson and Joseph (1961). That neoplasm measured  $16 \times 10 \times 6$  cm and weighed 542 g. High output cardiac failure and hydramnios occurred with a  $9 \times 8 \times 8$  cm mass studied sonographically by Eldar-Geva et al. (1988).

Thrombocytopenia is also often observed in the newborns whose placentas have chorioangiomas. It may be associated with heart failure and disseminated intravascular coagulation (Greene & Iams, 1984). Froehlich and Housler (1971) and Froehlich et al. (1971) described thrombocytopenia. The latter authors found the tumors to occur more frequently in white than in African-American mothers, more often with twins, and also more often with malformed neonates. They mentioned an association with fetal angiomas, as did Leblanc and Carrier (1979) and Bakaris et al. (2004). We have seen several neonates with hemangiomas whose placentas contained chorioangiomas, perhaps further supporting the notion that this tumor, as fetal angiomas, represents in reality some form

of congenital malformation, rather than a true neoplasm. Many authors have posed the same question. Bakaris et al. (2004) presented a case associated with neonatal hemangiomatosis and infantile angioma of the liver. Drut et al. (1992) reported the presence of hemangioendotheliomas and multiple chorioangiomas in the Beckwith-Wiedemann syndrome (BWS) (Fig. 24.10) and referred to a few case descriptions of similar combinations. Additional consideration of the BWS will be found below and in Chapter 22. The notion of "hamartosis" was also inconclusively discussed. Demonstration of factor VIII within the neoplastic cells suggested to Majlessi and coauthors (1983) that the origin of the large and unusually cellular tumor (327 g) they observed was endothelial. Sieracki et al. (1975), in a description of six cases, found one tumor that resembled pericytes. Accordingly, they suggested the diagnosis of pericytoma. Hydropic bovine fetuses have been associated with chorioangiomas (Corcoran & Murphy, 1965), and Kirkbride et al. (1973) found an

FIGURE 24.10. Chorangioma in placenta of infant with the Beckwith-Wiedemann syndrome. H&E  $\times 400$ .

aborted calf with dermal, oral, and placental angiomas. We saw a stillborn bongo (*Tragelaphus eurycerus*) with four huge chorangiomas (weighing up to 975 g) in which some smooth muscle fibers were frequent; also, bizarre multinucleated cells were found whose origin remains obscure. Limaye and Tchabo (1989) observed maternal thrombocytopenia during the course of a pregnancy that was complicated by a 5-cm chorioangioma. They believed that the thrombocytopenia was the result of necrosis in the angioma.

Several authors have noted that chorioangiomas were associated with preeclampsia (e.g., Heggtveit et al., 1965). Stiller and Skafish (1986) found fetomaternal hemorrhage with a placenta that had eight chorioangiomas. Santamaria et al. (1987) saw fetal exsanguination result from such tumors. Perhaps the significantly increased fetal circulation caused by large tumors produces fetal growth restriction (Müller & Rieckert, 1967; Mahmood, 1977; King & Lovrien, 1978). In a series of seven chorioangiomas, Philippe et al. (1969) found four underdeveloped fetuses. Adducci (1975) reported fetal distress resultant from a large chorangioma. Aside from hydramnios, it is frequently reported that premature delivery and placenta previa are associated with chorioangiomas. Asadourian and Taylor (1968) described the occurrence of abruptio placentae with this placental tumor. Premature separation was also seen by Sulman and Sulman (1949), who additionally reported elevated maternal human chorionic gonadotropin (hCG) titers. Others have also found altered levels of pregnancy hormones with large chorioangiomas.

Giant chorioangiomas have been alluded to in several publications (e.g., 570 g in Burrows et al., 1973); the record is probably held by the 1500-g ( $30 \times 20 \times 5$  cm) tumor described by Arodi et al. (1985). It was associated with breech presentation, placenta previa, hydramnios, preeclampsia, and abruptio placentae. The 32 weeks' gesta-

tion fetus weighed 1000 g and died from anemia and asphyxia.

Placental chorioangiomas present other challenging pathologic features. Although placentomegaly, often with typical hydropic villi, is probably directly related to cardiac failure, anemia, and hypoproteinemia, there is no good explanation for an associated umbilical artery thrombosis as described by Sen (1970). Perhaps it is easiest to explain the anemia by the proliferative response that has been identified by Kosanke et al. (1998). These investigators showed that the hypoxia resulting from anemia increased the proliferation of trophoblast and mesenchymal cells of the human placenta. Reiner and Fries (1965) found arteriovenous fistulas in their injection study of a chorioangioma; the neonate experienced rapidly disappearing cardiomegaly. Repetitive multiple chorioangiomas were noted by Battaglia and Woolever (1968), who speculated that sequestration of plasma proteins into the interstices of the lesion may have accounted for the associated hypoproteinemia and edema of their case. Other cases of recurrence have been described and were reviewed by Benirschke (1999). Ludighausen and Sahiri (1983) described a woman whose first and third gestation placentas had multiple chorioangiomas. They were the presumed cause of fetal demise in both. Likewise, Chan and Leung (1988) found recurrence of multiple chorioangiomas, both eventuating in fetal demise. We have observed a case of recurrent chorangiomas. The 2205-g boy was born after 39 weeks' gestation to a 17-year-old gravida II. He had Apgar scores of 9/9 and did well. The 430-g placenta had numerous typical chorangiomatic nodules (Fig. 24.11), was markedly congested, and had numerous NRBCs in the fetal circulation. Sonographically, "unusual notching of the umbilical vein" had been reported. A previous pregnancy, 1 year earlier, was also complicated by multiple placental chorangiomas. Thus, in all four families summarized here the recur-

FIGURE 24.11. Macroscopic appearance of placental slices in recurrent chorangiomatosis.

rent chorangiomas were composed of multiple lesions, perhaps best defined as chorangiomatosis. Whether isolated chorangiomas can occur repetitively is unknown. Earn and Penner (1950) depicted a chorioangioma that was separate from the placenta; it was attached by a long vascular pedicle whose vein was diffusely calcified. The macerated fetus associated with this placenta was hydropic. Sonographic diagnosis has repeatedly been made of chorioangiomas and was well described by Dao et al. (1981), who found two large tumors (see also Hirata et al., 1993).

Because we had previously found a severely retarded fraternal twin that had a chromosomal error [46, XX t (2q-; 15q+)], with angiomatous masses in the placenta (Wurster et al., 1969) (Fig. 24.12), we later studied a single chorangioma cytogenetically; it was normal (Kim et al., 1971). Ultrastructural studies done at the same time showed normal endothelial cells and capillaries. Subsequent electron microscopic studies of chorioangiomas were performed by Cash and Powell (1980); they revealed no major additional features. Soma et al. (1991) also studied the tumors electron microscopically and found them to be composed of angioblastic proliferation. The few other cases of chorangioma in twin gestations have been commented upon by Benirschke (1999); they are uncommon, although Wallenburg (1971) and Froehlich et al. (1971) thought otherwise. They are also more common in triplet gestations.

One publication suggested that a “missing link” might have been found between chorioangiomas and choriocarcinomas. Jauniaux et al. (1988) described a lesion they termed “chorangiocarcinoma.” The placenta of this 35 weeks’ pregnancy contained a solitary small nodule fairly

typical of a chorioangioma. Its surface, however, was covered by apparently proliferated trophoblastic epithelium. The mother and child did well; there was no other chemical or cytochemical evidence of choriocarcinoma. Electron microscopy also was no more decisive in suggesting that it was a combination of the two disparate tumors (see Chapter 23).

#### OTHER BENIGN TUMORS

Some benign tumors of the placenta have been discussed in Chapters 11, 12, and 25. There are, for instance, rare teratomas (Castaldo et al., 1972; Fox, 1978), possibly representing twins. The partial hydatidiform moles, not representing true tumors, are covered in Chapters 21 and 22. Heterotopic tissues, such as adrenal gland, have occasionally occurred in the placenta. They were never neoplastic, but they have occasionally been associated with a growth-restricted infant (Cox & Chavrier, 1980). Fox (1978) had suggested that acceptable placental teratomas should reside on the fetal surface of the placenta.

The report by Chen et al. (1986) presented a novel type of placental tumor. It was a presumed **hepatocellular adenoma**. The authors observed a small-for-gestational-age (1781 g at 37 weeks) infant with a 530-g placenta that contained a  $7.0 \times 4.2 \times 2.7$  cm firm mass. The tumor was tan-white, sharply delimited, and composed of polyhedral cells that had the appearance of hepatocytes. There was no bile pigment, but the cells contained glycogen, and some reacted with antibodies to  $\alpha$ -fetoprotein and  $\alpha_1$ -antitrypsin. Study by electron microscopy showed structures that strongly resembled bile canaliculi. The authors believed that the lesion was a “monodermal teratoma,” although it was not on the placental surface. The fetus and mother had an entirely benign course. Four additional hepatic adenomas were described in some detail by Khalifa et al. (1998). They were benign as well, and two had an intravillous and two a subchorionic location. Their histology and special staining characteristics were similar to those in the previous case, but hematopoiesis was a consistent finding. These authors believed that an origin from displaced yolk sac structures was the most likely. Guschmann et al. (2000) described a 2-mm nodule in the twin placenta of a mosaic Turner syndrome patient and interpreted

FIGURE 24.12. Placentas of dizygotic (DZ) twins at term. The mother had five pregnancies, was 34 years old, and suffered hydramnios at 36 weeks in this gestation. Twin A was a normal girl (2585g); the placenta weighed 420g. Twin B was a boy

(1642g), with a placenta weighing 3600g. It was interpreted as a “mole.” Microscopically, there was primarily angiomatous change of the entire placenta, and the fetus had a translocation with duplication. (Source: Wurster et al., 1969, with permission.)

it as a heterotopic adrenal lesion. The entire literature of benign, unusual placental tumors is here also competently reviewed. Doss and her colleagues (1998) reported on a hydropic neonate with hepatoblastoma of the liver whose placental vessels were crowded with metastatic hepatoblastoma cells.

## Chorangiosis and Chorangiomas

The terminology for chorangiosis and chorangiomas is poorly defined; indeed, Marchetti (1939) considered that this lesion was merely a diffuse ectasia of placental villous capillaries. One may possibly think of chorangiomas as representing multiple chorioangiomas, but chorangiosis is most certainly not a neoplastic condition. Because of its histologic similarity to some aspects of chorioangioma, it may as well be discussed here, although it has a decidedly different pathogenesis. Meyenburg (1922) had considered this lesion as “diffuse hemangiomas of the placenta,” but it was Hörmann (1958) who coined the term **chorioangioma**. Later authors suggested that it results from abnormal maturation of villi and hypoxia. In particular, the differentiation from the con-

gestion of diabetic mothers' placentas has caused confusion in the literature. It must also be cautioned that removal of blood from capillaries renders villi relatively bloodless and thus to appear as being without vessels, whereas infusion distends the capillaries and may produce pictures like chorangiosis. Care must be taken in interpreting the lesion properly.

Caldwell et al. (1977) considered this lesion to be a “vascular anomaly of the placental villi with increased capillarity of their stroma.” They saw a 3100-g infant whose mother had received isoxsuprine over 5 months for vaginal bleeding and uterine contractions. The infant had thrombocytopenia and petechiae. Also present were hydramnios and a circumvallate placenta that weighed 1770g and measured  $24 \times 23 \times 6.5$  cm. It was unusually thick. The villi had hugely distended vessels that were numerically increased. As is true with chorioangiomas, the depressed platelet count was probably the result of sequestration in the placental capillaries.

It was not until Altshuler (1984) considered this entity in considerable detail that some clarity resulted about the nature of chorangiosis. He diagnosed the condition

principally by low-power lens inspection of histologic sections (stained with hematoxylin and eosin, H&E): “Chorangioma was diagnosed when inspection with a  $\times 10$  objective, showed ten villi, each with ten or more vascular channels in ten or more noninfarcted and nonischemic zones of at least three different placental areas.” He graded chorangioma from grade 1 to 3, depending on the profusion of vessels within villi. He found an overall incidence of 5.5% among 1350 placentas and distinguished it clearly from congestion. Because of the frequency and importance of this condition, refinements of the numerical assessment have been made. Perhaps the most important observation is that by Mutema and Stanek (1998). They found that, when counting is done on slides stained with CD34 immunohistochemistry (endothelial marker), more vessels were counted in nonchorangiomatous villi (eight to 15), and thus when H&E staining only is performed, the frequency of chorangioma may be overestimated.

Chorangioma is not common but may have an ominous connotation (Benirschke, 1994a). Altshuler saw it associated with high frequency in stillbirths and many perinatal circumstances that suggested to him long-standing hypoxia. Thus, it is more commonly observed in the placentas of babies who develop cerebral palsy. We find it more often with cord problems of one kind or another (Benirschke, 1994b). The increase in capillary lumen cross sections seen in this lesion comes about, we believe, through endothelial proliferation. It thus takes time to develop. Perhaps it takes as much as weeks to develop full-blown, marked chorangioma. Its presence betrays a deleterious intrauterine environment for the fetus, and we see in its manifestation an attempt (teleologically speaking) of the placenta to enlarge its diffusional

surface. It is thus not surprising to note that somewhat similar observations were made in placentas from high altitude when they were quantitatively compared with those of lower strata (Jackson et al., 1987; Reshetnikova et al., 1993, 1994, 1996; and many others). When Ali (1997) compared stereologically the villous structure of placentas from high altitude (3000m) with those at sea level, his main finding was an increase in the number of cytotrophoblast at altitude. Birth weights, placental weights, and placental index were all lower at altitude. The increased recruitment of cytotrophoblast was thought to result from relative hypoxia and increased syncytial turnover. Although not discussed, the microscopic picture of villi shown suggests an increase in capillaries as well.

Placental villous congestion is particularly prominent with uncontrolled diabetes and, in our experience it may mask this lesion (chorangioma) if one is not careful (Fig. 24.13). In chorangioma, there is an obvious numerical increase of the vessels per villus (Fig. 24.14); with congestion, the vessels are merely distended. Chorangioma correlated significantly with perinatal deaths (39%) (e.g., Keenan & Altshuler, 1975) and congenital anomalies (27%) and was thus deemed to be an important signal for scrutiny, particularly in placentomegaly. Its final etiology, if a specific one really exists, remains to be elucidated. It must be cautioned, however, that not all infants whose placenta shows diffuse chorangioma are significantly affected. Thus, the case reported by de la Ossa et al. (2001) had as the only complication severe preeclampsia that necessitated a cesarean section. Despite the chorangioma, the infant developed normally, and no other features that might have induced chorangioma were known.

FIGURE 24.13. Severe villous congestion in mature placenta of trisomy 21. This picture is difficult to distinguish from that of chorangioma. Quantitative measurements and vessel counts are necessary to make a clear distinction. H&E  $\times 160$ .

FIGURE 24.14. Chorangiosis of villi in a placenta of severely growth-restricted neonate. The cause of chorangiosis in this case was not ascertained. H&E  $\times 160$ .

## Mesenchymal Dysplasia and the Beckwith-Wiedemann Syndrome

Chapter 22 discussed aspects of mesenchymal dysplasia because the morphology exhibited by this lesion is so often mimicked by features of partial hydatidiform moles. These considerations will not be repeated here. It is necessary, however, to draw attention to the overlaps with BWS and chorangiomas, as they are often very similar in morphologic expression. Indeed, a clear definition of mesenchymal dysplasia that separates these entities is still forthcoming. The recent cases of Paradinas et al. (2001) and Matsui et al. (2003) were cited because of such overlaps. Drut et al. (1992) had described a case of BWS and chorangioma that was also associated with abnormal kidneys and liver angiomas. Thus, clearly difficulties exist for a clean separation of these three entities. The photograph of the placenta in one of our cases with BWS (Fig. 24-10) exemplifies the chorangiosis in this condition. How can progress be made in this area of confusion? First it must be recognized that the BWS has many anomalies that are often minor and may not be recognized in the immediate neonatal period. Thus, it is uncommon that in the placental lesions here summarized, appropriate genetic studies are undertaken to rule out the syndrome. It is a syndrome whose gene appears to be located on 11p15 and has variability with respect to imprinting domains and mutations of p57(KIP2) (see

Niemitz et al., 2004). Deletions had not been recognized until their case was described; thus refined genetic scrutiny would be in order also for the chorangiomas, which, after all, also represent a form of neoplastic tendency as is the case with BWS. It just might be that some of the recurrent chorioangiomas thus find an explanation. Other recent studies of the molecular defect are those by Du et al. (2004) and Le Caignec et al. (2004), whose contributions should be consulted. Mesenchymal dysplasia is often associated with "cirroid aneurysms" of the placental surface, and the vascular abnormality may extend into stem vessels. Moreover, often one also finds some degree of chorangiosis. In addition, cases with an admixture of abnormal and dysplastic tissues should be studied chromosomally, as they may well be of chimeric nature. In any event, such studies, and the pursuit of angiogenic factor expression or their possible abnormalities may be of interest in the clarification of these dysplasias.

# Multiple Pregnancies

In a remarkable paper that correlates prenatal events and discordance of twins with postnatal outcome, Price (1950) emphasized the importance of “prenatal biases.” He was much concerned with the influence of placentation upon twin development, an aspect that had not often been considered in twin studies. Similar ideas were echoed by Phillips (1993), who emphasized the influence of the proximity of twin placentas on their ability to support fetal growth. But it was Galton (1875), cousin of Charles Darwin, and after whom the Galton Institute of Genetics in London is named, who was probably the first to suggest that twins, if properly studied, would yield information that might allow us to discriminate between the effects of heredity and those of the environment—his famous “nature vs. nurture” concept. The extensive studies conducted by Friedrich Schatz at about the same time, suggested that prenatal influences among twins found reflection in the ultimate the outcome of the twins. He was instrumental in clarifying that placental study is essential for this understanding. His extensive work is annotated in a bibliographic oddity (Schatz, 1900). It summarized all of his papers and citations therein. Some of his numerous contributions were partially translated for the book on twin placentation by Strong and Corney (1967). A concise review of the biologic aspects of the human twinning process was published by Benirschke and Kim (1973), and *Twinning and Twins*, by MacGillivray and his colleagues (1988), summarizes most relevant aspects of this interesting phenomenon of nature. Baldwin (1994) produced a remarkable volume that contains all relevant aspects of placentation of multiple pregnancies and it is well illustrated. Finally, Gall (1996) summarized all practical aspects of multiple gestations, especially the clinical manifestations and therapy. Several cases of hydatidiform mole in twin gestations have been reported (e.g., Chu et al., 2004). These are discussed in more detail in Chapter 22.

No doubt, the complexity of human twinning cannot be understood without knowledge of the placentation of

twins. Moreover, despite all the benefits reaped from animal studies, the placentation of most relevant species is often very dissimilar from that of humans. Thus, conclusions drawn from animal multiple pregnancies must be interpreted with great care. In recent years, ultrasonographic studies have added materially to our knowledge of prenatal events in twinning and its placentation. Of interest, for instance, are the remarkable observations by Arabin et al. (1996) of extensive inter-twin physical interactions. They were observed to occur earlier in monochorionic twins than in those with a dichorionic twin placenta.

## ZYGOSITY

There are “fraternal” (better named dizygotic, DZ) and “identical” (monozygotic, MZ) twins. In higher multiple births, these may be admixed. That such different classes of twins exist derives from several observations. Fraternal twins may be of different or like sex. A hypothesis is herein helpful: if all twins were DZ, then one would expect a similar sex ratio to be found as that for singletons, that is, approximately 50% MF, 25% MM, and 25% FF. This is not the case. When large statistics of infants’ sex at birth are examined, it is found that there is an excess of like-sex twins. This excess is presumed to result from the number of MZ (identical) twins. By subtracting these from the total number of twins, we have an estimate for the distribution of MZ and DZ twins in a population. This is the so-called Weinberg rule (1901). [Hrubec and Robinette (1984) pointed out that the basis for this rule had previously been published by Bertillon (1874).] Weinberg’s “differential method” can be stated with the following formula:

$$\text{MZ twins} = \text{Alltwins} - \frac{\text{Unlike-sex twins}}{2pq}$$

where  $p$  is the frequency of male births, and  $q$  is the frequency of female births in a population.

Weinberg’s formula should be taken as providing estimates, with considerable errors if it were taken literally. This is particularly understandable when one considers the frequencies of different classes of twins as they exist at the time of conception; for there is much evidence that MZ twins have a higher prenatal death rate than do DZ twins. The Weinberg method cannot correct for losses of only one twin in a gestation, information that is also usually not recorded in birth statistics. It is, therefore, not surprising that the method has often been criticized

(e.g., Renkonen, 1967, and reply by Cannings, 1969; James, 1971, 1984; Keith, 1974). Nevertheless, it is a unique and valuable tool to assess the approximate frequency of DZ vs. MZ twins in a population. Moreover, a prospective study that attempted to validate the method found that the results agree well with findings from placentation and known zygosity of twins (Vlietinck et al., 1988). An interesting observation by James (1971) is that, among DZ twins, there is an excess of like-sex pairs. This observation is based on small samples of twins whose zygosity was ascertained by blood grouping. It has so far remained unexplained, but some additional data (James, 1977a,b) show an even more marked excess of females among monoamniotic/monochorionic (MoMo) twins, and perhaps in twins with acardiacs. More light has been shed on this phenomenon by the large study of Derom et al. (1988), who provided data from the Belgian prospective twin study that included zygosity diagnosis and placental assessment. Not only was the proportion of males reduced in MZ twins (irrespective of chorion status), but also there was a marked reduction of male MoMo twins from what might be expected if this form of twinning occurred at random. The sex proportion of all MZ twins was 0.487, and that of MoMo was 0.231, whereas the DZ twins had a proportion of 0.518. Although no large data sets are yet available, the authors cited evidence that conjoined twins at term are more commonly females, whereas those of abortuses may be more often males. Of the two possibilities to explain this unexpected observation—greater frequency of late twinning in female conceptuses and greater abortion rate of male MoMo conceptuses—the authors favored the former. They referred to the suggestion made by Burn et al. (1986) that “unequal lyonization” of X chromosomes may be a cause of late twinning, and that feature is unique to females. But Goodship et al. (1996) found no support for this hypothesis when they examined X-inactivation patterns of umbilical cords of various types of twins. Monteiro et al. (1998a) studied this a little further by comparing X-inactivation patterns of lymphocytes and buccal cells of monochorionic (MC)-MZ and dichorionic (DC)-MZ twins. They assumed from earlier studies that lyonization occurs when there are 10 to 20 cells in the embryo and deduced from modeling that “MC-MZ twinning occurs three or four rounds of replication after X inactivation, whereas DC-MZ twinning event occurs earlier, before or around the time of X inactivation.” The apparent excess of female acardiacs is possibly further confirmation (James, 1977) of this phenomenon. The largest prospective survey of twins comes from Belgium (Loos et al., 1999), which encompassed 5089 twins, 158 triplets, and 14 quadruplets or higher multiples. In this survey, zygosity was established by sex, placentation, and genetic markers in over 95%. Dizygotic twins had the same sex proportions as singletons, whereas MZ twins had an excess of females.

Considerations of the MZ twinning rates come from Allen and Hrubec (1987), who proposed that a slight suggestion exists of a relationship of the MZ twinning rate to maternal age, as is very certain for DZ twins. These “constants” of DZ to MZ twin frequencies, identified from various statistical considerations, however, are still considered to be arbitrary, and they also appear to differ among various populations.

Other reasons for considering that a proportion of twins are identical, or monozygotic, come from the numerous reports on genetic identity, as well as the physical similarity exhibited by some twins. Twin research has traditionally involved ascertainment of zygosity by assessment of likeness. Dermatoglyphics (Newman, 1931a; Allen, 1968; Brismar, 1968; Herrlin et al., 1970; Reed et al., 1975), and blood grouping (Robertson, 1969; Selvin, 1970) are some of many parameters that have been employed. But these methods have not always been decisive in assigning the zygosity for an individual set of twins, although their general reliability is high. For that reason, methods such as mixed leukocyte stimulation (Jarvik et al., 1969), skin exchange graft survival (Stranc, 1966), and repeated blood group study (Osborne, 1958) have been advocated. Analysis of banded chromosomes, C-bands and Q-

bands, has also been used to ascertain monozygosity (Neurath et al., 1972; McCracken et al., 1978; Morton et al., 1981; Pedrosa et al., 1983). Until recently, this has been the most reliable methodology. These methods established mostly probabilities of twins' zygosity, and they were often somewhat imprecise. The mathematical aspects of phenotypic likeness studies have been treated by Meulepas et al. (1988). New methods have now been developed that are more decisive. How important they can be is manifest from the report by St. Clair et al. (1998). Unlike-appearing twins, thought to be dizygotic, had successful inter-twin renal transplant because of mushroom poisoning to one twin. DNA fingerprinting found them later to be monozygotic, whereupon the immunosuppressive therapy was successfully discontinued.

The techniques for the direct comparison of DNA variants have much to be recommended as primary tools. They determine the restriction fragment length polymorphism (RFLP) of twins, and cogent reasons for routinely employing this methodology have been advanced by Machin (1994). These methods of comparing fragments of DNA are quick and decisive, and can be executed on placental tissue, blood, and other tissues (Derom et al., 1985; Hill & Jeffreys, 1985). Importantly, the quantities of tissue needed for this study can be quite small when combined with polymerase chain reaction (PCR). Microsatellites have also proven to be useful and rapid in the definitive differential diagnosis of MZ vs. DZ twins (Erdmann et al., 1993; Becker et al., 1997). Thus, antenatal samples may readily be processed by this and related modern techniques for accurate determination of twin zygosity (Kovacs et al., 1988) and they have been decisively used to identify the genetic relationships between twins and triplets (Motomura et al., 1987; Azuma et al., 1989). It is of further interest that this method can also be used to identify DNA patterns of macerated stillborn fetuses (Derom et al., 1991). Neuman and her colleagues (1990) have proved with RFLPs the dizygosity of aborted tubal twins and suggested that the alleged common monozygosity of ectopic twins may be in error. Norton et al. (1997) advocated the use of DNA diagnostic study of discordant multiple gestational products when chorionic status is indeterminate or not helpful.

The least decisive method for the identification of the zygosity of twins, the likeness assessment, however, is also the most widely practiced. It is the easiest method to execute and it correctly asserts that physical characteristics are more alike in MZ twins than they are in DZ twins (e.g., tooth morphology: Lundström, 1963; skin color: Collins et al., 1966; cardiac findings: Preis & Srubarova, 1966; immunoglobulin levels: Sowards & Monif, 1972; cholesterol levels: Corey et al., 1975; etc.). A fairly reliable accuracy of zygosity diagnosis is said to be achieved with other simple tests, including the use of questionnaires (Cederlöf et al., 1961; Nichols & Bilbro, 1966). These oversimplifications, however, have also led to many misconceptions. Moreover, they have confused neonatologists who care for often markedly discordant twins in the neonatal period and who need better guidelines for care than are generally available.

It is now certain that MZ twins are frequently discordant in development; some of this discordance can be secondary to unique placental vascular relations between twins (Schatz, 1886; Verschuer, 1927; Price, 1950), others have their cause in abnormal placentation. Discordance for congenital anomalies is higher in MZ twins than in DZ twins, a feature that has been critically analyzed by Boklage (1987a), Mastroiacovo and Botto (1994), and Hall (1996). There are also other fascinating problems to be resolved; for instance, Zaw and Stone (2002) reported caudal regression syndrome in a set of monozygotic but dichorionic twins. Is that due to growth disparity of the twins or to the possibility that only one of the twins was exposed to the abnormalities of glucose imbalance of the MZ twins at the time of putative exposure? Some such questions can potentially be resolved by the twin methodology, and Hobbs et al. (2002) drew attention to this in

their review of the genetic aspects of congenital anomalies. Twins, in general, have also been found to have higher hematocrits and somewhat elevated levels of nucleated red blood cell counts, irrespective of prenatal hypoxia or intrauterine growth restriction (IUGR) (Sheffer-Mimouni et al., 2004). Triplets share this feature, according to Suslak et al. (1987). Melnick and Myrianthopoulos (1979) found that the twofold increase of anomalies in MZ twins cannot be validly ascribed to the monochorionic placental status that is so prevalent in MZ twins. An exception to this are acardiacs and the destructive results from prenatal disseminated intravascular coagulation (DIC) or acute blood loss, which may depend in their origin from the monochorionic status of their twin placenta. These authors suggested as a possible explanation, that the "impetus" for MZ twinning may be similar to that which is the cause of the developmental anomalies. In recent years, Steinman (2001a–c, 2002a,b, 2003) has proposed that the possible reason for MZ twinning is the deficiency of cellular adhesion between embryonic cells, mediated perhaps by calcium-dependent adhesion molecules. Some support for this hypothesis is afforded by the occurrence of MZ twins among assisted reproductive technology (ART)-derived multiples since the blastocysts are often cultured in ethylenediaminetetraacetic acid (EDTA)-chelating media for several days. The relative frequency of anomalies in MZ twins (6–9%, with 80% discordance) has important implications with respect to prenatal diagnosis of early embryos (Jarmulowicz, 1989). It has been suggested that, with the new methodology of PCR of DNA amplification, single blastomeres might be sexed and that they could then be genetically defined in the future. It is unknown at this time whether such loss of blastomeres could result in anomalies, and whether the discordant anomalies of MZ twins are perhaps caused by an unequal splitting of the morula. Also, monozygotic twins with discordance of organ laterality in ciliary dyskinesia (Kartagener syndrome) has important connotations for an explanation of this disorder (Noone et al., 1999). Similarly, the concordance of truncus arteriosus in MZ twins has implications for that anomaly (Mas et al., 1999). These and similar considerations are important questions for future research. Similarly, the monochorionic twins with significant phenotypic differences described by Gringras (1999) cannot presently be explained, but they need to be borne in mind when discussing identical twins. The PCR fingerprints of these twins were identical.

Twin studies, as advocated by Galton (1875), endeavor to distinguish between genetic and environmental influences on fetal development. To be successful, they require accurate zygosity determination of the probands. Walker (1957) stated this requirement emphatically. Moreover, it has been found that if the linkage of genetic traits is not taken into consideration in the zygosity assignment, the probability of monozygosity is overestimated (Sorensen & Fenger, 1974). Kempthorne and Osborne (1961) and Allen and Hrubec (1978) have developed models to undertake such analyses. Allen (1965) proposed excellent guidelines for the design of twin studies that should be consulted. Kruyer et al. (1994) used this sort of knowledge in ascertainment when the full implementation of the fragile X syndrome mutation is attained—postzygotically, as it turns out.

## The Placenta in the Study of Zygosity

To derive any benefit from placental studies for twin research, it is mandatory that the umbilical cords be labeled in the order the twins are delivered, for positive identification of the infants. This is best done by placing one or more ties or clamps around the placental cut ends of the cords. Examination of twin placentas (and those of higher multiple births) may then contribute to the

determination of zygosity and an understanding of abnormal events. It is also mandatory that a placental record be made. This is needed for an understanding of possible discordant development of twins, and for our understanding of many other pathologic features that twins present. The proposition that **all** monochorionic placentas belong to MZ twins (but that **not all** MZ twins have monochorial placentas) was first clearly stated in the seminal contribution of Curtius (1930). He then called for a detailed reexamination of the understanding of placentation in humans. In general, this proposition has been amply confirmed, for instance in the placental study of 182 like-sexed live-born twins by Ramos-Arroyo et al. (1988). But there are a few well-proven exceptions that are discussed below. The correlation of prematurity, twin development (growth and growth restriction), and placental causes of disturbances has been evaluated by Bleker and his colleagues (1979, 1988, 1995, 1997). Not surprisingly it was found that monochorial twins were delivered earlier and that they had a higher mortality than dichorionic twins. Abnormal cord insertion occurred more commonly in multiple gestations and was related to smaller fetal weights. The authors expressed the notion that placental weight importantly influences and often restricts fetal growth in multiple pregnancies. Min et al. (2000) compared the weights of a larger number of twins (according to chorionicity and sex as well) with those of singletons and provided an excellent reference table. They concluded that "well-grown twins and singletons do not differ as much as previously believed." Cooperstock et al. (2000) demonstrated that significant growth differences (40% before 32 weeks) among twins constitute a risk factor for premature birth.

In principle, there are two types of twin placentation: monochorionic and dichorionic. In higher multiple births, these may be admixed, or one or the other types may be present. Monochorionic placentas, so we believe, virtually **always** come from MZ (identical) twins. The reason for this assumption is that no verified monochorial human placenta has been associated with twins of unlike sex (there are only the rarest exceptions). Furthermore, when genetic markers are studied in monochorionic twins, they are always identical (Corney et al., 1968; the rare exceptions are discussed below). Dichorionic placentas, however, may be associated with both DZ and MZ twins; most are associated with DZ twins. A decisive study of this topic is that of Cameron (1968). He examined the placentas of 668 twin pairs and determined their zygosity with studies of blood groups and placental enzymes. From the fetal sex and the structure of the placental membranes alone, the zygosity could be ascribed accurately in 55%. Genotyping was necessary in the remaining 45%. His analysis gave the following results:

Of his 668 pairs, 80% had diamnionic/dichorionic (DiDi) placentas; and of these pairs, 90% were DZ. There were 20% monochorionic (and therefore monozygotic) twins. With the improved methodology of modern sonographic equipment, it is now usually possible to make the diagnosis of chorionic status before birth; however, discussion continues as to the sonographic accuracy and as to criteria to be employed at specific gestational ages. Irrespective of numerous papers urging that this diagnosis of chorionicity be made at birth in all multiple deliveries, Cleary-Goldman et al. (2004) found in their survey that this means of assessing some twins' zygosity is unknown to many obstetricians.

The sonographic appearance of the "dividing membranes" is now reasonably securely established by competent ultrasonographic studies. The development of the techniques employed and references to the findings made after 1985 are competently summarized by Tutschek et al. (1998). Thus, D'Alton and Dudley (1989) made the correct diagnosis in 68 of 69 prospectively studied cases using ultrasound and counting the layers of the dividing membranes. Winn et al. (1989) suggested sonographic criteria for assessing the width of "dividing membranes." When amniocentesis was done for genetic reasons, the thickness of this dividing membrane was measured in 32 patients. The cutoff point was 2 mm. An accuracy of 82% was said to be achieved by this means. This method may be helpful in the future management of twin gestations. Finberg (1992) found that the "twin peak sign" was diagnostic of dichorionic twinning. He showed that a triangular projection of membranes can be seen above the placental surface in dichorionic twins or triplets; Wood et al. (1996) agreed with that in their study. Monteagudo and her colleagues (1994) asserted from their large experience that transvaginal sonography before 14 weeks' gestation easily establishes the nature of the partitioning layers in multiple pregnancies. Sepulveda et al. (1996) nearly always succeeded sonographically to make a correct diagnosis by analysis of the so-called Ipsilon zone (the Y-shaped area of conjunction of sacs in triplets). Vayssi re et al. (1996) succeeded to a high degree of accuracy by counting layers of the dividing membranes in the second and third trimesters, whereas Stagiannis

et al. (1995) asserted that the method has a high intra- and interobserver variability. At least once, in a pregnancy with discordant twin growth and absent twin peak sign, monochorionicity was established by the injection of Levovist, a microbubble contrast enhancement agent. After injection into one twin's intrahepatic vein, the contrast agent later appeared in the other twin's heart (Denbow et al., 1997), thus confirming vascular anastomoses and, thereby, monochorionic status. Malinowski (1997) was able to reliably differentiate the twin membrane layers by transvaginal sonography as follows: DiDi at 4 weeks; diamnionic/monochorionic (DiMo) at 5 weeks; and MoMo vs. DiMo at 7 weeks of gestation.

Monochorionic twin placentas virtually always present as single disks. It is most unusual for monochorionic twin placentas to possess separate placental masses; and often they are then connected with small bridges. Nevertheless, Altshuler and Hyde (1993) have described such an exceptional case in which two completely separate disks were connected by a thin bridge. Underneath the chorion of this bridge was atrophied villous tissue. Rare observations of two disks in monochorionic twins have also been made in conjoined twins (see below). Monochorionic twin placentas fall into two categories: (1) the MoMo twin placentas, in which the twins are in the same sac; and (2) the DiMo placenta. The MoMo placenta is the less common. It is also associated with the highest perinatal mortality of twins because of cord entanglement. The higher mortality and complication rate for monozygotic twins has been critically examined by Kovacs et al. (1989). Multiple births not only have higher perinatal mortality but also have greater morbidity. Because of the inordinate contribution to adverse outcomes, Powers and Kiely (1994) provided ultrasound (US)-based population figures that suggested that "to lower the rates of adverse outcomes in twin pregnancies should become a major public health priority." Heyborne et al. (2005) have shown that much improved perinatal survival can be expected when mothers with known MoMo twins undergo early hospitalization for surveillance.

Dichorionic (DiDi) twin placentas may be fused into one mass (DiDi fused), or they may be separated (DiDi separate) organs (Benirschke, 1958). From a practical consideration of the analysis of the placentation of individual twins, it is important to first examine these membrane relations. It is most reliably done by making a cross section of the "dividing membranes," that is, the partition between the two sacs. By excising and rolling a square of these dividing membranes, the two types can then be differentiated (Fig. 25.1). As an alternative method, one may take for histologic study a section from the site where the membranes insert on the placental surface; two "T sections" are seen in Figure 25.2. This method has been particularly well illustrated by Allen and Turner (1971). Either of these methods for taking sections preserves a

FIGURE 25.1. A: Diamnionic (monochorionic) “dividing membranes” of identical (monozygotic, MZ) twins. There is always a space between the two amnions. The amnion consists of epithelial cells and connective tissue. B: Diamnionic/dichorionic (DiDi) dividing membranes. The right amnion is dislodged from the underlying chorion, a frequent artifact. The central trophoblastic remnants have fused. A, amnion; C, chorion; T, trophoblast. H&E  $\times 100$ .

permanent record. For the experienced placentalogist, it is just as effective to make the diagnosis of DiMo versus DiDi twin placenta by macroscopic inspection.

The dividing membranes of DiMo placentas are usually translucent (Fig. 25.3). They are thin and not opaque, and there are no blood vessel remnants within them. When

one separates the two amnions and comes to their insertion on the placental surface, one may continue to strip the amnions off a DiMo placenta, away from the chorionic plate (Fig. 25.4). In addition, the fetal surface does not show a ridge of fibrin, present as a slightly raised white ridge that is present in DiDi placentas. Bleisch (1964) emphasized this point effectively. DiDi membrane partitions are considerably more opaque (Fig. 25.5). They have remnants of villi and vessels in their four layers and when, by separating the two layers of each placental component, one comes to the chorionic plate, further dissection is impossible (Fig. 25.6). If one attempts to further cleave them, the surface of the placenta is disrupted.

As already stated, the advancements in sonographic equipment have made it possible to distinguish the thickness of the dividing membranes long before birth (Barss et al., 1985; Mahony et al., 1985; Hertzberg et al., 1987; Finberg, 1992). This diagnostic modality is particularly helpful in the diagnosis of MoMo twins who are at risk of cord entanglement. Belfort and his colleagues (1993) demonstrated, by color flow Doppler sonography, such cord entanglement in three sets of MoMo twins. They identified obstruction of flow in the umbilical vein by this means and made the point that this diagnosis can lead to improved outcome of these problematic gestations. It is the practice in our hospital now to hospitalize such patients for possible rapid intervention when problems arise.

The other important point to be made is that monochorionic twin placentas usually have blood vessel

FIGURE 25.2. Left: T-section of dividing membranes of monozygotic/diamnionic twins. Note the contiguity of the chorion over the surface of the placenta at bottom and the separation

of amnions. Right: T-section of diamnionic/dichorionic twin placenta. There are atrophic villi and trophoblastic remnants extending between the two chorionic membranes. H&E  $\times 40$ .

FIGURE 25.3. Diamniotic/monochorionic twin placenta. The dividing membranes are held up, to disclose their transparency. (See Figure 25.5 for contrast with DiDi placenta.)

FIGURE 25.4. Diamniotic/monochorionic twin placenta. The dividing membranes are being separated; at their base they are easily peeled off the chorionic surface. The vascular communications between the two fetal vascular beds are thus disclosed.

FIGURE 25.5. Dividing membranes of diamniotic/dichorionic twins are characteristically opaque. They are only rarely translucent.

FIGURE 25.6. Diamniotic/dichorionic twin placenta. The two amnions are being peeled off the central two chorionic leaves. The latter cannot be completely stripped off the placental mass without disrupting it.

connections between the fetal circulations; they are not generally present in dichorionic twin placentas. These anastomoses are discussed in greater detail later in this chapter. Note also that not all authorities have concurred with the ease of distinction between DiMo and DiDi placentas just elaborated. Thus, the famous gemellologist H.H. Newman (1931a) believed that one could easily mistake a DiMo for a fused DiDi placenta. This is certainly not the case in experienced hands, but it points to the desirability of examining histologic sections for affirmation. Moreover, it must be recognized that blood group studies in twins have the problem that fetal blood is commonly admixed because of the frequent blood vessel anastomoses in the monochorionic group. It then follows that if DZ twins were associated with a monochorionic placenta in which anastomoses existed, their different blood antigens would permanently mingle. Only a highly sophisticated analysis of their blood groups would ascertain the presence of "blood chimerism." The unusually high frequency (approximately 8%) of blood chimerism reported by van Dijk et al. (1996) remains puzzling and needs verification before it can be accepted as proven. On the other hand, Quintero et al. (2003b) reported a well-studied case of a DiMo twin placenta with discordant sex and unsuccessfully treated twin-to-twin transfusion syndrome, clearly a great exception. Also, the genital development of the twins was normal despite the blood

chimerism, unlike that found in Artiodactyla (freemartins) and similar to what is found to be so in marmosets (vide infra).

In this connection it is important to mention that Mortimer (1987) has challenged the concept that monochorionic placentas are diagnostic of MZ twins on the basis of blood studies. Cord blood grouping studies were conducted on 12 sets of monochorionic twins for 16 red blood cell antigens. In three sets, there were discrepancies between the antigens, despite the presence of artery-to-artery and vein-to-vein anastomoses. These discrepancies always involved single and minor blood groups. How such antigenic difference can come about is difficult to understand, as the anastomoses should have guaranteed complete mixing, as is the case in the few blood chimeras to be considered later. In our view, this study is insufficient evidence for Mortimer's proposition that 25% of the monochorionic twins studied were dizygotic. If this were so, there should be many more boy/girl twins found with monochorionic placentas, and it is not the case. Only two, perhaps three, such examples can be cited, and they were not well studied. The use of the DNA methods (with DNA to be obtained from solid tissues!) discussed earlier will dispel any doubt in the future if twins with such apparent discrepancies come to light.

After it was recognized that monochorionic placentation is useful for the identification of at least two thirds

TABLE 25.1. Distribution of placental types in twins

Source	DiDi (%)	DiMo (%)	MoMo (% or ?)
Szendi (1938)	66	34	0
Vermelin & Ribon (1949)	45 (like sex) 32 (unlike sex)	23	
Benirschke (1961)	68.5	30	1.5

Barss (1988)	74.2	24.2	1.7

of MZ twins, several larger series of twin placentas were published. They are summarized in Table 25.1. Note that marked differences exist in the distribution of the different twin groups in these reports. Thus, the frequency of monochorial (MZ) twins is much lower in Nigeria, where the incidence of twinning is especially high, owing to the high frequency of DZ twins in the Yoruba tribe. Knox and Morley (1960) found Western Nigerian Yoruba twin frequency as high as 5.3%, with 91% being DZ. The converse is true of some Oriental populations. Sekiya and Hafez (1977) determined the type of placentation in 84 sets of Japanese twins. They found that 40 were dichorionic [26 fused (31.0%), 14 separate (16.7%)]; 41 were DiMo (48.8%), and three were MoMo (3.6%) (Fig. 25.7).

The placental relations of DiMo and DiDi twins are easiest to identify in very young pregnancies (Fig. 25.8). The youngest implantation sites of DiDi twins (10 to 12

days) have been illustrated by Meyer and Meyer (1981). They featured tiny blastocysts that had implanted far away from one another in the uterine fundus. Parenthetically, it should be mentioned that Ohel et al. (1987) suggested that, as seen by ultrasonographic "grading" methods (calcifications), the placentas of twins exhibit advanced maturation compared to age-matched singleton placentas.

Twin placentas differ in many other respects from those of singletons (Table 25.2). The frequency of marginal and velamentous cord insertion has great relevance in interpreting birth weights and mortality. Succenturiate lobes are much more common, perhaps because of focal areas of placental atrophy, and they are more often immature structurally because of early delivery. It was surprising, though, to note less commonly a finding of meconium staining and villous infarcts, the reason for these differences being less clear.

FIGURE 25.7. Twin placentation in three racial populations. The figures for the Yoruba (left) are from MacGillivray et al. (1975); those for the U.S. population come from Benirschke and Driscoll

(1967); those for the Japanese population come from Sekiya and Hafez (1977).

FIGURE 25.8. Left: Uterus with diamnionic/monochorionic (DiMo) (identical, MZ) twins at 8 weeks' gestation. Note the two delicate amnions enclosed in a single chorion. Two yolk sacs are present at the arrow. Right: Uterus with diamnionic/dichorionic twin implantation. The uterus has been opened laterally, and the cervical halves are seen at top and bottom. The two separate placental membranes are easily seen. If these placentas later expand, they will certainly collide and fuse.

# Causes and Incidence of Multiple Births

A fundamental difference exists in the respective etiologies of DZ and MZ twins. DZ twins (and many higher multiples) are the result of polyovulation. It may be hereditary; it is certainly age-related and it can be induced by the administration of gonadotropins and other hormones. The strongest evidence that hormones (gonadotropins) are responsible for multiple ovulations comes from their therapeutic use in infertility patients. Intentional induction of multiple ovulations with gonadotropins is regularly employed in the livestock industry (e.g., Chupin et al., 1976), and is well studied in laboratory animals and, more recently, in during the practice of ART.

Milham (1964), therefore, hypothesized that spontaneous DZ twinning in humans may be explained by a maternal increase in pituitary gonadotropin production. He

based this idea on the increase in pituitary size with advancing age, the larger pituitaries found in African Americans, and the increase in size of the hypophysis after repeated pregnancies. These features correlate with an increase in DZ twinning rates. Numerous studies have since been undertaken to verify this hypothesis. In humans, there is now good evidence that the recruitment of follicles for ovulation is controlled by follicle-stimulating hormone (FSH) (Vermesh & Kletzky, 1987). Marshall (1970) reviewed the findings following ovulation induction by gonadotropic hormones and clomiphene. The administration of clomiphene led to a 6% incidence of twins, and gonadotropin administration was followed by a 5% to 50% incidence of twins. These variable frequencies were found to be dose-related. Nylander (1973) determined that Nigerian women of the Yoruba tribe, known to have very high rates of DZ twins, also had elevated levels of FSH and luteinizing hormone (LH), when compared with whites. Soma et al. (1975), noting the lower frequency of DZ twins in Japanese when compared to other populations, measured the FSH and LH levels in 10 Japanese women. They found significantly lower values for both hormones than are present in Nigerian women. The values were also lower than those reported for the American populations (Fig. 25.9). Because these two sets of data came from women near the time of expected ovulation, the validity of the results was questioned and the thesis then reexamined. Presumably, recruitment of follicles for the next ovulation takes place around the time of menstruation. For that reason, Martin et al. (1984a,b) undertook a study of various hormonal levels in women during the first 4 days of their menstrual cycles. They compared women who had at least one set of DZ twins with

TABLE 25.2. Cord insertions and other pathologic features of 7090 consecutive placentas of which 143 were multiple births (1985–1986)

	Singletons (%)	Multiple gestations (%)
Marginal insertion of cord	8.9	28.7
Velamentous insertion of cord	1.1	16.1
Meconium staining	14.9	4.9
Succenturiate lobe	7.6	37
Immaturity	7.8	37.8
Abruptio placentae	4.9	2.8
Infarcts	20.7	11.2

FIGURE 25.9. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels in women around the time of ovulation.  $\times$ , peak value in Yoruba tribe women of Africa;  $\Delta$ , peak value in U.S. Whites; solid line, 10 Japanese women. (Source: Soma et al., 1975, with permission.)

those who had no twins. They also found that FSH and LH (less so) were elevated in twin-bearing mothers. Estradiol was also elevated. Spellacy et al. (1982) attempted to ascertain if the pituitaries of twin-bearing women were more responsive to the injection of gonadotropin-releasing hormone (GnRH). It proved not to be the case. It must be cautioned, however, that Spellacy's studies were undertaken during the luteal phase of the cycle and may thus not reflect the natural effect on FSH production needed for follicle recruitment. Lambalk and Boomsma (1998) determined that in twin-prone women the elevated FSH levels are "entirely related to an increase in number of FSH pulses." The elevated FSH levels of older women, they argue, results from a decrease of ovarian inhibin production.

The aforementioned hormone studies supported the notion that the genesis of DZ twins is indeed the result of excess production of FSH. Milham (1964) had suggested that the higher gonadotropin production he assumed to be the basis for DZ twinning is a racial characteristic of the hypophysis. This idea was challenged by Eriksson (1964), who pointed out that in some countries the DZ twinning rate has recently declined and that it could not be explained by an assumed lowering of the age of pregnant women and by differences in racial composition. His point was that DZ twinning is a "genetic trait." We believe that the gene responsible for higher FSH levels must now be considered to be the principal agent in familial twinning. The hormonal assays from many sources all point in this direction. Whether the effect of increased FSH production is the sequel of more pituitary cells or more GnRH production, or is also due to greater follicle sensitivity, needs to be studied. A further investigation supports the genetic nature of the multiple ovulation event. When women who had delivered DZ twins were followed sonographically, it was found that

they had considerably more ovulatory activity than controls (Martin et al., 1991).

In addition to inducing twin gestations, hormonal induction of ovulation is often followed by the birth of triplets and higher multiples. Schenker et al. (1981) reviewed this topic in detail, including the complications that arise from such pregnancies. They also made recommendations as to the prevention and management of multiple births. Although it is true that multiple births are generally multizygotic, it has long been noted that, among such multiple offspring, there is often an admixture of DZ and MZ infants. For instance, Atlay and Pennington (1971) reported on quadruplets born after pituitary gonadotropin stimulation; two of the infants were mono-amniotic and thus MZ twins. Whether the incidence of twinning rises following the discontinuation of chemical contraception ("the pill") is controversial. Rice-Wray et al. (1971) found no such increase in their study of 516 women, whereas Rothman (1977) and Bracken (1979) found that twinning was about doubled when pregnancy occurred within 1 to 2 months after cessation of oral contraception. The increase was found to be due to DZ twins in both of these studies. Bracken inferred that it results from pituitary response to oral contraceptives. An interesting discussion followed Bracken's paper (Honore, 1979; James, 1979), which suggested that after oral contraception pituitary gonadotropin release may in fact lead to DZ twinning. Whether it is also responsible for an increase in embryonic aneuploidy (particularly the occurrence of triploidy as has also been suggested) awaits further study. It has been hinted that currently a general rise in MZ twinning rates is occurring, and that this is perhaps related to the use of oral contraceptives (Bressers et al., 1987). Possible other environmental agents, however, could not be excluded by these investigators.

As had been noted by Weinberg (1909), twinning may be familial. Weinberg asserted that DZ twinning is inherited; however, it was believed that hereditary factors played no role for MZ twinning. Hamamy et al. (2004) have now shown in a remarkable family that five generations had apparently MZ twinning (13 pairs in 2035 members interviewed) inherited by what they assumed to be an autosomal-dominant gene. Shapiro et al. (1978), who had already brought some similar, albeit smaller, pedigrees together, also assumed a possible autosomal gene, and advanced the view that one might look upon MZ twins as "altered morphogenesis." The situation in DZ twinning tendency differs. Such a possible genetic effect can be manifested only by a woman with the genetic background for twinning, not by the father of twins. He may pass on this gene to his offspring, but only double ovulation in women can **prove** the existence of the gene. It is thus sex-limited. The finding by Bulmer (1960) that increased twinning among relatives of fathers of twins is due to underreporting of singletons does not seem to

alter the inheritance of presumably higher FSH levels. These aspects are further elaborated by White and Wyshak (1964).

In our opinion, familial and racial predisposition to DZ twinning results from enhanced production of FSH. Montgomery et al. (2000, 2001, 2003; Duffy et al. 2001) have searched for possible gene linkage, finding none so far. It may be relevant, however, that McNatty et al. (2001) found an X-chromosomal mutation that leads to multiple ovulation and is dose-dependent, and Galloway et al. (2000) had similar findings in human families. Busjahn et al. (2000) suggested that a gene on chromosome 3 relates to DZ twinning; obviously more work will be done in the future and a more conclusive result can be anticipated. Others suggested that there may be an altered FSH receptor gene mutation, but that has not been firmly established either. Now, Montgomery et al. (2004) studied families with DZ twinning frequency and identified a deletion mutation in *GDF9* (on chromosome 5q31.1), much as had been seen in sheep. The racial relation to DZ twinning is most impressively shown by comparing the frequency in Nigerian women from the Yoruba tribe with Oriental women (Nylander & Corney, 1969; Nylander, 1971a). Nylander et al. observed that monochorial twins were rare in Nigerian women of the Yoruba tribe, and that zygosity determinations indicated a vast preponderance of DZ twins. The frequency of MZ twins was the same as that found in whites (4.5 per 1000). In the north of Nigeria, the twinning rate was 21 per 1000, in the midregion 31 per 1000, and in the west and east 45 per 1000. These data contrast with reports from Japan, where the overall twinning rate is 6.1 per 1000, with a 1.65:1.00 ratio of MZ/DZ twins (Inouye, 1957). Similar rates have been reported from Taiwan (Wei & Lin, 1967). In Europe there tends to be a "progressive decrease in the frequency of twins from north to south" (Eriksson, 1962).

The known higher frequency of DZ twins in older mothers may then also be due to their enhanced FSH secretion. There is a steady rise in DZ twinning to the maternal age of 35; after that age, there is a sharp decline in DZ twinning. Although longitudinal studies of FSH secretion have not been published for individual women, some data exist to indicate that FSH levels rise steadily with maternal age (Albert et al., 1956). This finding supports the notion that the increased DZ twinning frequency observed with advanced maternal age is due to enhanced FSH excretion by older women's pituitaries, but it does not prove it. The FSH levels are much higher still in postmenopausal women. Longitudinal studies are needed. Lawrence et al. (2004) tested the hypothesis that food fortification with folic acid might affect the twinning rate but found this not to be so.

The interesting question has been raised as to whether the higher gonadotropin secretion of individuals with the genetic trait to produce twins is also manifest in men. For

sheep and other domestic animal species, some evidence exists that, in individual races, there are differences in the frequency of DZ twinning (Land et al., 1973). It has also been suggested that the testicular weights from such animals is greater in males that carry the gene for twinning (Land, 1973; Islam et al., 1976). To study this aspect further, Short (1984) reported ethnic variations of testicular size in men and found that Orientals have smaller testes than Europeans. There are no data yet from Yoruba men, but racially different testosterone levels have been reported by Ross et al. (1986). They tend to support the same principle and are viewed as being in support of the marked differences in prostatic cancer (Gittes, 1991). These and related aspects were considered in some detail in Diamond's stimulating editorial (1986). The differences of placentation in three well-studied racial groups are depicted in Figure 25.7, which displays graphically how meaningfully different the placentas of twins are constructed when their zygosity is so variable.

The **cause of MZ twinning** is not fully understood. Whereas DZ twins (and multiples) derive from the fertilization of more than one ovum, MZ twins must originate from the spontaneous separation of blastomeres. Although this process occurs in all animals species with approximately the same frequency as that observed in humans, there are two nearly similar species in which this polyembryony occurs with regularity: the two *Dasypus* species of armadillo—*Dasypus novemcinctus* (nine-banded armadillo) and *Dasypus septemcinctus al. hybridus* (seven-banded armadillos; mulita) (Fernandez, 1909; Newman & Patterson, 1910; Hamlett, 1933). The precise understanding of the mechanism of their polyembryony eludes us. Hamlett (1933) was critical of the statements made by Newman, who had inferred that it was the delayed implantation of armadillos that leads to impoverished nutrition and deficient oxygenation of the blastocyst, and it was thus the cause of polyembryony. It is of additional relevance that other species with delayed implantation do not share this phenomenon of polyembryony. Hamlett advocated that segregation of blastomeres is determined by genetic factors. Loughry et al. (1998) advanced the notion that this feature resulted from the small implantation site in a unique uterus, but they cautioned that this needs further analysis. They were the first, however, to show clearly the monozygosity of the litters by their finding complete identity of DNA microsatellites.

The nine-banded armadillo, ranging from Texas to Uruguay, always has identical quadruplets; the mulita may produce seven to 12 male or female identical offspring. Although the mulita is much smaller, the two species are closely related and possess, for instance, identical chromosomes. The mulita is a common animal in Uruguay and Argentina; it has a single blastocyst (and corpus luteum) in a pregnancy that is also characterized

by delayed implantation. Immediately after implantation, the embryonic mass separates into multiple offspring. Whether it is by “fission or budding” was a hotly contested point of the discussions between Newman and Hamlett. In contrast to the monozygotic twinning in other mammals, the production of multiple births of these two armadillo species is so well regulated that anomalies, such as conjoined twins, acardiacs, and most other abnormal events occurring in human MZ twins, have not been observed (Hamlett, 1933). We deduced that one reason for these discrepancies may be that, in these species, the splitting of blastomeres is a precisely timed event. Also, placental anastomoses do not occur in armadillos (Anderson & Benirschke, 1963), possibly because of the different timing of their placentation. Perhaps it is the reason for their relative freedom from placental problems.

Other mammals, those that have approximately similar rates of MZ twinning as humans, have no precisely timed MZ twinning period. In them and in humans, the splitting of the embryonic mass appears to occur at random during the early embryonic period. It has also been observed that MZ twins commonly occur after surgical transfer of single bovine blastocysts into pseudopregnant cattle recipients (Moyaert et al., 1982; Kraay et al., 1983). Paulson et al. (1988) reported that triplets were born after the transfer of two previously frozen human embryos. Surprisingly, after assisted reproductive help, monochorionic, even monoamnionic multiple pregnancies have repeatedly been reported, by Edwards et al. (1986) and by Salat-Baroux et al. (1994). Massip et al. (1983) observed cinematographically the atypical hatching of a cow blastocyst *in vitro* and suggested that it may be the mechanism by which dichorionic MZ twins take their origin. They observed partial protrusion of blastomeres from a zona; and after the “hatching” was complete, the two-cell masses were connected only by a diminutive bridge. That hatched blastocysts are capable of twinning was demonstrated by surgical division of sheep embryos (Willadsen, 1979) as well as in mice (Tsunoda & McLaren, 1983), horses (Allen & Pashen, 1984), goats (Tsunoda et al., 1985), pigs (Nagashima et al., 1989), and other animals. In many such experiments implantation led to normal development of these split embryos. Nevertheless, a prospective study by Blickstein et al. (1999) came to different conclusions. They studied the outcome of human *in vitro* fertilization (IVF) results with those of single sperm injection fertilization. Although the former procedure had a 12 times the expected MZ twinning rate, the latter technique (although presumably more destructive to the zona pellucida) produced no twins. Their conclusion was that it is perhaps the handling of eggs during *in vitro* fertilization that results in the splitting. Steinman (2001a–c, 2002a,b, 2003) incriminated the adverse role of ethylenediaminetetraacetic acid (EDTA) (calcium-depleting) in the culture media. The true cause remains elusive, however.

It is necessary to recognize that there are many temporal differences in the development of the inner cell mass and the setting aside of the trophectoderm in animals. Thus, when different species are compared, it is difficult to draw precise analogies to human development, especially to placental growth. Thus, the mouse segregates embryo from trophectoderm at the fourth cleavage stage (about 12 to 16 cells). The peripheral cells develop tight junctions and form the future placenta (Ziomek & Johnson, 1982), an event taking place much later in the sheep and cow. In humans, similar to the mouse, the event occurs at about the fifth division of cells. In 1% of cultured mouse embryos, spontaneous separation of blastomeres into MZ twins takes place, analogous to what would be expected of the process that leads to conjoined twins (Hsu & Gonda, 1980). Runner (1984) observed two inner cell masses in a mouse blastocyst at the stage of proamniotic cavitation, which suggested to him late division of the embryonic mass and development of mirror imagery, which is also more commonly seen in MZ human twins. Experimental fission of quail embryos has also produced conjoined twins (Lutz & Lutz-Ostertag, 1963). The production of MZ twins in sea urchins was demonstrated by the isolation of first-cleavage blastomeres (Driesch, 1891). These embryos were rarely normal. Marcus (1979) showed that by shaking fertilized sea urchin eggs to remove their envelope and with subsequent exposure to hypertonic water, he was able to promote separation of blastomeres. Many of these MZ twins were also underdeveloped. It is particularly interesting to note that there were many inter-twin morphologic differences. Ludwig (1927) had commented on the irregular division of “hereditary material” in MZ twins, but did not believe that blastomeres were capable of separating. He thought twinning to be a late event and also expected that MZ twins would often be different.

When pregnant mice were exposed to low doses of vincristine on days 7 and 8, unexpectedly many MZ twins developed, some being monoamnionic (Kaufman & O'Shea, 1978). Kaufman and O'Shea cited the few other reports of conjoined twins produced by experimental teratogens. Perhaps best known are the experiments of Witschi (1934), in which he produced twins in the frog by fertilizing eggs that were 3 to 5 days overripe. Witschi observed the development of several blastopores and gastrulation. Other sporadic observations of MZ animal twins have been cited by Corner (1955). He reviewed the few available specimens of early human MZ twin embryos, which are not dissimilar from those observed in experimental animals. Corner also cited the interesting observation of frequent admixture of MZ and DZ twins, to which we previously alluded.

The results of statistical surveys suggest that multiple ovulation due to hormonal stimulation is not the sole cause of enhanced multiple gestations. Derom et al. (1987)

observed that MZ twinning (1.2%) is significantly higher than would be expected from random births (0.45%). Boklage (1987a) has in fact gone so far as to ascribe the causes of MZ twinning to factors that differ little from those that induce DZ twins. When all evidence is taken together, it must be said that spontaneous MZ twinning is still a poorly understood phenomenon. Boklage (1981) takes exception to the notion of embryonic "splitting" as the etiology of MZ twinning. He pointed out that the high embryonic mortality that occurred in the early experimental studies makes splitting an unlikely cause of MZ twins. There is no doubt any longer, however, that splitting can take place in mammals and it can definitely be done experimentally. Boklage also stated that none of the many experimental chimeras that have been produced in mice experimentally had resulted in MZ twins. This, in itself, however, is insufficient proof against splitting, it seems to us. Few mice eventuate in MZ twins in the first place, and not many offspring of experimental chimeras have been sufficiently studied to identify their possible monozygotic derivation. The arguments on this topic are not unlike the controversy of "splitting versus budding" of the past, and these are well denominated as being a "skirmish in semantics" by Hamlett (1933).

To explain MZ twinning, Boklage conceived that forces responsible for organizing a field or gradient in early embryos may be the reason for the MZ twinning event. He opined that a "weakness in the enforcement of that directive might allow a second such organizing center to induce a second developmental scheme." He was particularly concerned with understanding neural symmetry and with mirroring in twins. McManus (2002) produced an interesting book on the mirroring aspect of twinning and other events of asymmetry.

In our opinion, the armadillo is the best animal from which to gain a better understanding of this puzzling yet frequent event of embryonic duplication. It is to be regretted that they are difficult to breed in captivity, which makes it difficult to accumulate the relevant observations. Other than for the pregnancy outcome, there is no good evidence that heredity in some way controls the MZ twinning event (other than in armadillos). The incidence of MZ twinning is nearly the same throughout the world and it is not significantly influenced by maternal age or the environment. It appears to be a sporadic event. Because of the nature of the fetal placental membrane relation in human MZ twins, one assumes that MZ twinning can occur at any time during the first 2 weeks of development. It then appears to be randomly distributed.

For lack of a better term and better insight into the etiology of MZ twinning, we have referred to the cause as the "twinning impetus." We make further inference that this impetus affects the developing embryos at random and that, because of this randomness of the timing, the different placental membrane relations shown in Figure 25.10 come about. We believe this impetus to be effective from days 1 to 14 of embryonic development. Our hypothesis further assumes that it is impossible for the impetus to split an already formed embryonic cavity such as the yolk sac, chorionic cavity, or amnion. The monozygotic twinning process, then, is a biologic continuum during this early period.

The phenomenon was discussed by Gould (1982) in an entertaining thesis on the not-so-trivial question as to whether conjoined twins are one or two persons. Finally, an interesting result, with experimentally derived MZ mouse twins, has been published by Gärtner and Baunack (1981). They produced MZ twins at the eight-cell stage

FIGURE 25.10. Interpretation of early events in the MZ twinning event. The earliest observed embryonic events of various are depicted in the upper portion. The bottom portion suggests that certain placental structures result if twinning occurs at certain times. Note that the DiDi/DiMo frequencies correspond roughly to the observed 1:3 ratio. It is also assumed that with later development (after day 8) MZ twinning becomes ever more difficult because of the enlarging embryonic/placental masses. Once the primitive streak is formed, conjoined twins may develop at first. Soon, however, the presumed twinning "impetus" is ineffective.

and compared their growth with that of DZ twins in the same strain of mice. Despite the fact that they worked with an isogenic strain, the DZ twins differed more from each other in a variety of characteristics than did the MZ twins. The cause of this unexpected finding is not yet understood.

### THIRD TYPE OF TWIN

The possibility of the existence of a "third type of twin" is occasionally considered in discussions of the twinning events. It proposes that MZ twins do not consist solely of identical twins, but that nonidentical twins, arising from a single ovulation event, make up part of the spectrum. It may amount to some 1% of twins who would usually be classed as DZ twins because of some dissimilarities of their genotypes. This

concept envisages that polar body fertilization may occur. Thus, the twins would then come from a single maternal, but two paternal, genomes. They would be intermediate in their genetic configuration between MZ and DZ twins. Such a possibility is supported by the occasional finding of polar bodies that have a similar size as the normal oocyte. This is especially so in some bat species. Furthermore, there are some theoretical considerations detailed by Mijsberg (1957) that suggest the existence of "third twins." In fact, the fertilization and further development of polar bodies has been observed. Dixon (1927) has described human polar bodies in mitosis, synchronous with the oocyte mitosis. It is also noteworthy that, in humans and in a variety of animals, binucleated ova are observed. They may produce such twins or even result in the development of chimeras. Binucleated eggs have been described repeatedly in the ovaries of a variety of animals, in women (Kennedy & Donahue, 1969) (Fig. 25.11), and in children. Manivel et al. (1988) found binucleated oocytes in 19%, and binovular follicles

FIGURE 25.11. Four Graafian follicles with abnormal ova whose future potential cannot be anticipated. A,B: Binucleate ova in Graafian follicles. C: Binovular follicle. D: Segmenting ovum within graafian follicle. H&E  $\times 100$  (A);  $\times 160$  (B);  $\times 80$  (C);  $\times 100$  (D).

FIGURE 25.12. Cross section of an ovary at 8 weeks' gestation with two corpora lutea of pregnancy. One is hidden from external view because of its position, so only one would have been recognized by inspection. This specimen is from the diamnionic/monochorionic (hence assumed to be MZ) twin gestation shown in Figure 25.8. H&E  $\times 4$ .

in 52% of their pediatric autopsy material. The fertilization of such abnormal ova has been observed by Zeilmaker and colleagues (1983).

The occurrence of "third twins" would explain the occasional finding of a single corpus luteum associated with fertilizations that were diagnosed to be DZ twins. The concept has been considered in some detail by Elston and Boklage (1978). Later, Boklage (1987b) suggested the term **tertiary oocyte**, rather than **polar body fertilization**, and critiqued the acceptance of the Weinberg formula in assigning zygosity, in particular for discordant twins. He also favored the notion that over-ripe ova may be responsible for some of these abnormal fertilization products. It must be cautioned, however, that mere inspection of ovaries (at operation) is insufficient evidence for the presence of a solitary corpus luteum only. A second corpus luteum may be present and found buried underneath another, as is shown in Figure 25.12. The macroscopic inspection of the ovary in this case would have been misleading. Further complicating the resolution of the question is that two normal ova may reside in a single antrum (Fig. 25.11). Such a graafian follicle would result in a single corpus luteum and yet possibly produce fraternal twins. Finally, it can be said that a possible instance of polar body twins, one an acardiac fetus with triploid chromosome constitution and the other diploid, has been studied in detail described by Bieber et al. (1981). On the other hand, employing molecular methodologies, Fisk et al. (1996) were able to rule out polar body fertilization in nine sets of twins with acardiac gestations. This subject is discussed in greater detail below (see Acardiac Twins).

## Twinning Incidence

The incidence of multiple pregnancies has been the topic of numerous investigations. This aspect was particularly well covered by Bulmer (1970) in his classical book on twinning in humans. It has also been the topic of several discussions, published in the third issue of the *Acta Geneticae Medicae et Gemellologiae* (Vol. 36, 1987). The rate for dizygotic twinning in various populations has been summarized by Diamond (1986), whose data are shown in the table below.

Ethnic group and locality	DZ twinning rate (per 1,000 births)
Asians	
Japanese	
Hawaii	2.2
Japan	2.3
Chinese	
Formosa	1.4
Hawaii	2.1
Malaya	2.8
Singapore	4.1
Hong Kong	6.8
Malays	
Hawaii	2.2
Manila	2.7
Malaya	5.2
Hawaiians	
Hawaii	3.9
Koreans	
Korea	5.1
Korea	5.8
Korea	7.9
Indians	
Bombay	6.8
Bangalore	7.3
Calcutta	8.1
Caucasians	
Europeans	
Spain	5.9
France	7.1
Switzerland	8.1
Holland	8.1
West Germany	8.2
Norway	8.3
Sweden	8.6
Britain	8.9
African blacks	
Bantu	
Johannesburg	16.0
Leopoldville	19.0
Yoruba	
Ibadan	40.0
Ilesha	49.0

These data impressively show that DZ twinning has a profound racial variation. In contrast, the MZ twinning rate "is nearly constant at about three and a half per thousand in all races" (Bulmer, 1970). Eriksson (1962) has drawn attention to the decline of twinning rates from north to south in Europe, which is due to variations of DZ twinning rates. The twinning rates and outcomes for a large U.S. population have been analyzed by Myrianthopoulos (1970a,b). He reviewed the data of the United States Multicenter Collaborative Study, which analyzed 56,249 pregnancies with known outcome. It contained 615 twins (1 per 91.5 births). The differences in the ethnic background of that U.S. population and its relation to multiple pregnancies can be seen in the following data from his report:

Group	Twins (No.)	Population (No.)	DZ twins (No./births)
Whites	259	25,991	1/100.3
Blacks	331	26,080	1/78.8
Puerto Ricans	25	4,178	1/167.1

The zygosity of 508 of these twins was examined as best as then possible, but a large number of twins remained unclassified. The results were as follows:

MZ = 29.6%

DZ = 51.4%

?Z = 19%

The profound influence of maternal age is well documented in these reports. The incidence of DZ twinning rises until, at 35 years maternal age, there is an abrupt fall in the incidence. A greater frequency of twins in the U.S. black population had also been noted in the large database summarized by Guttmacher (1953). He reported on the frequency of triplets and higher multiple births at a time that preceded the use of fertility drugs. Over a 22-year period, viable twin births occurred in 1 per 92.4 (whites) and 1 per 73.8 (blacks); triplets occurred in 1 per 9828 (whites) and 1 per 5631 (blacks).

The occurrence of higher multiple births, such as triplets, quadruplets, has commonly been estimated by the Hellin-Zeleny hypothesis: If twins occur with  $1/n$ , then triplets occur with  $(1/n)^2$  and quadruplets with  $(1/n)^3$ . This method is merely an approximation and is subject to maternal age, medical therapy, race, and other factors.

Multiple pregnancies showed a progressive decline from 1938 to 1949; later declines in the twinning rate have been studied by a number of investigators. Akesson et al. (1970) showed that the incidence of twinning in Sweden fell from 1.4% in 1871 to 1.1% in 1960. This change was due to fluctuations in the number of DZ twins born. Changes in maternal age were considered but they were not deemed to be the cause of this decline. Reports from the United States, Canada, Australia, and other countries have been similar (Elwood, 1973; James, 1973). The decrease in twin births in Holland was believed to be secondary to a decrease in maternal age at conception (Hoogendoorn, 1973). James (1975) suggested that either the decline may relate to exogenous agents or it is secondary to voluntary birth control. That the latter effect may have some significance is borne out by the apparent cessation of the DZ twinning decline in Canada (Elwood, 1983) and Hungary (Métneki & Czeizel, 1983); but James (1983) was not convinced. Allen (1987) provided data to show that there was no decline in U.S. twin births from 1964 to 1983. Imaizumi (1998) has summarized the twinning and triplet rates for 16 countries from 1972 to 1996 and indicated that most countries have a slightly **rising** rate of multiples.

In recent years, however, there has been a remarkable increase in multiple gestations and much of it appears to be the result of ART. It is the case also in other developed countries; in the U.S. the frequency of multiple births is now 1:30, perhaps as a result of this practice (Martin et al., 2003). Interestingly, only certain regions and populations are so affected but the results are startling. Thus, a review by the March of Dimes (MOD) Foundation (2003) states, "Fewer than 1% of live births result from IVF, they account for about one third of all twin births and more than 40% of triplets or higher-order births in the US." There has been much discussion as to the value and nature of ART; because superovulation so often leads to an uncontrolled number of fertilized eggs (and the frequent need for fetal "reduction"), Vidaeff et al. (2000) thus suggested that blastocyst transfer by ART may be more appropriate for infertile couples. Gleicher et al. (2000) examined the risk of higher numbers of conceptuses by superovulation and suggested that a smaller amount of gonadotropins needs to be employed than was then used. But this still does not really control the process, which is what is hoped for. The practice of ART is also changing over time; it consists of IVF, intracytoplasmic sperm injection (ICSI), blastocyst development by culture in vitro for up to 7 days (see Sills et al., 2003; also many different culture media are used), and transfer of a variable number of blastocysts to the recipient uterus. Rijnders and Jansen (1998b) stated that not all fertilized ova developed normally in vitro, which, in part at least, may be responsible for some of the abnormal outcomes that are observed, especially in implantation and placental development. The ova to be fertilized are obtained following superovulation by hormonal means.

Additionally, there are other modalities employed such as transfer into a surrogate uterus and employment of donated sperm and eggs, and other practices are under development. Small wonder, then, that the outcome varies as to the number of embryos resulting (often depending on how many blastocysts are transferred), sacrifice (reduction) of one or more embryos depending on the numbers conceived, and frequently abnormal placentation. Daniel et al. (1999) even found that singleton placentas of pregnancies conceived by ART are abnormal (slightly larger and thicker, abnormal cord insertion). The highest numbers of successfully transferred embryos we have seen are sextuplets delivered from a compound placenta at 28 weeks' gestation. Most remarkable has been the frequency of the development of more than the number of transferred blastocysts by the splitting of one or more blastocysts (Rijnders and Jansen, 1998a; Behr et al., 2000; Lancaster, 2004). Platt et al. (2001) estimated that 15.7% of ART twins are monozygotic, and that monochorionic twins are more problematic is well demonstrated by Dubé et al. (2002). Sills et al. (2000) impressively discussed the possible mechanisms by which monochorionic

placentas can develop in such manipulations, perhaps by alteration of the zona pellucida, a concept to be discussed more fully below. Daniel et al. (2000) found among the twin pregnancies so conceived that they were more commonly undertaken in older mothers, that they more often were prematurely delivered, and that they were associated with pregnancy-induced hypertension (PIH) and various other complications of pregnancy. Later (2001) they described the abnormality of placental development in such nonreduced twin gestations; they found mostly DiDi placentas that were thinner, more infarcted, and had anomalous cord insertions.

The economic impact and other aspects are discussed by Nkemayim et al. (2000), who also present suggestions for the limitation of the blastocysts transferred, now lawful in several European countries (see also Ozturk & Templeton, 2002, who suggest limiting transfer to two blastocysts). Templeton (2004), Nunley (2004), and an editorial in *Lancet* (2003) addressed the problems attending ART and the social implications faced by its practitioners. Jain et al. (2004a) summarized these trends of transferring fewer ova in recent years, concomitant with a greater survival of the ART gestations. Most recently, Thurin et al. (2004) compared single- vs. double-embryo transfer in women younger than 36 years in order to reduce the number of multiples. Blickstein (2005) reviewed in detail the frequencies of MZ splitting in ART and its various forms of embryo culture and comes to the conclusion that exact genetic diagnosis of such multiples is necessary. Finally, it must be mentioned that the neonatal outcome is often suboptimal, aside from their prematurity and number. Some of these concerns have been reviewed by Schieve et al. (2002) and Strömberg et al. (2002). The latter paper led to intensive discussion (Akanke & Murphy, 2002; Leviton et al., 2002; Davies & Norman, 2003).

The incidence of DZ twinning has also been shown to have a seasonal relation. Timonen and Carpen (1968), who observed this phenomenon in the Finnish population, deduced that this results from the continuous light stimulation, which induces enhanced gonadotropin release. The peak of twin births occurred during early spring and summer. Elwood (1978) found the peak for a Canadian population to be in October, whereas Edwards (1938) had reported two peaks for conceptions (February and August) in a British population. The effect was more pronounced with twins than with singletons. Harlap et al. (1985) raised the possibility that an increase in DZ twins results from the development of overripe ova.

#### SUPERFETATION AND SUPERFECUNDATION

Twins may have different fathers through the process known as **superfecundation** (two ova are fertilized by spermatozoa from different

fathers). That the concept is valid was proved by finding human leukocyte antigen (HLA) differences in the twins studied by Terasaki et al. (1978). In the accompanying editorial, Ryan (1978) referred to other cases and to its occurrence in "test-tube babies." Another report, with one white and one black twin, was forthcoming from Harris (1982). This report is most remarkable because the fertilizations apparently occurred 1 week apart. Verma et al. (1992) proved superfecundation by two different fathers with cytogenetic markers but were refused DNA fingerprinting. Harris (1982) also referred to a case of **superfetation** with twins of apparently different gestational ages (34 and 37 weeks). Rhine and Nance (1976) described the pedigree of a relevant family. They suggested that superfetation was the basis for the repeated dissimilarities of twins. They assumed it to be inherited as a dominant trait and expressed through a putative placental inability to suppress new ovulation after conception.

## Vascular Anatomy of Twin Placentas

One of the most important observations to be made in the study of twin placentas is the accurate determination of the nature of fetal surface blood vessels. Their relation to one another is perhaps the single most important determinant for the outcome of many twin pregnancies. These aspects were first clearly demonstrated by Friedrich Schatz, whose numerous contributions have been summarized in English by Strong and Corney (1967). Price (1950) considered the various vascular anastomoses of monochorionic twin placentas to be the most important determinants for the frequently discordant development of MZ twins. This notion dates back more than a hundred years, and many observers since then have reached similar conclusions that anastomoses have a profound influence on outcome.

The demonstration of anastomoses is relatively simple. Once the anatomy of the placental vascular architecture is learned, injection studies are rarely necessary, they aid, however, in delineating the patterns for the novice and should be performed routinely. A simple method for the detection of anastomoses has been described by Coen and Sutherland (1970). They used milk for injection because it is so readily available and demonstrative, but other liquids are equally useful. For the purposes of injection it is best to cut the umbilical cords near their placental surface, so as to reduce vascular resistance. One should also have stripped the amnion from the chorionic surface, which exposes the fetal surface vessels well (Fig. 25.13). The general examination of the placenta should have been completed, but samples for histologic study should be taken only after the injection has been done. For optimal results, several tools are desirable and they are depicted in Figure 25.14. It must be admitted, however, that a simple syringe and water are usually adequate. One must inspect the surface of the placenta carefully, follow major vessels to their ends, and determine, visually at first, which vessels are likely to have communications between the two fetal circulations. In the normal placenta, the fetal

FIGURE 25.13. Diamniotic/monochorionic twin placenta (26 weeks' gestation) with velamentous insertion of one cord. This twin had a much smaller portion of placental tissue and died.

arteries terminate in the periphery, dip into the villous tissue, and emerge nearby as veins, which then course back toward the same umbilical cord. The arteries are recognized as those vessels that cross *over* veins, particularly those of a larger caliber. A 1:1 relationship is usually found in the final vascular ramifications: one artery to one vein. Bajoria et al. (1995) demonstrated that the likelihood of the presence of the typical twin-to-twin transfusion syndrome (TTTS) is greater when fewer anastomoses are present.

When no returning vein can be identified to accompany a peripheral arterial branch in a twin placenta, an artery-to-vein (AV) communication may exist from one twin to the other. This area then becomes important for the exploration of a so-called deep anastomosis. These

AV anastomoses perfuse a common (or shared) cotyledon and form the basis for the transfusion syndrome, discussed below. They are common and constitute the "third circulation" of twin placentas. Most frequent are artery-to-artery anastomoses (AA shunts); vein-to-vein (VV) communications are the least frequent types of anastomoses, as found by Schatz in 1875 and more extensively in 1886. He believed that AA anastomoses are more common because of the higher blood pressure existing in arteries; therefore VV anastomoses are rare, and they were thought to obliterate more commonly before birth.

To document the presence of a direct AA or VV anastomosis, it is often sufficient to stroke blood back and forth through a major shunt. If one wishes to demonstrate

FIGURE 25.14. Ideal set of tools to inject twin placentas: syringe with beaded needle, string to tie needle in place, colored liquid (e.g., milk), clamps, and forceps.

FIGURE 25.15. Injection of DiDi twin placenta. A potential anastomotic area has been isolated, the amnion is stripped, and a needle is inserted and tied in place.

it conclusively, injection of milk, colored water, or similar solution is feasible. To do so, one inserts a needle near the point of presumed anastomosis and then gently injects the liquid, which usually readily passes to the other side of the twin placenta (Figs. 25.15 to 25.16). The injection of as little as 5 to 10 mL of fluid is usually sufficient. Note from Figure 25.15 that it may help to have a needle with a bead and to tie it into the vessels to allow more pressure to be exerted during injection. Usually, grasping the end of the needle in the vessel with the thumb and index finger of the other hand is sufficient to allow injection of fluid with some pressure. It is also important to recognize that one should not attempt to inject the entire placental bed from the vessels near the cord insertion. This measure requires so much volume of injection fluid that pressures are generally insufficient to demonstrate finer anastomoses (Fig. 25.17). Moreover, the villous tissue of twin placentas is often damaged during delivery, and the placenta then leaks when injected from the umbilical cord. This frequent disruption can make adequate demonstration of anastomoses difficult.

The identification of AV shunts is usually the most difficult. It is best to inspect the surface carefully to identify possible areas of AV shunts and then inject them successively. It is immaterial here whether one fills them from the arterial or the venous end. When the fluid is injected slowly under some pressure, one sees an area of placenta distend and increase in thickness. After a short while, the fluid emerges from the other side, and it can then be traced to a larger vessel where its nature (artery or vein) can be ascertained. The delineation, direction, and number of these shunts are especially important if one wishes to understand the basis for the transfusion syndrome. Finally, it is recommended that a drawing of the entire vascular relation is made for the record at the end of the procedure. Figures 25.18 and 25.19 show various types of anas-

FIGURE 25.16. Vascular equator of a DiMo twin placenta to show artery-to-artery (AA) and artery-to-vein (AV) anastomoses, as well as the normal cotyledonary supply. The diagram (bottom) is self-explanatory.

FIGURE 25.17. A DiMo twin placenta with amnion stripped off; the right side has been injected with barium sulfate through one umbilical artery. There are no anastomoses. Both cords have a marginal insertion; arteries cross over veins. This method failed to disclose two small AV shunts (bottom) because of the lack of sufficient pressure exerted when the entire tree is filled. (Courtesy of Dr. S. Romney, New York, New York.)

FIGURE 25.18. A DiMo twin placenta with single large AA anastomosis (A) at top left. It has also been injected with barium. Finer AV areas have not been filled.

FIGURE 25.19. A DiMo twin placenta, vascular equator. The amnions have been removed and the various types of anastomosis are delineated on pieces of paper.

FIGURE 25.20. A DiMo twin placenta that has been injected with colored plastics and then made into a corrosion cast. A pink vessel, injected from the left half can be seen over the yellow injected vessels on the right. The possible presence of “shared cotyledons” is impossible to identify.

tomoses in two monochorionic twin placentas at their “vascular equators.”

If one wishes to make injections of the placental vasculature with plastics for later corrosion, special procedures are necessary. The placenta must be intact. It must first be washed out with warm dextran to open all vessels and to remove the fetal blood. Saline has been found to be less satisfactory (Robertson & Neer, 1983). After the specimen has been flushed, one can then achieve gradual filling with plastics solutions in different colors and with ever-increasing strengths (see Torretta & Cobellis, 1966). A DiMo twin placenta, thus prepared, is shown in Figure 25.20. As will be seen, there is slight filling of a (pink) arterial branch over the yellow-injected placenta, but only exhaustive examination of such a specimen allows one to identify the possible presence of shared cotyle-

dons. By and large, these preparations are more beautiful than they are useful. Only experienced observers such as Hyrtl (1870) have profited from their preparation.

One might suspect that the proximity of cord insertions in twin placentas may influence the frequency and type of anastomoses, but that has not been our experience. Although it is true that in placentas with cords next to each other, as depicted for instance in Figure 25.21 (also see Figs. 25.26, and 25.38), large communications often exist whose injection is scarcely needed, they cannot be assumed a priori. Many MoMo placentas have no communications, irrespective of their cords' proximity. This point was well made in the study by Wenner (1956). He was surprised to find no anastomoses in the placental vascular ramifications of a thoracopagus. The demonstration of anastomoses is most difficult when one fetus has

FIGURE 25.21. A monoamniotic/monochorionic (MoMo) twin placenta with amnions removed. The cords insert next to each other, adjacent to major anastomoses.

FIGURE 25.22. A DiDi twin placenta with minute anastomosis coursing over the dividing membranes. The associated like-sex twins were MZ. (Source: Cameron, 1968, Figure 5, with permission.)

died before birth. It is thus often impossible to demonstrate vascular connections in DiMo placentas with a fetus papyraceus and also when the placenta has been fixed in formalin beforehand.

Despite numerous injection attempts, we have never seen anastomoses between blood vessels of dichorionic twin placentas. That they may exist in rare cases is not doubted. The finding of rare blood chimeras (*vide infra*) and occasional reports of such connections by competent observers (Fig. 25.22) (Cameron, 1968; see his Figure 5) make them a reality of great interest. In contrast, anastomoses occur frequently in the DZ twins of some other species, such as marmosets, monkeys, and cattle. This aspect is discussed further below.

The observed frequency of inter-twin blood vessel anastomoses in human MZ twins is difficult to assess because of the differences in techniques employed for their demonstration. We previously reported the following relationships of anastomoses in 60 injected monochorionic twin placentas (Benirschke & Driscoll, 1967):

Type of anastomosis	Total found	Infant survival (No).
AA (one or more)	17	12
AA + AV	17	14
AA + VV	5	3
VV	3	2
AV	7	3
AV + VA	2	1
None	9	6

Similar findings have been published by others. Robertson and Neer (1983) reported on 278 twin placentas (of 23,810 births; incidence 1/86; seven triplets). They used dextran and heparin for injection, cannulated the

vessels, and injected 100 mL over 30 minutes. The vessels were then infused with warmed solutions of dyes in colloid suspension. India ink did not work well. Nineteen placentas were damaged and excluded; 97 placentas were separate masses. Of 162 successfully injected fused placentas, 96 (59%) were DiDi; the remainder were monochorionic. Of 56 monochorionic twin placentas studied, all but one had demonstrable anastomoses. The one placenta without anastomoses had an infarcted area that had produced a separation between the two halves. There may have been a communication in the past, as obliteration of such anastomoses is not uncommon. In one dichorionic placenta, the injection material exchanged between the two sides through a tiny villous area. The long-term outcome of these twins is not known, as is true for Cameron's case (Fig. 25.22). These twins had identical blood groups, even though the pair was dichorionic. As we indicated above, identical blood groups should be expected when vascular shunts exist in the placenta of twins. Four cases of the typical transfusion syndrome were found in the study by Robertson and Neer (1983).

The topic of DZ twins having a monochorionic placenta and vascular inter-twin anastomoses is somewhat controversial. Scipiades and Burg (1930) first described anastomoses in two boy/girl twin placentas. Lassen (1931) and Tüscher (1936) each added a rare case of MZ dichorionic twins with fine anastomoses. It must be emphasized, however, that some of these cases are not well supported by pictorial or other conclusive evidence. Even Lassen (1931), who performed stereoradiography on a placenta, was not absolutely certain of the connections he demonstrated. The technique of stereoradiography is not very satisfactory, as the findings in seven placentas from DZ twins with anastomoses have shown (Pérez et al., 1947). Szendi (1938) admitted this lack clearly in his discussion of the stereoscopic analysis in four of 20 dichorionic placen-

tas with putative anastomoses. Bleisch (1964) found arterial anastomoses in all 18 monochorionic, but in none of 42 dichorionic, twin placentas. He also succinctly explained why one should not accept the diagnosis of MoMo placentation in the boy/girl twin placenta reported by Pickering (1946). Wenner (1956) reemphasized Schatz's point of the rarity of VV anastomoses. He found only three such cases among the perhaps 100 placentas that were studied. He suggested that this type of connection may have lethal consequences because "one fetus aspirates blood through these anastomoses from the other," a point to which we return later. In a later study, Bleisch (1965) found that all of his 75 monochorionic twin placentas had anastomoses. In all but one case the anastomoses were grossly identifiable, and the sizes of anastomoses were partially related to the distance of the cord insertions. He was unable to identify any specific reasons for the directions of flow, but death of one twin was associated with thrombosis. Only one VV anastomosis was found, and Bleisch hypothesized first that the possibility exists for large blood shifts through large anastomoses, particularly given different intrauterine pressures, a point that is especially relevant when intrauterine demise of one monochorionic twin occurs. No connections were found between the circulations of dichorionic twins.

Twin placentas have other vascular peculiarities. Bhargava et al. (1971) made a detailed study of the vessels in the chorionic plate of 166 placentas from twins and triplets. They found many more placentas with arterial and venous tortuosities, "arteriovenous dissociations," and reversal of arteriovenous relations when they compared twin placentas with 167 singleton placentas. Their conclusion was that these vascular abnormalities are determined "mainly under the influence of the functional demands of the corresponding foetus." Identification of these anomalies may enhance our understanding of prenatal development.

The frequency of abnormal insertion of the umbilical cords in multiple gestations is particularly important, as was demonstrated in Chapter 12, Table 12.3. Kobak and Cohen (1939) described the incidence of velamentous insertion of one cord as being nine times higher in twins (routinely in triplets, according to De Lee, as quoted by Kobak and Cohen) than the 1% or so found in singleton placentas. Similar results were reported by Englert et al. (1987), when they observed abnormal placental shapes and cord insertions in multiple pregnancies after IVF. Eberle et al. (1993), who investigated the placental pathology of weight-discordant twins, found that discordant placental lesions were correlated more with dichorionic than monochorionic twins, rather than this discordance being correlated with placental weight. Feldman et al. (2002) found that velamentous cord insertion in triplets correlated significantly with fetal growth restriction. Likewise, in the searching review of placental lesions with

abnormal growth in twins, Redline et al. (2001) found that peripheral cord insertion and, less significantly, avascular villi and evidence of reduced maternal perfusion are associated. Further, Benirschke and Masliah (2001) have reviewed the issue of discordant placental development in DiMo and DiDi placentas and considered the "competition for space" as one possible reason for the differences occurring in the placental development of multiples conceived by ART. Abnormal cord insertions are of concern to the perinatologist because of the possibly greater frequency of vasa previa in twins. Kobak and Cohen (1939) described the stillbirth of a twin following vaginal bleeding that had resulted from disrupted vasa previa. Two similar cases of DiMo placentas and vasa previa were described by Whitehouse and Kohler (1960). Three of their six reported infants died from exsanguination. When this problem is anticipated, Kleihauer stains of the vaginal blood disclose the presence of fetal blood. We have seen several similar cases. In one, the fetal blood loss was recognized, and immediate neonatal transfusion with 100 mL of maternal blood saved the infant. A similar case has been described by Duenhoelter (1989). In another case we saw, vasa previa were present in the dividing membranes of DiDi twins. They ruptured, and fatal exsanguination occurred within 3 minutes of the second sac's rupture (Figs. 25.23 to 25.25). Because there are often large anastomoses between DiMo twins, rapid exsanguination of the second twin may also occur when vasa previa are ruptured in the first twin. It can also occur through an untied umbilical cord after delivery of the first twin. This potential exsanguination of a second twin is allegedly the reason for routine clamping of the placental end of the umbilical cord, lest an undiagnosed twin bleed

FIGURE 25.23. A DiDi twin placenta with velamentous insertion of the cord from twin B. He exsanguinated within 3 minutes after rupture of the second sac. There was disruption of the velamentous vessels (arrows).

FIGURE 25.24. A DiDi fused twin placenta with large vessels of twin A coursing over the dividing membranes. Twin A has a single umbilical artery. These twins delivered at 34 weeks' gestation. The superficial chorionic veins of twin B (right) were nearly completely thrombosed. The infants survived.

from the cut end of the first-born. Velamentous vessels of twins may thrombose before birth, or they may atrophy. Rarely are they of vitelline origin and then of no importance (Fig. 25.26).

Antoine et al. (1982) grossly underestimated the reported frequency of vasa previa in twin placentas, when they cited only eight cases. They described a case in which sinusoidal fetal heart rate patterns initiated appropriate fetal studies, for example, amnioscopy and examination of the blood. Despite these efforts, both DiMo twins exsanguinated. Ramos-Arroyo et al. (1988) have also found that abnormal cord insertion was higher in twin gestations. Velamentous or marginal cords were found in 27.4% of monochorionic placentas, compared with 13.8% in dichorionic organs. They considered this as evidence in favor of trophotropism (see Chapter 7). Conversely,

Gavriil et al. (1993), who studied the placentas of IVF, interpreted the more frequently eccentric insertion in twins as resulting from "oblique orientation of the blastocyst at the nidation" but provide no further explanation why this should happen. The excess frequency of velamentous cords in DiMo twin placentas has significant correlation with the transfusion syndrome. Fries et al. (1993) found that one third of DiMo twin placentas had such abnormal cord insertions and that 64% were involved with transfusion syndrome cases and delivered significantly earlier. They thus sought an etiologic role for this abnormal insertion. It may also be considered that velamentous insertion is so common in this syndrome because normal placental development failed to take place.

Bruner et al. (1995) found a similarly high frequency of velamentous cord insertions of the donor twins, and

FIGURE 25.25. A DiDi fused twin placenta with velamentous cord insertion of the left cord. Its fetal vessels are markedly dilated and course over the membranes at left. Note that the major vessels of these twins do not approach the dividing membranes.

FIGURE 25.26. Immature DiMo twin placenta whose translucency of the dividing membranes is apparent. The cords seem to arise at the same spot but are nevertheless in separate amniotic compartments. Note the remains of a single yolk sac (arrow), whence omphalomesenteric vessels course toward the cords.

Mari et al. (1995, 1998) also felt that it may have an etiologic role in causing the imbalance that leads to the transfusion syndrome. We believe this to be possible because of the constant slight drainage of blood that occurs from the placenta with the velamentous cord into the other twin. Therefore, this placenta with reduced pressure may not have grown as avidly and centrifugally as it should have. The primacy of the vascular component in villous capillary development was addressed by Giles et al. (1993). These authors studied sonographically abnormal umbilical artery waveforms [systolic/diastolic (S/D) ratios] in twins and correlated these with villous vasculature. They found that “microvascular disease” of villi (reduction) correlates with growth restriction and abnormal S/Ds. Velamentous cord insertion was found as frequently as in 45% of monochorionic twin placentas by Machin (1997). He opined that it was an added risk factor of the twinning phenomenon and found growth discrepancies more commonly in central/velamentous cord insertions of monochorionic twins. Also, AV anastomoses were more common in this situation.

There is a wide spectrum of vascular relations in twin placentas. How do they come about, and what is so different in other species? In marmosets the assuredly DZ twins always have placental anastomoses; in Artiodactyla (especially *Bos* but also *Sus*, *Ovis*, *Bubalus*, and others) DZ twins often have fused placentas, and blood traverses from one fetus to the other. In marmosets it leads invariably to blood chimerism, but, other than for an occasional fetus papyraceus, the anastomoses cause no known complications. With Artiodactyla, however, in addition to the blood chimerism, the female twin becomes a freemartin (v.i.) when she is connected to a male’s placental circulation.

This is not the case in humans, where dichorionic twins rarely have anastomoses, but where they have clearly occurred because of blood chimerism. Heterosexual blood chimerism is rare and it is not associated with sterility, that is, freemartinism in women (see Quintero et al., 2003b).

The reason for the differences must be found in the early embryologic development of the embryo and placenta. In marmosets, fusion of chorions occurs very early (Benirschke & Layton, 1969), but in human DZ twins no such fusion of chorionic circulations occurs. Here, the placentas may become intimately fused, but they do not develop interplacental vascular anastomoses. Indeed, despite numerous suggestions to the contrary, villi do not fuse in the human placenta, however closely they may become approximated. When sections of India-ink-injected, intimately fused dichorionic twin placentas are prepared, one observes that the villi may intermingle, but they do not connect with one another. No blood vessels traverse from the villi of one fraternal twin to those of the co-twin.

To understand the vascular commonality of monochorionic twin placentas, it is easiest with a review of their early embryology (Fig. 25.10). We suggest with this diagram that, in human placental development, the single chorionic sac has long since formed when vessels develop from the yolk sac or in situ, on about the 13th day. One must envisage that these primitive vascular precursors sprout all over the inner surface of the primitive chorionic membrane and, when the fetal heart gradually begins to pump, these fine vascular precursors begin to fill with blood. The vessels undoubtedly link with one another at this early time. The type of anastomosis that ultimately develops is probably a matter of chance. Whether the

vessels become arteries or veins is determined by the direction of blood flow and its pressure. Some of the anastomoses are kept open, and others atrophy, depending on the velocity of flow. It may also be presumed that MZ twins often derive from embryonic splits with unequal cell numbers; it is therefore possible that one heart beats sooner or stronger, and that this influences the direction of flow in the anastomoses.

## Monoamnionic/Monochorionic Twin Placenta

The MoMo twin placenta is the least common type. It occurs in approximately one or two of 100 sets of twins in the U.S. population but has now a nearly 40% perinatal mortality. Barss (1988) found that fetal demise occurred mostly before 24 weeks, when enough room for fetal motions and entanglement was still available in utero; Carr et al. (1990) found that after 30 weeks no further deaths occurred. Similarly, Tessen and Zlatnik (1991), who reviewed 21 sets of MoMo twins, found that fetal death did not occur after 32 weeks. Double survival used to be so uncommon that many papers were published with the title "MoMo Twins with Double Survival." The classical paper on MoMo twins is that by Quigley (1935), who believed the condition to occur only once in 60,000 pregnancies. Quigley found only one case report in the preceding 12 years. Altogether perhaps 110 cases had been reported at the time of his review. More recent papers give an incidence of 1:10,000 to 16,000 pregnancies. Quigley found double survival in only 15.6% and an overall fetal mortality of 68%.

Most commonly, fetal death is due to entangling of umbilical cords because of fetal movements. This knotting of cords is unpredictable and is often found in very young pregnancies, with abortion ensuing. It can now be visualized sonographically before birth, and management of such cases is changing. Thus, Belfort et al. (1993) identified not only cord entanglement but also venous obstruction by color Doppler flow study. This diagnosis led to successful interruption of an otherwise endangered pregnancy. More surprising is the case described by Krause and Goh (1998). Their twins had clearly entangled cord with compromise of the circulation, but a monochorionic placenta with diamnionic membranes was found. There must have been a window in the dividing membranes of this DiMo twin placenta for the entanglement to have occurred. Shahabi et al. (1997) were unable to save one twin despite making the diagnosis at 20 weeks; such cases are the reason why in our hospital these twins are hospitalized early, so that we can intervene quickly when flow compromise is diagnosed. Tabsh (1990a) suggested that the diagnosis of monoamnionic twin placentation is easily

made at amniocentesis by injection of indigo carmine, but the sonographic demonstrations by Belfort and his colleagues (1993) indicated that this new modality is superior to previous studies. They found cord entanglement and venous obstruction with Doppler flow studies that led to better management of their three pregnant patients. Abuhamad and his colleagues (1995) reported similar findings in two MoMo twin pregnancies. Rodis et al. (1997) studied 13 MoMo twin pregnancies with 26 live-borns (two died neonatally for other reasons) and deduced that their early diagnosis and appropriate management improved perinatal survival. Cord entanglement was noted in eight of their twins, and two sets had the transfusion syndrome. These authors found 96 publications on the topic, with 202 sets of MoMo twins. Other complications occur in MoMo pregnancies, such as prenatal coagulation, exsanguination through placental anastomoses, or bleeding from one twin into the other through anastomoses, and congenital malformations. Westover et al. (1994) found rare nuchal cords by Doppler imaging in MoMo twins that allowed appropriate management at delivery. Quintero et al. (1997) successfully ligated one of the umbilical cords in MoMo twin pregnancies when one twin was diagnosed as being nonviable.

Other obstetricians have also hoped, as did Belfort et al. (1993), that through early prenatal diagnosis (Dunnihoo & Harris, 1966; Sutter et al., 1986) the chances of MoMo twin survival can be improved. Rodis et al. (1987) managed three sets of twins successfully despite severely knotted cords; they also made suggestions for management. They identified one of these twins as having the typical transfusion syndrome. Driscoll (personal communication, 1970) has also seen the transfusion syndrome in MoMo twins. To find the transfusion syndrome in MoMo twins is otherwise uncommon (Wharton et al., 1968).

Table 25.3 presents a summary of some of the relevant literature on MoMo twin survival. Of 169 sets of MoMo twins, only 202 infants (60%) survived. The causes of death were predominantly cord entanglement [with still-birth (Fig. 25.27; also see Fig. 25.35) or neonatal death], prematurity, and congenital anomalies. The aim of prenatal surveillance is to prevent the knots or entanglements of the cords becoming fatal. It is not known when knots first form, but because it requires considerable fetal mobility to produce knots, they are frequently found early in pregnancy, when more fluid exists (e.g., Fig. 25.27). On the other hand, it must be noted that term neonatal MoMo twins can have extensive knotting without compromise of the umbilical circulation. One assumes that space limitations in the uterine cavity prevented the formation of new knots with advancing gestation, which may also be the reason why such knotting is uncommon in triplets. Only knots that are already present from an earlier gestation may have the potential to compromise the fetus.

TABLE 25.3. Reports of monoamniotic twin pregnancies (incomplete)

Source	Year	Sets of MoMo twins	No. of survivors	Remarks
Quigley	1935	1	1	Review of 109 cases
Litt & Strauss	1935	1	0	Knots, one anencephalic
Parks & Epstein	1940	1	2	Knot, no anastomoses
Coulton et al.	1947	2	4	No entangling
Wilson	1955	5	4	Anencephaly, CHD, knots, tangles, anastomoses, fold
Whitehouse	1955	1	1	1 Papyraceus, knots, anastomoses
Craig	1957	1	2	Entangling; 166 cases cited
Librach & Terrin	1957	3	6	One knotted
Walters & Whitehead	1957	2	2	Both knotted
Sinykin	1958	1	3	First triplets, entangling
Pickhardt & Breen	1958	1	2	No knots; anastomoses
Semmens	1958	1	0	(1) Anemia, RDS; (2) CHD. No knots
Green et al.	1960	1	2	Knot, entangling
Zuckerman & Brzezinski	1960	2	1	2 sets macerated, knots; other knots; 1 lived, 1 macerated
Tafeen et al.	1960	3	4	2 knotted
Raphael	1961	5	5	2 anomalies; 4 knot/entangling
Wensinger & Daly	1962	3	5	3 knots/entangling
Timmons & Alvarez	1963	4	4	3 knots; 1 CNS damage; 1 fold
Goplerud	1964	1	2	No knots/entangling
Benirschke & Driscoll	1967	3	3	Knots
Dunniho & Harris	1966	1	2	No knots
Simonsen	1966	2	2	1 Knots
Wharton et al.	1968	18	24	1 CHD, 1 palsy, anastomoses
Larson et al.	1969a	1	0	Forked cord
Larson et al.	1969b	1	1	Both anomalies; no knots
Moestrup	1970	2	2	1 SUA (third case); no knots
Israelstam	1973	1	0	Knotting
Chapman	1974	3	2	Knotting
Mauer et al.	1974	1	1	Both discordant anomalies
Averback & Wigglesworth	1977	1	1	No knots
Litschgi & Stucki	1980	1	1	Macerated, entangling
McLeod & McCoy	1981	1	2	Cord of No. 2 around neck of No. 1, cut during delivery, both velamentous, IUD
Colburn & Pasquale	1982	1	2	Entangling
Colgan & Luk	1982	1	1	Torsion & thrombi of cord
Berry et al.	1984	1	1	SUA, severe anomalies; knots
Lumme & Saarikoski	1986	23	13	4 anomalies; knots, entangling
Sutter et al.	1986	1	2	Knots
Rodis et al.	1987	3	6	3 knotted
Barss	1988	5	9	Knots in 1; transfusion syndrome; anomaly; twinning in 1/87 pregnancies, after 20 weeks
Lee et al.	1988	59	77	Review of prenatally diagnosed MoMo twins
Tessen & Zlatnik	1991	21	28	Controlled study; no deaths after 32 weeks
Tabsh	1990	2	4	Method for diagnosis <i>in utero</i>
Total		192 (384 twins) 100%	234 Survivors (60%)	150 Dead (40%)

RDS, respiratory distress syndrome; CHD, congenital heart disease; IUD, intrauterine death; CNS, central nervous syndrome.

Lee et al. (1988) endeavored to ascertain the best mode of pregnancy management when MoMo placentation is diagnosed sonographically. They surveyed perinatologists and ascertained 59 pregnancies with an overall perinatal mortality of 34.7%. A much higher mortality was found when the diagnosis was made before 25 weeks' gestation than later. Although entangling of cords was an important cause of late deaths, there was an astonishing frequency of transfusion syndrome fatalities during earlier

gestation. Frequent nonstress tests were recommended as the principal strategy for supervising these gestations.

The proximity of cord insertion is apparently not the principal determinant of knotting. We have seen extensive knotting in cords that were inserted at opposite margins of the placenta and no knots in some placentas whose cords arose next to one another (see Fig. 25.20). When a cord is obstructed for long periods, it may become very thin (Fig. 25.28), a condition described in several

FIGURE 25.27. Macerated monoamniotic twins (12 weeks) with extensive knotting and entangling of cords. Fetal movements must have been extensive at an early embryonic age.

papers (Table 25.3). But the long-standing obstruction that can occur when MoMo twins' cords entangle is often evidenced by thromboses in placental surface veins (Fig. 25.29). Even when these twins survive, defects may have been caused by such hypoxic states. One complication of MoMo twinning is that the accoucheur may inadvertently cut the wrong umbilical cord during delivery. Donald (1964) described such a case, and a similar set of MoMo twins was observed by McLeod and McCoy (1981). When the first twin could not be delivered because the cord was extensively entwined about the infant's neck, the cord was severed. Only after the fetus was fully extracted was

it realized that a mistake had been made. After rapid delivery of the second twin, both twins survived.

The placental surface of MoMo twin placentas usually has a continuous sheet of amnion without folds between the cord insertions. However, there have been four observations of the existence of folds. Timmons and de Alvarez (1963), in their report of four cases of MoMo twins, found "a short fold of what was thought to be membrane . . . present in the midportion of the fetal surface but [it] did not extend between the origins of the umbilical cords." Another plica ("fringe") was described in one of the five MoMo twins reported by Wilson (1955). It inserted

FIGURE 25.28. MoMo twins at 38 weeks' gestation with fetal death of one at 23 weeks (20-cm crown-rump length, 400-g macerated). Survivor is alive and well. Note the entangling and

knotting of cords, the thin cord of the dead twin, and the extensive infarction of the right placental half. Anastomoses cannot be demonstrated this late after fetal death.

FIGURE 25.29. Monoamniotic twin pregnancy with extensive entangling of umbilical cords. One (dark) twin was stillborn, the other died with extensive areas of cerebral necrosis. Note the

calcified veins in the liveborn twin (top) and more recent thrombi (right, at white arrow).

between the two cords of a set of MoMo macerated twins born with a surviving DZ triplet. A similar case has been described by Wolf (1920), and another is shown in Figures 25.30 and 25.31. One of these twins had the Klippel-Feil anomaly and died during the neonatal period. The cords arose from a single point and had six vessels that merged into three (arrow in Fig. 25.30) at their base. A thin, fal-

ciform plica extended from the cords to the margin of the placenta. The tip of this plica, which consisted of two fused amnions, showed degenerative changes and scarring (Fig. 25.31). It is possible that disruption of the dividing membranes of two former amniotic cavities had occurred. It is also possible that the twinning took place just about at the time (7 days) when the amnion is first

FIGURE 25.30. A MoMo twin placenta; one twin had Klippel-Feil syndrome. The two cords arise from the same spot, where vessels merge (arrow). Thin plica, composed of two amnions,

extends from cord insertion to the margin. It is presumably the remains of an early attempt at formation of two amniotic cavities, interrupted by the twinning event.

FIGURE 25.31. Sections through the tip of the plica shown in Figure 25.30. Note the degeneration of amnionic epithelium and the scarring of underlying connective tissue. H&E  $\times 260$ .

set aside, thus preventing the formation of two complete amnionic sacs. It is difficult to conceive that an apparently single cavity could form from the spontaneous breakdown of the dividing membranes in a DiDi placenta, although this was assumed by Pickering (1946) in his description of boy/girl twins with a MoMo placenta. Nylander and Osunkoya (1970) also described “heterosexual twins with monochorionic placenta.” They depicted a ridge with DiDi configuration present in one part and a DiMo relation in another portion of the placenta. Another unexplained case of monochorial placenta with fraternal twins was recorded by Van Verschuer (1925). He relied on the placental diagnosis of an assistant, and the dizygosity was based only on some physical differences (e.g., hair color). Gilbert and his colleagues (1991) not only identified several new cases of twins with rupture of the dividing membrane occurring in utero (“pseudomono-amniotic,” according to Megory et al., 1991), but also highlighted the morbidity that may ensue, such as entangling of extremities in bands and entangling of cords. Diamniotic placentas can also be transformed into MoMo organs by amniocentesis and funipuncture (Magyar et al., 1991; Feldman et al., 1998) and spontaneously, perhaps by fetal activity. In tracing the history of MoMo twinning one step further, one may postulate that the placenta of Figure 25.32 was determined shortly after that which yielded the plica. Here the two cords, arising

nearly one from the other, are bound together by a delicate amnionic membrane.

We have observed a placenta from a set of MoMo twins with unusual findings that are relevant to the understanding of prenatal injury. One of the twins had cerebral atrophy that was attributed to the entwining of the umbilical cords. There was focal amnion necrosis, but this was confined to the regions directly above the fetal surface blood vessels; elsewhere the amnion was intact. This finding and the observation that the nodules of amnion nodosum are generally absent on cord and free membranes and that they occur primarily in amnion between the surface vessels led us to speculate that the amnion maintenance depends on the oxygen supplied from different sources. Oxygen tension in amniotic fluid is low (Jauniaux et al., 2003), and it is possible that it is augmented by oxygen from fetal surface vessels, the decidua capsularis, and the vessels in the umbilical cord. Further evidence for this surmise is that partial necrosis of thrombosed vessel walls can be seen in some cases with occluded cord vessels (see Chapter 12). Thus, in the present case with cord entanglement, we hypothesize that the entanglement led to reduced flow of one twin’s vasculature (hence the cerebral atrophy of that twin) and the necrosis of the surface vasculature’s amnion.

Anastomoses of fetal blood vessels appear to occur even more commonly in MoMo placentas than in DiMo

FIGURE 25.32. A MoMo twin placenta at term with extensive interfetal vascular anastomoses. The nearly commonly arising cords are bound within an amniotic fold. This stage presumably arises shortly after the placenta shown in Figures 25.30 and 25.31.

twin placentas when injection studies are made (Bajoria, 1998), this perhaps being the reason for the rarity of the twin transfusion syndrome in MoMo twins. Umur et al. (2003a) came to the same conclusions in their review of 24 MoMo vs. 200 DiMo twin placentations. The proximity of the cord insertion may be one determinant, as the cords are more often centrally located. Of great importance also is that, when large inter-twin communications exist, the cell and blood traffic between the two fetuses may have greater influence on the fetal well-being. The example depicted in Figure 25.33 features the placenta of a macerated MoMo twin and a co-twin who expired soon after birth (Benirschke, 1961). This case has aroused much interest subsequent to its occurrence. The initially surviving infant died within 62 hours. Bilateral renal cortical necrosis, cerebral liquefaction, and other degenerative changes, including thrombi and focal mineralization (Fig. 25.34), were present. These findings are descriptive of the sequelae from DIC. We then postulated that thromboplastin from the macerating twin had entered the survivor's bloodstream via interplacental anastomoses prior to birth and had thus initiated DIC. The development of DIC, as resulting from thromboplastins liberated by the dead twin, now seems to us to be far-fetched, because the fetus is dead and cannot contribute much to the survivor's circulation. But, there have been several other reports of neonatal deaths with findings of DIC (Table 25.4). During the past few years we have been consulted with many similar cases, where the medicolegal question arose as to possible preventive cesarean section after the death of one twin. Many of the descriptions in the literature are also similar to the case here shown, but conclusive proof of prenatal DIC with definitive coagulation studies has been difficult to obtain. In a case of macerated MoMo twin with a term liveborn co-twin, Bulla et al. (1987) found neonatal platelet counts of  $67,000/\text{mm}^3$  that later rose to

$300,000/\text{mm}^3$ . The infant died on day 10 with bilateral renal, splenic, and central nervous system (CNS) necroses. Patten et al. (1989b), who examined five co-twins with one fetus having died prenatally and who used the term **twin embolization syndrome (TES)**, identified active consumptive thrombocytopenia in one of their cases with renal and CNS defects. Microcephaly and various other CNS abnor-

FIGURE 25.33. A MoMo twin placenta with one macerated fetus (dark cord). The survivor, who had disseminated intravascular coagulation, died at age 62 hours (see Fig. 25.34) (Source: Benirschke, 1961, with permission.)

FIGURE 25.34. Organs of a premature neonate whose placenta is shown in Figure 25.33. There were bilateral renal cortical necrosis and widespread thrombosis when this infant died at 62 hours (left). The kidney had diffuse, yellow, cortical infarction. Center: Microscopic appearance of renal cortical necrosis. Right: Splenic thrombus.

malities, in addition to intestinal, peritoneal, and renal destructive lesions, were the focus of their observations. They urged prenatal sonographic studies of such pregnancies. As to the evidence of consumptive coagulopathy, diligent study of some other cases ruled out their existence when fetal demise of one twin had occurred (Hanna & Hill, 1984). Okamura et al. (1994) did funipuncture in seven surviving twins following the demise of the co-twin. Coagulation parameters were not abnormal, although three infants suffered cerebral abnormalities. This was seen as strong evidence for the primacy of acute anemia due to presumed acute hypotension (shunting through anastomoses) as the cause of the cerebral destruction, rather than DIC or embolization. This is further discussed subsequently and was eloquently shown to be correct by prenatal blood sampling (Nicolini et al., 1998).

This is a complex issue of great importance. Many investigators have tried to answer the many questions that arise from these observations. Litschgi and Stucki (1980) reviewed their twin material and found that in 13 cases of 191 twin pregnancies (6.8%; 0.07% of all births) a macerated fetus was delivered with a live twin. They found one MoMo, seven DiMo, and five DiDi cases, and suggested that immediate delivery is not advisable when one twin has died. In view of the distribution of deaths in relation to ultimate delivery, they recommended that all such pregnancies be terminated by 39 weeks. This aspect is discussed further in the section on fetus papyraceus as this pathologic feature is not limited to MoMo placentation but affects all monochorial twins. Because the probability of thromboplastin infusion from a dead twin is actually highly unlikely (because its circulation has stopped), alternative explanations have been sought. They are completely summarized in a large paper by Liu et al. (1992) and are further discussed later in this chapter. Specifically, Liu et al. suggested that acute hypotensive events occur in the surviving twin immediately after one twin dies because of the common placental vasculature. Jou et al. (1993) even observed sonographically the reversal of blood flow in the umbilical cord after fetal death of one twin. Less decisive flow disturbances after demise of one twin were recorded by Malinowski et al. (1996). That such an event may occur is also evident from the detailed postmortem description of the original Siamese twins Chang and Eng Bunker (Kormann, 1869). After the death of Chang, Eng complained of chest tightness and expired within 2 hours. Large anastomoses were present in their xiphoid connections at autopsy through which exsanguination of Eng presumably occurred, and autopsy indicated exsanguination of Eng into Chang. An important case report has been published by Sherer et al. (1993), who showed the rapid development of the cerebral consequences of such fetal demise. They followed a twin transfusion set of twins with fetal death of one at 23 weeks, followed by spontaneous resolution of hydrops.

TABLE 25.4. Summary of twins with prenatal damage perhaps due to vascular transport of coagulation products or acute blood loss

Source	Year	Placenta	Remarks
Benirschke	1961	MoMo	Macerated twin; survivor with renal cortical necrosis, porencephaly; presumed DIC (Figures 25.33 and 25.34)
Figure 25.35	1959	MoMo	Macerated twin, thrombi in umbilical vessels; survivor died with extensive cerebral palsy
Figures 25.39 and 25.40	1986	MoMo	32 weeks; stillborn 1800g, survivor 2400g died with hydrops (? due to cord tangles); AA, AV anastomoses, arthrogryposis, CNS atrophy
Figure 25.41	1986	DiMo	Fetus papyraceus, velamentous cord; survivor has porencephaly; <b>mother</b> had DIC after delivery; transfusion syndrome
Timmons & Alvarez	1963	MoMo	Case 4 had cerebral palsy from "embarrassed circulation"
Rosenquist	1963	DiMo	Adrenal, pulmonary, renal calcifications in donor of transfusion syndrome
Moore et al.	1969	DiMo	(1) Singleton with velamentous cord and DIC. (2) Monochorionic, macerated; survivor developed DIC and died; blood studies were normal; (3) DiMo, one macerated stillborn, other had anemia and bilateral renal cortical necrosis, but survived
Dimmick et al.	1971	DiMo	Velamentous cord, CNS and renal necroses; unable to identify anastomoses; secondary to cord insertion?
Thomas	1974	Tri?Di	Male had intraventricular hemorrhage (IVH) and coagulation disorder; one female macerated, one with mild coagulation disorder
Durkin et al.	1976		Review of 8 cases; monochorionics at highest risk
Mannino et al.	1977	DiMo	Fetus papyraceus with aplasia cutis in survivor; review
Melnick	1977	?	Macerated twin; CNS damage in survivor who died with CNS necrosis; review of Collaborative Study and risk assessment
Yoshioka et al.	1979	?, MZ	Three sets of twins had porencephaly and macerated stillborn; thrombosis of cerebral artery; authors considered emboli as cause
Jung et al.	1984	?	Review of hydranencephaly and porencephaly; 11% had twins, most were macerated
Barth & Harten	1985	DiMo	Term with macerated twin (death at 13–16 weeks); gastroschisis, CNS damage
Nakayama et al.	1986	DiMo	Macerated fetuses with infarcts of CNS, kidney, spleen, liver; reviewed 14 twins, only monochorionics had poor prognosis
Hughes & Miskin	1986	DiMo?	Fetal death at 20 weeks, following which prenatally diagnosed CNS cysts developed, microcephaly, renal dysplasia
Yoshida & Soma	1986	DiMo	Review; macerated with cerebral palsy in survivor; skin defects in male; macerated female co-twin
Szymonowicz et al.	1986	? DiMo	Six cases with survivors having CNS deficits; other infarcts; review of total literature (53 cases)
Bulla et al.	1987	MoMo	Renal and CNS necroses; other was a macerated fetus AA and VV anastomoses
Leidig et al.	1988	?	Two of four cases with prenatal IVH were twins
Jones	1988	?	Hydranencephaly; 30cm fetus papyraceus
Patten et al.	1989b	DiMo	5 cases with various brain, kidney, and intestinal defects
Fisher & Siongco	1989	DiMo	Massive porencephaly; renal splenic infarcts
Cherouny et al.	1989	MoMo	20 cases; one MoMo twin developed brain cysts, prenatal evaluation was reassuring
Anderson et al.	1990	DiMo	Four cases, second trimester fetal deaths, CNS lesions GI lesion in 2
Larroche et al.	1990	DiMo	15 monochorionics, vascular "instability"
Fusi et al.	1991	DiMo	CNS and renal necroses, no coagulation defect, transfusion
Margono et al.	1992	DiMo	Foot necrosis before birth
Liu et al.	1992	DiDi/DiMo/MoMo	38 twins, 3 triplets; damage in 19 offspring (72% monochorionics)
Grafe	1993	DiMo	CNS necroses in both twins

They were able to demonstrate sonographically that echogenic changes had become prominent in the brain of the survivor within 48 hours already. The authors considered these to be hemorrhages that eventuated into a severely microcephalic anomaly. Death of one MZ twin was observed at 27 weeks by Lander et al. (1993). Doppler sonographic observations within 24 hours after the death showed "remarkable variability in flow velocity waveforms in the umbilical artery of the surviving fetus.

Changes from reversed to normal end-diastolic flow velocities were recorded within 6 minutes."

These are simplistic hemodynamic explanations for a very complex dynamic state that exists in utero of ill-defined vascular communications. Because hemodynamic results of these anastomoses have been largely inaccessible to us until the event of Doppler flow studies, relatively little hard information is available at this time, and it is common to oversimplify from our incomplete knowledge.

That the situation is much more complex in utero is to be inferred from the case report of Grafe (1993). She described DiMo liveborn premature twins, both with antenatal white matter necrosis; they died subsequently. Aside from a velamentous insertion of twin A's umbilical cord, there were AA and VV anastomoses. We assume that irregular flow back and forth through these anastomoses was responsible for the cerebral destruction. Perhaps such variable blood exchange occurs often in monochorionic twins.

At this point, it is important to understand the possible fates of placental tissue when one twin dies. If there are large interfetal vascular communications, the placental half of the dead fetus may continue to be perfused by the survivor. If, on the other hand, the anastomoses are small, the placenta of the dead fetus gradually atrophies and eventually appears as though infarcted. It is much the same as what happened to placental tissue when experimental fetal removal was practiced in rhesus monkeys. There is gradual atrophy of placenta, with much deposition of intervillous fibrin.

The problem of **maternal** DIC with a dead fetus is often discussed under the heading "dead-fetus syndrome" (Strauss et al., 1978). Although it has been described in some cases where one twin had died in utero (Skelly et al., 1982; Romero et al., 1984), in other patients it did not develop (Wittmann et al., 1986; Cherouny et al., 1989). The reason for the differences is not clear. When Zorlu et al. (1997) examined what happened to maternal coagulation parameters in 25 women with one dead twin, they found that coagulation parameters were temporarily abnormal in two, but rectified by delivery. They felt that, for the mother's health, no undue concern needs to be had. This complex aspect is not treated further in this text.

To explain some cases of prenatal damage observed in twins after the death of the co-twin, it has also been postulated that thrombi in the fetal circulation embolize via

the interfetal anastomoses, from the dead to the living twin. Although it is true that thrombi from fetal vascular occlusions can embolize to the fetus (Wolf et al., 1985), the lesions usually seen in the survivors of pregnancies with a macerated co-twin, however, are not typical of those caused by emboli. Yoshioka et al. (1979) postulated that the CNS damage of the twins they examined, which had macerated co-twins, resulted from occlusion of large vessels. They believed that emboli from macerated co-twins were the most reasonable explanation for the damage. In support of this hypothesis, they cited a case by Clark and Linell (1954), who described an erythroblastic stillborn whose mother had been treated with cortisone and had an occlusion of the internal carotid artery and cerebral vessels. The authors suggested that, because the thrombus did not look like loose clot, it probably originated from an embolus; and they opined that it represented embolized "placental tissue." This assumption cannot be the case, for there were no villous remains in the clot. Admittedly, it contained erythroblasts, but degenerating placental tissue never embolizes to the fetus. Clots could embolize from venous vessels, which have occasionally been shown to be thrombosed. Such an event is shown in the fetal vessels in Figure 25.35.

Massive plethora in a macerating twin masqueraded as the recipient of the twin transfusion syndrome in several cases. The transfusion syndrome could be ruled out, however, because the twins were of the same size and had similar-sized hearts, and there were large placental anastomoses. We assumed that the plethoric twin had recently received large quantities of blood from the survivor via large vascular communications in the placenta. This acute transplacental fetus-to-fetus bleeding, with resulting plethora of one twin, was first mentioned by Lehdorff (1961) and was also described by Cameron (1968). Lehdorff correctly hypothesized that marked shifts may occur through large anastomoses during, or even before,

FIGURE 25.35. Macerated stillborn MoMo twin with extensive knotting of cords. The surviving infant died 3 months later with extensive brain necroses.

delivery. Later, Bleisch (1965) had the same thought. This phenomenon is different from the typical transfusion syndrome, which constitutes a specific entity and is discussed below, and it should not be labeled as such.

All these cases have assumed great importance in the legal realm because cerebral palsy is so common in twins (Durkin et al., 1976; Scheller & Nelson, 1992). Eastman et al. (1962) estimated it to be five times more common than in controls and assigned as the chief cause the prematurity of twins and an unfavorable intrauterine environment. This higher incidence of cerebral palsy (and of mental deficiency) affects primarily monozygotic twins (Berg & Kirman, 1960; Russell, 1961). Furthermore, a characteristic type of skin defect that is secondary to prenatal dermal necrosis (aplasia cutis) is also primarily associated with DiMo placentation and fetus papyraceus (Mannino et al., 1977). It is thus challenging to better understand what causes these prenatal insults. Moreover, as stated, there has been much litigation in cases of twins with cerebral palsy. In these legal suits it is commonly assumed that the obstetrician must be at fault when brain damage occurs in one twin because, according to these suits, this damage would not have occurred had a quick cesarean section been done. It must be pointed out in this context that Bejar et al. (1990) have shown that porencephaly may already be present at birth, and that it correlates best with one of two circumstances: (1) fetal infection (chorioamnionitis, funisitis); or (2) MZ twins having placental vascular anastomoses. Leviton and Paneth (1990) reviewed the possible causes of CNS white matter necrosis. They concluded, as did Larroche et al. (1990), that circulatory phenomena were important aspects in the causation of cerebral palsy. Fusi and colleagues (1991) found no coagulation disorder but observed acute twin-twin transfusion as the cause of brain damage. They were emphatic that intervention would have to take place before fetal death occurred if CNS sequelae were to be prevented. Norman (1980, 1982) made somewhat similar observations on prenatal brain necrosis in DiMo twins. A large retrospective review of brain damage in twins was undertaken in Sweden by Rydhstroem (1995). He found no difference in relation to birth order and like-sex vs. unlike-sex status, but there was an increase of cerebral damage in the heavier of twins. Interestingly, Maier et al. (1995), who assessed degrees of hypoxia in twins, found that the smaller twin has higher concentrations of erythropoietin. The principal reason for CNS damage was seen to be the increased prematurity of multiple gestations, with cystic periventricular cystic white matter necrosis following (Allan et al., 1994). The outcome is not significantly different from that of singleton premature infants (Kilpatrick et al., 1996; Nielsen et al., 1997) when matched for gestational age.

For all these reasons it is of future importance that we delineate more precisely the pathogenesis that leads to this prenatal CNS damage, so that it may be anticipated

and prevented, if possible. Hurst and Abbitt (1989) observed that encephalomalacia and intraventricular CNS hemorrhage developed prenatally in a set of twins with the classical transfusion syndrome. In the case described by Hughes and Miskin (1986), bleeding complicated a known twin pregnancy at 20 weeks, and subsequently one twin became macerated. In the survivor, brain cyst development could be followed sonographically after 30 weeks and was found in the newborn after cesarean section at 37 weeks. Interestingly, the kidneys of this microcephalic and porencephalic infant had cystic changes, which we assume stemmed from former focal areas of necrosis. Nakayama et al. (1986) studied 14 liveborn twins with macerated co-twins. Among the three with neonatal death, CNS, renal, splenic, and liver necroses were found. Several other relevant contributions have been forthcoming (Dudley & D'Alton, 1986; Liu et al., 1992), but a consensus as to the best management of monochorionic and monoamniotic twin pregnancies has not yet emerged (Hagay et al., 1985). Melnick (1977) estimated that some 3% of near-term monozygotic twins have a dead co-twin. Furthermore, one third of the survivors, or possibly 1% of MZ twin births, have severe brain defects as a consequence of putative DIC (Jones, 1988).

These considerations are especially important in view of the evolving practice of intentional fetal elimination when discordant anomalies of twins are found, when too many multiples are conceived, during the therapy of the prenatally diagnosed transfusion syndrome, and for prenatally diagnosed genetic disorders (Åberg et al., 1978). In these situations, it must be recognized that there are possible consequences for the second twin when one is eliminated and the status of anastomoses not ascertained (Wittmann et al., 1986). Yamagishi et al. (1998) reported on the discordance of male MZ twins with deletion of a chromosomal band in No. 22 (22q11.2). The twins had the TTTS, and one twin (the donor), but not the other, had tetralogy of Fallot. Prenatal cardiovascular adjustment to the TTTS was considered to be the reason for the major discordance. Discordance for some diseases may also be the sequel of the TTTS. Thus, Lazda (1998) recorded the occurrence of endocardial fibroelastosis in the larger of two recipients of this unequal blood sharing of twins prenatally. Other unusual features may occur. We draw attention to the fetal demise due to hydrops from parvovirus 19 infection in a DiDi twin placenta in which the other fetus survived and did not have the infection (Foster & Allen, 2004). Remarkably, the gravida developed DIC 4 weeks after fetal demise.

The possibility of DIC developing in the remaining living twin, after one had died, led Cox et al., (1987) to sample the fetal vasculature of 19 twins. This evolving technique of fetal blood sampling promises much insight into the prenatal vascular relations among twins. It is for these complex reasons that we have summarized relevant case information in twin pregnancies with fetal death in one twin (Table 25.4). Other large

tables may be found in Liu et al. (1992), where all relevant literature is also discussed. As will be seen, there is a good possibility that the survivor in cases of prenatal twin death experiences significant acute blood loss through superficial, large interplacental anastomoses. One can envisage that when one twin dies the other bleeds into this vascular bed, now devoid of counterpressure. Indeed, paradoxical plethora has been seen in discordant twins, in which the smaller (earlier dead) twin is plethoric. Modern studies with Doppler sonography have come closer to an understanding of the redistributive changes of blood in twin placenta-tion (Gaziano et al., 1998). These authors found a much more important and more frequent effect of the vascular anastomoses in DiMo placentas than originally anticipated and discuss eloquently the impact of these on cerebral arterial perfusion in the fetus.

To accumulate relevant prenatal information of such occurrences, Toubas et al. (1981) studied the fetal response to acute hemorrhage (15%) in the lamb. The arterial blood pressure, pH, and heart rate of the fetus fell significantly, and the cardiac output decreased. The blood flow in the fetus (kidneys, gastrointestinal tract, and lungs) and to the placenta were markedly reduced. Toubas et al. did not report any structural changes of these organs due to the hemorrhage. It will be necessary in future cases of prenatal death of one MZ twin to accumulate information on neonatal hematologic parameters. Measurements of hematocrit, deformed red blood cells (schistocytes), split fibrin degradation products, platelet changes, and nucleated red blood cells can provide some of the information needed for better understanding this entity.

MoMo twins presumably arise at approximately days 8 to 10 of fertilization age and are next to last in the spectrum of the MZ twinning events (Coulton et al., 1947). This type of placenta is also nearly always found with conjoined twins, only one exception having been published (Weston et al., 1990). Monoamniotic twins may have a single or a forked umbilical cord (Fig. 25.36; see also Fraser et al., 1997, who reported liveborn twins), or there may be two separate cords. Forked cords are occasionally found also in completely separate MoMo twins (Fig. 25.36). In other MoMo twins, the cords originate close to each other on the placental surface, as in the cephalopagus conjoined twins whose placenta is shown

FIGURE 25.36. Forked umbilical cord of MoMo twin abortuses at 17 weeks' gestation. The smaller twin (right) had a single umbilical artery but no other anomalies. (Courtesy of Dr. Marilyn Jones, San Diego, California.)

in Figure 25.37. Forked cords have been described by Larson et al. (1969a) in a set of macerated abortuses. MoMo twins often have extensive vascular anastomoses between the fetal circulations, particularly when the cords are in close apposition (Figs. 25.38 to 24.40). The impact that the cord position may have on the outcome of the surviving MoMo twin (after fetal death of one) is further documented in Table 25.4. When velamentous insertion of one cord complicates placentation in such cases, growth restriction and fetal death are especially common (Fig.

FIGURE 25.37. Forked umbilical cord of MoMo cephalopagus conjoined twins. (Courtesy of Dr. S. Romanski, Los Angeles, California.)

FIGURE 25.38. Term MoMo twin placenta. Note the extensive vascular anastomoses on the fetal surface.

25.41). Monoamniotic twins, as other MZ twins, may have remarkably different development, as was true of the case described by Larson et al. (1969a). Discordant anomalies are particularly common. Observations on MoMo twins have led to a better understanding of some types of congenital anomaly. Thus, the occurrence of renal agenesis in one of MoMo twins (unilateral agenesis in the other, who survived) was not associated with the Potter syndrome, as expected. Rather, the adequate production of amniotic fluid by the more normal twin prevented this phenotype and indicated that lung development depends purely on the volume of amniotic fluid present (Mauer et al., 1974). The anomalous twin also had normal respiratory function. It died of uremia at 12 days of age. Similar observations were later made of MoMo twins, where one had sirenomelia.

Monoamniotic placentation has also been observed in MZ triplets. Sinykin (1958) described the triple survival of MoMo triplets whose placenta is shown in Figure 25.42. We have observed a monoamniotic triplet placenta of stillborns. The pregnancy was terminated with prostaglandins at 27 weeks when fetal death had become evident. One was a tiny acardiac fetus, one was an anencephalic, and the third was a normal macerated fetus

FIGURE 25.39. A MoMo twin placenta with entangling of umbilical cords. Twin B (top left) died from nonimmune hydrops. At autopsy no cause was found for the hydrops. It was assumed to be the result of interference with venous return from the placenta. Figure 25.40 shows the large anastomoses after the cords have been untangled.

FIGURE 25.40. Large anastomoses are seen between cord vessels of the MoMo twin placenta in Figure 25.39.

FIGURE 25.41. A DiMo twin placenta with macerated fetus papyraceus at left, having velamentous insertion of its cord. The surviving fetus had porencephaly and was presumed to be the recipient in a transfusion syndrome.

(Fig. 25.43). The long-standing nature of thrombotic events in such twins is evident from the frequent mineralizations found in their placental vessels (Fig. 25.44).

It would be expected that MoMo twins, who are probably determined between days 8 to 10 of development (see Fig. 25.10), may differ in the number of yolk sacs they

possess. Figure 25.45 shows two early gestations of MoMo twins with an only partially divided yolk sac. It is considered to be the product of splitting on day 11 if the developmental table shown is precise enough for such inference. In another set of stillborn MoMo twins (with a dichorial triplet) we have seen two yolk sacs; that placenta also had two velamentous cords and presumably had its embryologic origin prior to the placenta with partially divided yolk sac.

FIGURE 25.42. A MoMo triplet placenta at term. There were anastomoses among all circulations and no entangling of cords. The triplets survived. (Courtesy of Dr. M.B. Sinykin, San Antonio, Texas.)

FIGURE 25.43. Monoamniotic triplets, all of whom were macerated. Labor was induced at 27 weeks. Triplet A was structurally normal; B was anencephalic; C was a diminutive acardiac fetus. Note the extensive knotting (large arrow).

FIGURE 25.44. Calcification of the vascular wall and an old thrombus in the placental surface vessel of one of MoMo twins that was macerated.

## Diamnionic/Monochorionic Twin Placenta

The DiMo twin placenta is the commonest form of placentation of identical or monozygotic twins. Each twin is enclosed in its own amniotic sac, and the dividing membranes are composed of two amnions only (see Figs. 25.1 to 25.4). As will be seen in these photomicrographs, the amnion possesses epithelium and connective tissue. The presence of a layer of connective tissue has occasionally been mistaken, regrettably, as being diagnostic of chorion; that is the reason for being so adamant about the identification of these dividing membranes. These amniotic membranes can be moved freely over the chorionic surface. Because they are often moved before birth, it is not unusual to find the dividing membranes at a place that does not correspond with the vascular equator of the two twins' placental halves (Fig. 25.46). DiMo placentas usually have two yolk sacs, and virtually all of them have vascular anastomoses, as was delineated earlier in this chapter. The cord insertion, as in all twin placentas, is more often marginal or velamentous than that of singletons. Single umbilical artery (SUA) is also commoner in one or both of these twins (Thomas, 1961). Yoshida (1998) found that SUA occurred in 3% of twin gestations, whereas it was found in 0.53% of singletons. Because the amnion does not have its own blood vessels, the dividing

membranes must survive on the nutrients and oxygen contained within the amniotic fluid. This notion is supported by the finding of amnion necrosis in cases of fetal death, or amnion nodosum when one of the twins is oligohydramniotic (Fig. 25.47). In such cases, only the amniotic epithelium degenerates. The underlying connective tissue is generally preserved. In cases of prenatal infection, the inflammation is also lacking in these dividing membranes, and meconium pigmentation is sparse when it is found elsewhere in the amniotic cavity. What has been surprising with the increasing practice of ART is the fact that MZ twinning is often superimposed upon multiple embryo transfers and that the placentation of these twins is then usually (or always?) a DiMo placenta. This does not jibe with the notion that MZ twinning is perhaps due to improper handling of the blastocysts and disruption of the zona pellucida before implantation, as this would be expected to have led to DiDi MZ twins. Jain et al. (2004b) have examined some aspects of this topic and found that MZ twinning was higher when blastocysts were directly transferred than when 3-day embryos were implanted. At present the mechanism that leads to MZ twinning in ART is not fully understood.

FIGURE 25.45. Monoamniotic twin abortuses, structurally normal (top). Note the partially duplicated, bean-shaped yolk sac (arrow). Therapeutic abortion of DiMo twins was done at 33 days' gestation (bottom).

FIGURE 25.46. A DiMo twin placenta with apposing amnions (A, A) meeting at angles to the vascular equator (arrowheads). Note the marginal insertion of the cord at left.

The lack of intersac transfer of solutes is illustrated by the results from injection of hypertonic saline when abortion is intended. Kovacs et al. (1972) injected 200mL of a 20% NaCl solution into one sac after having removed 380mL of amniotic fluid at 22 weeks. Cardiac activity stopped in 2 hours in one twin, and labor commenced 20 hours later. The DiMo twins weighed 300g each; the injected fetus was macerated, but the other was alive at

delivery. Only the amnion of the injected side was necrotic. Hoch et al. (1972) made similar observations in a dichorionic twin pregnancy, but in this placentation it is more expected that solute transfer does not occur between the two sacs. Finally, a most unusual DiMo twin placenta, sent to us in consultation, is illustrated in Figure 25.48. This placenta shows one amniotic sac contained within the other; the twins differed appreciably in size.

FIGURE 25.47. Various degenerative features of the left amnion of dividing membranes in cases of DiMo placentas with one fetus dead (center, right) and amnion nodosum (left).

FIGURE 25.48. A DiMo twin placenta (550g) of MZ twins. One amniotic sac is enclosed by the other. The outer sac contained a smaller fetus with velamentous insertion of the cord. (Cour-

tesy of Drs. V. Anderson and Z. Weinraub, Martin Luther King Hospital, Los Angeles, California.)

### Diamnionic/Dichorionic Twin Placenta

The DiDi twin placenta may be composed of separate disks, or the two placental portions may be intimately fused. It is the most common type of twin placenta

and shares with the other types an increased frequency of marginal and velamentous insertion of umbilical cords. The fused placentas present the appearance seen in Figure 25.49. When the fetal vessels are injected, there is no exchange of the injection fluid between the two fetuses.

FIGURE 25.49. A DiDi twin placenta, intimately fused. Left cord has a single umbilical artery (SUA); right cord is being injected without transfer of fluids.

FIGURE 25.50. A DiDi fused twin placenta, maternal surface. Twin at left is Rh-negative and living; twin at right is Rh-positive and macerated. There were two corpora lutea at delivery. Note the clear dividing line between the two placentas.

FIGURE 25.51. A DiDi twin placenta with irregular chorionic fusion. The chorion laeve of the left placenta overlaps one third of the placenta at right. There is no vascular fusion.

This finding is also borne out by a sharp line that divides the placentas, easily seen when one twin has died before birth (Fig. 25.50). A frequent and unusual feature of DiDi twin placentas is the phenomenon of irregular chorionic fusion, a feature well shown in Figure 25.51. In such placentas, the membranes do not meet over the areas perfused by the individual fetuses; in fact, the placentas may be separated, and a portion of one may be covered by

the membranes of the other. This phenomenon is best explained by assuming that the intraamniotic fluid pressure of one cavity gradually expands its sac, pushing the other away (Fig. 25.52). It is not unlike the process of lifting the marginal chorion in cases of circumvallate placentation. It has no influence on the well-being of the fetuses, and no vascular fusion takes place in the areas of overlap.

FIGURE 25.52. Presumed mechanism that leads to irregular chorionic fusion as in Figure 25.51.

When the fetal outcome of fused DiDi twin placentas is compared with that of separated DiDi placentas, Buzzard et al. (1983) found that there is a greater difference in birth weights with fused placentas. The inference is that placental proximity has a prenatal influence on fetal development, perhaps because of competition for space during placental expansion. On occasion, prenatal diagnosis mistakes the membrane relations and other features of consequence to fetal survival. Thus, Baergen et al. (1995) described a placenta after recurrent leakage and hemorrhage, also with SUA; the placentas were fused but one twin had died because of being born within an extramembranous gestational condition.

## Vanishing Twin Phenomenon

It is not uncommon that one twin dies long before birth. If the pregnancy continues undisturbed, this fetus may disappear when it is very young. It may become flattened (fetus compressus, fetus papyraceus), or when it is large, it may macerate, lose much of its fluid, and become misshapen. Although fetus papyraceus has long been known, the phenomenon of a "vanishing twin" is a more recent addition to our nomenclature. The term should be reserved for multiple pregnancies that are identified sonographically during the first 15 weeks of pregnancy and that have, as their outcome, a single fetus. It must be appreciated, however, that the rate of occurrence will always be underestimated. For instance, we have seen many placentas from ART practices where we know that several blastocysts were placed and implanted but in whose placentas there was no morphologic evidence of a vanished twin.

The seminal report on the vanishing twin was that of Levi (1976), who repeatedly studied sonographically 6690 early pregnancies. Of 118 patients identified to have twins, only 86 sets of twins were delivered. When the diagnosis of twins was made prior to 10 weeks, the disappearance rate was 71%. When the diagnosis was made between 10 and 15 weeks, the disappearance rate was 62%. When twins were first diagnosed after 15 weeks, none disappeared. Similar figures of twin resorption (70%) were reported by Robinson and Caines (1977).

The vanishing twin is thus a feature of early pregnancy; its diagnosis is made by the ultrasonographic finding of two echogenic "rings" denoting the presence of two sacs. Although the existence of vanishing twins is not doubted, the possibility of error in the diagnosis of twin gestations was mentioned by Levi. It was expanded upon in greater detail by Landy et al. (1982), who reviewed the literature and wrote a letter of inquiry to colleagues. It is possible

that a yolk sac or amnionic sac that is still separate from the chorion or other features of early embryonic life are occasionally mistaken for twin cavities (e.g., Green & Hobbins, 1988). Moreover, only rare reports of placental examination have accompanied these studies. Even more rarely have empty sacs or old hemorrhages been identified. An exception is the report by Jauniaux and his colleagues (1988). They reported the placental findings of 10 such cases, five of which came from IVF, and five were spontaneous. First trimester bleeding was the only clinical evidence of this occurrence. In five cases, the vanished twins were identified as "well delineated plaques of perivillous fibrin deposition, associated in one case with embryonic remnants." There are other reports of frequent early vaginal bleeding episodes in these patients. Those events may represent the spontaneous abortions of twins. If the reported cases are applicable to the general population, the excessively high frequency of calculated twin gestations is surprising.

The term *vanishing twin* was perhaps first used by Jeanty et al. (1981). It is now an established entity in obstetrics, and more careful study of the placenta is needed to secure its place. When such a twin is found sonographically or only a remnant of a second sac is identified, every attempt should be made to obtain some karyotype information from the chorionic sac at birth. The results from such studies may eventually indicate whether these vanishing twins are chromosomally abnormal. Additionally, RFLP should define zygosity readily.

Such fetuses would perhaps have been aborted were it not for the presence of a normal twin in the same uterus. Gruenwald (1970) described three such specimens, two of which, however, are best considered to be fetus papyracei. One specimen consisted of a local thickening in the membranes that, when sectioned, disclosed ribs and other fetal tissues. We have seen numerous placentas with vanished twins enclosed in the membranes, but their presence had not been detected sonographically or was not anticipated. Figures 25.53 to 25.56 show what their appearance may be. In all of these specimens, clear evidence of a second sac existed. In two of these cases and in several others we have observed, tiny embryos could be identified. Those embryos had surely died before 8 weeks' gestation. The fact that they were still recognizable suggests that when a vanished twin cannot be detected in the term placenta, the diagnosis must have been either erroneous, or an empty sac of a "blighted" ovum had been present and aborted. It is surprising in the embryos shown here how long an embryonic structure can coexist with a normally developing twin. A similar early, vanished embryo was first shown by Bergman et al. (1961) in their description of a "blighted" fetus. The tiny embryo, also present in the membranes, was essentially similar to the one shown in Figure 25.54. The empty-sac feature was further

FIGURE 25.53. A DiDi separated twin placenta at term. The patient presented with alleged “abruption.” A normal term twin was delivered; a second placenta with a tiny (2 cm) embryo was

found in the membranes. When its sac was opened (right), a yellow embryo of the opposite sex was attached to a swollen umbilical cord.

FIGURE 25.54. A term placenta with a separate embryo in the membranes (arrows). This embryo is similar to that shown by Bergman et al. (1961). The ocular pigment is readily seen. No placental remains were seen.

discussed in the prospective study of 1000 pregnancies by Landy et al. (1986). The authors calculated a minimum twinning incidence from this material as 3.29%, if not 5.39%. This is very much higher than the currently esti-

mated twinning frequency of the general population. These authors suggested that vanishing twins may possibly be the source of rhesus sensitization. In view of the small quantities of blood potentially present to stimulate

FIGURE 25.56. Mature placenta with vanished twin. A subamniotic sac containing debris is the remnant of a DiMo placenta. Note the squamous metaplasia (right), vacuolation (center), and amnion nodosum-like degeneration (left top). H&E  $\times 16$  (left);  $\times 40$  (center);  $\times 60$  (right).

the mother, this proposal seems to represent an unduly pessimistic concern. Sulak and Dodson (1986) have presented evidence for two vanished triplets by demonstrating an empty chorionic sac. When the placental sac of the surviving singleton was studied, it was found to be filled with debris. Kapur et al. (1991) found an empty cavity of a former twin associated with a sirenomelic co-twin whose pregnancy was terminated at 18 weeks. Triplets had been diagnosed sonographically 4 weeks after conception by IVF. It is more difficult to be certain that such structures as are shown in Figure 25.57 are the remains of vanished embryos, in this case a triplet, although we prefer to believe this view rather than ascribing these rests to be teratomas. In their study of 189 sonographically studied twin pregnancies, Yoshida and Soma (1986) found that 21 twins died. Nine qualified for the term *vanishing twin*. The association with prenatal bleeding was also emphasized by these observers. Sebire et al. (1997c) identified 102 monochorionic and 365 dichorionic twins between 10 and 14 weeks; they found a higher fetal loss rate in the former (12.2% vs. 1.8%) before 28 weeks. Perinatal mortality and prematurity were also significantly higher in monochorionic twins.

In the differential diagnosis, it must be cautioned that retromembranous hemorrhages may occur after amniocentesis and they can also occur spontaneously, that is, without our knowing the cause. Such hemorrhages must not be mistaken for vanished twins. The typical sonographic appearance of a small vanishing twin with normal co-twin at 14 weeks is shown in Figure 25.58.

FIGURE 25.58. Sonogram at 14 weeks with one normal and one dead ("vanishing") twin. The latter still has a separate cavity and measures 1.7 cm. (Courtesy of Dr. J.D. Stephens, San Jose, California.)

FIGURE 25.59. Diminutive fetus papyraceus in the membranes of a normal twin's placenta (arrows). Its dichorionic placenta was a flattened mass of fibrin.

The presence of vanished twins or of a fetus papyraceus has posed other difficult clinical problems. It has thus been reported that the maternal  $\alpha$ -fetoprotein (AFP) may be significantly elevated in pregnancies complicated by a vanishing twin (Lange et al., 1979). The finding of high AFP and acetylcholinesterase levels has led to therapeutic abortion, the vanished twin not having been diagnosed (Winsor et al., 1987). There may also be an elevation of the amniotic fluid acetylcholinesterase levels. In the case described by Cruikshank and Granados (1988), this elevation was blamed on coexisting aplasia cutis. It goes without saying that such gestations also are not recorded as twin gestations in most hospital statistics.

### Fetus Papyraceus

A fetus papyraceus forms when one of twins or higher multiple pregnancies dies during gestation and becomes compressed as pregnancy continues. There is no clear distinction between the vanishing twin and a fetus compressus or papyraceus. Although such fetuses exist fairly frequently, they are often overlooked. They may be so compressed that small ones are found only when a careful inspection of the placenta and its membranes is made (Fig. 25.59). We recommend that radiographs be obtained when such areas of thickened membranes are found and that the area be dissected carefully. The case shown in Figures 25.60 to 25.63 is a typical circumstance

FIGURE 25.60. Sonogram of twin pregnancy with fetus papyraceus. The skull is seen at the arrows; the normal twin's skull is next to it (left); femora are at the bottom. (Courtesy of Dr. G.R. Leopold, San Diego, California.)

FIGURE 25.61. The specimen at term shown in Figure 25.60. The fetus papyraceus was in a separate mass at left.

(Jackson & Benirschke, 1989). Sonographically, a typical fetus compressus was demonstrated (Fig. 25.60); at delivery it was a separate mass of fibrin compressed in the membranes of the normal twin's placenta (Fig. 25.61). Careful peeling of the DiDi membranes showed the fetus compressus with umbilical cord (Fig. 25.62), whose skeleton was normal by radiography (Fig. 25.63). The fetus compressus of Figure 25.64, on the other hand, was enclosed in a separate amnion. It was an acardiac twin with SUA and had six toes. The frequency of finding a fetus papyraceus has increased substantially in recent years. This is mostly the result of intentional reduction of fetuses in ART patients in whose pregnancies too many embryos existed, where premature birth was anticipated, or in whom a smaller number of infants was requested. This ablation is commonly undertaken by intracardiac

injection of 1 ml KCl and example is shown later (see Fig. 25.98). It is advantageous to take radiographs of such fetuses because these occasionally disclose unknown anomalies; in this case, an encephalocele was discovered. Yaron et al. (1999) incisively discussed this issue in their study of 143 triplets (12 controls) that were reduced to twins. It lowered the frequency of prematurity and IUGR.

Several of these compressed fetuses had living co-twins with skin defects (Fig. 25.65). Some have well defined, infarcted placentas (Figs. 25.50 and 25.65). In others, one can demonstrate that twisting of the umbilical cord at its fetal insertion was the presumed cause of demise. The cause of death, however, is not always discerned. Thus, when the donor in the transfusion syndrome dies, its placenta may be so atrophied or infarcted that the causative

FIGURE 25.62. Same case as in Figures 25.60 and 25.61. The dissected fetus is attached to a short umbilical cord.

FIGURE 25.63. Radiograph of the specimen in Figure 25.62, showing a normal skeleton.

vascular anastomoses can no longer be verified. Chromosome preparations of the macerated twin are rarely feasible because of the advanced state of maceration. Cytogenetic examination may be possible, however, from samples of the chorionic membranes, as would be an RFLP study, which should be attempted. At least once, such a study of the DNA of a fetus papyraceus showed it

to have a dizygotic relation to the living twin (Lemke et al., 1993). Acardiac fetuses are readily distinguished radiologically and by dissection from the normal, usual fetus papyraceus. A careful study of these vanished twins is doubtlessly worth the effort. Although it seems useless to dissect a fetus papyraceus, it proves to be quite feasible when it is done in a continuous stream of water. It has been suggested that vanishing twins may be associated with the CNS defects of cerebral palsy in the survivor (Pharoah & Cooke, 1997), but their later systematic inquiry (Newton et al., 2003) showed this not to be the case. Moreover, the detailed study of Hargitai et al. (2003) of placentas in patients with cerebral palsy found no vanished twins. When fetal demise occurs later in the gestation of monochorionic twins with vascular anastomoses (and then usually with larger fetuses), however, cerebral palsy (CP) in the survivor is a distinct possibility, as Liu et al. (1992) determined (see also Glinianaia et al., 2002). A thoughtful comment on the (small) prevalence of CP in twins vs. the overall CP problem needs to be considered; this is important so that in larger prospective series zygosity, ART and chorionicity can be individually dissected for their individual relevance to the origin of CP in multiples (Blickstein, 2004). Other investigators have weighed in on the possible neurodevelopmental sequelae of TTTS. Thus, Cincotta et al. (2000) followed 23 children and found that 22% had significant abnormalities. Banek et al. (2003) studied outcomes after laser ablation and identified minor abnormalities in 11%; major CNS deficits were found in another 11% of cases. The ensuing letters by de Lia and Worthington (2003) and the replies need to be read for a complete assessment, regarding not only the complex methods of surgery but also the difficulty of correct evaluation. When no laser ablation is

FIGURE 25.64. Fetus papyraceus in a separate amnion (DiMo placenta). It had SUA and six toes, and was an acardiac upon dissection.

FIGURE 25.65. Typical fetus papyraceus with cord visibly attached to the infarcted twin placenta (DiMo). The surviving twin had scalp defects.

undertaken, the CNS morbidity is even higher (Lopriore et al., 2003). It might also be mentioned that, on very rare occasion, after demise of the recipient twin, the donor (!) may develop acutely hydrops fetalis (Ries et al., 1999). Wataganara et al. (2005) showed that laser ablation in TTTS leads to a persistent elevation of circulating fetal DNA levels in the maternal circulation.

When maceration is advanced, the fetus may have the appearance of a **lithopedion** (Fig. 25.66). This feature is more commonly found when a fetus is retained for months beyond the expected gestation; indeed, it need not even be a twin (e.g., El-Sherbini, 1963). The formation of a lithopedion is particularly commonly described in retained fetuses of nonhuman primates (e.g., Mueller-Heubach & Battelli, 1981; Swindle et al., 1981). Miller and Dillon (1989), who cited relevant literature on the frequency of lithopedion, estimated that perhaps 400 cases had been described. They presented the case of a 94-year-old woman with lithopedion that had been present for probably 61 years without doing harm. One of the most unusual placentas of a presumed former twin in our collection is depicted in Figure 25.67. It is the placenta of a normal infant at term, with marginal insertion of the cord. In the center of the larger placental mass was what appeared to have been the site of insertion of another cord, with fetal vessels radiating to it. No twin was found, as was also the case with Moshiri et al. (1996), who found 16 cases of lithopedion reported in the literature. They added another case, occurring in an 86-year-old woman and presumably having originated 44 years earlier. Not to be outdone, Speiser and Brezina (1995) found a lithopedion in a 92-year-old woman that had been present

FIGURE 25.66. Fetus papyraceus with the appearance of a lithopedion.

FIGURE 25.67. Term placenta with near-marginal insertion of the cord. At the arrow is a structure that has the appearance of a second cord, with fetal vessels radiating toward it. No twin was found.

presumably for 60 years. It had the size of a 31-week-gestation fetus.

On occasion, a large fetus papyraceus presents with dystocia at delivery (Leppert et al., 1979). A fetus papyraceus may also be one of triplets (Roos et al., 1957; Benelli, 1962) (see Fig. 25.43). It has also been reported to us that a triplet placenta was associated with two fetus papyracei (Shih, personal communication, 1986; see also Esposito, 1963). They may be of monochorionic or dichorionic gestations; congenital anomalies other than acardia have been occasionally identified on dissection. The co-twin of a fetus papyraceus may also have anomalies, such as microcephaly, absent ear (Roos et al., 1957), gastroschisis (Weiss et al., 1976), ileal atresia (Saier et al., 1975), or pulmonic stenosis (Baker & Doering, 1982; reviewed by Szymonowicz et al., 1986). In a discussion of a case of ileal atresia, Sander (1983) drew attention to the possible cause of these anomalies. He suggested that they may have a prenatal thrombotic etiology, in analogy with the phenomenon of DIC discussed above. Whether the occasional scalp lesions in co-twins of fetus papyracei are analogous to the aplasia cutis described by Mannino et al. (1977) is not clear. Demmel (1975), who reviewed all types of neonatal skin defect, does not mention the occurrence of macerated co-twins with these cases, but then the placenta was probably not examined in his somewhat older case population. A case similar to that of Mannino et al. (1977) was presented by McCrossin and Robertson (1989). Although their case was complicated by toxoplasmosis, the extensive skin defects of this neonate were essentially similar to the aplasia cutis described by Mannino et al. They were also in the process of healing at birth, and as early as 18 weeks' gestation a macerated, much smaller twin was demonstrated sonographically. Lemke and colleagues (1993) described extensive aplasia cutis in a twin associated with a dizygotic fetus papyraceus; regrettably the placenta was not studied.

Innumerable reports of fetus papyracei have been published in the literature. The bulk of these cases from the older literature may be found in the comprehensive review by Kindred (1944) and publications of the material from the clinics of Litschgi and Stucki (1980), Yoshida and Soma (1986), and Johnson et al. (1986). Kindred reviewed 150 cases that had been published up to 1944. Of the 141 cases with adequate information given, 66% were dichorionic twins and three cases were MoMo twins. Mills (1949) was critical of many of Kindred's concepts. He reported three sets of monochorial twins, one of which was macerated. He wanted to distinguish mummified from compressed fetuses when many authors make no such distinction. In our opinion, that question is moot. Litschgi and Stucki (1980) observed five dichorionic and eight monochorial (one MoMo) twins. They suggested that when a macerated twin is recognized, delivery should occur by the 39th week. That this advice is not uniformly accepted was mentioned earlier in the chapter.

For unknown reasons, death of the other twin may follow when a fetus papyraceus is present (Camiel, 1967; Yoshida & Soma, 1986). Forman (1956), who described a case with dichorionic placenta, stated that fetus papyraceus was first mentioned by Pliny (70 A.D.). Johnson et al. (1986) attempted to ascertain the incidence of fetus papyracei in 34,677 deliveries from their hospital. A total of 515 twins were observed, of which 27 (5%) had a single intrauterine fetal death; 16 of 25 (64%) liveborn co-twins survived. The placenta was monochorial in 70%. One survivor had multiple infarcts, another had a gangrenous leg at birth, and several had thrombi. Puckett (1988) discussed the management of pregnancies when a second trimester twin dies, and Chescheir and Seeds (1988b) observed the spontaneous disappearance of hypofibrinogenemia following in utero death of a twin. They suggested that prophylactic heparin therapy is not warranted when one of twins dies. Enbom (1985), who reported two cases of antenatal death of one of DiMo twins, was also fearful of this thrombotic complication and reviewed the literature. The survivors did not show sequelae of DIC. Foot necrosis and thrombosis of placental vessels were recorded in the survivor after fetal death of one twin by Margono et al. (1992). That this can occur in the living recipient twin of TTTS was shown by Hecher et al. (1994b). They observed necrosis of digits while the donor twin was still living and attributed it to both the recipient's high hematocrit and "steal" because of the presence of a single umbilical artery. Bass et al. (1986) observed persistently elevated amniotic fluid AFP and acetylcholinesterase levels after death of one twin, findings supported by Streit et al. (1989).

Carlson and Towers (1989) also found that in the 17 multiple gestations with fetal death of one twin they studied, there was significant risk

to the survivor. Their review suggested that fetal death of one twin occurs as often as in 2.6% of multiple gestations and three times more often in monochorionic than dichorionic twins. This occurrence is the reason why Cox et al. (1987) have used fetal blood sampling in the surveillance of such surviving twins.

Szymoniwicz et al. (1986) reported six cases of a monozygotic twin surviving with CNS defects after the death of a co-twin 1 to 11 weeks before delivery. They also reviewed the 16 reports in the literature (with a total of 53 such cases) and concluded that delivery should be seriously considered when one twin dies in utero. In their survey of these cases, 72% had CNS defects, 19% had gastrointestinal (including liver and spleen) defects, 15% had renal lesions, and 8% had pulmonary lesions. Anderson et al. (1990) found not only CNS necrosis but saw also bowel injury in two of four cases with prenatal demise of a monochorionic twin. Szymoniwicz et al. described placental thrombi in some of their cases and continuing hematuria that lasted 2 weeks in such a survivor, suggesting a continuing process that was initiated before birth. Their vascular disruption hypothesis suggested infusion of thromboplastins, but they gave no account of the placental vascular anastomoses of their cases. The report by Liu et al. (1992) of 41 cases with one prenatal death gave similar findings and suggested that exsanguination is the primary cause of injury to the survivor. Other aspects of intrauterine death of one twin are discussed in some detail by D'Alton and Simpson (1995).

## Twin-to-Twin Transfusion Syndrome

The twin-to-twin transfusion syndrome (TTTS) is considered to be a specific entity in twins, caused by the unidirectional, prenatal transfusion of blood through AV anastomoses in the monochorionic twin placenta. It occurs in approximately 10% of monochorionic twins with dismal prognosis (Gul et al., 2003). One twin is the

“donor” and the other is the “recipient.” Its severity totally depends on the nature and direction of the anastomotic circulation. The syndrome was first clearly delineated by Schatz (1882, 1886), when he observed a set of monochorial twins with gross discordance in size and development. One was edematous and urinated many times before dying at 12 hours of age; the other was a hypotrophic twin who never urinated and who had an empty bladder at death (53 hours). The atrophic twin had decubiti of the knees and ankles, much like the aplasia cutis described by Mannino et al. (1977). Schatz (1882) had already suggested that the fetal vessels were anastomotic through a “third circulation,” which he was subsequently able to demonstrate clearly by injection of the DiMo placenta. He hypothesized also that the anastomoses were the cause of the fetus papyracei. In fact, he had described the “stuck twin” from clinical observations alone. This “third” circulation was then clearly perceived as proceeding from one of the donor’s superficial (terminal) arteries into a shared cotyledon, whence it drained into the venous circulation of the recipient (Fig. 25.68). This anastomosis is thus a capillary one. It is not always easy to demonstrate unless careful injections are made with thin liquids of selected areas in the placenta. It is highly speculative just how it is that such complex anastomoses of twin placental vascular beds develop and why they are so variable. Gaziano et al. (2000) produced a diagram of the hypothetical implantation of such twin blastocysts and suggested that the monochorionic monozygotic “twin blastocyst has an intrinsic polarity

FIGURE 25.68. Top: Principal vasculature connection that causes the transfusion syndrome of MZ twins. Bottom: The shared cotyledon here was injected with water; it appears blancher. Note that the right half of this placenta is paler than the recipient’s left half.

defect at implantation.” This is difficult to comprehend, and, naturally, it lacks anatomic support at this time. Perhaps the embryo splits with different cell numbers and hence the onset of cardiac perfusion of placental villi differs. All is speculation at this time, and the only new insight that we can foresee about how new data can become available is by descriptions of really early stages of DiMo twin specimens. With the advent of successful therapy by laser ablation of the connecting vessels by De Lia et al. (1985a), there has been a veritable flood of publications, some of which are discussed here in some detail. Insight has come from four or five different centers in Europe and the U.S., centers that have dominated in the practice of laser therapy. Often they have also differed in their approaches, the results, interpretation of the fluid mechanics of this syndrome, and other aspects that pertain to interpreting the TTTS. Moreover, De Lia et al. (2000) stated that the syndrome is influenced by aberrations of the maternal metabolism and that these need to be corrected in order to optimize fetal survival.

Because AV anastomoses may be multiple and of varying size, and they may also proceed in opposite directions, the syndrome is variable in its consequences. This point has been elegantly shown with Doppler ultrasonographic studies of pregnancies complicated with this syndrome (Pretorius et al., 1988a). Pretorius et al. found it easy to demonstrate greater placental vascular resistance in one fetus, findings that were also shown in the therapeutic intervention in this syndrome by De Lia and Cruikshank (1989). Pretorius et al. (1988a) were unable to predict from their studies which was the donor, and they were also unable to anticipate the outcome. They confirmed that “the transfusion syndrome is an extremely complex dynamic physiologic state.” Hecher et al. (1994a) delineated the Doppler signals of AA anastomoses and later described the various anastomoses as they were identified during surgery (Diehl et al., 2001). In 126 cases of severe TTTS they saw AV anastomoses in all, 31% also had AA, and 12% had VV connections. Denbow et al. (2000) as well as Umur et al. (2002) found that AA anastomoses largely protected against the severe forms of the TTTS, whereas VV connections reduced perinatal survival. Denbow et al. (2004) were able to determine modest flow rates in AA anastomoses by Doppler waveform analysis. Similarly, Tan et al. (2004) demonstrated the flow and concluded that “detection of A-A anastomosis predicts higher perinatal and double survival in TTTS, independently of disease stage.” In an interesting case report, Tan et al. (2004) showed the acute first onset of TTTS in a twin gestation in which a previously patent AA anastomosis became obliterated. A somewhat oversimplified classification (A to D) was proposed for monochorionic placental anastomoses by Bermúdez et al. (2002). Nevertheless, it demonstrated that, in general,

only the “deep” AV anastomoses are the critical ones. But other problems with this system as well as the method of demonstrating anastomoses for this classification were pointed out by Taylor et al. (2003). This reply to the paper addresses primarily the method of demonstration of anastomoses and the protective effect of large direct surface AA connections. Needless to say, these points are critical for understanding TTTS and, especially, for appropriate therapy. To anticipate more adequately the timing and method of therapy, Quintero et al. (1999, 2003a) introduced a method of staging the TTTS (stages I–IV). It has also allowed better follow-up of the results and is now being widely employed, albeit with modifications (Fisk et al., 2004). De Lia and Cruikshank (1989) found markedly greater vascular resistance in the donor. Bromley et al. (1992) suggested from their experience with 12 sets that, when clinical manifestations were clear-cut at 20 weeks, the prognosis with conservative therapy was poorer than when the syndrome was diagnosed later in gestation. In general, TTTS has a poor prognosis if it remains untreated. A later review of the sonographic techniques, especially the findings at Doppler study and others employed in this differential diagnosis, is to be found in the publication by Plath and Hansmann (1998). Taylor et al. (2000a) attempted to predict the outcome of TTTS by prenatal sonographic features; absent AA anastomosis, abnormal venous pulsatility, and reversed end-diastolic flow in the donor’s artery had poor prognosis. Later (2000b) they were able to detect AA anastomoses (better in later gestation) and mapped sonographically also the AV connections (2000c). Ishii et al. (2004) have since shown that excessive flow in the umbilical vein of the recipient changes after laser surgery. But there is still much controversy over the presence of AA anastomoses in stage III TTTS, as can be seen in the contribution by Taylor et al. (2004) and the detailed criticism by Van Gemert et al. (2004). Indeed, what is observed endoscopically as specific color or pulsatility may not reflect in what is seen by injection studies later. Actually very few publications discuss injected placentas from the postlaser studies, and these show that some AV areas were missed at surgery (De Paepe et al., 2004). As indicated above, Bermúdez et al. (2002) have proposed a categorization of TTTS placental types: A, no anastomoses (0%); B, only deep anastomoses (100%); C, only superficial anastomoses (5.6%); and D, deep and superficial anastomoses (79.12%). They recommended this classification for the purposes of adjudicating results from laser surgery and thereby suggested also that, despite direct superficial connections, TTTS may still occur.

It is important to realize that the precise angioarchitecture of cotyledonary perfusion has not been sufficiently delineated, and that this is extremely difficult to do. The focal injections with milk, water, air, etc. do not

provide a permanent record that can be scrutinized minutely. Therefore, plastic injections have been performed such as shown in Figure 25.21. Even when these are handled with a delicate digestion procedure, they are hard to interpret. The situation is worse when a placenta has had laser surgery and is perhaps weeks after the procedure. Wee et al. (2005) have attempted to correct this in a plastic injection procedure that is detailed and followed by acid corrosion of monochorionic placentas (one with TTTS). Their findings contradict what has been generally assumed to be the case for “shared cotyledons.” They suggest from their study that intercotyledonary fine anastomoses exist below the chorionic plate that cannot be seen externally by inspection. When examining the color pictures in some detail, we conclude that this possibility cannot be completely ruled out but also that these putative anastomoses are hard to characterize because the acid digestion has also removed the chorionic plate. If these subchorionic anastomoses truly exist (and their mechanism of formation is hard to envisage), then this would make selection of shared cotyledons for laser ablation even more difficult than it already is. But also, the success with most ablations becomes more difficult to understand. More work of this type is needed.

Clinically, the transfusion syndrome is typically first recognized by acute hydrops that develops around mid-gestation. Many authors have made crucial observations since Schatz’s description (e.g., Wurzbach & Bunkin, 1949), and a summarizing review comes from Lopriore et al. (1995). When sonograms or radiographs are obtained after the hydrops appears, the presence of a twin pregnancy is often recognized for the first time, although the sizes of the twins may already be significantly different (Schneider et al., 1985; Brown et al., 1989). In these cases, the placenta is later almost always found to be monochorial. The occurrence of acute hydrops is considered to foreshadow a somber prognosis (Weir et al., 1979); one twin may show edema, best recognized sonographically in the scalp (Wittmann et al., 1981). The amounts of amniotic fluid vary enormously. Thus, we have learned of a remarkable case of DiMo twins with severe hydrops; at 20 weeks’ gestation, the amount of amniotic fluid was 5000 mL (withdrawn); another estimated 2000 mL was left unexpired (K.L. Staisch, personal communication, 1976).

Not all authors agree with the concept that anastomoses may be the ultimate cause of the hydrops in monochorionic twin pregnancies (Krauer, 1964). Perhaps the first to voice his opposition to Schatz’s notion of excessive urination of the recipient twin was Forsell (1912). He incorrectly interpreted that the placentas had “endarteritis” in their main-stem vessels, and that the cause of the hydrops was a degenerative amniotic

epithelial change. These changes are clearly secondary. There is so much variation in the clinical expression of the transfusion syndrome that care must be exercised before making the diagnosis on clinical grounds alone (Wenstrom et al., 1992). Magnetic resonance imaging (MRI) has been usefully employed for the differential diagnosis (Brown & Weinreb, 1988). Not all hydrops with twins, particularly chronic hydrops, is due to the transfusion syndrome (Dorros, 1976). Accurate sonographic differentiation of the dividing membranes, therefore, should be attempted (Mahony et al., 1985; Townsend et al., 1988; D’Alton & Dudley, 1989). When acute hydrops is found in a twin pregnancy, the second twin often has little or no amniotic fluid (oligohydrops). This twin may move much less than the recipient, so the term *stuck twin* has been applied to this feature (Hashimoto et al., 1986; Brown et al., 1989; Patten et al., 1989a; Mahony et al., 1990). When Berry et al. (1995) evaluated hematologic and chemical parameters in such twins by cordocentesis, they found that all stuck twins had a minimally 2.4 g/dL less hemoglobin concentration. On rare occasion a stuck twin may result from triploidy (Wax et al., 1998).

To better explain the mechanism of hydrops in this syndrome, Nageotte et al. (1989) proposed involvement of the atrial natriuretic peptide (atriopeptin) in the pathogenesis. In two cases they found markedly elevated atriopeptide levels in the recipient and lower levels in the donor of this syndrome (2251 vs. 43 pg/mL, and 134 versus 79 pg/mL). They suggested that the hormone is released because of the recipient’s hypervolemia, and that its elevated levels may be responsible for the renal effects. Talbert et al. (1996), as well as Bajoria et al. (2002, 2003), found elevated atrial natriuretic peptide and endothelin-1 levels in the recipient twin and inferred it to be a sequel of failing heart in the recipient, perhaps also being important for amniotic fluid regulation.

This prenatal unidirectional exchange of blood results in deprivation of nutrients from one twin and excessive development of the other. The twins may be remarkably discordant, as seen in the classical example shown in Figures 25.69 to 25.71 (also see Fig. 25.73). One twin was dehydrated and anemic, and possessed organs that were significantly smaller than expected for the stage of development. The recipient was plethoric and had much enlarged organs and higher mean arterial blood pressure after birth that quickly became normal (Cordero & Johnson, 2002; Cordero et al., 2003). The discrepancy was particularly striking in the heart, but other organs were similarly affected. Lazda (1998) believed that the discordance of fibroelastosis occurring in two recipient twins were the ultimate result. In the absence of AA anastomoses, the hydrops leads to very premature labor or to rupture of the membranes, with delivery before the 30th week of gestation. Alternatively, one twin may die

FIGURE 25.69. Twins with the typical transfusion syndrome. MZ twins at 27 weeks, delivered after two amniocenteses (4000 and 3000 mL) had partially relieved the hydramnios. Recipient (left): 540 g, edema, heart 12.5 g, liver and one kidney less severely hypertrophied. Donor (right): 410 g, heart 2.7 g.

FIGURE 25.70. The placenta of the DiMo twins in Figure 25.69. Recipient had an edematous cord (left). The cord of the donor (right) is torn and was marginal. Note the area of common villous district (arrow; see also Figure 25.71).

FIGURE 25.71. Common villous district of the case in Figures 25.69 and 25.70 is shown at the arrow. An artery from the donor (at right) dips into the placental tissue and emerges as a congested vein, coursing to the recipient (at left). The oval body at top is the remains of the yolk sac (single); there is also slight amnion nodosum in this cavity of the donor, who had oligohydramnios.

FIGURE 25.72. A DiMo twin placenta with fetus papyraceus. Severe hydramnios at 20 weeks abated spontaneously. One twin died at that time: The pregnancy normalized, and a normal twin was delivered at term with this fetus compressus. Its placental portion was completely infarcted.

and become a fetus papyraceus (Fig. 25.72). In that case, the hydramnios ceases nearly immediately and the pregnancy may reach term. The same is true when the anastomoses are obliterated by laser therapy (De Lia et al., 1990, 1993). Another alternative of the development of TTTS was described in some detail by Nikkels et al. (2002). They found acute onset of TTTS at 25 weeks following spontaneous thrombosis of a venous connecting branch.

The development of intracranial hemorrhage in the recipient has been witnessed to occur already in utero, and periventricular encephalomalacia in the donor of this syndrome may also take place (Hurst & Abbitt, 1989). Other pathophysiologic consequences of the syndrome have occasionally been recorded when prompt neonatal studies were undertaken. The set of DiMo twins with the transfusion syndrome whose data are shown next were delivered at 27 weeks' gestation and they were studied unusually well. The mother had preeclampsia, hydramnios, and placenta previa, and she had required a cesarean section. Both twins developed hyaline membrane disease and intraventricular hemorrhage. Their data were made available to me by colleagues from Minnesota. Because the results are so impressive they are shown here:

Parameter	Donor twin	Recipient twin
Age at death (hours)	25	28
Birth weight (g)	732	1100
Head circumference (cm)	23.5	26
Initial hemoglobin (g/dL)	3.2	22.4
Initial hematocrit (%)	12	70.5
Blood pressure (mm Hg)	20	50
Liver at autopsy (g)	42.4	32.2
Pancreas (g)	1.5	2.1
Kidneys, two (g)	7.7	13.8
Adrenal glands, two (g)	3.9	3.1

Some other cases in which clinical values are given are listed as follows (weight in grams, hemoglobin in grams per deciliter, hematocrit in percent):

Source	Donor	Recipient
Klingberg et al. (1955)		
Weight (g)	1770	2690
Hemoglobin (g/dL)	3.7	25.2
Hematocrit (%)		87
Sacks (1959)		
Weight	1431	2084
Hemoglobin	5.5	24
Weight	1424	1843
Hemoglobin	18	30
Hematocrit	58	75
Weight	2041	2523
Hemoglobin	12.8	33
Hematocrit	93	
Weight	1021	1162
Hemoglobin	15	27
Hematocrit	41	80
Kresky (1964)		
Weight	1900	2600
Hemoglobin	11.3	22.1
Hematocrit	42	77
Bolens et al. (1968)		
Weight	2410	2510
Hemoglobin	25.9	13
Hematocrit	90	47

Many other reports of blood values at birth have been published, with wide variations. At times, the hematocrits reached astounding values. In a case referred to us, the plethoric newborn had necrosis of one leg due to arterial thrombosis. The other extremities infarcted shortly thereafter (Dr. J. Pritchard, personal communication). Partial necrosis of the left foot of a recipient twin was seen by Hecher et al. (1994b) at fetoscopic laser surgery of a case

FIGURE 25.73. Macerated DiMo twins with the transfusion syndrome at 28 weeks' gestation. The donor (B) is plethoric, the recipient (A) is edematous and pale. A: 285 g; 15-cm crown-rump (CR) length; heart 3 g; lungs 10 g; liver 17.5 g; kidneys 1.5 g.

B: 189 g; 13-cm CR length; heart 0.7 g; lungs 3 g; liver 4 g; kidneys 1 g. The plethora of twin B is thought to be due to this twin's earlier death, with exsanguination of A into B.

of TTTS. The fetus had an absent right umbilical artery, and vascular "steal" was assumed to be the etiology. Polycythemia was believed to have been the cause of necrosis of the lower extremity in a recipient twin reported by Scott and Evans (1995). Similarly, Dawkins et al. (1995) found a foot necrosis due to hyperviscosity of a recipient twin whose TTTS had been managed aggressively with amniocenteses. Skin necrosis on the thigh, resembling aplasia cutis, was observed in the survivor of a transfusion syndrome case with laser surgery at 16 weeks (Stone et al., 1998). It is not certain how this defect occurred; it healed quickly after birth at 31 weeks. Some of the reports contain expressive color photographs of the twins (Becker & Glass, 1963). There is no correlation between the infants' size, the length of gestation, and the degree of plethora observed at birth. Moreover, the plethoric twin may be the smaller of the two, as seen in Figure 25.73. This discrepancy can be explained only when the anastomoses are carefully delineated, and the circumstances of birth are known. This topic was especially well discussed in the case reports by Donnenfeld et al. (1989), and Bendon and Siddiqi (1989). An equally striking case is shown in Figures 25.74 and 25.75. The DiMo twins were both stillborn, but histologic preservation was better in the anemic twin, and it is assumed that it died last. The

FIGURE 25.74. DiMo twins, the smaller being severely plethoric. The smaller size of the twin at right is due to the velamentous insertion of the umbilical cord.

FIGURE 25.75. Same twins as in Figure 25.74. Note the smaller heart in the smaller and plethoric twin (right). See text.

weights of such twins (Figs. 25.74 to 25.76) are important and are as follows:

Organs	Anemic twin	Plethoric twin
Body (g)	550	410
CR length (cm)	20	17.5
Heart (g)	11.3	3
Lung (g)	11.9	5
Spleen (g)	1	0.5
Liver (g)	37.2	8.3
Adrenals (g)	2.3	1.4
Kidneys (g)	4.9	2
Thymus (g)	0.9	0.2
Brain (g)	0	40

The smaller twin was growth-restricted because of its velamentous insertion of the cord. This case does not represent a twin transfusion syndrome. The plethora was caused by reverse flow from the now-anemic twin, occurring through the large AA anastomosis (demonstrated with milk injection) because of his longer survival. In several other cases of discordant twins that we autopsied,

FIGURE 25.76. Placenta of twins in Figures 25.74 and 25.75. One large AA anastomosis exists. Through this anastomosis, the larger twin, who died last, must have exsanguinated into the plethoric twin. This situation is not the transfusion syndrome.

the donor was plethoric. Clinical information and sonography indicated in each case that the plethoric twin had died first; the anemic recipient died later (in one case from listeriosis). Autopsy confirmed the transfusion syndrome from the marked discordance of cardiac size (Benirschke, 1992, 1993; Benirschke & Masliah, 2001). Indeed, it is our opinion that discordance of relative cardiac size is the most important means for the diagnosis of the transfusion syndrome. The fact that after birth of one twin (and after demise as well) rapid blood shifts may occur between the twins often negates the usefulness of hematologic values; furthermore, the placenta is frequently too damaged for accurate analysis of anastomoses. This is forcefully supported by the studies on fetal organ growth of Naeye (1964a,b), Pridjian et al. (1991), and Barr (1996). Moreover, Lachapelle et al. (1997) found in all recipient twins they studied echocardiographically thickened ventricular walls, and Simpson et al. (1997) reported common cardiac dysfunction in the recipient twins, as did Bajoria et al. (2002). A thoughtful review of the diagnostic pitfalls comes from Weiner and Ludomirski (1994), who diagnosed the disease by finding divergent hematologic values from prenatal cordocentesis. They also showed that amniocentesis did not alter the degree of blood shunting between the twins.

Several authors have addressed similar unusual findings. Lehdorff (1961), who also reviewed the relevant literature, assumed that in most cases the transfusion takes place during the terminal periods of delivery, when pressure changes occur because of uterine contractions. Klebe and Ingomar (1972) also believed that much of the transfer occurs during labor. With variable cord clamping practices, it may occur immediately after birth. We have seen a pertinent case. New term twins with significant birth weights had hematocrits of 32% and 63%, respectively. The smaller twin was plethoric and had no problems; the larger twin was anemic and required transfusion. The smaller twin had velamentous insertion of his umbilical cord, with much old retromembranous hemorrhage behind the cord insertion. Injection of the DiMo placenta showed that two large AA anastomoses existed, in addition to AV shunts. The villous blood content appeared similar, but the smaller twin's placental portion was much smaller. Our interpretation is that the growth-restricted twin (because of the velamentous cord insertion) was eventually unable to withstand the pressure column exerted from the larger twin that took place through the AA anastomoses; he thus became plethoric, perhaps during the terminal stages of labor. No cardiac hypertrophy was found in the larger twin, there was no hydramnios, and the fact that this pregnancy went to term suggested that it was not the classic twin transfusion syndrome. Features of long-term circulatory aberrations include cardiac hypertrophy, thromboses, and the presence of nucleated red blood cells. These findings bespeak the prolonged prenatal problem of adjustment to different circulatory phenomena.

The youngest specimens that we have observed to have signs of a well-established circulatory imbalance were a set of DiMo twin abortuses of about 10 to 12 weeks' gestation (Fig. 25.77). Although those twins were still similar in size, their hearts were already grossly discordant. In another specimen of stillborn twins at 15 weeks, the plethora of the recipient was evident and the cardiac hypertrophy already well expressed (2.28g vs. 0.67g). Despite this marked discrepancy, the bodies were virtually identical in their sizes and weights. The differences of fetal size commence later in gestation, usually after 25 weeks

FIGURE 25.77. DiMo twin abortuses with the transfusion syndrome, at about 11 weeks' gestation, weighted 31 and 20g; 8 and 7cm CR length; and the hearts weighed 440 and 193mg. This picture is the earliest evidence of the transfusion syndrome, with marked cardiac enlargement but relatively few bodily differences as yet.

(see also Benirschke & Masliah, 2001). Aherne et al. (1968) and Arts and Lohman (1971) reported that the anastomoses in typical transfusion syndrome twins are usually transvillous and do not involve the larger surface vessels. It must be reemphasized that the mere plethora of one twin and anemia of the other do not necessarily signify the existence of the transfusion syndrome. To make the diagnosis of the transfusion syndrome it is important that the twins be of different size; and as minimal criteria they should have different heart sizes as well. It is clearly possible that large AA or VV anastomoses allow rapid transfer of blood when pressure relations change during parturition, and that the anastomoses can result in anemia or polycythemia, but differences in blood values alone do not justify the term *transfusion syndrome*. Indeed, there is much argument as to what clinical parameters to use when designating a set of twins as having the transfusion syndrome. In some opinions, it is a hemoglobin difference of more than 5g/dL; others also wish to include a coincident weight difference of more than 20%. These aspects were discussed by Danskin and Neilson (1989), who studied 178 consecutive twin pregnancies with a variety of parameters. They concluded that generally acceptable guidelines are not yet available, as dichorionic twins with such differences were found in their series who clearly did not have the syndrome.

Quantitative placental studies have rarely been undertaken on the placentas of the transfusion syndrome. Sala and Matheus (1989) addressed this issue with a relevant

case. They found that the plethoric recipient had thinned trophoblastic villous covering and that the villous vessels were markedly distended. In contrast, the anemic “donor” had thick trophoblast and frequently “empty” villous capillaries. They also undertook a stereologic study of the villous architecture and provided quantitative data of differences in villous development. Their case is unusual in several ways. The hydramnios that one might have expected was apparently not present; it was presumably absent because the pregnancy came to near term. That is distinctly unusual for the untreated transfusion syndrome. Although there was the expected marked difference in neonatal sizes (2470 vs. 1920 g), hemoglobin levels (29.3 vs. 10.0 g/dl), and hematocrit values (75% vs. 24%), the placenta had an AA anastomosis. The smaller twin had velamentous insertion of the cord. The fact that there was an AA anastomosis and that the pregnancy was carried to 36 weeks’ gestation makes this observation less typical, and the data may not fit the usual cases of the immature gestation with the classical syndrome. Bendon (1995) made a thorough study of 21 monochorionic placentas with injection of different colors. His findings indicated that the placental features are complex in the TTTS and that placental weight correlated with fetal weight, whereas hematologic values were often erroneous. Because of this remarkable complexity Van Gemert and Sterenborg (1998), and Van Gemert et al. (1997, 1998a,b) and Talbert et al. (1996) have constructed dynamic computerized models in order to understand the contribution of different types of anastomoses to the TTTS. They help in understanding the intricacies of the “third circulation” and must be read in the original because of their complexity. It is likely that through greater accuracy of

Doppler flow observations in the placental surface vessels of monochorionic twins (see Gaziano et al., 1998) and such physical models, we will learn more precisely what pathologic alterations of blood flow are most responsible for the syndrome. This will also help the laser surgeon in the elimination of the offending vessels, and Van Gemert et al. (1998c) have suggested how therapy based on knowledge influences outcome. Because the umbilical cord coiling index (Chapter 12) in the recipient twin of three cases studied was twice that of the donor, Strong (1997) suggested that this “pump” may have implications in the etiology of TTTS. How best to demonstrate the third circulation (i.e., shared cotyledons) is shown in Figure 25.78. The always available milk was used to inject specific suspicious shared cotyledons. They are thus clearly distinguished.

The frequency of the transfusion syndrome is difficult to estimate, but observations suggest that it is more common than is usually cited (Shah & Chaffin, 1989; see also Lopriore et al., 1995). Urig et al. (1990) reviewed their cases of all twins and found the transfusion syndrome to have occurred in one of 30 twin pregnancies. They also emphasized that there is wide spectrum of severely affected twin pregnancies and less severe cases; thus, assigning a precise frequency, and accurately assessing therapeutic efficacy, is difficult. For unknown reasons the syndrome has been reported to be very much more common in female twins (Nores et al., 1997). Bebbington and Wittmann (1989) found 25 cases in their series of 595 multiple pregnancies, that is, approximately 4% of twin gestations, which perhaps involves 5% to 10% of twins with monochorial placentas. Reviews of the syndrome are to be found in papers by Kloosterman (1963), de Marco

FIGURE 25.78. DiMo twin placenta whose arteries were injected with milk. The “shared cotyledons” can be identified by the color change as the milk returns from the villous capillaries and is pink. A, artery; V, vein.

(1964), Rausen et al. (1965), and Corney and Aherne (1965) and in more recent textbooks, but agreement about the precise criteria is not easily obtained among the many points of view (Bruner & Rosemond, 1993). Single cases from different countries make other literature available: Littlewood (1963), Van der Kolk (1964), Verger et al. (1963), Tojo et al. (1971), Koranyi and Kovacs (1975), Tuncer (1970), Sekiya and Hafez (1977), and others too numerous to cite. When the condition is diagnosed before 28 weeks of gestation, the overall survival rate was found to be only 21% (Gonsoulin et al., 1990b). Hydrops correlated with poor survival in this study, but decompression by amniocentesis was not beneficial in the outcome. The condition has also been described in one of triplets and higher multiple births, as for instance in the triplets described by Sekiya et al. (1973), another by Chasen et al. (2002), and yet an additional case reported by Baschat et al. (2003). Berg et al. (2002) reported onset of TTTS at 11 weeks in an ART-conceived quadruplet gestation with quadramnionic, trichorionic placenta. The most remarkable and exceptional case of TTTS was reported by Quintero et al. (2003b), who described a male/female set of twins with monochorionic placenta-tion and anastomoses.

Aside from differences in weights and blood values, the transfusion syndrome has many other consequences. For instance, hyperbilirubinemia is often seen in the recipient (Conway, 1964), and Reisner et al. (1965) found symptomatic hypoglycemia in the donor to be a frequent neonatal complication. They speculated that it may be an etiologic factor for "mental subnormality" in the twin's future. Falkner (1965) challenged this idea on the basis that the investigators had inadequate data. Reduced placental perfusion in the territory of the donor was held

to be responsible for the marked differences seen during placental examination of these twins (Aherne et al., 1968). They suggested that the small placental volume may also have consequences related to reduced nutrient retrieval from the placenta, which they deduced would lead to fetal malnutrition. Conversely, one may speculate that the presumably lower blood pressure of the donor circulation prevents a normal placental expansion and that it may relate to the high incidence of velamentous cord insertion. The constant loss of blood proteins into the recipient twin through the arteriovenous shunt may be another important factor for poor fetal growth. Oberg et al. (1999) for instance showed remarkably different development of the renal tubular apparatus. They interpreted this to general hypoperfusion of the donor twin. Abraham (1967) has shown dramatic differences in the villous structure of the two twins' placental villi. He suggested that the term *parabiotic circulation*, as used for experimental animal studies (Linke & Kuni, 1969) and sometimes applied to this syndrome, is not an appropriate designation. The term was popular at a time when immunologic phenomena were first studied in depth, but it should no longer be used for twins. Abraham (1967) showed the lack of uniform concordance of hemoglobins with birth weights of 53 pairs in an interesting way:

Twin	No. with low hemoglobin	No. with high hemoglobin
Big	6	24
Small	19	4

The remarkable anemia of one twin's placental portion and polycythemia of the other's placenta was studied by Michaels (1967), and Aherne et al. (1968). Not only are the macroscopic features striking in their color difference, but the histologic structure of villi can differ substantially as well (Figs. 25.79 and 25.80). The discordant organ development in twins with the transfusion syn-

FIGURE 25.79. A DiMo twin placenta at 34 weeks. Recipient had congestive heart failure (2160g, hyperbilirubinemia, blood pressure 70mmHg). Its placental portion (left) is plethoric and thicker. The donor (anemic, thin portion of placenta at right) weighed 940g and died neonatally. (Courtesy of Dr. S. Kassel, Fresno, California.)

FIGURE 25.80. Histologic appearance of the two twins' placental portions. The donor's placenta (left) is much more immature in appearance than the villi of the recipient (right), which are smaller and congested. H&E  $\times 160$ .

drome has been variously studied by several authors. Thomas (1962) found not only hypertrophy of cardiac muscle fibers in the plethoric twin but also that hyperplastic changes existed. Fesslova et al. (1998) observed echocardiographically features of cardiac hypertrophy in this condition, judged to be reversible. Barrea et al. (2005) studied the cardiovascular response of TTTS in more detail and with sophisticated methods. Their conclusion was that the recipient more commonly suffers damage and has cardiac hypertrophy and predominantly ventricular dysfunction, and that despite amnioreduction, the cardiovascular dysfunction persists. Naeye (1964a,b, 1965; Naeye & Letts, 1964) undertook the most comprehensive organ analyses. Within this framework he was much concerned with hypoglycemia. By quantitative studies of tissue components, he found that the donor had significantly reduced, and the recipient had significantly increased, cytoplasmic material. Differences of nuclear size and composition were less striking. He likened the findings to malnutrition in the donor and was particularly concerned with the reduction of brain weight. Studies of fetal growth parameters in various categories of twins (grouped according to placental type) confirm the essential findings of Naeye (Pridjian et al., 1991). DiMo twins were found to "have a high degree of brain-sparing growth restriction in the smaller twin and cardiac hyperplasia in the larger twin, most likely caused by hemodynamic inequalities." When Chauhan et al. (2004) studied the chorionicity of 126 sets of twins sonographically in an effort to determine if IUGR related to the type of placentation, they found that monochorionic twins had twice as much discordance in growth when compared with dichorionic placentation. Winner (1963) asserted that the different development was perhaps due to unequal

genetic contribution from unequal splitting of the twins. That opinion does not bear in mind the complex nature of the syndrome. It is an ill-founded criticism. Naeye correctly retorted (1963), for example, that the presumed erythropoietin production by the donor would be equally distributed between the twins, and that the already plethoric twin would be stimulated to even greater hematopoiesis by infusion of blood from the anemic co-twin. Schwartz et al. (1984) described subcutaneous erythropoiesis in the donor twin, akin to the familiar "blueberry-muffin spots" of newborns with cytomegalovirus and rubella virus infections.

Marx (1956) described the glomerular hyperplasia of the recipient twin's kidney in a report of a hydropic triplet with the transfusion syndrome. He conjectured that the increased perfusion of the kidney, under higher pressure, was responsible for this enhancement of glomerular development. He deduced, as did Schatz, that this situation led to the increased urination and hydramnios. The urine output (Kirshon, 1989) and pathophysiology of the syndrome were further elaborated on by Achiron et al. (1987), but the direct cause of this glomerular hyperplasia remains unresolved. Studies in patients with polycythemia (Corrin, 1961) have shown that it is not the cause. Glomerular hyperplasia has been observed in patients with tetralogy of Fallot (Bauer & Rosenberg, 1960) and cor pulmonale (Ellis, 1961). In these situations, hypoxia was thought to be the most important etiologic factor. In addition to changes in glomerular structure, Naeye and Blanc (1972) found dilatation of renal tubules. They deduced that excessive urination was the cause of the hydramnios. That the recipient urinates excessively had been decisively demonstrated by Schatz (1882). In the interesting discussion that followed that paper, Schatz expressed the opinion that the donor may have some amniotic fluid remaining because of sweating. Shah and Chaffin (1989) found a 55% overall mortality due to this syndrome. An interesting observation was reported by Popek et al. (1993). They found three monochorionic twins with prenatal calcification of the pulmonary artery in the absence of valvular anomalies. Two twins were "pump" twins of an acardiac fetus, the other the "recipient" of the transfusion syndrome. The authors speculated that this complication was due to increased prenatal cardiac output (see also Samon et al., 1995).

Mahieu-Caputo et al. (2000) and Kilby et al. (2001) studied the renin-angiotensin system in the kidneys of donor and recipient twins and found overexpression of renin in the donor's glomeruli. Various renal sequelae were found and discussed extensively such as tubular apoptosis (De Paepe et al., 2003). They are secondary phenomena, however, not primary features of the TTTS. It should also be mentioned that Bajoria et al. (2000), finding significantly amino acid concentrations in the two twins, believed that this is an indication that the severe growth restriction of the donor may not be due primarily to the anastomotic loss of blood but that it is the possible result of impaired transplacental transport of amino acids. We differ with this interpretation.

We have twice attempted to re-create the transfusion syndrome in sheep, pregnant with fraternal twins (Resnik & Benirschke, unpublished). Having inserted intravascular catheters, we transferred daily 10 mL of blood from the female to the male twin over 17 days. Our findings included the following male/female weights: total, 3600/3375 g; hearts, 24.5/23.5 g; livers, 96.5/86.0 g; spleens, 10.5/5.2 g; kidneys, 27/22 g; and cotyledon, 440/370 g. The second experiment, done closer to term, gave similar results. Thus, one can simulate the transfusion syndrome experimentally and perhaps better understand the adaptations that occur subsequent to the twin transfusion. Wilson (1979) studied the postnatal growth of dissimilar twins and concluded that "monozygotic twins become progressively more concordant with age . . . while dizygotic twins became less concordant."

It was earlier stated that the recognition of twin-related hydramnios during early pregnancy has a bad outcome unless one twin dies. The transfusion then stops, and often the survivor is delivered near term and is normal (Fig. 25.72). At the other end of the spectrum, various management schemes have been proposed for the twins after their birth, for example, that by Shorland (1971), which sought to correct the anemia, hypoglycemia, polycythemia, and hyperbilirubinemia. Before birth, incisive treatment is more difficult and controversial. The thoughtful review by Blickstein (1990) puts the various diagnostic modalities and treatment regimes into an unbiased perspective. Temporizing for a month by repeated amniocentesis and withdrawal of fluid is sometimes feasible for a while (Figs. 25.69 to 25.71) but not for long (Feingold et al., 1986; Vetter & Schneider, 1988; Lange et al., 1989; Elliott et al., 1991; Elliott, 1992; Reisner et al., 1993). There is a large literature on this topic, and the results are not uniform. Nevertheless, when an international trial of amniocentesis vs. laser ablation was conducted, it was stopped prematurely because the results were infinitely better with laser therapy (Senat et al., 2004). That publication (and two publications by Ropacka et al., 2002, and Odibo & Macones, 2002) reviewed many of the prior publications of various techniques (corticoids, amnioreduction, septostomy), and it was followed by a succinct editorial by Fisk and Galea (2004). At present, then, careful sonographic evaluation, followed by laser ablation of the offending anastomoses would seem to be the best means of treating TTTS. Presumably then, the results of therapy depend on the nature of the anastomoses and on the timing of onset of hydramnios. Gary et al. (1996) have shown significant pressure differences in TTTS. Some authors strongly advocate amniocentesis as therapy

(Mahony et al., 1990; Urig et al., 1990; Elliott et al., 1991; Saunders et al., 1992; Dickinson, 1995; Dennis & Winkler, 1997), whereas Gonsoulin et al. (1990a) showed in a careful study that the 21% overall survival rate was not improved by amniocentesis when the syndrome is diagnosed before 28 weeks. Pinette et al. (1993) also showed that early aggressive amniocentesis is an effective therapy, but prolongation of gestation was minimal. Bromley and colleagues (1992) found only a 25% survival rate when the diagnosis was made before 20 weeks, which was higher when the diagnosis was made later and when conservative therapy was instituted. Grischke and colleagues (1990) were similarly skeptical, and one wonders why the therapy is still being used at all. Bebbington and Wittmann (1989) found that gestational outcome depends mostly on age at delivery and that amniocentesis may be beneficial. In a pregnancy in which hydrops and hydramnios had developed, Trespidi et al. (1997) were also more reserved, although their results are fairly encouraging. Smith et al. (1997) provided some Doppler study evidence of "improved hemodynamics" after many amnioreductions. Despite this, there were many dysmorphic findings in the still small donor at delivery. Garry et al. (1998) measured intramniotic pressures in TTTS, before and after amniocentesis. It was significantly higher than in normal gestations and was reduced to normal levels by amniocentesis, findings similar to those obtained by Meagher et al. (1995). In the editorial comments preceding this paper, however, cautionary words are introduced that do not correspond with our views. It was suggested that hemoglobin differences in TTTS were not necessarily correlated with hydramnios, but the fact that exchange of blood through anastomoses at the time of delivery can obscure such data was not considered. The accumulation of fluid is primarily the result of fetal urination, and this has been examined and modeled in great detail by several investigators (Umur et al., 2001a,b, 2002). It is too complex for consideration here. The developing hydramnios is the primary cause of premature delivery in untreated TTTS; rarely, it can also lead to uterine rupture. Tutschek et al. (2004) reported such a case where rupture occurred at 19 weeks, presumably because of previous uterine scarring. De Lia et al. (1985a) treated the mother of a TTTS in utero with digoxin at 27 weeks. They observed reversal of fetal cardiac failure in the recipient twin. The fetuses survived after cesarean section, which was done at 34 weeks. It is worth mentioning that these authors estimated that 2200 fetuses succumb annually in the U.S. from this syndrome alone. Moise (1991) and Jones et al. (1993) failed to arrest the syndrome in three pregnancies by administering indomethacin, whereas Al-Takroni et al. (1995) seem to have more success in their case. Another means of therapy is to divide the intervening amniotic membranes. Saade et al. (1995) did this in two cases with instant filling of the stuck twin's sac; they did not report the outcomes, however. In

the nine cases done by Berry et al. (1997), no cord entanglement occurred; there was a change in arterial flow, but no real impact on survival seems to have occurred.

Wittmann et al. (1986) chose to sacrifice the donor of a severe transfusion syndrome case at 25 weeks' gestation. They inserted a needle into the heart under sonographic guidance. After the fetus died, the hydramnios disappeared and the pregnancy stabilized. No obvious maternal coagulopathy developed, and the healthy 2890-g survivor was born at 37 weeks. The fetus papyraceus weighed 180g. The placenta was DiMo. Subsequently, Baldwin and Wittmann (1990) summarized their favorable experience with this procedure in three cases of the transfusion syndrome. Weiner (1987) had earlier reported a similar experience. In the days that long preceded sonography, we had unsuccessfully attempted a similar procedure (Benirschke & Driscoll, 1967). Another failure was reported by Chescheir and Seeds (1988a). They filled the pleural space of the donor with fluid until there was cessation of cardiac activity. This maneuver normalized the urine output of the survivor, but the hydramnios did not abate. Infection terminated the pregnancy prematurely. One certain way of preventing CNS damage of one of the twins is cord ligation, as was practiced by Crombleholme et al. (1996) in the abnormal MZ twin affected by congenital heart disease.

Under ideal circumstances, it may become possible in the future to obliterate the interfetal vascular connections, which should then lead to complete normalization of the pregnancy. Schatz (1886) already proposed that some vessels may thrombose and thus compromise further blood exchange. De Lia et al. (1985b, 1989) began experimentation with the obliteration of selected fetal surface vessels in experimental animals by treatment with neodymium:yttrium-aluminum-garnet (Nd:YAG) laser. They were successful with this procedure in sheep and rhesus monkeys and then successfully treated three patients with the transfusion syndrome (De Lia & Cruikshank, 1989). Delivery occurred several months after the vascular obliteration, and marked improvement of urination in the donor, with expansion of its amniotic sac, occurred immediately. The placentas showed the scarred cotyledons supplied by the coagulated vessels. Such therapy has now been tried in many cases of the transfusion syndrome. De Lia et al. (1990, 1996) have published much greater details of their experience, including a set of triplets in other articles. These publications also provide additional insight into the instrumentation, methodology, and vascular findings in the twin placentas. In the meantime, De Lia has done more than 100 cases (personal communication, 1998). The results have improved over time, and now at least 80% of patients can take one healthy child home after this therapy. The procedure is now referred to as fetoscopic laser occlusion of chorioamniotic vessels (FLOC). In one case, the authors pursued

the vessels across a tear made in the dividing membranes. This disruption of dividing membranes may not be without hazard. As indicated earlier, amniotic bands may form or the MoMo twins resulting may entangle cords. The prenatal therapy by laser obliteration of vessels has since been practiced successfully by other teams (Natori et al., 1992; Ville et al., 1992, 1995, 1998). It is now even possible to undertake the ablation when anterior placentas are present and, with the exception of the complexity and the need for instrumentation, it is clearly the most decisive therapy for the transfusion syndrome. There is evidence that laser surgery executed by competent surgeons yields better results than repetitive amniocentesis (Ville et al., 1998). An unexplained finding in the transfusion syndrome is the recognition that the recipient has much higher levels of proteins, but that immunoglobulin G (IgG) levels were much out of line in a study by Bryan and Slavin (1974). On occasion the laser ablation fails; this may be the result of failure to recognize all arteriovenous shunts or due to unusual connections. Thus, Poch et al. (2005) have described such a failure and attributed it to the existence of a direct arteriovenous fistula in the donor twin's vascular bed. Only once or twice before have such *direct* AV connections been reported to exist in singletons. They are clearly exceptional. As mentioned earlier, TTTS can occur in triplet or higher number gestations as well. That they are also accessible to fetoscopic ablation was detailed by Sepulveda et al. (2005).

This chapter is not the place to review in detail the ultimate outcome of twin pregnancies. One aspect, nevertheless, is noteworthy. Because monozygosity largely eliminates genetic effects, the transfusion syndrome has served as a model to analyze aspects of the etiology of mental retardation. Several investigators have found that the smaller of MZ twins has a slightly lower IQ than the larger twin (Kaelber & Pugh, 1969; Hohenauer, 1971; Babson & Phillips, 1973). The larger the twins' size difference was at birth, the greater were the effects. Record et al. (1970) did not confirm these results using the data from the Birmingham Twin Study; they pointed out that the differences are postnatal in origin, rather than due to monozygosity and placentation. Likewise, Fujikura and Froehlich (1974) and Buckler and Robinson (1974) studied the postnatal equilibration of MZ twins who had been born with marked natal differences. They found only "negligible differences in . . . intelligence and educational attainment." The complexity of the problem is exemplified by reanalyses of the various data published by Munsinger (1977) and his critic Kamin (1978). The former believed that prenatal influences can be shown to have this deleterious effect; the latter did not. Both affirmed that future studies of this vexing question must include placental data. Denbow and colleagues (1998) found CNS damage in both the donor and recipient of the TTTS and called for more detailed follow-up studies as well. The criticism of former studies is echoed by O'Brien and Hay (1987) in an incisive analysis. These authors found differences when male co-twin development was compared with that of female co-twins. They also studied the effect of placentation on handedness. Left-handedness is known to be more frequent in "birth-stressed" individuals, and it may be for that reason that left-handedness is more frequent among twins (Coren, 1994). A good example of left/right-handedness of MZ twins is shown by Frothingham (1997/8) in twins, one of whom suffered adrenal insufficiency, but the twins were also

opposite-handed and cut their hair on opposite sides. This topic, however, is most complex as was decisively reviewed by McManus (2002) in an excellent book.

## Acardiac Twins

Acardiac twins are the most severely malformed fetuses that one can imagine. They range from small, teratoma-like masses to large fetuses with a great variety of anomalies. The absence of a heart is not obligatory to the diagnosis of this entity, as a severely malformed heart is occasionally present. Schatz has used the terms *hemicaudia* and *hemiacardius* to referred to these twins, but Frutiger (1969) pointed out that these terms are incorrect. He proposed the term **pseudoacardius** for those cases in which remnants of cardiac structures are found. A wide variety of names have been applied to this spectrum of acardiac fetuses; a veritable taxonomy was created, as in Schwalbe's and Schatz's writings. The most comprehensive treatise that encompasses all these attributes is the seminal book of Schatz (1898), who made the major contribution to our understanding of acardiaks. A total of 88 cases from Japan were summarized by Sato et al. (1984), and we have reviewed 49 acardiac pregnancies (Moore et al., 1990).

A human acardiac fetus is one of MZ twins or higher multiple births whose development is severely disturbed, and who usually has no cardiac remnants. There is good evidence that acardiaks are more common in higher multiple births than in twins (James, 1977b). That an acardiac can develop at all is due to the presence of two anastomoses in the monochorial placenta. An AA anastomosis brings blood from an usually normal co-twin to the "monster," and a VV anastomosis returns the blood. The normal twin provides the cardiac flow to the monster but in a reversed fashion. The reversal of blood flow has been

proved to exist with the use of Doppler sonography (Pretorius et al., 1988b; Zucchini et al., 1993; Quintero et al., 1994; Coulam, 1996). One interesting exception to the nature of the twin placenta has been published by French et al. (1998), who found a typical acardiac amorphous with anastomoses to a normal twin in a verified DiDi placenta and determined by genetic studies that the twins were monozygotic as well. This challenges our understanding of how the chorionic vascularization in early placentation is accomplished. Schatz observed that the frequent presence of omphaloceles in acardiaks is an important obstruction to venous return, and he believed in an etiologic role. Later studies have not borne out this finding, as many acardiaks lack an omphalocele. Schatz believed that this kind of obstruction could be the cause of many such anomalous infants. We believe that the presence of the two types of placental anastomoses is the fundamental cause of the acardiac dysmorphism and it is just possible that an absent Hyrtl anastomosis contributes. Dichorionic (and DZ) human twins cannot develop into acardiaks as they lack the placental communications, but very rare exceptions have been recorded in which the two placentas have vascular fusions. No blood would be circulated through fetal vessels if a spontaneous acardia were to exist in a DiDi twin, and such an embryo would vanish early. The fact, however, that such placental communications do exist among many fraternal (DZ) twins of some other species was already recognized by Schatz, who discussed the acardiaks found in ruminants and carnivores.

The wide spectrum of the appearance of acardiaks that one can observe is illustrated in Figures 25.81 to 25.85. One of these fetuses had the appearance of a teratoma, turned inside out (see also Jamal, 1999), another had remnants of a face and arms, and the third is unusual in that it had an exceptionally long umbilical cord. Despite

FIGURE 25.81. Acardiac twin, having the appearance of a teratoma. The normal twin was 2910g, the acardiac ("holoacardius amorphous") weighed 40g, had a diminutive cord, and was in a MoMo placenta with large anastomoses. (Courtesy of the late Dr. N.J. Eastman, Baltimore, Maryland.)

FIGURE 25.82. Well-formed 1210-g male acardiac delivered at 28 weeks. Co-twin died neonatally and had aortic hypoplasia. The acardiac had a skull, remnants of brain, a small spinal cord, and many other organ remnants. (Courtesy of Dr. J.D. Wilkes, New York, New York.)

the absence of any cerebral structures, the last-mentioned acardiac was sonographically witnessed to move actively. Also well shown in this fetus was the plethora, frequently observed in acardiacs. We believe it represents stagnation of blood, transfused by the pale, normal co-twin. The increased resistance to perfusion has been demonstrated by prenatal Doppler velocimetry (Sherer et al., 1989). The fetal mobility of an acardiac may be so great on occasion that they die because of cord entanglement (Fig. 25.84). In all of the twins shown, the placenta was MoMo but many others have been described with a DiMo placenta. In such cases, there is usually amnion nodosum of the acardiac's cavity because of its deficient or absent urine production. Sonographic examination of such cases then discovers a "stuck twin." Among the 30 acardiac twin pregnancies we studied and that had enough infor-

mation, DiMo placentation was found in 22 cases and MoMo in eight cases (Moore et al., 1990).

Dissection of the fetuses shows many gradations, ranging from a total absence of most organs to well-differentiated structures of others, including gonads. Only liver tissue has never been observed by us. Schatz has written of the same experience. More recently, however, Giménez-Scherer and Davies (2003) demonstrated some liver tissue (with degenerative changes) in three of 18 acardiac fetuses they dissected. Upper limb anomalies were the most prominent findings. Driggers et al. (2002) found a small liver in an interesting acardiac anomaly. It was extremely hydropic and possessed a "severely malformed, almost nonexistent heart." They suggested that at one time in early gestation there had been a TTTS but, because of the cardiac anomaly, twin reversed arterial perfusion (TRAP) developed and caused the edema and other abnormalities. This is a novel way of interpreting the genesis of these complex anomalous twins. A female sex preponderance of acardiacs has been noted by James (1977b). For the study of acardiacs, it is usually best to

FIGURE 25.83. Exsanguinated premature MoMo twin with plethoric acardiac fetus. This specimen is unusual because of the long umbilical cord. The fetus had been seen to move at sonography; it had no brain but a normal spinal cord.

FIGURE 25.84. Macerated MoMo twins, one an acardiac (150 and 20g). The twins died because of entangling of cords. Note the single umbilical artery of the cord and large AA and VV anastomoses. The acardiac had a remnant of heart with calcification in the remaining muscle fibers. H&E  $\times 160$ . (Courtesy of Dr. S. Kassel, Fresno, California.)

FIGURE 25.85. Unusual acardiac twin whose abdominal contents were embedded on the placental surface (Emery et al., 2004).

FIGURE 25.86. Acardiac quintuplet in monochorial placenta with five amniotic sacs (bottom right). Note its plethora. Three yolk sacs were identified. (Source: Hamblen et al., 1937, with permission.)

obtain a radiograph of the specimen before dissection, as it gives some idea of the complexity of the abnormality, enables better classification, and delineates if a skull is present (Dicker et al., 1983; Bhatnagar et al., 1986).

Most acardiac fetuses have only a single umbilical artery. The absence of one umbilical artery, though, cannot be held responsible for the development of the anomaly because it is not invariable. In contrast to Schatz's ideas, an omphalocele has been absent in at least half of the cases we have seen. One of the few hemiacardiaks we dissected possessed a two-chambered heart (Benirschke, 1970a). This heart and that of another hemiacardiak exhibited endocardial fibrosis. The first twin shown here also had a fairly well formed head with a brain and a bilateral cleft palate. One of monochorionic quintuplets with five amnions was an acardiac fetus (Hamblen et al., 1937) (Fig. 25.86), and we described triplets with one acardiac in the previous edition of this book; many other triplets, one being an acardiac, are recorded in the literature (e.g., Sanjaghsaz et al., 1998). They may be MZ trip-

lets (Ross, 1951; Landy et al., 1988) or multizygotic (Stoeckel, 1945; Wylin, 1971; Kirkland, 1982). The acardiaks described by Amatuzio and Gorlin (1981) were conjoined and associated with a MoMo triplet in heart failure. Parenthetically it may be mentioned that some pregnancies complicated by an acardiac (as in fetus papyraceus, discussed earlier) have unexplained high levels of  $\alpha$ -feto-protein and acetylcholinesterase in their amniotic fluid (Winsor et al., 1987; Entezami et al., 1997). Kaplan (1994; see her Figs. 6 to 12) depicted monochorionic triplets, two of whom had the TTTS, and a third was acardiac.

One of the most remarkable specimens is that described by Fujikura and Wellings (1964) and shown in Figure 25.87. This malformed specimen was attached to the chorionic surface 1.5 cm from the insertion of the umbilical cord of a larger fetus. This more normal twin had amelia of the right arm, phocomelia of the right leg, hydrocephaly, and myelomeningocele; his right umbilical artery was absent. The acardiac was described as a teratoma-like mass. Another description of what we consider to be more likely to have been an acardiac fetus rather than a teratoma is the case discussed by Sironi et al. (1994). We have previously expressed our reservation about chori-

FIGURE 25.87. Diminutive acardiac that was likened to a teratoma. It is 1.5 cm from the cord insertion of a malformed twin with single umbilical artery (SUA). Large vessels led to the mass. (Courtesy of Dr. T. Fujikura, Portland.)

onic teratomas and prefer to think of this specimen as acardiacs who lacked the development of a defined umbilical cord. The presence of a cord is usually a prerequisite for the diagnosis of "acardiac fetus" (e.g., Joseph & Vogt, 1973), although the length of umbilical cords of acardiacs varies from 0 cm as in Figure 25.81 (see also Frutiger, 1969) to 53 cm as in Figure 25.83. The "lack of organization," as emphasized by Fox and Butler-Manuel (1964) in a similar case, is not a strong argument that these masses are teratomas. Such disorganization occurs often in small "holoacardii amorphi" with good umbilical cords. Holoacardii amorphi are not true neoplasms ("teratomas"); they are part of the wide spectrum of acardiac twinning. Kreyberg (1958) reported a similar case and had the same opinion. The differential diagnosis (acardiac or teratoma) was further considered by Stephens et al. (1989), who reviewed 96 cases and presented an additional bovine acardiac fetus. It was their opinion that the presence or absence of an umbilical cord was insufficient evidence for diagnosis, and they relied more heavily on the finding of an axial skeleton. Emery et al. (2004) reported another most unusual case of acardiac twin in a MoMo gestation. Completely separated from the macerated acardiac was its intestinal content enclosed in a sac on the surface of the placenta (Fig. 25.85). It was conjectured that the phenomenon arose from a "detached" omphalocele. As stated earlier, Schatz had even suggested that the omphalocele was the cause of acardiac twin formation; thus this may not be so surprising after all. An excellent example of such large omphalocele was provided by Chmait and Hull (2001).

The **incidence** of acardiac pregnancies is difficult to ascertain, as most are not reported. Gillim and Hendricks (1953) estimated it to be 1 per 34,600 births, or approximately 1 in 100 MZ twin pregnancies. This finding agrees with that derived by Napolitani and Schreiber (1960). Bhatnagar et al. (1986) based their estimate of 1 per 48,000 births on data from a variety of studies. They admitted the probability of a gross underestimate and we agree with this, especially because the advent of ablation by various means of cord obliteration has led to a flood of publications. Most acardiacs are probably not reported in the literature. Well over 600 cases have been reported, and there are probably hundreds that go unpublished. Our own series now exceeds 50 cases, and many of these cases will remain undescribed.

Acardiacs often develop hydrops, and the pregnancy is thus frequently complicated by hydramnios. Hydropic acardiacs may then become much larger than the normal co-twin. The hydropic acardiac described by Pavlica (1967) was such a case. It weighed 2150 g, whereas the co-twin was only 850 g. It was further remarkable that its umbilical cord forked from that of the normal co-twin. Markavy and Scanlon (1978) described additional hydropic acardiacs with hydramnios and considered that

this problem may result from hypoproteinemia. They also observed thrombosis of one umbilical artery in one of these acardiac fetuses.

Because the hydramnios may be severe and the large acardiac may present problems with dystocia (Loughead & Halbert, 1969), Platt et al. (1983) proposed that a ligature be placed around its umbilical cord through an amnioscope. Simpson et al. (1983) were successful in treating a pregnancy with a hydropic acardiac by digitalization. The mechanism of hydramnios and congestive heart failure is complex. It is likely related to the size of the acardiac fetus, but suggestions in the literature allude to a correlation with the presence of renal tissue in the acardiac (Moore et al., 1990). Prospective studies, with ascertainment of urination by the acardiac, are needed. Sullivan et al. (2003) recommended a conservative approach to the treatment. Nevertheless, they lost one "pump" twin of the 10 cases studied.

Another way of treating an acardiac pregnancy is by selective removal of the anomalous twin. Intervention in acardiac pregnancies has been advocated by Healey (1994), who reviewed the outcome of 184 such gestations. He found that 35% of the "pump" twins died (45% in triplets), mainly from prematurity. He also ascertained other risk factors associated with acardiac gestations, such as SUA and MoMo placentation. Selective removal of the acardiac has been successfully accomplished by Robie et al. (1989), who removed a sonographically identified acardiac fetus at 22.5 weeks' gestation that weighed 710 g. A normal twin was subsequently delivered at 33 weeks' gestation. Ash and colleagues (1990) successfully managed such a pregnancy with indomethacin. It led to marked reduction of amniotic fluid volume so that a normal fetus (and 785-g acardiac) were delivered at 34 weeks. Porreco et al. (1991) occluded the umbilical artery of an acardiac fetus in utero with a metal coil. It stopped the reversed flow and led to normal delivery at 39 weeks. Rodeck et al. (1998) successfully thermocoagulated identified connecting vessels in four acardiac gestations. The short cords of most acardiacs was one reason for choosing this new methodology of therapy. McCurdy et al. (1993) endoscopically attempted to ligate the umbilical cord of an acardiac fetus at 18 weeks. Both twins died. Quintero et al. (1994) succeeded with ligating the umbilical cord near mid-gestation through a fetoscopic approach and salvaged the normal twin. The acardiac weighed 31 g at birth. Johnson et al. (2001) provided evidence that the cord can be effectively obliterated by bipolar cauterization in acardiacs as well as the TTTS (Taylor et al., 2002), and Porreco (2004) used percutaneous sonographically guided injection of alcohol successfully. In a DiMo twin with one twin having Turner's syndrome, Tsao et al. (2002) and Shevell et al. (2004) used radiofrequency obliteration of cord vessels successfully. Tan and Sepulveda (2003) reviewed the outcome of 74 acardiac twin pregnancies

that were treated by different, minimally invasive methods. These included alcohol injection, monopolar diathermy, and interstitial laser and radiofrequency ablations. Their conclusion was that "intrafetal ablation is the treatment of choice . . . because it is simpler, safer and more effective when compared with the cord occlusion techniques." Selective removal of an acardiac fetus was undertaken at 23 weeks after her death in utero by Ginsberg et al. (1992), with the normal twin proceeding normally to 39 weeks. Interestingly, the two cords branched one from another at their marginal insertion on the placenta and both fetuses as well as normal members of the family had a chromosomal inversion [46,XX,inv(10)(p12q25)]. Wenstrom (1993) felt that elective removal of this acardiac was unnecessary. Chitkara et al. (1989) reported on selective termination of 17 anomalous twins, 14 of which were aneuploid, but not acardiac fetuses. They emphasized the need for operator skill in this procedure, and had much better success later on in their series. Intracardiac injection of potassium chloride was the most effective means to accomplish the feticide. Neither the mothers nor the surviving twins suffered DIC. Other cases were reviewed by Donnenfeld and his colleagues (1989). They attempted to ascertain the presence of inter-twin anastomoses by prenatal angiography because of hydrocephaly in one twin. Complications led to fetal death and exsanguination of the normal twin into the abnormal fetus. Large AA anastomoses were found in the monochorionic placenta. Holzgreve and his colleagues (1994) injected through a spinal needle multiple pieces of ethanol-soaked suture material into the umbilical cord of an acardiac, with immediate cessation of blood flow. Hydramnios disappeared and a healthy twin was born. Sepulveda et al. (1995) succeeded by injecting alcohol into the abdominal portion of the umbilical artery at 23 weeks' gestation. Again, hydramnios and heart failure abated promptly. Foley et al. (1995) ligated the umbilical cord of an acardiac fetus with a special device, followed by rapid resolution of hydramnios. These results all support the notion that hydramnios in such pregnancies results from cardiac failure of the "pump" twin. It was therefore of interest to Martinez-Poyer et al. (1997) to follow the redistribution of blood in the survivor after cord ligation in five sets of twins (four pump twins survived), done by Doppler flow studies. They concluded that ligation was not associated with an increased impedance to the blood flow of the survivor, although a significant influence on venous flow was seen. Coincidentally, in several of these reports normal karyotypes were observed. Arias et al. (1998) successfully used endoscopic laser coagulation to stop the reversed perfusion.

Another acardiac fetus with forked cord ("funiculopagus") has been described by Averback and Wigglesworth (1978), who also reviewed the literature of this uncommon event. Their acardius was in a separate amnionic sac and

was rather well developed. The umbilical arteries, derived from the umbilical cords that had joined close to the placental surface, fused and provided a completely common circulation. It is interesting that this could occur at all because of the presence of umbilical cord furcation, and in a DiMo placenta. When we ascertained the frequency of SUA in acardiacs, we found that SUA occurred 16 times in 29 cases; 13 had normal cords. Of 27 normal co-twins, four had SUA and 23 were normal (Moore et al., 1990).

Not only are the acardiac twins malformed, but many of the co-twins also have congenital anomalies. Schinzel et al. (1979) suggested that about 10% of the co-twins are malformed. It is important to note that, with one possible exception, the sex of human acardiacs has been the same as that of the co-twin, providing it was accurately ascertained by, at least, a sex chromatin study (Benirschke, 1959), morphologic identification of gonads (Kappelman, 1944), or cytogenetic analysis. Only Buxbaum and Wachsmann (1938) described an aberrant case, that of a female twin with an apparently male acardiac co-twin. The sex of the latter was assessed by finding "a structure that closely resembled a penis." That this finding is insufficient evidence for its male gender has been demonstrated to us. We saw an acardiac with a sonographically identified penile structure that was subsequently delivered with a normal female co-twin. On dissection, this penile structure was an enlarged clitoris, and normal ovaries were present. The reason for the clitoral enlargement remained obscure. C. Kaplan (in letters) found an anomalous pump twin with encephalocele, including imperforate anus, an absent kidney, and many other anomalies in 46,XY twins. The acardiac had a single-chambered heart and SUA. Baldwin (1993) has made similar observations.

The most controversial aspect of acardiacs is their pathogenesis and etiology. Frutiger (1969), who described five acardiac cases, believed that the absence of the heart was secondary to the acardiac suffering a deficient oxygen and nutrient supply, a suggestion that had previously been made popular by Loeschke (1948). He had the idea that the acardiac twin suffered malnutrition and hypoxia because it developed in the decidua capsularis, which, however, is clearly often not the case. Alderman (1973) challenged this notion and proposed a "primary failure of organ development." Köhn (1953) and Dahm (1955) also favored primary developmental problems. They suggested that "pathologic division" of the embryo and perhaps extraneous factors were responsible for acardiac development. They entertained the possibility of heritable causes. Gruenwald (1942) described a young, partially duplicated human embryo that might well have become an acardiac twin. He considered the two principal and opposing theories: (1) primary maldevelopment, and (2) vascular reversal leading to suppression of cardiac development. His statement, "an anomaly, anatomical or functional, intra-embryonic or extraembryonic, may turn one twin into an

acardius if its circulation becomes dependent on that of the other embryo," probably best reflects our current thinking about the nature of these monsters. Lachman et al. (1980) have also presented reasonable theories of etiology in their discussion of a relevant case.

That vascular reversal nourishes the acardiac is without question. Much of the failure of organ systems to develop at all, or to do so in a diminutive fashion, is due to a deficient circulation. The circulating blood not only is deoxygenated but also arrives at a reduced pressure. The fact that the lower limbs of acardiaks are usually better formed than the arms has been considered to result from preferential perfusion of the legs as they are closest to the incoming reversed arterial flow. The fact that the central nervous tissue is often reasonably well developed contradicts some notions that unimpaired neural development guarantees limb development, an area that has been summarized by Boulgakow (1926).

An important etiologic consideration for the development of acardiaks is that these anomalies may occur in one of dizygotic twins of certain animals. Some species, in contrast to human twins, share anastomoses between fraternal twins. This situation is best known from the freemartin condition of cattle (Lillie, 1917). Here, the male twin is responsible for atrophy of the female genitalia of the co-twin, with which he is vascularly connected, the basis of freemartinism. These connections also lead to permanent blood chimerism. Similar anastomoses are regularly present in the twins of marmosets and tamarins (Benirschke et al., 1962). In these species, however, sexual disturbances

do not occur. Schatz (1898) had remarked that there are many ruminant acardiaks. Occasionally, they are found in carnivores but not in horses. Figure 25.88 shows a bovine acardiac monster, and such a twin from a goat is seen in Figure 25.89. Table 25.5 summarizes some of the literature of animal acardiaks. They are a crucial component in the consideration of the genesis of these anomalies. One may speculate that these fraternal twins were originally normal but that, because of happenstance chorionic anastomoses, they became anomalous by virtue of circulatory reversal. This speculation is supported by the hypothesis of original normality, first enunciated by Claudius (1859) and later by Ahlfeld (1879). Schwalbe (1907) sided with Schatz, in that he assumed a primary inequality of the twins, and that secondary alterations (macrocardia, microcardia, SUA, omphalocele) determine its ultimate outcome.

Evidence for a primary anomaly of at least some acardiaks has been gathered from cytogenetic studies. In a few acardiac monsters, investigators have found abnormal karyotypes that were different from those of the co-twin. Other acardiaks have had normal chromosomal complements identical with those of the normal co-twin, as in the example shown in Figure 25.90. These interesting findings are summarized in Table 25.6. One must caution, however, that only those studies in which the chromosome analysis was undertaken from the solid tissues of the acardiac specimens can be considered valid. The lymphocyte populations would be admixed a priori, and thus their karyotypic analysis is not helpful. Moreover, it is known that the lymphocyte contribution of the acardiac,

who also usually lacks a thymus, may be minimal (Nigro, 1977). Therefore, the new molecular studies by Fisk et al. (1996) are of importance. These authors studied the DNA of placental and fetal solid tissues in acardiacs and their placentas, to find evidence of the monozygotic derivation of these unusual gestational products. Finally it is of interest that at least two "normal" co-twins of acardiacs have had an abnormal chromosomal constitution (Table 25.6). Thus, the cytogenetic picture is complex and does not lend itself to a resolution of the question of which event is primary in the etiology of acardiacs. Acardiac twins may be observed at young gestations and then already

have all the characteristic stigmata (Fig. 25.91). We have concluded that, whatever happens to their anatomic development, it is an early process. Our own concept is that the reversal of circulations is the cause of the anomaly.

The characteristic vascular arrangement pertaining to most acardiacs is illustrated in Figure 25.92. It mirrors many descriptions of former authors. The term TRAP has been applied to this syndrome (Van Allen et al., 1983). In this paper, which presents 14 acardiac cases, the spectrum of anomalies is well delineated. They described an additional specimen with chromosomal error. We have

FIGURE 25.91. A DiMo twin abortus at approximately 9 weeks' gestation. At left is a degenerating acardiac. Note that it has a large amniotic cavity.

recently karyotyped two new acardiaks and their co-twins and found both to have normal chromosome complements in solid tissues. An excellent review of the origin of acardiac twins and TRAP can be found by Malinowski and Wierzbka (1998). They also gave frequency figures for the various anomalies of acardiac fetuses. That acardiac fetuses may even have a more developed cephalic portion

was presented by Mohanty et al. (2000); likewise, Sergi and Schmitt (2000) presented an acardiac with microcephaly and discussed various CNS anomalies found in such cases. Petersen et al. (2001) even reported the relative normality of development in an edematous acardiac that was thought to have been dead sonographically.

## Conjoined Twins

Incompletely separated twins (conjoined, Siamese, x-pagi, double monsters) presumably take their origin after day 13 of embryogenesis. Because it has been most seriously questioned whether conjoined twins are one person or two, the reader is directed to the searching review of this topic by Gould (1982), who concluded that this question is not answerable, and perhaps it may even be an erroneous inquiry. The MZ twinning process is a continuum, and sharp divisions do not exist, as is often the case in biologic phenomena. It is even more problematic to make clear decisions as to the classification of whole-body chimerae, as we will see below. Moreover, the precise manner of the formation of conjoined twins is uncertain. Opposing views suggest incomplete splitting and partial fusion of embryonic precursors. The reader is referred to the searching reviews of over 1000 cases by Spencer (1992, 2000, 2003), who has clearly had the greatest experience with this topic. Spencer's special interest has been the embryologic development of conjoined twins, and she posits as her basic tenet that fusion (rather than incomplete splitting) is the principal mechanism of their formation. The reason for her view is primarily that many cases of conjoined twins cannot possibly be

FIGURE 25.92. Usual vascular relations (anastomoses) among an acardiac and co-twin.

explained by a fission event although she begins the evolution of conjoined twinning by assuming a primary MZ splitting event (see also the review by Kaufman, 2004). The reader is led to believe that, because the MZ twins are oriented on either an amnionic "bubble" or large yolk sac, their potential proximity leads to this fusion. It must be pointed out, though, that to the best of our knowledge, all conjoined twins have been of the same sex, which one might not expect if fusion were the principal mechanism. In another contribution, Spencer (2001) suggested that conjoined twins, fetus in fetu, parasitic twins, and acardiacs really form a spectrum and that the primary abnormality is a cardiac malformation; it is of further interest that she also supported the abundance of female conceptuses and that there is often a history of familial twinning. Another detailed study from the same author discusses the rare occurrence of rachipagous conjoined twins (Spencer, 1995). In addition, an encyclopedic review book was published by Quigley (2003) that addresses many of the ethical and social issues confronted by these twins; another book by Dreger (2004) is perhaps more directed to the lay public but it discusses some serious scientific issues. Even more provocative is the observation by Logroño et al. (1997). They reported a "heteropagous" conjoined twin with male pelvis and lower extremities attached to the chest of a male autosite and inferred from a fluorescent *in situ* hybridization (FISH) genetic study of the dizygosity of these joined parts. The autosite also had a cardiac anomaly, but the placenta was not described. The unequal craniopagi reported by Aquino et al. (1997) had two umbilical cords with velamentous insertion, one being diminutive and with a single artery. There were surface placental anastomoses. We have observed exactly the same features in one of the many acardiac pregnancies sent to us.

Most fused twins are joined at the chest (thoracopagus), but all sorts of unions have been described (Harper et al., 1980). Numerous triplets have included conjoined twins (Koontz et al., 1985; Seo et al., 1985; Gardeil et al., 1998). In triplets, the placentas may be monochorionic (Tan et al., 1971b), with the conjoiners living in their separate amnionic cavity, or they may be dichorionic (Vestergaard, 1972). We have observed term thoracopagus girls with a monochorionic (diamnionic) normal female co-twin. The umbilical cord to the conjoined triplets was split (two arms with artery and vein each) at the placental surface, which then joined to produce a cord with two arteries and two veins. Another of these rare diamnionic twin placentas with omphalopagus conjoined twins has been described by Weston and colleagues (1990). The typical placenta of conjoined twins, however, is a monoamnionic/monochorionic one. The former speculations that fusion of fraternal twins may be a mechanism of conjoint twinning is no longer tenable. For instance, chromosome studies of the twins have

always been identical (Kreutner et al., 1963; Kim et al., 1971). In one case, the twins and their mother had a pericentric inversion of one chromosome 9 (Delprado & Baird, 1984) and all have been of the same sex. Mackenzie et al. (2002) studied the natural history of 14 conjoined twins diagnosed prenatally; the frequency of serious anomalies thus identified allows more definitive decision regarding potential viability. This is an important consideration for the possible future treatment of conjoined twins in whom perhaps survival of one is unlikely and where decisions of surgery are paramount. The intervention by the courts and the problems arising from this decision to seek its advice are highlighted in an excellent article by Annas (2001). Surprisingly, approximately 70% of conjoined twins are females (James, 1980). Burn et al. (1986) used this fact to support their hypothesis that unequal lyonization is associated with MoMo twinning. MacKenzie et al. (2004) have contributed another most unusual set of conjoined twins, a fetus with a partial twin joined on the abdomen, and differentiated it from TRAP sonographically. Incompletely separated twins have been described in a wide variety of species, for example, rat (Levinson, 1973; Mutinelli et al., 1992), swine (Selby et al., 1973), turtle (Szabuniewicz & McCrady, 1967; Lewis et al., 1992), and Cetacea (Kawamura, 1969; Kawamura & Kashita, 1971). We have seen several California king snakes, calves, kittens, and other animals with double heads. Even in plants this event occurs with some frequency (Ahmad et al., 1977) (see also Fig. 25.93) and is there referred to as fasciation. It is remarkable and not yet fully understood why MZ bird twins have all been female. Conjoined chicken twins, described by Munro (1965), shared the single yolk sac.

Conjoined twins occur in approximately 1 of 50,000 births (Schmidt et al., 1981), or in 1 of 600 twins. The figures vary substantially among surveys (Tan et al., 1971a; Bankole et al., 1972; Harper et al., 1980; Castilla et al., 1988). They are reported to be much higher in the Japanese population (Miyabara et al., 1973). Reports have also indicated that this anomaly occurs more commonly in Nigeria, and Bhattay et al. (1975) suggested a much higher rate to exist in South Africa. This statement, however, has been criticized by Hanson (1975). Difficulty of ascertainment is further discussed by Viljoen et al. (1983) in a large series of conjoined twins from Southern Africa; contrary to earlier reports, these authors found no skewing in favor of the black population. Milham (1966) analyzed 22 sets and suggested local clustering of this anomaly. That suggestion was supported by Viljoen et al. (1983). The ultrasonographic diagnosis of conjoined twins can now be made as early as at 8 weeks' gestation (Lam et al., 1997, 1998), and three-dimensional sonography is helpful in further diagnosis of their anomalies (Maymon et al., 1998). This is also important for the selective termination of such anomalous conceptuses.

FIGURE 25.93. Conjoined “twin” Transvaal daisy (*Gerbera jamesonii*). The stem is fused; the flowers, with their identical number of petals (55/55), are separate.

The **etiology** of conjoined twinning remains unknown. Sporadic reports have suggested that it is due to teratogen exposure (e.g., griseofulvin) (Rosa et al., 1987), and that its prevalence may include seasonal fluctuation. The relation of conjoined twinning to griseofulvin intake was disputed by the large data collected by Knudsen (1987), however. Ingalls (1969), who applied heat and hypoxia to zebra fish, was able to observe eight conjoined fish among 5000 specimens; he described an “epidemic” in trout. Ferm (1969, 1978) found four conjoined hamsters whose mothers were subjected to teratogens. When Kao et al. (1986) injected solutions of lithium chloride into a blastomere of 32-cell-stage *Xenopus* eggs, a second head developed. Wan et al. (1982) observed conjoined twins in 0.4% of Swiss-Webster mice and in 0.06% of triplets. Treatment with vincristine or other manipulations did not increase the yield. Whether these data are relevant to the human condition has not been decided. It is known, however, that conjoined twins frequently have other congenital anomalies, including cleft palate, anencephaly, and particularly congenital heart disease (Noonan, 1978; Marin-Padilla et al., 1981; Seo et al., 1985). Newman

(1931b) noted marked differences in the development of various structures. Finally, arguing against the notion that fusion is the principal mechanism of conjoined twinning, the complex case of Bannykh et al. (2001) (and other similar complex instances) needs to be reviewed. This (male) singleton had two sets of external genitalia, portions of bowel, meningocele and cardiac isomerism that can hardly be explained by a fusion event.

Keeler (1929) suggested that **mirror imagery** existed in 77% of conjoined twins, compared with 22% in monozygotic, separate twins. It must be cautioned, though, that situs inversus and mirroring are complex problems (see McManus, 2002). Torgersen (1949) identified it to occur in 0.01% of a large population of Norwegians studied by mass radiography. Its incidence paralleled that of twinning, and he found that it was “not much higher” in MZ twins and was “rare” in DZ twins. For further insight into situs inversus and related aspects, see Layton (1976) and McManus (2002). Hydramnios is said to occur in about half of conjoined twins (Wedberg et al., 1979). The frequencies of various types of conjoined twins has been given by Edmonds and Layde (1982), with thoracoomphalopagus (28%) being the commonest form.

The placenta of conjoined twins is usually a single disk with MoMo membranes. The structure of the umbilical cords, however, varies widely, approximately 6% having two cords (Spencer, 1992). This fact much supports her view of fusion. The umbilical cord in Figure 25.94 was

FIGURE 25.94. Thoracoabdominopagus twins with monoamniotic placenta and a single umbilical cord.

single and contained two arteries and a vein. It is similar to those described by Kreutner et al. (1963), de Leon (1974), and Itoh et al. (1974), who observed that the co-twins had a fused subdiaphragmatic aorta whence the umbilical arteries originated. Gilbert et al. (1972) and Tan et al. (1971b) described thoracopagi with one artery coming from one twin and the other from the second twin, who also received the single vein. The twins in Figure 25.95 had a single umbilical artery and a velamentous insertion of the umbilical cord. An SUA was also found in four of seven conjoined twins reported by Miyabara et al. (1973). Kim et al. (1971) described thoracopagi with a single cord that possessed six vessels—four arteries and two veins. Mitrani (1968) saw one conjoined set of twins with six arteries and two veins. In the cases reported by Seo et al. (1985), two placentas had single cords with four arteries and one vein, one had three arteries and two veins, and three had normal cords with two arteries and one vein. Two placentas, however, were separate disks; one of them had a fused cord. Delprado and Baird (1984) reported cephalothoracopagi with two cords. One was thick, ran in the membranes, and contained one artery and one vein; the smaller cord contained only one vessel. Another thoracopagus set of twins was reported

by Freedman et al. (1962). They had two separate cords that inserted 1.5 cm apart and fused 13 cm from the placental surface. The fused structure contained three arteries and two veins; the placenta was DiMo and contained a triplet of the same sex. Wiegenstein and Iozzo (1980) found two separated cords (11 cm apart) in a conjoined twin. The cords fused after having entangled in the placental portion and ran in a tented segment of amnion. A case with similarly fused, but separately originating cords was described with a dicephalus, dibrachius (Beischer & Fortune, 1968). In the thoracopagi examined by Marin-Padilla et al. (1981), the single cord split 9 cm before reaching the placental surface. One branch contained two arteries; the other cord had a velamentous insertion and contained the single vein. An interesting set of vessels was found in the umbilical cord of a thoracopagus studied by Chaurasia (1975). The smaller twin had a rudimentary heart, a large left and diminutive right umbilical artery, and no vein; the larger twin had a single large artery and vein. Reversal of circulation in the smaller twin was considered.

There is thus great variety in the spectrum of cord vasculature and structure, and no clear relations emerge as to the associated type of conjoined twin. One might expect that embryonic splitting at slightly different times produces different fusion anomalies and different cord structures and insertions. Future correlations may uncover these as yet unknown parameters. It is especially noteworthy that not all MoMo placentas of conjoined twins with two umbilical cords have vascular anastomoses on the placental surface. Finally, there exist anomalous fetuses with diminutive parasitic “twins” presenting as inclusions or appendages. They represent transitions to the next topic. Four such cases were described in some detail by Drut and colleagues (1992). Because they have no relation to placental pathology, they will not be discussed further.

FIGURE 25.95. Conjoined twins (ischiopagi) with a MoMo placenta, a single velamentous umbilical cord, and SUA. They were delivered at 40 weeks' gestation. One had a cleft face and microcardia. There were two female genital tracts. (Courtesy of Dr. S. Sekiya, Tokyo, Japan.)

## Sacrococcygeal Teratoma and Epignathus

Sacrococcygeal teratoma and epignathus are, in our opinion, malformed twins that represent a part of the spectrum of the monozygotic twinning continuum, and Spencer (2001) has a similar opinion. Some may take exception to this concept; nevertheless, findings of perfectly formed extremities, digits, and other structures favor this view. These are occasionally combined with more disorganized tumors (Cousins et al., 1980; Tokunaga et al., 1986). Schwalbe (1907) and Willis (1958) extensively discussed this aspect with illustrative material that also supports this notion. Exelby (1972) reviewed the origin and therapy of these tumors and found them to be

FIGURE 25.96. Villi of immature placenta in a patient with a large sacrococcygeal teratoma. Placenta weighed 880 g at 31 weeks. The neonate died with extensive cerebral necroses. The villi are irregular and patchily edematous, and have distended fetal capillaries. There is focal hemorrhage, and numerous nucleated red blood cells are present. The cytotrophoblast is more prominent than expected at this age. H&E  $\times 160$ .

much commoner in females (4F:1 M); they also indicated that there is frequently a strong family history of twinning. In one parturient whose child had a large sacrococcygeal teratoma, an ovarian teratoma was found simultaneously (Rayburn & Barr, 1982). These authors emphasized that genetic study had shown that these neoplasms have different genetic backgrounds.

There are also frequent concurrent anomalies in children with these tumors. Most of the neoplasms are benign, which is different from the rare teratomas of other sites, in which prenatal metastases have been reported (Semchyshyn et al., 1982). At times, however, an apparently benign sacrococcygeal teratoma eventuates in a malignancy. Lack et al. (1993) found an eventually fatal adenocarcinoma in a man 40 years after a sacrococcygeal teratoma had been incompletely removed at age 2 months. An alternate etiologic point of view is that sacrococcygeal tumors and epignathi derive from misplaced germ cells. In a study of obstetrical complications with sacral tumors, Spitzer (1932) commented on the female sex preponderance and noted that the tumors are often complicated by hydramnios during pregnancy. That point has been reiterated in other publications about the prenatal diagnoses of these lesions (Horger & McCarter, 1979; Hallgrimsson, 1981).

Placentomegaly has often been described to be a complication of sacrococcygeal teratomas (Cousins et al., 1980; Gergely et al., 1980; Kohga et al., 1980; Feige et al., 1982). The same is true of the placenta in epignathi (Kaplan et al., 1980; Chervenak et al., 1985), and yet other teratomas may be associated with hydramnios and fetal hydrops (Rosenfeld et al., 1979; Banfield et al., 1980; Semchyshyn et al., 1982; Mostoufi-Zadeh et al., 1985). The placental enlargement may be striking, and it is then usually exceptionally pale. There is severe edema of villi, which often appear to be excessively cellular, contain numerous Hofbauer cells, and are severely congested

(Fig. 25.96). One often finds numerous nucleated red blood cells in the fetal placental vessels. Ultrastructural examination of such specimens was first undertaken by Arai et al. (1977; see also Soma et al., 1979). It showed marked alterations of the syncytium, with distention of the transport vesicles (Fig. 25.97), and unusually dense mitochondria. We believe that placental enlargement is the result of high output failure of the fetus and that it is similar to that found with large chorangiomas. This concept finds confirmation in the frequently present fetal cardiac enlargement. In effect, the teratoma acts as an arteriovenous fistula. This is further supported by the experience of Langer et al. (1989). They resected one of the tumors at 24 weeks and returned the fetus to the uterus (of three cases described). Hydrops improved and Doppler study showed a decrease in cardiac output. Nakayama et al. (1991) made similar observations when they resected the tumor in a newborn. Feige et al. (1982)

FIGURE 25.97. Ultrastructural view of villi in a sacrococcygeal teratoma, showing hugely distended syncytial transport vesicles. Data: 28 weeks' gestation, hydramnios; elevated human chorionic gonadotropin (hCG) levels (9,830,400 IU/L), 680 g placenta.  $\times 5600$ . NU, nucleus; rER, rough endoplasmic reticulum. unreasonably claimed that the placentomegaly represents an attempt by the placenta to compensate for the increased needs of the fetal tumor. Whenever karyotypic analysis has been done, the chromosomes of the tumors have been normal and identical to those of the host (Kaplan et al., 1979; Cousins et al., 1980). An interesting question remains regarding the “hairy polyp” removed from the throat of occasional patients (Isaacs, 2002). Should it be regarded as an epignathus or teratoma? We have seen such an anomaly in a newborn with respiratory distress. The polyp impinged upon the defective soft palate. After removal, it was found to have a lanugo-covered skin and, internally, it was composed of fat, cartilage, nerve, and skin remnants.

## CONGENITAL ANOMALIES

Twins have congenital anomalies more often than do singletons. Hendricks (1966) evaluated the outcome of 438 multiple pregnancies and found not only that their perinatal mortality rate is “startlingly high” (14%) but also that anomalies occurred with a frequency of 10.6% (approximately three times that of singletons). In a review of anomalies of Swedish twins, Källén (1986) noted that some anomalies (posthemorrhagic hydrocephaly?, patent ductus) are undoubtedly an effect of the prematurity of many twins. Other anomalies, notably those referred to as the VACTERL association [vertebral, anal, cardiac, tracheal, esophageal, renal, and limb anomalies, a variant of the VATER (vertebral, anal, tracheal, esophageal, and renal) association] and anencephaly were overrepresented in twins. A new international study of malformations in twins was authored by Mastroiacovo et al. (1999). Of 260,865 twins, 5572 malformations were identified, affecting virtually all organ systems. The associations previously already known to exist were confirmed, although higher rates were found. James (1976) found that anencephaly occurs in DZ twins with the same frequency as in singletons, but that its incidence is increased in one or both of MZ twins. When it occurs in dichorionic twins, expectant management is advocated (Lipitz et al. (1995), although hydramnios may occur. In contrast, when it is found in monochorionic twins, “expectant management is associated with a high rate of intrauterine lethality of the normal twin” (Sebire et al., 1997a). Of 11 such pregnancies, these authors observed fetal demise of both twins in three pregnancies.

Schinzal et al. (1979) studied the structural defects of MZ twins in greater detail. They considered that some of these anomalies are related to the MZ twinning process per se. This concept is certainly true for the acardiacs, the conjoined twins, and probably also for those defects that arise as the result of vascular anastomoses (e.g., porencephaly, intestinal occlusions). When twin abortuses were studied, it was found that the incidence of twinning, particularly MZ twinning, is much higher than expected (1 in 35 abortions). The rate of associated anomalies was not significantly different from the rate in the total population (Livingston & Poland, 1980). Livingston and Poland (1980) found that 35 of 53 pairs were monochorionic MZ, two were opposite sex (DZ), and 16 were same sex and dichorionic. Uchida et al. (1983) found seven of 15 to be opposite sex. In other situations, MZ twins apparently react differently to environmental teratogens, as was the case of the MoMo twins of Reitnauer et al. (1997).

A striking increase in twinning was found in infants with sirenomelia (symmelia). Usually, only one of the twins had that anomaly. Only rarely have both of MZ twins been concordantly affected by anomalies in general and symmelia in particular (Roberge, 1963). Davies et al. (1971) gathered 327 cases of sirenomelia from the literature and found that there is a 100-fold increase of this anomaly in MZ twins when compared with singletons. We have previously discussed how the

hypoplasia of sirenomelics' lungs, the Potter syndrome features, and amnion nodosum are prevented by the presence of the normal amniotic environment, guaranteed by a normal co-twin. This idea is beautifully demonstrated in the case described by Kohler (1972), and McNamara et al. (1995) added two more cases. Klinger et al. (1997) found additional support for this idea. They reported absence of “Potter” features in a MoMo twin with absent kidneys, genitalia, anal atresia, and SUA. Kapur et al. (1991) described sirenomelia in one twin, the other (dichorionic) having vanished.

Discordance for major anomalies in MZ twins seems to be the unexplained rule rather than the exception. It has been the topic of numerous publications (e.g., Fogel et al., 1965; Benirschke & Masliah, 2001). Machin (1996) has summarized all known or hypothesized facts and theories of such unusual cases. Imaizumi (1989a) found that concordance of congenital hydrocephalus in Japan was only 15% for all twins (21% in like-sex twins), but that the corresponding figures from the literature were 4.6% and 7.8%, respectively. They also saw two like-sex sets with anencephaly and hydrocephaly. Hernandez-Johnstone and Benirschke (1976) cited much of the relevant literature. This concept, however, has been considered to be a “tautology” (Boklage, 1987b). Boklage suggested that most surveys of anomalies in twins employ the Weinberg formula for the assignments of zygosity. We cannot agree with this statement. In numerous studies, the chorionic status was the method that decided the presence of MZ twins. Boklage was also critical of the concept that MZ twinning and anomalies are related processes; he favored the interpretation that, because such features as non-right-handedness and familial twinning are overrepresented in these anomalous twins, the relation between MZ twinning and anomalies does not hold. His concept was that many such twins derive from “polar body” fertilization, which he considered to be tertiary oocytes. That twinning and cardiovascular anomalies may have common origins was detailed in a large study by Berg et al. (1989). Most remarkably, Hamasaki et al. (1998) found discordance of the expression of the mutated prion that leads to Gerstmann-Sträussler-Scheinker disease in identical twins. Both had the mutation, but only one twin expressed the symptomatology.

In some cases, major disruptions of fetal structures can be explained by amniotic bands or adhesions of fetus to large sheets of amnion (Khudr & Benirschke, 1972; Donnenfeld et al., 1985). Boulout and colleagues (1990) proposed that the anencephaly-like anomaly they observed may have resulted from injury at “embryonic reduction.” It is of parenthetic interest to point out that the presence of placental anastomoses in DiMo twins, one being anencephalic, has served to better understand the regulation of fetal adrenal development (Kohler & MacDonald, 1972).

In most of these anomalies, there is no evidence of a genetic component. It is perhaps even more surprising to learn that anomalies with a strong genetic etiology, for example, cleft lip and cleft palate, are frequently discordant in MZ twins. Metrakos et al. (1958) reviewed 108 twin pairs and found the concordance in MZ twins to be 31%; in DZ twins it was 6.3%. These authors and others proved monozygosity for some pairs by means of exchange skin grafts. Discordance of facial clefts is unusually common in MZ twins. Their evidence and that from many other studies clearly indicates a familial disposition of cleft lip/palate. Murray et al. (2004) searched for gene abnormalities in twins discordant for clefts and detected none. They concluded that this “supports the hypothesis that non-etiological post-twinning mutations are rare.” Studies of twins for other defects (e.g., club foot, dislocated hip) have led to the concept of causation by “polygenic genetic predisposition interacting with additional unknown intrauterine environmental triggers” (Carter, 1968). This concept of a quasicontinuous variation or a threshold character with anomalies of multifactorial etiology (Fraser, 1970) is currently the best way to interpret these seemingly contradictory findings. It remains to be elucidated as to what the prenatal factors are that place the affected twin beyond the critical threshold. It could be adverse placentation (e.g., velamentous insertion of cord or SUA), as

FIGURE 25.98. Triplet fetus papyracei from assisted reproductive technology (ART) gestation. The triplet at right has an encephalocele that was not recognized macroscopically. The radiograph shows the value of taking x-rays of such fetuses.

we have championed, or it could be one of many, as yet undetermined, other factors. It may relate to unequal splitting. Too little is known of the placental conformation of most such twins to allow us to come to any definitive conclusion. More data must be collected on the precise placentation of twins with discordance for defects. The relative frequency of intestinal atresias reported may have a more direct relation to monochorionic twinning as they are overrepresented in like-sex twins. Perhaps it is caused by periods of hypotension, so-called vascular disruptions (Cragan et al., 1994). Discordance of twins, one with the Beckwith-Wiedemann syndrome (BWS), is definitely more frequent in monochorionic twins. In one relevant case that we observed there were calcified thrombi in superficial placental veins of both twins, aside from massive enlargement of the affected twin's umbilical cord. Other MZ twins with discordant BWS were reported by Weksberg et al. (2002), who suggested that this imprinting abnormality (on chromosome 11p13–15) perhaps predisposes to MZ twinning. Much other work on the imprinting abnormality in BWS and Angelman's syndrome has recently been conducted, and at least some findings suggest that there is a higher incidence when ART is performed for conception (Fig. 25.98) (DeBaun et al., 2003; Gicquel et al., 2003; Maher et al., 2003).

Two major reviews of discordant anomalies in twins were undertaken in an effort to delineate the prognosis of such gestations (Malone et al., 1996; Alexander et al., 1997). Both groups of authors came to the conclusion that this constellation significantly increases the risk of premature delivery. Malinowski and Biskup (1997) found two sets of monochorionic twins in whom the survivors had gastroschisis, and they related this anomaly to possible ischemia of the abdominal wall occurring at the time of fetal demise of their co-twins.

## Cytogenetics and Heterokaryotypic Monozygotic Twins

Twins may have the same chromosomal errors as singletons. Rohmer et al. (1971) described a set of DZ twins with Down syndrome and collected 200 cases of trisomy 21 in the twin literature. One of these twins was a pure trisomic; the other had a small, subsequently diminishing

population of trisomic cells; it had a normal phenotype. The authors speculated that blood chimerism might exist but were unable to verify it; the DiDi placenta contained no anastomoses. Most commonly, MZ twins are concordant for a particular aneuploidy (e.g., 48,XXXYY in Simpson et al., 1974). Mosaicism has been observed on occasion, as in the MZ twins with trisomy 21 described by Shapiro and Farnsworth (1972).

A number of unusual, so-called heterokaryotypic twins have been reported. They were monozygotic by various criteria, but their chromosome number differed. The list of these heterokaryotypic MZ twins reported has become so large that it is impractical to summarize all the reports here. Reasonably complete reviews may be found in the contributions by Dallapiccola et al. (1985) and Machin (1996). The former authors described a heterokaryotypic triplet and summarized, in table form, the 25 cases reported prior to their publication. Monteiro et al. (1998b) investigated the X-inactivation of the X chromosome in twin girls and found that different inactivation pattern occurred only in dichorionic twins. From a comparison of blood and buccal cell X-inactivation patterns they reason that splitting of the MZ twins occurs **after** the timing of this chromosomal inactivation, around day 4 (see also Goodship et al., 1996; Machin, 1996). Cantú et al. (1998) did an interesting study of the segregation of X-chromosomal variants of the fragile-X gene in a set of MZ triplets. The **paternal** gene was identical in all, but the **maternal** gene was different in all three triplets. This effectively eliminated their prior hypothesis of a single chromatid mutation **before** ovulation but also indicated that, despite physical similarity of these MZ triplets, their genetic disposition was different. The authors went so far as to state: "Genomically speaking, there are no identical twins."

The commonest chromosomal variant is discordance associated with the Turner syndrome. The 45,X genotype is prone to abort during early gestation. Of the relatively few survivors, most had mosaicism for cells composed of 45,X and 46,XX (or XY) genotypes. Mosaicism results from the simultaneous occurrence of twinning and somatic nondisjunction of chromosomes. If the Y chromosome of a 46,XY embryo is lost by nondisjunction during early development, male and female (45,X) MZ twins may be the outcome (e.g., Schmid et al., 2000; Wachtel et al., 2000). This formerly inexplicable situation, MZ twins of different sex, has in fact been recorded in several instances to have resulted in this fashion, as for instance by Gonsoulin et al. (1990a). The 45,X MZ twin of their report was additionally hydropic. Shevell et al. (2004) ablated such an abnormal MZ twin with 45,X by using radiofrequency obliteration of the umbilical cord. Investigators have more often documented MZ twins with various degrees and types of mosaicism, of X, XX, and XXX, or Y chromosomes. There is a wide spectrum. Kurosawa et al. (1992) have reported a set of MZ twins who were mosaic for two populations of cells, 45,X and 47,XYY, in lymphocytes and fibroblasts. One twin had a greater proportion of male-determining cells and had a male phenotype, and the other had a female phenotype. The fact that often both twins are mosaic may betray the influence of monochorionic placentation with anastomoses (when the mosaicism is confined to lymphocytes). Alternatively, when the fibroblasts of only one twin are mosaic or have a different complement from the karyotype of the co-twin, it may suggest the loss of one chromosome in one twin after splitting has occurred. Such is likely to have occurred in the two sets of mosaic monozygotic twins (45,X/46,XY) reported by Costa et al. (1998), who also reviewed the entire literature of this unusual phenomenon. Most of the placentas associated with this phenomenon have been DiMo, but an occasional twin has had a MoMo placenta. Precise studies of placenta and of lymphocyte, fibroblast, and chorionic karyotypes will enhance our knowledge as to the timing of this unusual event.

Prenatal diagnosis of such errors was once difficult because the intentional sampling of individual amniotic cavities was impractical. Young et al. (1974) introduced a feasible method to sample the individual cavities for the surveillance of Rh-sensitized pregnancies. It has now been reported to be successfully accomplished for 79%, 94%, and 98% of cases, respectively (Librach et al., 1984; Taylor et al., 1984; Tabsh et al., 1985). This methodology has not only allowed precise diagnosis but has led to fetal transfusions, now practiced routinely (Bowman, 1985; Pijpers et al., 1988). An alternative method for aspirating the two cavities was advocated by Jeanty et al. (1990). They were nearly uniformly successful but the possibility of destruction of the dividing membranes exists with this

technique. Selective feticide can then be undertaken when fetal trisomy is diagnosed by any of these techniques (Kerenyi & Chitkara, 1981; Chitkara et al., 1989; see also Donnenfeld et al., 1989). Pijpers et al. (1988) studied 83 pregnancies and obtained karyotypes of both twins in 77 cases (93%). They found elevated AFP levels (in both sacs) in two cases that were due to renal abnormalities. This finding suggested to them that AFP diffuses through the membranous partition. Unfortunately, the types of placenta present in these cases were not recorded. Franke and Estel (1978) had previously found that AFP permeates the membranes.

## Chimerism and Mosaicism

It is not uncommon in cytogenetic studies to identify cell lines with different chromosome number or different complements. This has most recently become a problem in amniocentesis and placental cell cultures. The latter aspects were considered in Chapter 21; here it is essential to make the differential diagnosis of mosaicism and chimerism. Whole-body chimerism may develop when, in very early stages of development, dizygotic twin embryos fuse to form a single individual. The resulting genetic chimera, a "whole-body chimera" is an individual composed of two populations of cells whose origin are two genetically completely different fertilization products. In addition to this mechanism, the possibility exists that two spermatozoa fertilize an ovum and a polar body, and that these structures then make up a single embryo. This second explanation is the mechanism that is favored by most investigators for the production of chimeras. Chimeras differ from mosaics and they should be clearly distinguished.

Mosaics are individuals composed of different cell lines but derived from a single embryonic precursor. Because of the process of "lyonization," all females are considered to be mosaics. Not only may mosaics have different cell lines with different chromosome numbers but, because of mutations, they may also have lines of cells with different phenotypic expression. An individual with cancer, for instance, could be a mosaic; one line of cells would be the normal body constituents, the other would be those cells that form the neoplasm. Healey et al. (2001) examined lyonization in MZ twins genetically and deduced from their findings of 20 discordant female twins that adult height was not correlated with different lyonization patterns. It is convenient and important to distinguish two pathogenetically different types of chimeras: (1) blood chimeras (also called "twin chimeras" by Tippet, 1984); and (2) whole-body chimeras ("dispermic chimeras").

**Blood chimeras** have been long been known to occur in cattle. In bovine fetuses the placentas often fuse, the fetal blood vessels join, and blood is exchanged between the embryonic twins. Because embryonic blood is largely

like bone marrow, there is seeding of the other twin's marrow space with genotypically different hematopoietic elements and lymphocytes. It results in a lifelong admixture because these cells are not rejected by the immunologically impotent embryo; the foreign cells are subsequently regarded as "self." When male and female bovine fetuses are thus joined, it is easy to identify clones of male lymphocytes in the female and vice versa. This phenomenon is restricted to motile hematopoietic system cells. The fixed tissue cells do not participate.

The fact that chimerism first was recognized in cattle results from the masculinization of the female twin in heterosexual bovine co-twins. The female becomes a "freemartin" (Lillie, 1917), an animal that has external masculinization, an absent uterus, atrophied ovaries, and female genotype. The degree of masculinization does not depend on the percentage of chimeric male hemopoietic cells (Herzog, 1969). Complex chimerism may be detected when triplets or quadruplets are thus admixed (Basrur et al., 1970). Although long known, the virilization of female artiodactyl twins has not yet been satisfactorily explained. Lillie (1917) and most subsequent investigators have assumed that it was the result of embryonic hormone action, secreted by the male gonads. Such an obvious hypothesis proved facile when it was discovered that marmoset monkeys of South America not only always have DZ twins but also regularly have fused placentas, and that they are all blood-chimeric. Although 50% are XX/XY chimeric, the females are not sterilized in analogy with the freemartin effect (Benirschke, 1971; Gengozian, 1971). Currently, no rational explanation exists for this discrepancy among species. One might speculate that there are differences in the müllerian inhibiting substance or the receptor because they are not subject to hormonal influences. We have always assumed that these are analogous in different taxa, but perhaps it is an error to make such an assumption. Niku et al. (2004) showed that among the hematopoietic precursors are some remarkably multipotent cells that are irregularly distributed throughout the body and that become especially prominent in granulation tissue. From the same laboratory comes evidence of the variable percentage of B and T cells. These systems are currently of particular interest as the role of circulating stem cells is central to our understanding of chimerism (Pessa-Morikawa et al., 2004). Freemartinism occurs in other artiodactyla, in birds, and in a few other species. We used to believe that some primitive germ cells might also travel through embryonic inter-twin anastomoses to take up residence in the opposite-sex host; findings by Gengozian et al. (1980), however, have made this unlikely. In addition, many investigations have addressed issues of immunologic tolerance in chimerism (Porter & Gengozian, 1969; Tippet, 1984).

In contrast to marmosets and cattle, anastomoses between DZ twin placentas of humans are rare indeed.

One dichorionic twin placenta with an anastomosis has been described by Cameron (1968) and is depicted in Figure 25.22. Genetic study of the twins, however, showed them to be MZ. Lage et al. (1989) presented a dichorionic twin placenta with anastomoses that was also accompanied by a mild form of the transfusion syndrome. The hematocrits of the twins were 43% and 59%, respectively. Molnar-Nadasdy and Altshuler (1996) saw a similar case at autopsy of macerated immature fetuses. The female stillborns possessed dichorionic dividing membranes (with velamentous cords) and had marked discrepancy in heart weights and coloration. Another unusual set of twins is that recorded by King et al. (1995). These presumably MZ twins had DiDi placentation, with ink-injection confirmed anastomoses. Although blood exchange had occurred, the typical TTTS was absent; one fetus had died with hydrocephaly before the other was aborted. More recently, Souter et al. (2003) reviewed the topic and presented a set of monochorionic, heterosexual twins conceived by IVF and who also had blood chimerism. The chimerism must have resulted from the "fine arterial-to-arterial anastomoses" that were identified by fluid injection. Redline (2003), who made editorial comments on the case, reviewed the development of twin embryos and also entertained the possibility that the IVF manipulation could have been a factor in the genesis of these unusual twins. As has been indicated earlier, the occurrence of monochorionic twins after IVF and embryo transfer is not uncommon now, and the dogma that monochorionic twins *must be* MZ twins is no longer tenable. To prove the existence of such unusual placentas, it is necessary that injection of the vessels be done. Therefore, another report, of anastomoses in a dichorionic twin placenta of twins with CMV infection, is more difficult to interpret (Foschini et al., 2003). The anastomotic arrangement was suggested only by stereomicroscopy of formalin-fixed placentas and described as being subchorial. Because there are generally never any subchorial anastomoses in any placenta, we reserve judgment on this case. More challenging still is the report by Quintero et al. (2003b) on a set of heterosexual twins with TTTS (unsuccessfully treated with laser ablation of AV anastomoses) and DiMo placenta; this is truly exceptional but points to the need for full genetic and pathologic study.

These cases are truly exceptional. In addition to these observations it must be recorded that spontaneous "blood chimerae" have been observed in a few other occasional human fraternal twins. They have had no sexual abnormalities and are like marmosets in that respect. When their *fixed* tissue has been studied, it was not found to be admixed. The chimerae, therefore, must have received the foreign clone of blood cells either through placental anastomoses or, less likely, transplacentally. Kadowaki et al. (1965) reported the transfer of maternal lymphocytes to the fetus. They described a phenotypically normal male

with XY/XX blood chimerism and apparent graft-versus-host rejection disease. Such transplacental exchange of lymphocytes, however, must be uncommon (Olding, 1972). Only on rare occasions have prospective studies shown minor transplacental lymphocyte chimerism. This transplacental traffic of cells was discussed in Chapter 17; it may affect singletons as well as twins and has recently been of great interest because the resulting microchimerism of blood and stem cells finds correlation with maternal autoimmune diseases (Johnson et al., 2001; Nelson, 2001; Srivatsa et al., 2001; Adams & Nelson, 2004).

The occurrence of blood chimerism in human DZ twins was first demonstrated by Dunsford et al. (1953). Since then, more than 30 cases have been described (Tippett, 1984). They are usually detected when blood group tests have peculiar results that necessitate full genetic investigation; it usually happens long after birth. The associated placenta of such a chimera has been fully studied only in the case of Nylander and Osunkoya (1970). Hartemann et al. (1963) suggested that placental study of twin placentas would more often identify anastomoses among fraternal twins. This has not been our experience, despite the fact that we have tried on many occasions to verify anastomoses among DiDi twins by the use of dye injections. Anastomoses that become apparent by radiographic examination of injected twin placentas and those discovered by corrosion casts made following plastics injection (Scipiades & Burg, 1930; Pérez et al., 1947), give unreliable results. Crookston et al. (1970) described the unusual and complex immunologic breakdown of tolerance that rarely occurs in such twins. On occasion, most unusual situations are encountered with chimerism; thus, O'Donnell et al. (2004) found blood chimerism for 47,XY and 47,XY+21 in a monochorionic set of twins that was naturally conceived. Genetic analysis revealed monozygosity; how the trisomy then developed in a DiMo placenta is a bit speculative. "Trisomy rescue" is often assumed but not easily compatible with a DiMo placentation.

## Whole-Body Chimerism

In whole-body chimeras, the entire body consists of cells with two or more genetic lineages that are derived from separate fertilization products. Most common among them is probably the fertilization of an ovum and a polar body by two spermatozoa, with the maternal contribution being similar. Such individuals represent, genetically speaking, fraternal twins fused into one body. They are not necessarily clinically manifest and may be fertile, even when XX and XY lineages coexist. The topic was discussed in great detail by Yu et al. (2002) because of the discovery of a fertile 46/XX/46,XX woman who was tested for transplantation antigen. It is accompanied by excellent drawings and discussion. Most total body chi-

merae, however, are discovered when the two populations of cells have different sex chromosomes (XX/XY), which frequently results in gonadal abnormalities, most common among which is true hermaphroditism (see also Kim et al., 2002). The diagnosis was initially made by amniocentesis in a detailed report by Lawce (1985). The male neonate was entirely normal and had an overall 48/98 XX/XY cell admixture. Remarkably, the ratio was 40:8 in placental membranes but 1:39 in placental tissue. Other cytogenetic errors with multiple karyotypes are also known (Moreno & Sánchez, 1971). Whole-body chimeras may also be discovered during routine blood grouping tests. Still others may be found because of unusual phenotypic features, such as heterochromia (eyes of different color). Some such cases may even possess "striping" of skin, or they may have abnormal patches of the skin, resulting from the irregular distribution of melanocyte precursors that are derived from different genotypes (Zuelzer et al., 1964; Corey et al., 1967). An especially striking case of chimerism was reported by Karam and Baker (2004). The neonate had a vertical pigment difference, right-sided male genitals, and left-sided female genitals, and was 46,XX/46,XY on karyotyping. This skin coloration is particularly obvious in the rare male tricolored (tortoiseshell) cats because the colors black and orange are allelic on the X chromosome in felines. Tricolored cats must all be female, or else they have chimerism (rarely are they endowed with 39,XXY chromosomes) as the basis for their abnormal coloration (Centerwall & Benirschke, 1975). It is thus important to clearly distinguish between mosaicism and chimerism, something often not duly considered in the literature. The placentas of these individuals never seem to have been examined but then there is no reason to believe that they would be unusual.

The question of how spontaneous whole-body chimerism originates is not yet completely answered. It is readily achieved experimentally by fusing morulae of experimental animals after their zonae pellucidae have been removed (Tarkowski, 1961). How this happens in vivo is speculative. The finding of diploid/triploid chimeras (e.g., Van de Berghe & Verresen, 1970) was taken as evidence that fertilization of a large polar body (common in mice) produced such abnormal individuals (dispermic chimeras). Other proposed mechanisms, such as secondary nondisjunction of whole haploid sets (Jenkins et al., 1971), are much less likely. De la Chapelle et al. (1974) suggested, as did other investigators, that early fusion of two embryos may be the way that whole-body chimeras are produced spontaneously, much as in the experimental model. This idea has subsequently been disputed because of the paucity of markers available. These concepts and the wide complexity of chimerism and hermaphroditism are topics of the review by Tippett (1984). Finally, an interesting true hermaphrodite (46,XX/46,XY) was

described by Strain et al. (1998). It resulted most likely from fusion of two early fertilized ova and was the result of IVF and implantation of three fertilized ova; a male singleton resulted in an inguinal hernia that contained an ovary tube and uterine horn. Whole-body chimerism was elegantly proved by DNA study, and the occurrence suggests that manipulation of early ova may have such undesirable result. Since that report, other cases of abnormal blastocyst behavior following IVF have been reported, especially the increased frequency of MZ twins among multiples, when smaller numbers of ova were transferred than babies born.

## Triplets and Higher Multiple Births

The frequency of spontaneously conceived higher multiple births is customarily estimated with the help of Hellin's rule, which was discussed earlier. Because of ovulation induction with hormones, many higher multiple births have occurred; nonatuplets hold the record, but they did not survive. Survival of septuplets was first observed in the U.S. in 1997, and surviving, prematurely delivered octatuplets were delivered in Houston in 1998. For reasons of widespread hormone usage in assisted reproduction, it is presently difficult to ascertain the real and spontaneous occurrence of higher multiple births in any population. Many excessive numbers are reported in the newspapers, and they are usually artificially induced. The patient who aborted the nonatuplets during the 12th week of pregnancy was not further described. Octuplets, born prematurely to a Mexican woman who had taken contraceptives until 8 months earlier, all died from complications of prematurity (Anonymous, 1967). The frequency of higher multiple births has increased significantly in recent years because of the practice of "assisted reproduction." Thus, Collins and Bleyl (1990) were able to summarize results of 71 quadruplet pregnancies. They advocated delivery by the 34th week of pregnancy because of the growth deficit occurring thereafter. Elliott and Radin (1992) reviewed their own 10 quadruplet pregnancies and made specific management recommendations. They had no bad outcomes, even though their gestations terminated at about 32.5 weeks. Interestingly, the older the mothers of quadruplets and quintuplets, the better were the outcomes (Salihu et al., 2004a). Kiely et al. (1992) surveyed the trends of higher-order multiple births from 1972 to 1989. There had occurred a 113% increase among white and a 22% increase among African-American mothers, with a 50% reduction in perinatal mortality. We have recently had surviving sextuplets (six chorions) at 28 weeks with three separated placentas on each anterior and posterior portions of the uterus. They were conceived after hormonal superovulation and survived. At the same time sextuplets were born at 32

weeks in Pennsylvania, also after hormonal medication usage.

When Allen (1960) applied the Weinberg formula to higher multiple offspring, he observed for triplets that the proportion of MZ/DZ/trizygotic (TZ) was 1:3:2 among African Americans, and 1:2:1 among whites; quadruplet whites were 2:6:5:4. In Japan, with different rates of multiple births, the ratios for triplets were more like 2.5:1:1, reflecting the lower DZ twinning rate of this genetically different population (Imaizumi & Inouye, 1980). The high DZ rate of Nigerians is reflected in their distribution of zygosity in triplets, approximately 1:4:6 (Nylander, 1971b). The frequent admixture of MZ and DZ twins in plural births is well reflected in their placentation. They may all be monochorionic or they have mono-, di-, and trichorionic placentation. Nylander and Corney (1971) found in the Yoruba population of triplets one monochorionic, 10 dichorionic, and 29 trichorionic specimens. Most other reports are of single gestations or are from smaller series than those collected by Nylander and Corney. Boyd and Hamilton (1970) had the following placentation in their eight triplet pregnancies: four monochorionic, three dichorionic, and one trichorionic. They were thus different from that in African women, which reflects the different causes of twinning in the populations studied. Not all dichorionic triplets are polyzygotic. Thus, the dichorionic triplets described by Komai and Fukuoka (1931) were shown to be monozygotic.

Triplets and higher plural births not only are smaller than expected for their gestational age (McKeown & Record, 1952) but also commonly deliver much earlier than twins or singletons. The perinatal mortality of 59 triplet pregnancies was 23% in the study of Itzkowicz (1979). This investigator emphasized that "cervical incompetence" was not a significant factor in their premature deliveries. Others (Gabos, 1972) reported that cervical failure may require surgical intervention in these higher multiple gestations. O'Sullivan (1968) even advocated it routinely in multiple pregnancies with hydramnios. Michlewitz et al. (1981) found a perinatal mortality of 13% past 20 weeks and 7% when 15 triplet pregnancies past 28 weeks were studied. A very large experience of the outcome of assisted reproduction from Norfolk (Seoud et al., 1992) found that there was the expected progressive increase of perinatal complications and prematurity with higher-order births. Keith et al. (2002) edited a book on all aspects of triplet deliveries.

Lipitz and his colleagues (1989) showed that the outcome of triplet pregnancies was improving. They studied 78 triplet pregnancies between 1975 and 1988, with 88% occurring after ovulation induction. Their finding was that elective cerclage neither improved fetal loss nor enhanced the length of gestation. Of the babies they were able to follow, 10.5% had severe neurologic handicaps. Some triplets have been delivered with long

time intervals. Simpson et al. (1984) had the first infant born at 23 weeks' gestation (neonatal death with 505 g weight, congenital infection), and 99 days later (with Shirodkar stitch, antibiotics, and isoxsuprine) a cesarean section was done at 37 weeks. One triplet was macerated, and the other lived (2580 g); the placenta was a fused TriTri organ. Cardwell et al. (1988) described the survival of one triplet, with the first being born at 23 weeks (hyaline membrane disease); the second was born 4 days later and died with hyaline membrane disease. The third triplet delivered 16 days after the first and survived. Chorioamnionitis complicated this pregnancy as it does in many plural pregnancies. A pregnancy with one triplet aborting during the 16th week of pregnancy and the other triplets surviving to delivery at 35 weeks was reported by Banchi (1984). The aborted triplet had a separate chorionic sac; the survivors had a DiMo placenta. A most remarkable case of triplets in a uterus didelphys was described by Mashiah et al. (1981). The clomiphene-induced pregnancy resulted in triplets: two in one horn and one in the other. One was found dead at 22 weeks; and at 27 weeks, uterine contractions expelled a macerated triplet from the right horn, but cesarean section was done to deliver its co-twin who later died. The left horn did not go into labor. At 37 weeks, a normal triplet was delivered by cesarean section. R. Gonen et al. (1990a) reported on five triplet gestations with fetal death of one or two fetuses. Four of these were monochorionic and delivery took place 30 ( $\pm 26$ ) days after the diagnosis of fetal death. Blickstein et al. (2003) found frequently large discrepancies in birth weight and implied "exhaustion of

fetal growth potential." Salihu et al. (2004b) compared survival of triplets in white and black populations, finding substantially higher mortality in the black population, being highest postnatally. Al-Kouatly et al. (2003) commented on the high frequency of thrombocytopenia in triplets and inferred that its commonest cause was pre-eclampsia. Luke et al. (2002) found that the outcome of 178 sets of triplets was most favorable when there was a prior gestation with good outcome, adequate weight gain, and greater length of gestation.

The various types of triplet placentations are shown in Figures 25.99 to 25.103. In addition to these three variants, the placentas of DiDi triplets may be separate. This is relatively uncommon, however, as the uterine surface area available for the implantation of multiple placentas is not large enough for them to remain separate. The liveborn monozygotic triplets whose placenta is shown in Figure 25.99 were monoamniotic and monochorionic (Sinykin, 1958). Triplet pregnancy does not always prevent entangling of cords when they are monoamniotic, as in the case shown in Figure 25.104, although entangling is less common in triplets than in twins. In this case, one anencephalic and a tiny acardiac fetus were associated with a normal triplet. All were aborted because of cord entanglements. Kohler and MacDonald (1972) reported triplets, one of whom was anencephalic and who had a normal DiMo co-twin. There was a normal separate chorionic triplet. The DiMo twins of the TriDi placenta shown in Figure 25.100 had suffered the typical transfusion syndrome, with A being the runted donor and B the recipient who died neonatally. All were females, with C represent-

FIGURE 25.99. A MoMo triplet term placenta, without entangling of cords but anastomoses among all circulations. The triplets survived. (Source: Sinykin, 1958, with permission.)

FIGURE 25.100. Triamnionic/dichorionic triplets, all females. A is the donor of the transfusion syndrome, and B is the recipient in a DiMo placenta. C has a separate amnion and chorion, and blood groups different from those of the twins. (Blood groups courtesy of Dr. F.H. Allen, New York, New York.)

FIGURE 25.101. Triamnionic/monochorionic triplet placenta at term. Many large anastomoses are present.

FIGURE 25.102. Triamnionic/trichorionic term placenta. There are no anastomoses and, despite intimate fusion, no blood chimerism. Note the velamentous cord insertion of No. 3.

FIGURE 25.103. Triamnionic/dichorionic triplet placenta at 36 weeks' gestation, all males. The diamnionic set of twins are at right with a single AV anastomosis from C to B. All survived. The slightly separated dichorionic placenta of triplet A (at left) has an area of circummargination at top, where the membranes of the right triplets pushed its membranes away.

FIGURE 25.104. A MoMo triplet placenta from a spontaneous abortion. Note the entangling of all umbilical cords. One was a normal fetus, and one an anencephalic; the small fetus, placed separately on the piece of paper, was an acardiac.

ing a separate zygote, as established by blood grouping (courtesy of Dr. F.H. Allen, New York, New York). Another TriDi set of triplets is seen in Figure 25.103.

It has long been known that an admixture of MZ and DZ multiple births is more common than would be expected by chance, but the reason is not clear. In addition to these examples, we have seen a DiMo triplet pregnancy abort with two monoamnionic pygopagous twins, a term DiMo triplet placenta with one set of thoracopagi, as well as a TriTri triplet pregnancy with two fetus papyracei, the other fetus coming to term and being normal. The prenatal death of the two fetuses may therein have been due to their velamentous cord insertions. A triplet pregnancy produced by IVF was reported in Chapter 6. Five ova had been transferred, three implanted, and one became a placenta percreta that had to be removed from its interstitial implantation during the second month of pregnancy. The two remaining fetuses were delivered by cesarean section near term, one having amniotic bands. We have witnessed yet another triplet placenta percreta. Thus plural pregnancies can present multiple problems with many anomalies of placentation alone.

It has often been asked how triplets or quintuplets (e.g., the famous Dionne quintuplets) can be MZ, as one might expect even numbers to result. Uneven numbers of monozygotic multiples may be explained by assuming that, on occasion, one embryo may not have survived or that “one division may set back development of the daughter products so that secondary division can occur at the same stage or even an earlier stage than did the primary division . . . or . . . three or more embryonic centers might arise simultaneously instead of two” (Allen, 1960). Allen presented a graphic demonstration of the genesis of multiple embryos, assuming binary divisions as

the principal *modus operandi*. Monochorionic, tetraamnionic quadruplet girls have been recorded by Steinman (1998); born by cesarean section, they weighed between 940 and 1440 g and did well.

Quadruplets and quintuplets have also become more common in recent years. Whereas in the past most had not been induced by hormone administration, such treatment is clearly now a factor. We have met a diabetic patient who had three sets of fraternal triplets and then a set of fraternal twins, and her uterus finally had to be removed when it ruptured with a quadruplet pregnancy. Sinclair (1940) depicted the QuaTri placenta of a set of surviving quadruplets. A similar placenta from three-egg quadruplets was described by Ryan and Wislocki (1954). Hamilton et al. (1959) reported the quadrichorial placenta depicted in Figure 25.105. They found in the 16 cases of the English-language literature that “every possible combination of ovulation had occurred except for double monozygous, often stated never to appear.” Diddle and Burford (1935), however, described just such a case in stillborns. Atlay and Pennington (1971) observed a quadruplet pregnancy after ovulation induction with pituitary gonadotropins. It was composed of a set of monoamnionic twins, the others all having their separate amnion, and they were of different sex. The 30 weeks’ gestation quadruplets had a good outcome. In this contribution, Atlay and Pennington provided much hormonal data that may be helpful in the surveillance of plural pregnancies. McFee et al. (1974) reported on two sets of quadruplets, among which only one of the eight premature newborns succumbed. The authors gave detailed and helpful instructions as to preparations needed by staff and family for the anticipated delivery of plural births. Williams (1926) described the quadruplet pregnancy of a 38-year-old woman whose

FIGURE 25.105. Quadruplet placenta with four chorionic sacs, all surviving. (Source: Hamilton et al., 1959, with permission.)

offspring all died. The placenta was TriTri and fused. He also reported on the fact that 24% of the 280 sets of twins observed at the Johns Hopkins Hospital were monochorionic; of four triplets, three were TriDi and one was TriTri. We have seen several quadruplet placentas with four chorions and one with four amnions and three chorions (Fig. 25.106). Imaizumi (1989b) reported on 16 sets of quintuplets from Japan. Three sets were liveborn, eight were stillborn, and five were live- and stillborn, with 51 of 80 offspring being stillborn. The mean weight of 40 quintuplets was 1048 g.

Nichols (1954) published a list of 17 quintuplet births in the United States and two in Canada, as well as five sextuplets in the United States. An editorial (Anonymous, 1968) estimated spontaneous quintuplets to occur as rarely as 1 in 8 million to 54 million births. The combined weights for four surviving sets were 10.61, 14.08, 12.11, and 23.52 pounds. We have seen surviving quintichorial quintuplets, conceived after clomiphene citrate (Clomid) induction and delivered at 31 weeks. Their combined weight was 8200 g (1420 to 1820 g). Three of the umbilical cords had marginal insertions. As can be imagined, such enormous uterine distention gives rise to maternal dyspnea, hydramnios(?), excessive weight gain, pre-eclampsia, edema, varices, and cardiac failure. In another

FIGURE 25.106. Quadruplet placenta (QuaTri), with DiMo MZ twins at bottom left, one having marginal insertion of the umbilical cord (35 weeks, 920 g).

FIGURE 25.107. Monochorionic (quint-amnionic) quintuplet placenta, immature. All infants died from hyaline membrane disease; No. 5 had SUA. Large anastomoses are present. (Source: Gibbs et al., 1960, and Neubecker et al., 1962, with permission.)

editorial (Anonymous, 1963a), 50 sets of quintuplets were listed as having been reported in the entire medical literature. It is interesting to note that several of the well-described quintuplet placentas were diagnostic of MZ quintuplets, as were the Dionne quintuplets. The fact that one of the latter gave birth to a set of male twins is presumably a random occurrence.

A monozygotic quintuplet placenta was superbly studied by Gibbs et al. (1960); it is depicted in Figure 25.107. This placenta had a single chorion and five amnions. There were many vascular anastomoses on the chorionic surface; several cords inserted marginally, and that of No. 5 had a single umbilical artery. All these extremely immature infants succumbed from hyaline membrane disease. The placenta was redescribed by Neubecker et al. (1962). Quintuplets reported by Berbos et al. (1964) were QuiQua (quint-amnionic; quadri-chorial); a quintuplet pregnancy induced with gonadotropins and studied by Aubert (1960) resulted in three male and two female infants, with QuiQua placenta, and the successful quintuplet pregnancy reported by Liggins and Ibbertson (1966) had five chorionic sacs (QuiQui). Bender and Brandt (1974) studied a quintuplet placenta by morphometry. It was induced by hormones and had QuiQui membranes. These authors drew attention to the irregular chorionic fusion of the dividing membranes, discussed earlier and depicted in Figures 25.51 and 25.52. Altshuler (personal communication, 1975) also observed a QuiQui placenta that, when injected with milk, exhibited no anastomoses. Finally, the monochorionic quintuplets (QuiMo) with one acardiac fetus reported by Hamblen et al. (1937) are shown in Figure 25.86.

No sextuplet placentas had been described as far as we can ascertain from the literature, and few sextuplets have been reported to have occurred. Figure 25.108 shows such a specimen from a patient treated with fertility drugs that was provided by Dr. M.A. Fletcher from a delivery

FIGURE 25.108. Sextuplet placenta with six chorionic sacs and a male fetus papyraceus. (Courtesy of Dr. M.A. Fletcher, Washington, D.C.)

in Washington, D.C., in 1983. It was a fused placenta with six amnions and six chorions. It also contained a fetus papyraceus, estimated to have died at 20 weeks' gestation. That fetus had a normal skeleton, but its cord had velamentous insertion, and this insertion was the presumed reason for his demise. Three other fetuses had marginal cord insertion. Two cords had a left, and three a right, spiral; that of the fetus papyraceus was not spiraled at all. One specimen of a septuplet pregnancy, induced by gonadotropins and prematurely delivered (Turksoy et al., 1967) was depicted by Boyd and Hamilton (1970). The sacs each had their own chorion and amnion; one was separated, and the others were fused. The cords were mostly marginal and one had SUA.

Because plural gestations generally have poor outcomes, their early diagnosis and selective reduction of some cases is currently being advocated. By ultrasonography, Campbell and Dewhurst (1970) diagnosed hormone-induced quintuplets as early as at 19 weeks' gestation. The pregnancy went to 31 weeks. Labor ensued and the healthy quintuplets were delivered by cesarean section. Kanhai et al. (1986) punctured the hearts of three quintuplets at 10 weeks' gestation (one was repeated at 11 weeks). The mother subsequently delivered full-term healthy twin girls. The placenta had only one 2.5-cm embryonic rest. Various authors have addressed fetal reduction of multiple gestations in recent years, primarily, we believe, because of the poorer outcome of multiples and because so many more large "litters" are being produced. Thus, Miller et al. (2000) addressed the fiscal aspects of hospitalization and those occurring in later life. Stone et al. (2002) found that additional fetal losses occurred mostly in sextuplets, less so with other multiples, and found an overall loss rate of 5.4% in 1000 (!) consecutive cases. Fetocide was performed for a variety of reasons, and its frequency had been steadily increasing in these authors' experience, with more mothers now opting to retain a singleton rather than twins. The authors' previous publications on this topic are referred to in this paper as well, and the rate is compared to the findings of other institutions. In the second paper of this institution (Eddleman et al., 2002), the authors reviewed 200 terminations for anomalous multiples and caution that dichorionicity needs to be established sonographically before an attempt at potassium chloride injection is done. It is also interesting to note that, when Dickey et al. (2002) studied the *spontaneous* reductions of multiples, they found that more than 50% of triplets had intrauterine fetal deaths (IUFDs) before 12 weeks (36% of twins, 53% of triplets, 65% of quadruplets). Similar findings come from La Sala et al. (2004). Heyborne and Porreco (2004) used reduction in three cases of severe preeclampsia complicating twin gestations with discordance and found that PIH resolved in all three and allowed lengthening of gestation.

Most commonly, this reduction is accomplished by cardiac injection of KCl, but on occasion this is dangerous, as the maternal cardiac arrest (resolved) in a patient reported by Coke et al. (2004) describes. They reviewed the usage of KCl injection in general. Another hormone-induced quintuplet pregnancy was managed by Farquharson et al. (1988). At 9 weeks two embryos had intracardiac injection of hypertonic saline. Five days later the procedure was repeated with another embryo. The maternal serum human chorionic gonadotropin levels declined substantially and, at 37 weeks, heterosexual twins were delivered vaginally. Their placenta was DiDi. In the membranes, a plaque of atrophied villi and a cavity (but no fetuses) were found.

Evans and colleagues (1988) presented four such cases of therapeutic intervention. They also discussed the legal and other implications that attend this novel therapy. Their first case had nine gestational sacs at 7 weeks. Three fetuses were "needled" at 8 weeks and three additional ones at 9 weeks. The patient delivered two healthy males at 35 weeks. Their second case was a hormone-induced quadruplet pregnancy with elimination of two sacs by cardiac puncture at 10 weeks. Two healthy children delivered at 36 weeks. In the third case, IVF led to implantation of four embryos; two embryos were eliminated at 10 weeks. One remaining fetus was then found to have Potter's syndrome. The other died in utero. In their fourth case, four fetuses had been induced with hormones, and two were eliminated at 11 weeks. The remaining twins were aborted because of "cervical incompetence." They delivered, despite cerclage, at 19 weeks; the placentas were not described by these authors. They emphasized ethical issues and the need for regulated hormone induction of pregnancy for infertile patients, an aspect that was further elaborated on in discussion by Weiner (1988). It might be mentioned parenthetically that there has been much discussion as to whether cerclage is indicated in multiple pregnancy because of the frequently observed cervical dilatation. Michaels et al. (1991) recommend that it not be used routinely; they used ultrasonic criteria to select those patients who might benefit from this operation. Their results suggest that some patients' twin pregnancy is lengthened when cerclage is done. Berkowitz et al. (1988) reported their experience with selective embryocide in 12 multifetal pregnancies (2 in sextuplets; 1 in quintuplets; 5 in quadruplets; 4 in triplets). They reduced the number to two fetuses in 11 pregnancies and to three fetuses in one pregnancy. The surgery was undertaken between 9 and 13 weeks. Seven healthy twins were born. One produced a healthy singleton, and four had only fetal deaths. Later, these authors reported on 200 multifetal reductions (Berkowitz et al., 1993), and Boulot et al. (1993) concluded that the reduction reduces but does not prevent preterm labor. The difficulty and rationale for the procedure were highlighted in an editorial by

Hobbins (1988). One problem is the development of unforeseen complications in the survivor. Mahone et al. (1993) had such an experience. They described a twin transfusion syndrome at 23 weeks' gestation where the selective feticide of the hydropic recipient was followed quickly by hydrops in the remaining donor. They speculated that perhaps one mechanism of cardiac failure in the donor was the additional blood loss into the plethoric donor. Their photograph of the twins supports this notion. It also suggests to us that the best therapy for this ominous syndrome is the interruption of the anastomosing vessels, as practice by De Lia (see below).

Since these earlier reports on embryo reduction, there have been numerous reports that should be consulted. Thus Wapner et al. (1990) reviewed 46 cases with 80 fetuses remaining; 94% of these survived. Lynch et al. (1990) discussed 28 triplet, 47 quadruplet, four quintuplet, four sextuplet, one septuplet, and one nonatuplet pregnancies with reductions, usually to twins. Their outcomes were excellent. Tabsh (1990b) reviewed 40 cases, and Melgar et al. (1991) suggested that their results from the reduction of quadruplets indicated marked improvement in outcome, whereas that for triplets remains controversial. The intentional delivery of a 710-g acardiac fetus at 22 weeks' gestation by Robie et al. (1989) is also relevant in this regard. It was followed by delivery of a normal girl. The case is of special interest because the acardiac had a penile structure, yet possessed ovaries. She also had a normal female karyotype, and the co-twin was a normal girl. Itskovitz et al. (1989) and Gonen et al. (1990b,c) elected to use a transvaginal ultrasound approach for selective embryo reduction. The latter authors used intrathoracic KCl injection and had one case of chorioamnionitis follow the procedure. They considered the procedure to be not without significant risk. Tabsh (1993) reported the result of 131 transabdominal reductions done by one practitioner, with 103 deliveries ensuing. He had a 7% pregnancy loss rate from the intervention that occurred within 4 weeks and concluded that this is a safe procedure. Macones et al. (1993) showed that reducing triplets to twins markedly improves fetal survival. A large international experience was summarized by Evans et al. (1994), with the majority of infants being born after 33 weeks when reduction had been done. The procedure was judged to be safe. Other studies to be consulted are those by Lipitz et al. (1994, 1997), Berkowitz (1996), Haning et al. (1996), Lynch et al. (1996), and Smith-Levitin (1996). Sebire et al. (1997b) reported less fortunate results when reducing triplets to twin pregnancies, whereas Albrecht and Tomich (1996) and Lipitz et al. (1996) suggested they had better successes. Finally, Evans et al. (1995) reported that, despite increased triplet and quadruplet pregnancies, higher multiple conceptions have declined because of better management of the superovulation techniques.

## Twins in Abortion and Ectopic Pregnancy

Multiple pregnancies occur also as abortions and in ectopic gestations, but they are not often reported or perhaps they are frequently overlooked. Many specimens from spontaneous abortions do not contain an embryo, many are chromosomally abnormal, and many are fragmented when they are observed in the laboratory. Javert (1957) reviewed most of the relevant literature. He found citations of twin frequencies ranging from 6% to 20%. In his own material of 2000 abortuses, he had an incidence of only 1.2%. Our own observations have yielded a still lower figure (0.3%) (Benirschke & Driscoll, 1967). There is general agreement, however, that monochorial twins are overrepresented in abortion material. Numerous MoMo twins, for instance, vanish during early development (Figs. 25.43 and 25.84); and still other twins succumb from the transfusion syndrome or because they are acardiacs (Fig. 25.91). It is impossible to give accurate figures. The great student of twinning, Guttmacher (1937), believed that twins were twice as common in abortions as in births (1 in 37 versus 1 in 86.5), and the investigations of Livingston and Poland (1980) and Uchida et al. (1983) pointed in the same direction.

It should be easier to identify ectopic twin gestations, as they are generally better preserved. Indeed, many such cases are on record (e.g., Starks, 1980). The exceptional case of a tubal triplet gestation was reported by Forbes and Natale (1968), who believed it to be only the fourth case published. It was TriMo, and only a single corpus luteum cyst was found. Fujii et al. (1981) described a unilateral tubal quadruplet pregnancy with QuaMo placenta and unequal development of the embryos. Twin ectopics have been seen more often. Considering the frequencies of ectopic pregnancy and twinning, it is surprising that Storch and Petrie (1976) found only 87 reported cases of ectopic twins. More astonishing still is the fact that most tubal ectopics are monochorionic. This finding is much out of proportion to the general distribution of twin placentation, and the topic is discussed in detail by Neuman et al. (1990). They proved with RFLPs the dizygosity of tubal aborted twins, and suggested that the alleged common monozygosity of ectopic twins may be in error. Arey (1923a,b) was the first to report that ectopic twins have a 15 times greater frequency of monochorionic placentation than do intrauterine gestations. He reported MoMo twins, quintuplets, three triplets, and one thoracopagus and, in an earlier publication (Arey, 1922), suggested that these findings argued in favor of chorionic fusion. The proof of this contention, the occurrence of monochorial heterosexual twins, has not been reported. Later, Arey considered the possibility of an environmental insult that produced MZ twins in this abnormal loca-

tion. It is our opinion that most case reports are incomplete and too superficial; thus, usually they do not allow a clear decision on this interesting point. Perhaps monochorial gestational sacs are larger *ab initio*, and have more difficulty passing through the tube. Even less commonly described are twin ovarian ectopic pregnancies. Kalfayan and Gundersen (1980) reported a case of DiDi ovarian gestational sacs in a patient wearing an intrauterine device. They found three other reported cases.

"Heterotopic pregnancy is defined as a coexisting, intrauterine and extrauterine pregnancy" (Goodno & Gentry, 1962). It is apparently more common than is usually assumed. Gamberdella and Marrs (1989), who described a much higher frequency in ART, considered heterotopic pregnancies to occur 1 per 30,000 pregnancies. It often involves an interstitial (cornual) and an intrauterine gestation. Sotrel et al. (1976) suggested that more than 600 cases had been reported in the literature. They identified a case that occurred after ovulation induction. These pregnancies are often complicated by placenta accreta/increta (Starks, 1980) and they are usually dichorionic. Because they were able to make the diagnosis early, Porreco et al. (1990) electively eliminated the ectopic fetus and allowed the intrauterine gestation to proceed to term. Laband et al. (1988), who reported four such cases, suggested that the incidence of this unusual, dangerous gestational complication may be greater than 1 in 30,000. Payne et al. (1971) have seen triplets in this situation after ovulation induction. A similar case is reported in Chapter 6 with interstitial placenta percreta, removed during the second month, with twins remaining in the uterus.

It is also surprising how many cases of twin gestation have been described in uterus didelphys and how frequently they have been delivered at different times. Laird et al. (1957) reported on a miscarriage from one side, 6 months before the delivery of a normal twin from the other. Dawson and Ainslee (1958) saw premature twins delivering from a bicornuate uterus in short succession. Kennedy (1959) delivered an asphyxiated infant from one side, and 3 weeks later the other twin was born from the other uterus. Mingeot and Keirse (1971) delivered such twins within 9 hours of each other. Brown and Nelson (1967) reported that a patient with completely split genital tracts intentionally became pregnant on separate occasions in each uterus, with live infants resulting. A complex case was seen by Zervoudakis et al. (1976) in which curettage emptied an aborting pregnancy, but the patient remained pregnant in a blind uterine horn. Six weeks later, the horn was surgically emptied when a chemical interruption failed. There were no apparent connections, although Loendersloot (1977) later suggested that a perforation may have been present from first curettage. Nhân and Huisjes (1983) induced the second uterine horn after delivery of a normal child from one horn. Finally, Ahram et al. (1984) delivered twins

from both horns of a bicornuate uterus. They, as many before, had to initiate labor of the second horn before delivery could be effected. In most of these cases the placenta is not described. When it is discussed, the twins are usually considered to be binovular.

In a review of the obstetrical performance of 150 cases with uterine anomalies (with 325 pregnancies), Jones (1957) noted that twinning was not more common in these women. It may also be noted that delivery of twins at different times has been described in women with normal uteri. Thomsen (1978) reported a case where the first twin was delivered at 27 weeks and the second at 31 weeks. We have seen twins deliver 4 weeks apart, with the placenta of the first twin remaining in utero and becoming atrophied. The second twin survived. Previously, the maximum interval of 65 days was reported by Drucker et al. (1960), but Feichtinger et al. (1989) described an even longer interval: The patient delivered one twin at 21 weeks' gestation, followed by tocolysis and cerclage. She delivered a healthy 1750-g twin 12 weeks later; the placenta was dichorionic and had an infarcted portion. The survivor had a velamentous cord insertion. There was no inflammation. Another recent report on delayed delivery of second twins comes from Vancouver (Wittmann et al., 1992). The authors observed four cases with delivery intervals ranging from 41 to 143 days, and then reviewed 21 cases from the literature. The overall salvage rate was 84%; careful management protocols are suggested by these authors.

## Morbidity and Mortality

An abundant obstetrical literature discusses the causes of the excessive mortality of twins and the frequent obstetrical complications encountered during their delivery. Relatively rare but easy to understand is the phenomenon of "locked twins." Khunda (1972) discussed 37 such cases and estimated that it occurs with a frequency of 1 in 1000 twin deliveries, and that it has a high stillbirth rate. Breech/vertex presentation of twins is the commonest factor; also common are primigravidity and large pelvis. Cohen et al. (1965) had previously reported similar figures. In their experience, interlocking was present once in 817 twin deliveries and once in 87 breech/vertex presentations of twins. It is a particularly serious event when it occurs at or below the pelvic inlet, with death of twin A quickly ensuing. Amniotic sac dystocia has been described once, by Nickerson (1967). The membranes from the second twin then prolapsed in front of the first delivering twin. This abnormality was easily corrected, and delivery accomplished.

Of the numerous maternal complications that attend multiple gestations, Seski and Miller (1963) listed in descending order of frequency: premature delivery, pre-

eclampsia, hydramnios, placenta previa, abruptio placentae, cord prolapse, uterine inertia, and postpartum hemorrhage. Placental abnormalities often mirror these events. Hydramnios in twin pregnancies is most commonly due to the transfusion syndrome; good evidence exists that the amniotic fluid index of normal twin gestations is the same as in singletons (Hill et al., 2000). Next most frequently, hydramnios results from fetal or placental anomalies. It has been debated as to whether preeclampsia is commoner with DZ twins than with MZ twins; that it is more frequent in twin gestations is not disputed. We have seen numerous dizygotic twin placentas in which only one placental half was affected with infarcts and decidual atherosclerosis. It suggests that fetal and maternal interactions of respective genotypes are critical in the determination of PIH and preeclampsia. Campbell et al. (1977) studied this subject in greater detail and reviewed the literature. They analyzed 343 twin pregnancies, with exact zygosity determination, and found that DZ and MZ twin pregnancies had the same incidence of mild and severe toxemia of pregnancy. Skupski et al. (1996) found that the rate of PIH is higher in triplet gestations conceived by IVF than if conceived spontaneously and when reduced to twins. Maxwell et al. (2001) found no difference in the risk for PIH with twin zygosity.

Perhaps the most debated topic in the management of twins is the manner in which the second twin is to be delivered and how rapidly it must be accomplished. Increased fetal mortality for the second twin has often been suggested but was also frequently not confirmed by studies in detail (Adam et al., 1991). In almost all respects (e.g., Apgar score, pH, and weight) twin A is said to be favored (Young et al., 1985). The higher mortality of twin B was particularly evident in Spurway's report on the management of twin deliveries (1962). Others have not found such dramatic differences, particularly when cases in which prenatal deaths (macerated stillborns, acardiacs) and infants weighing less than 1500 g were excluded from such analyses (Thompson & Johnson, 1966; Rayburn et al., 1984; Adam et al., 1991). Nevertheless, the mortality of twins is much greater than that of singletons, and reports from the American, European, and African literature are summarized in the thoughtful review by Powers (1973). Those reports are listed in Table 25.7, as are later surveys. In general, the perinatal mortality of twins hovers around 10%, but the statistics are largely influenced by the inclusion or exclusion of twins from early gestations and also depend on the date of the study, as marked improvements have been achieved. Thus, in a case-control study of Spellacy et al. (1990), the overall mortality of twins more than 500 g in weight now was 4.88% for twin A, and 6.41% for twin B. As in this study, there is little doubt that prematurity, often the result of hydramnios, is the most important factor in determining outcome. Rouse et al. (1993) related fundal height measurement to

preterm delivery. They decided that single measurement excessive fundal height does not predict premature labor. This was to be expected, as excessive size alone cannot be the trigger for labor; rather, it is the rapidity of increase in uterine size (as occurs in hydramnios from the transfusion syndrome) that has this effect. At times, preterm labor is heavily influenced by the presence of the amniotic fluid infection syndrome (chorioamnionitis). Thus, Naeye et al. (1978), who recorded a 13.8% twin perinatal mortality, found that infection was the cause of twin deaths in 2.3%, in contrast to 0.6% in singletons. It was much higher (13.0% versus 1.8%) in Ethiopia. Premature rupture of membranes occurred more commonly in twins than singletons, but its outcome (latency to labor, infection) did not differ from singleton pregnancies (Mercer et al., 1993). These authors remarked on the paucity of abruptio occurring in multiple gestations. No significant differences between twins were found in the occurrence of the respiratory distress syndrome (Arnold et al., 1987) or cerebral hemorrhages (Pearlman & Batton, 1988). Most impressive, however, is the difference of perinatal mortality between monochorial and dichorial twins. Monochorionic twins have a significantly higher mortality, and that of monoamniotic twins is the highest (Benirschke, 1961; Cameron, 1968; Fujikura & Froehlich, 1971). On occasion it may be necessary to delay delivery of a second twin after premature birth of one. This topic was addressed by Arias (1994), who found it possible to occasionally significantly delay the birth of a second twin with cerclage and other modalities.

Early bed rest has been proposed to improve twin survival (Anonymous, 1963b). The cost of this measure is formidable (Powers & Miller, 1979), however, and careful appraisal with random trials has shown that it is inefficacious. In fact, with early admission and bed rest, the prematurity rate is increased. Robertson (1964b) who had earlier sought statistical improvement from early admission and did not find it, thought that random trials would be unethical. One study of the possible benefits comes from Rydhstrom (1988). Pregnancy outcome for 78 twin-bearing women who were prescribed prophylactic leave of absence from work to prevent preterm delivery was compared with a group of 78 twin-pregnant controls who did not take prophylactic leave. Gestational duration and birth weight did not differ between the two groups. The results indicated that prophylactic leave of absence from work did not improve the outcome of a twin pregnancy. Crowther et al. (1989) and MacLennan et al. (1990) also found that bed rest had no beneficial outcome in twin survivals. Indeed, "evidence is accumulating that rest may even increase premature labour" (Thornton & Rout, 1990; see also Andrews et al., 1991). Although cesarean section rates had increased from 3% (1963–1972) to 51% (1978–1984), Bell et al. (1986) were unable to show that even this modality of care improved the condition of

twins at birth (see also Saunders et al., 1985, and Greig et al., 1992). Only attendance at prenatal twin care clinics seemed to have had a beneficial effect on outcome (Ellings et al., 1993).

The excessive mortality of multiple offspring has been given as one reason for selective reduction during early pregnancy. Layzer (1988) noted that a 16% perinatal mortality exists in triplets, and another 15% do not

survive infancy. The figures for quadruplets and quintuplets are 21% and 22%, respectively; for sextuplets the respective figures are 41% and 50%. At the other end of this spectrum, large twins have also been recorded. Leonard (1957) has reviewed this topic and reported twins weighing 4075 and 5180 g (20.4 pounds together). They were dichorionic (male/female) and are the largest recorded in the literature.

## HORMONES IN TWIN PREGNANCY

In efforts to predict twin pregnancies, various serologic parameters have been studied for better surveillance. Halpin (1970) found excessively high human chorionic gonadotropin (hCG) titers in a twin pregnancy, and Thiery et al. (1976) determined that hCG titers in twins were 2.5 times higher than in singletons. This increase was confirmed by studies of Jovanovic et al. (1977). Thiery et al. (1976) also reviewed the literature on the elevation of chorionic gonadotropin levels in pregnancy and simultaneously studied the human placental lactogen (hPL) levels. The latter were found to be 1.5 times higher than in singleton pregnancies. Other investigators have made similar observations (Gennser et al., 1975; Grennert et al., 1976a; Mägiste et al., 1976; Daw, 1977). In general, the values are 1 standard deviation above those for singletons, and when one twin dies, a noticeable fall has been recorded (Kenney et al., 1976). It has also been shown that, following elective embryocide, there is a marked fall in chorionic gonadotropin levels, but that progesterone and estradiol levels remain stable (O'Keane et al., 1988).  $\alpha$ -Fetoprotein was found to be elevated in seven of 10 twin pregnancies reported by Ishiguro (1973), as was the level of cystylaminopeptidase (Einerh & Jacobsson, 1976). Because of the considerable scatter of hPL values in pregnancy, Dhont et al. (1976) suggested that simultaneous determination of hCG and hPL values gives more reliable results in the anticipation of twins [see reply by Grennert et al., 1976b].

Numerous litigations against hospitals and obstetricians take place in which the placental findings become an important participant in advising the disputing parties on perinatal circumstances. These litigations are initiated most often on behalf of children with cerebral palsy, occasionally with malformations, stillbirth, or with other less than optimal or expected outcomes (Rosenblatt & Hurst, 1989; Richards & Thomasson, 1992). Record keeping of the clinical circumstances and a professional placental study prove to be of great importance in many cases. Weinstein (1988), who wrote a concise review on the topic, asserted that such litigation is principally the result of the following:

1. Society's belief that all wrongs must have a reason and that the wrongs must be put right
2. The pervasive lottery mentality
3. The inability of many individuals to accept responsibility for themselves or their actions
4. An increasing incidence of true medical negligence

Many physicians who have become involved in this legal process in one way or another have witnessed that Weinstein's third point is now common reality. Physicians frequently take care of pregnant patients who continue the use of alcohol and tobacco during pregnancy despite many personal or public warnings against it. Other pregnant patients abuse themselves with cocaine, crack, and other agents and thus endanger their fetuses simultaneously. This aspect of modern society was discussed in an incisive paper on wrongful births by Fleischer (1987). Unfortunately, these facts are rarely taken into serious consideration when malpractice claims are litigated, or they are casually dismissed as not likely to be contributory. Other physicians argue that the fourth of the above statements is incorrect; they believe that there has been no true increase of medical malpractice—only the lawsuits that claim it to be true have increased. Sandmire (1989) provided cogent evidence for this view. No doubt, there has been an increase in the overall incidence of

cerebral palsy as a result of the increasingly smaller babies for whom care is provided (Anonymous, 1989; Kuban & Leviton, 1994). Moreover, with increased usage of fertility assistance, more multiple births occur prematurely, and older women have children, factors that are of importance in the determination of palsy. Conversely, older causes of cerebral palsy-like conditions, such as kernicterus, have all but disappeared, and fewer term babies now suffer this fate. But the oversimplified allegations of intrapartum hypoxia and its blanket alleged relationship to neonatal pH or Apgar score and the ultimate infant performance are often incorrectly assessed, and assumption of negligence or guilt on the part of a perinatologist is frequently not justified. The understanding of how cerebral palsy develops is still imperfect, but it is under intense scrutiny in important studies by Depp (1995) and Marin-Padilla (1997). Some aspects have been reviewed by Nelson and Leviton (1991), and others by Kuban and Leviton (1994), but cases such as the one described by Lopez-Zeno et al. (1990) should always be remembered before hasty conclusions on etiology are drawn. These authors observed the survival of a normal child, delivered by cesarean section 22 minutes after maternal cardiac arrest had occurred, which was 45 minutes after the fatal shooting occurred. Follow-up failed to show neurologic damage; the placenta was not described. This complete anoxia that was incurred by this fetus is much longer and certainly more severe than is the case for many alleged cerebral palsy hypoxia cases. Thus, careful evaluation is indicated. In a thoughtful review, Perkins (1987) examined this very complex field. It should be required reading before unwarranted conclusions are drawn. It is especially noteworthy that Perkins concluded that "the number of infants injured before labor is highly underestimated," whereas that "of infants injured during labor is highly overestimated." The placental record can help materially in sorting out these discrepancies.

"The examination of the placenta may be viewed as a diary of the pregnancy," as Gillan (1992) has aptly stated,

and the placenta, therefore, has become an increasingly important organ in adjudicating medicolegal allegations (Benirschke, 1990, 1996; Kaplan, 1995). The recognition that placental examination can be of material help in adjudicating perinatal asphyxia litigations has even been recognized by the legal profession. Schindler (1991) concluded that defense verdicts were issued in the 12 cases in which both the placenta and the cord were available for presentation at court. A monograph by Fisher (1996) on risk management techniques in perinatal and neonatal practice asserts the same view. Regrettably, this aspect was not considered in the last review on cerebral palsy by Kuban and Leviton (1994). Even now, the principal reason for submitting a placenta to the scrutiny of the pathologist remains that it comes from a surgical intervention (Booth et al., 1997). This makes little sense in that a large number of such interventions are routine repeat cesarean section deliveries, not the potentially fetus-endangering gestations. Altshuler and Herman (1989) reviewed the specific needs to be addressed by pathologists, and they also considered some of the epidemiologic principles in an incisive review of this medicolegal topic. Of particular interest is their capsular review of relevant pathologic features of the placenta and the possible correlations of lesions with fetal hypoxic states. They were correct in reiterating that the placenta "is an objective diary, related to the outcome of pregnancy." Later, Altshuler (1993a,b, 1999) wrote three incisive reviews of the principal lesions of the placenta that may be of paramount importance in reflecting a prenatal onset of hypoxic insults. These papers suggested that the presence of nucleated red blood cells at term, chronic villitis, meconium damage, excessive fibrin deposits, chorioamnionitis, chorangiosis, and "placental dysmaturity" are the most important aspects to be considered in this context. These papers also provide a triage for placental study, and the third paper (Altshuler, 1999) is directed to nonpathologists as well. Furthermore, an important meeting of pathologists, perinatologists, and the legal profession resulted in a volume that attempts to address the complexity of the medicolegal aspects of placental pathology (Travers & Schmidt, 1991; Langston et al., 1997). More quantitative data to ensure that pathologic interpretations by different pathologists are meaningful can be found in Beebe et al. (2000).

The pathologist is often consulted to render specific advice on pathologic findings and on other perinatal aspects of pregnancies with poor outcomes. This consultation prominently includes considerations of findings made at placental examinations. All too often, however, the placental material available is insufficient for an expert opinion. Recommendations are made here about how to collect placentas for such possible need of the future. Altshuler and Herman (1989) suggested that one should briefly record findings from placental examination of all deliveries because cerebral palsy may also occur

with entirely normal deliveries. We agree with this view but found it to be an impractical task for most hospitals. To have placental material available for possible future study, the authors also suggested that formalin-fixed samples be embedded in paraffin and archived as uncut specimens. In our view, the value accruing to the child and pediatrician from an examination of the placenta at the time of delivery supersedes the storage of unexamined material.

It is particularly regrettable, as happens occasionally, that erroneous testimony is given in best faith because the consultants have not properly evaluated the entire facts of a given case. They may have reviewed only the slides without knowing the gross findings of the placenta, for instance, and may have based their opinions solely on those histologic findings that were available, whereas detailed study of perinatal circumstances might have provided a more educated judgment. Pathologists should not be put into the position of making judgments on monitor strips and the like. They must, however, have a general idea of the entirety of these complex cases before the placental examination can be meaningfully interpreted. Even more unfortunate still is testimony by "experts" who have little experience in placental pathology. Likewise, pathologists must be mindful not to render expert opinions on areas that are outside of their field of competence, for instance regarding the findings of heart rate monitoring.

Litigation has had an impact on the practice of perinatal medicine, without having much improved our knowledge of the cause(s) of cerebral palsy. But because the placental study often provides significant insight into prenatal life, it has become apparent to many health care providers that, when caring for problematic neonates or when difficulties in labor and delivery are encountered, the placenta should be examined professionally.

The notion that it is imperative to examine the placenta, if only to establish the cause of perinatal deaths, is not new. For instance, in efforts to understand the causes of fetal demise, Davies and Arroyo (1985) were able to ascertain the cause of perinatal death by autopsy alone in 47.6% of their cases. For the purpose of ascribing a cause of death, however, placental study was necessary in an additional 34% of their cases. We have reviewed our material of perinatal autopsies over 2 years and found that the true cause of perinatal death could not be established in 15.6% of the cases (Fig. 26.1). Thrombosis of vessels (Kraus, 1997), maternal floor infarct, villitis, and abruptio placentae are major reasons in singletons why the placenta must be studied. Driscoll (1965) found it also to be true for 16% of her case material; Salafia and Vintzileos (1990) were equally emphatic about the need to examine all placentas.

If the cause of perinatal mortality is strongly corroborated by placental findings, the same is likely to be true

FIGURE 26.1. Perinatal autopsy findings in 122 consecutive cases (University of California, San Diego, 1981 to 1982). Placental examination was necessary in 19 (16%) to provide the cause of death. In many others, especially the premature infants and anomalies, there were abnormal placental findings such as inflammation and single umbilical artery, but these were not the cause of death. HMS, hyaline membrane syndrome.

of possible perinatal fetal or neonatal damage, making the examination of this organ all the more mandatory. So that one may have the placentas of neonates with developing problems available for study, suggestions were made in Chapter 1 how best to store placentas. This triage for the selection and other related aspects of placental study were well detailed in tabular form by Altshuler (1993a,b). Aside from the aspect of placental storage, to facilitate examination of the placenta in cases of possible neonatal difficulties, it is our opinion that all placentas of twins, those of premature infants, and of deliveries in which meconium staining or other obvious perinatal problems are apparent should be studied by the pathologist. It is imperative that these findings then also become an entry in the patient's record. This practice is not only desirable for adjudicating many legal cases in which placental pathology can be helpful, but it may materially assist the obstetrician when counseling about future pregnancies and in the accumulation of data that may ultimately help our understanding of perinatal problems.

We have often wished in legal consults that a photograph of the placenta was available, particularly when confronted with the record of a poorly described or inadequately studied placenta. This desire has been made light of in litigations, but photography can be easily accomplished on delivery floors, where pictures of neonates are taken routinely. This has also been advocated for regions where pathologic support is inadequate (Ward, 1991). If photography is impractical, a drawing of salient findings, for example, to indicate the insertion of the umbilical cord or the presence of twin vascular anastomoses, is often more helpful than a poor description of the gross features. Ideally, all placentas would have an examination by a knowledgeable pathologist, but this is not likely to happen routinely. Those placentas that are studied, however, must be adequately sampled for histology. At least three sections of villous tissue plus at least one of cord and at least one membrane roll are optimal. When selecting the villous tissue, it is important that

more than the obviously infarcted or pathologic areas are sampled; most infarcts look alike microscopically. An estimate of the percentage of the villous tissue involved with a gross lesion or lesions is most helpful. For an appreciation of the placental status, for example, for the identification of Tenney-Parker changes in preeclampsia or chorangiosis and villitis, the more normal-appearing villous tissue is usually more informative than are sections of infarcts. In the membrane roll, the decidua capsularis must be included, as it is the best site for an analysis of maternal vessel pathology and for the appreciation of inflammatory processes. Formalin fixation of placentas before examination provides much less valuable information than the examination of a fresh organ. The sooner the placenta is studied, the better the results; however, storage in a refrigerator preserves the salient feature for many days. There is little autolysis when the placenta is refrigerated; it only loses some weight during storage by extrusion of villous water, particularly edematous organs. The pathologist must also become familiar with the artifacts produced by fixation, especially being cognizant of changes in weight after fixation (the weight increases).

As stated earlier, litigation has involved, most importantly, deliveries in which cerebral palsy became a problem in the future development of an infant. This is, in general, much more common in prematurely born infants, in multiple pregnancy, and in infants who come from prolonged pregnancies. The study of the causes of cerebral palsy is a difficult aspect of medicine, as no single etiology can possibly be assigned, despite the efforts expended in the large, prospective Collaborative Perinatal Study. Rosen and Dickinson (1992) estimated that 2.7 per 1000 children age 5 to 7 years suffered a form of this illness. Nearly 36% occurred in children with birth weights of less than 2500g, and the authors suggested that 70% had an antenatal onset. Interestingly, Rosen and Dickinson (1993) provided evidence that electronic fetal monitoring was unable to predict the development of cerebral palsy, even though this had been the original intent for

this technology. Nelson et al. (1996) also examined in a very large population whether heart rate abnormalities correlated with the development of cerebral palsy. They also found a high degree of unreliability of this procedure and indicated that, were reliance principally based on irregular heart monitor findings, an excessive and unwarranted cesarean section rate would follow. Other authors have related similar views, although employing different criteria (Yudkin et al., 1994; Depp, 1995; Goodlin, 1995; Lien et al., 1995). Because they have little relation to placental pathology, they are not discussed here, but the interested reader will want to review these contributions as well. Naeye and Peters (1987) examined the 7-year outcome of children from the aforementioned large Collaborative Perinatal Study of 56,000 pregnancies. Their overriding conclusion was that chronic, rather than acute, hypoxia has a greater influence in causing abnormal brain development (see comments by Harkavy, 1987, and those by Durant and Woodward, 1987). This study, as many others, well demonstrated how complex is the topic of the cause of cerebral palsy (see also Naeye et al., 1989; Naeye, 1992). The two reviews of Altshuler (1993a,b) cited many additional studies that should be consulted by the reader who wishes to obtain a well-rounded appreciation of this complex topic. At the same time, cerebral palsy also has great social and medical importance; the disease often represents a major tragedy to the families involved and to the child. One of the most thoughtful reviews of this complexity was provided by Perkins (1987). Additional studies from Australia were summarized in the Collaborative Perinatal Study involving 608 children reported by Aylward et al. (1989). These authors also found only weak correlations to perinatal variables. Their instructive tables showed impressively that many time-honored indicators of asphyxia have little or no bearing on cerebral outcome of the neonate. Regrettably, items such as meconium staining and many more conditions of concern were not studied. Grant et al. (1989) also concluded from their randomized study of the benefits possibly coming from intrapartum monitoring that prevention of cerebral palsy is difficult. This study and others have been succinctly annotated in editorial comments (Anonymous, 1989; Freeman, 1990).

The findings made during a competent placental examination, including histologic study frequently identify abnormal prenatal circumstances that had not been recognized clinically. Grafe (1994) made the same point after correlating placental pathology with central nervous system (CNS) necrosis, hemorrhage, and gliosis. In a large study that correlated placental features with perinatal asphyxia, Beebe et al. (1996) sought to identify specific features that were more important. Villous ischemic changes, meconium damage, and chorioamnionitis stood out as most important. Nevertheless, the authors urged that long-term follow-up is needed to ascertain precisely

what the impact of certain lesions may have been. Thus, results from placental studies have often materially aided in advising the legal profession accurately. For the purpose of this chapter, we will summarize salient points that have come from our experience in this arena. More details on the conditions to be described are to be found in the relevant sections of this book. It must be reemphasized that an interpretation of the placenta alone is often insufficient to arrive at a full appreciation of the complexity of individual cases. It is frequently necessary to know many other factors than only the placental findings in order to render appropriate advice. For instance, one may need to know the identity of microorganisms in infectious cases, etc. The social history may be of considerable importance, and an accurate estimation of the length of gestation, the complications known to have occurred during pregnancy, and so on must all be weighed in the context of the placental findings. These items give valuable information with which one is in a better position to interpret subtle placental findings. Reviewed here are only some of the more common placental problems that we have encountered, and observations we have made in litigation proceedings.

## Twinning Problems

Placentas from twins provide the pathologist with the unique opportunity to compare different placental features with neonatal outcome. Thus, the fetus accompanied by a velamentous insertion of the umbilical cord is usually more growth-restricted than one with a normal cord and is thus uniquely exposed also to the prenatal hazards of anomalous cord insertion. Multiple births also have not only a much higher incidence of prematurity but they also suffer a manifold increased frequency of cerebral palsy compared with singletons. Studies have suggested that some of these cerebral lesions may have a prenatal onset because cystic areas of former white matter necrosis can be evident at birth (Bejar et al., 1990). Larroche (1986) described a case that also demonstrated these prenatal lesions; she found other cases of prenatal encephalopathies with trauma and other prenatal events. Central nervous system damage of prenatal onset appears to be commoner in monozygotic, monochorionic twins than in dizygotic multiples. It is therefore imperative that the membrane relation of all twins be firmly established at the time of delivery or during placental study, if one wants to understand the origin of the lesions. This point is particularly important when one twin has died prenatally. Coagulative, destructive events in the survivor are then especially common and these are usually confined to monochorionic twins. They generally have a prenatal onset, as sonographic studies have clearly shown (Patten et al., 1989), and commence soon after the death of one

fetus (Liu et al., 1992; Benirschke, 1993). A particularly illustrative case with which we have had personal connection demonstrates clearly how such problems may be inaccurately adjudicated. It was superbly summarized in a book by Werth (1998).

As stated earlier, monochorionic twins not only have a higher rate of prematurity but they suffer perinatal mortality more frequently (Baldwin, 1994). The highest mortality attends monoamniotic twins. Monoamniotic/monochorionic (MoMo) twins entangle their cords frequently and this may cause restrictions to venous return from the placenta. This complication often kills one or both fetuses; in others one can infer venous return problems from existing thrombi. Further, vascular anastomoses between twins may allow rapid shifts of blood from one twin to the other, which may lead to acute anemia and hypotension in utero. Neonatal anemia seen in one of twins, where the other had recently died in utero has been difficult to interpret prior to detailed placental studies. It goes without saying that the umbilical cords of twins must be labeled at delivery, so that it becomes possible to assign specific placental lesions to individual infants. It is also necessary to identify and record the presence of a fetus papyraceus, as it may have great relevance in affecting the development of the surviving twin through interplacental vascular anastomoses. Perhaps the cause of the death of one twin was sublethal to the other.

Inflammatory processes also have an important impact on fetal well-being and they are frequently correlated with cerebral palsy. As was discussed in some detail in the consideration of infections (Chapter 20), in twins, chorioamnionitis much more often affects twin A, that is to say the twin closest to the cervical os. When one has knowledge of the location of twins in utero, this may lead to a better appreciation of possible aspiration pneumonia and other fetal effects.

Twins have a high frequency of velamentous and marginal insertion of their umbilical cords, and these insertional abnormalities are often correlated with single umbilical artery. The membranous vessels may have ruptured during delivery and have caused acute anemia, or they may be thrombosed, which often produces dire fetal sequelae. Cords with a single umbilical artery are more common in twins, and not only when the cords are marginally inserted. When twins are delivered by cesarean section, the twin located in the lower uterine segment may actually be delivered as the second twin. Therefore, recording the distance of membrane rupture from the edge of the placenta aids in assigning the correct position of twins in utero when labeling of cords is inadequate. This point has particular relevance with respect to inflammation and to the possible rupture of velamentous vessels.

Twins with velamentous insertion of the umbilical cord are usually smaller than those with more normal cord

position. Such discrepancy in size does not automatically affirm the diagnosis of the transfusion syndrome, as is all too readily done; that diagnosis requires the demonstration of the responsible arteriovenous (AV) shunts in the monochorionic twin placenta. The twin-to-twin transfusion syndrome (TTTS) is a most important aspect of monozygotic twinning. It is largely responsible for the frequent occurrence of hydramnios in twin pregnancy that leads to the high frequency of premature delivery of monochorionic twins. Although anemia and plethora of the neonatal twins may be obvious, this finding alone does not accurately attest to the underlying cause, the presence of an AV fistula in the placenta. Plethora can occur in one twin when for instance the first-born twin has been allowed to drain blood into the second, while this one was still in utero. This is sometimes referred to as acute rather than chronic twin-to-twin transfusion. A surviving twin also may partially and acutely exsanguinate into a stillborn twin while in utero, with resulting acute hypotension. Knowledge of the time when clamping of the cords was done may also be important when interpreting discordant hemoglobin values of twins. When one twin is small for gestational age, possibly because it had a velamentous insertion of the cord, large surface anastomoses may drain blood from the larger twin into the smaller member while still in situ, an apparent paradox to the findings of the transfusion syndrome. But this is not the equivalent of the classical transfusion syndrome. For all these reasons, it is important that the nature of interfetal placental blood vessel anastomoses be ascertained, possibly by injection of the placental vasculature. The findings are best recorded by making a drawing of these connections; they cannot otherwise be readily reconstructed.

## Inflammation

As with the cause of some premature monochorionic twins, chorioamnionitis (membranitis) and funisitis are much overrepresented in children who develop cerebral palsy (Redline et al., 1998). These pathologic changes are now clearly established as being the result of ascending infection. They cannot be explained by hypoxia occurring during labor or be assigned to changes in amniotic pH, as had been previously suggested. Infections not only are much more common in premature deliveries, but also are indeed probably a main reason for most premature births before 30 weeks' gestation (see Ornoy et al., 1976, for a consideration of its importance in stillbirths). Ascending infection also correlates with prenatal cystic changes in the brain. Studies have suggested that the hypoxia may be the result of vasoconstriction, engendered by the release of prostaglandins, tumor necrosis factor, or other vasoactive agents that come either from the inflamma-

tory exudate or from bacterial products suspended in the amniotic cavity. Indeed, the current suspicion exists that some cytokines may be the direct cause of cerebral degenerative changes (Yoon et al., 1996).

Culturing the surface of the placenta is usually not so helpful for studying the cause of chorioamnionitis as is a meticulous histologic study. The causative organisms of chorioamnionitis frequently do not grow readily in the laboratory, or they require special microbiologic attention that is not always available. Moreover, the placenta is frequently contaminated by the birth process, making most routine cultures worthless, or the patient has received antibiotics before delivery. It may be more practical to obtain material for culture from underneath the chorionic plate or to make touch preparations of the placental surface for the identification of organisms. Chorioamnionitis is also an occasional cause of thrombosis in fetal surface vessels, which can be identified macroscopically by the appearance of white-yellow streaks on the surfaces of blood vessels. Altshuler and Herman (1989) referred to the mural thrombi as "cushions," following De Sa's (1984) lead (see Chapter 12, Fig. 12.24). They must be sampled for histologic study. Their relevance to medicolegal issues has been well described by Kraus (1997).

When thrombi have developed in large fetal surface vessels, the distal fetal villous vascular bed degenerates, leading to defoliation of vascular endothelium, dispersion of blood, and disorganization of the vessels. It produces the appearance of hemorrhagic endovascularitis (HEV), which we consider to be not an inflammatory process but rather a degenerative one. It is commonly found in the main stem placental vessels of stillborn infants, but this endothelial degeneration has then usually occurred after the fetus's death. Unfortunately, much inappropriate testimony has been given in the past with this confusing entity of HEV, supposedly indicating the existence of an undiagnosed virus infection before birth. Perhaps the most informative finding for an understanding of HEV has come from finding the lesion confined to the placental portion of only the dead MZ twin of a diamniotic/monochorionic (DiMo) twin placenta. The fact that the surviving twin's placental bed did not have HEV nearly invalidates the possible inference that HEV is a specific pathologic finding of prenatal infection. In his study of placentas from stillborn fetuses, Genest (1992) depicted these changes and placed a time frame on their occurrence (see Chapter 12).

Villous tissue should be sampled for microscopy in all cases of a suspected virus infection because it must be admitted that many virus infections are difficult to identify precisely by histopathologic study alone. For instance, the immunodeficiency virus that is responsible for the acquired immunodeficiency syndrome (AIDS) leaves no characteristic alterations in the placenta. Hepatitis, Coxsackie virus infection, and other virus-caused diseases

cannot be reliably diagnosed histologically from placental material alone. Therefore, these diseases cannot always be ruled out by placental study alone. Cytomegalovirus (CMV) infection is perhaps the most common prenatal virus infection of relevance to cerebral palsy-type lesions. Significant damage to fetal brain and other organs occurs frequently from CMV infection, and the placenta often shows characteristic alterations. But these changes are frequently widely scattered in the placenta, sometimes affecting only a few villi, and they may be difficult to find. It is one of the reasons why several blocks of villous tissue should be prepared for histologic study. It is probably best to obtain five blocks so as to optimally sample the suspect material. Of considerable importance is the prenatal infection with herpes virus, as it may be responsible for porencephaly and neonatal death. It is commonly assumed that the infection is only acquired during the delivery process and thus cesarean section is often practiced when genital blisters exist. Less well known is that a number of cases have been described in which the infection was acquired before birth and where neonates had blisters from herpes simplex virus (HSV) infection with positive cultures (see Chapter 20). These infants may progress to destructive encephalopathy, and when they come to autopsy, neither culture nor electron microscopy identifies the now vanished agent. For that reason, Schwartz and Caldwell (1991) proposed that *in situ* DNA hybridization studies be done on placental tissue for the correct diagnosis. Few absolutely specific placental changes of this virus infection exist, although Robb et al. (1986a,b) identified suggestive features.

Premature infants delivered because of chorioamnionitis are often associated with decidual hemorrhage that clinically may give the appearance of an abruptio placentae. This hemorrhage, however, is usually due to bleeding from deciduitis with thrombosis of decidual veins at the placental margins and cannot be compared with the classic abruptio placentae seen with toxemia and trauma.

Villitis of unknown etiology (VUE) is a severe alteration of villi that includes infiltration with T lymphocytes and macrophages but only rarely with plasma cells; it usually leads to destruction of villi. It may be indistinguishable from CMV-induced villitis. Considerable experience may be required to differentiate the two and it may occasionally be impossible without the use of CMV probes. Villitis of unknown etiology definitely reduces the area of placental exchange and is also often associated with fetal death and with growth restriction. The etiology of VUE is unknown at this time, but the dire significance of the entity cannot be in doubt. There are, however, also cases of VUE that have no apparent effect on fetal development. Villitis of unknown etiology has a tendency to recur in future pregnancies. Evaluation of the significance of finding VUE in the placenta of a retarded

child may be difficult, and it requires much experience with placental study.

## The Green Placenta

The presence of meconium at birth was a frequent reason for alleging that birth was delayed or inappropriately handled in the British examination of obstetrical malpractice claims (Capstick & Edwards, 1990). These authors doubted that preventive measures could avoid the alleged accidents and recommended that attention be paid to the immediate handling of incidents. Interestingly, meconium staining of the placental surface is not only a frequent finding in mature placentas, it is usually not associated with fetal distress or cerebral palsy. In our experience, meconium staining/discharge occurs in about 17% of all births, most often when they occur after 40 weeks' gestation. Almost all neonates are normal. One should also consider the possibility that, when a meconium-stained placenta has been standing unrefrigerated for very many hours, some of the meconium pigment may actually travel slightly into the amnion and it may perhaps even minimally discolor the chorion. Usually, however, this is then also associated with some autolysis of tissues and is thus recognizable by the pathologist as having been artifactually caused. Refrigeration minimizes this problem, an important point, as the legal profession often disputes the age of meconium presence in placental sections. Because of the nature of the hormonal control of the propulsion of intestinal content, meconium staining is more common in postmature organs and it is extremely rare in immature placentas. Some of the legal guidelines pertaining to meconium staining have been examined by Sepkowitz (1987). In his 8-year experience, 4.3% of newborns (1368) were meconium-stained. His further data suggested that, because of legal negotiations, from 1982 to 1985 there was a marked increase in the reported incidence (14.4%) of meconium staining. Therapeutic measures such as laryngoscopy and oxygen administration to the neonate were increased as a consequence of these interventions, but they did not guarantee an overall improvement of the neonatal outcome. The author concluded, "While the issuance of medical guidelines alone had little effect on the incidence and care of the meconium-stained newborn, the combination of the legal imperative with medical guidelines had a profound and corruptive effect."

Prolonged pregnancy is significantly correlated with meconium discharge, as are the complications from its aspiration and other hazards of prolonged pregnancy (Arias, 1987). The results of Arias' study suggested that "the increased incidence of complications in pregnancy prolonged beyond 40 weeks cannot be adequately predicted with antepartum electronic monitoring, and ultrasound evaluation of fetal size, placental grade, and

amniotic fluid volume." It is also noteworthy that not all meconium-stained placentas are accompanied by fetal meconium aspiration (Altshuler & Herman, 1989). Sunoo and his colleagues (1989) clearly identified that meconium discharge and aspiration may occur before labor and without evidence of fetal distress. They made a detailed study of 75 cases of meconium aspiration (among 14,527 deliveries) and identified four infants in whom the aspiration occurred during early labor and in whom it was accompanied by normal fetal heart tracings. Postmaturity in itself is also often a reason for litigation when it is associated with a cerebral palsied offspring. Whether these are truly related events remains to be established. But the oligohydramnios and meconium discharge that so often occur after 40 weeks' gestation are often considered to be signs of placental insufficiency, a concept espoused by Vorherr (1975). We have not been impressed that good evidence for placental dysfunction has been identified, and Naeye (1978) agreed with this notion. Thus, a definitive deleterious influence of postmaturity on placental growth and function needs yet to be established.

When a placenta from a premature infant has a green surface, one must consider the possibility that this discoloration is not due to meconium but represents hemosiderin and related precursor pigments. Hemosiderin deposits most frequently accompany the peripheral hemorrhages of circumvallate placentas, but retromembranous hematomas, thromboses, marginal hemorrhage, and fetal hemolysis (after demise) can cause hemosiderin deposits on the placental surface because of hemolysis. An iron stain of the placenta quickly reveals the nature of the pigment when doubt exists. Other discolorations, from brown to green, may be the result of other insults, for instance the infection with fusobacteria. The nature of those pigments is not always understood. Finally, it must be cautioned that the bilirubin pigment of meconium-laden macrophages will bleach when slides lie in sunlight or fluorescent light.

Because meconium is gradually processed in macrophages, moving from the amniotic surface toward the chorion, a rough estimate of the minimum time elapsed between discharge and delivery may be available from microscopic examination of the placental surface; or when the amnion is stripped and the underlying chorion is examined and found to be green at gross examination, an approximate time frame is indicated by the depth of staining. It must be emphasized, however, that this evaluation is subject to a few errors that must be borne in mind when, as is so frequent in giving testimony, one is asked what the probability is for the meconium to have been discharged at such and such a time. And in our estimation these parameters are not really decisive in understanding cerebral palsy anyway; rather, it may be the *consequences* of meconium discharge that are relevant. Furthermore, meconium may have been discharged days before

delivery, and most of it may already have been transported away from the fetal surface when the placenta becomes available for study. It is also probable that repeated meconium discharge can occur in utero, which would be most difficult to discern from placental examination alone. Thus, an estimate of time, based on the only in vitro study of meconium transport, may be misleading (Miller et al., 1985). But that is the best estimate we have at present. It is our opinion that the legal profession is overemphasizing the importance of meconium discharge, without appreciating the complexity of this process and the complex etiology of spastic quadriplegia and other features of cerebral palsy. At the same time, when a damaged infant, even a stillborn, is under consideration and its birth had not been accompanied by meconium discharge, the question why this dead baby was *not* meconium-stained is never asked. Interestingly, most stillbirths we see have no meconium staining, even though, ultimately, anoxia was the cause of their death.

Meconium may be otherwise injurious to the fetal well-being, in part because of its effect on the umbilical circulation. It also causes severe degenerative changes in the vascular walls of the placenta and cord, as it does in the amnionic epithelium. Some evidence now exists to show that vasoconstriction is a consequence of meconium exposure rather than its cause (Altshuler & Hyde, 1989). Thus, although meconium discharge has become the “red flag” in legal cases, in which it is usually suggested that the passage of meconium alone must be evidence of fetal distress, it is more likely that it is the meconium that damages the fetus by acting as a vasoconstrictive agent on the umbilical and superficial placental vessels. In so doing it perhaps reduces the venous return of oxygenated blood from the placenta; of course, there could also be constriction of arteries with reduced blood flow to the placenta (Naeye, 1995). These avenues are now being explored experimentally, but the courtroom treats the association of meconium and cerebral palsy as being causally related as given facts, unjustly in our opinion. Similar suggestions of umbilical cord vessel constriction by bacterial products in the amnionic sac infection syndrome have come from experimental studies by Hyde et al. (1989), and Mazor et al. (1995) found meconium staining and bacterial infection with poor outcomes to be linked. Finally, we speculate that the real damage of the “meconium aspiration syndrome” of neonates may be a chemical injury to the alveolar epithelium, similar to its effect on amnion and cord vessels.

## Vascular Abnormalities

Abnormalities of the umbilical cord and placental surface vessels are important findings in placental examinations. It has long been obvious that it is important to record the

absence of one umbilical artery, as this frequent finding correlates well with a variety of fetal congenital anomalies and with growth restriction. But it is particularly important also to look for thromboses in the fetal surface vessels of every placenta. Most surface vascular thrombi are evident macroscopically by the yellow-white streak that then accompanies a chorionic vessel, but may not be appreciated by the inexperienced observer. Thrombi are more difficult to spot in the umbilical cord unless the cord is routinely sectioned in areas of discoloration that were not caused by clamping. Thromboses have many causes. They develop usually over a long period, although we have seen fresh, occlusive thrombi in cases of recent cord entanglement with stillbirth. The thrombi definitely point to significant prenatal fetal problems. We find thrombi most frequently to be associated with excessively long and heavily spiraled umbilical cords, less often in association with maternal lupus anticoagulant, and often with chorioamnionitis. Cytomegalovirus infection also has the propensity to affect endothelium and to produce thrombi. Thrombosis of surface vessels may be a feature of diabetes complicating pregnancy and of toxoplasmosis. In banal chorioamnionitis one often finds mural thrombi and occasionally organized thrombi, the so-called cushions. We have reported that thrombi may embolize to the fetus and there they may cause infarcts. However, unless such an infant comes to autopsy, embolic sequelae are usually not evident.

Complete vascular obliteration leads to atrophy of the villous district subserved by the vessel. It is the frequent cause of avascular, apparently hyalinized villi, which may thus reduce the quantity of available “exchange membrane”; for this reason, chronic thrombosis correlates with growth restriction and hypoxia. Some fetal thrombi are found in association with lupus anticoagulant, a condition that must be actively investigated, as it may produce few maternal symptoms. There are additionally many placentas with, at times, extensive thrombosis, in which the etiology of the thrombi remains obscure. Some may well be the result of inherited coagulation disorders and then be associated with CNS damage. This was well delineated by Thorarensen et al. (1990) and speculated upon by Kraus (1997). Relevant studies are now feasible but rarely undertaken. An unknown etiology is particularly true for the arterial thrombi. For the purpose of legal adjudication, it is important to recognize this point and to acknowledge that thrombosis is a long-standing event and that it can usually not be anticipated before birth. We have seen a child with cerebral palsy in whom one umbilical artery was nearly completely occluded by an inflammatory thrombus. The pregnancy was not complicated in any way and, upon arrival at the hospital, a cesarean section was performed for fetal distress immediately. Still, the jury was led to believe that this tragedy could have been averted by better prenatal care, despite having knowl-

edge of the placental findings. Redline (2005) has recently summarized his findings in the pathology of placental vascular lesions (thrombosis, VUE, inflammation, meconium damage) in 125 legal cases and compared these with random placentas. He found a remarkably good correlation of these lesions with neurologic impairment.

## Umbilical Cord

Aside from the cord accidents that occur with monoamniotic twins, the cord displays lesions that often have a significant impact on fetal well-being. Green discoloration of the entire Wharton's jelly can be observed only macroscopically, as the relatively small number of cord macrophages in the umbilical cord does not stain prominently. The cord is also often discolored from hemolysis, especially when thrombi are present or when prenatal bleeding has occurred. At the site where the cord has been clamped, hemorrhage is frequent, but it can be distinguished from spontaneous hemorrhage by the marks of the serrated clamps that are left embedded on the cord's surface. We have seen in a child with cerebral palsy that a true cord hematoma had histologic features of an angioma, presumably secondary to its "organization." The mother had been traumatized during pregnancy. The surface of the cord may have tiny granular protuberances from candidal infection. The compression from knots or prolapsed cords may be seen macroscopically. When it is present, there may be marked distention of blood vessels on one side but not the other, betraying the prenatal compromise of the circulation. The presence of knots in the umbilical cord may be of great significance. It may be the cause of death but it also betrays the possibly long existence of an impediment to venous return. Such has at least once been clearly demonstrated in a Doppler flow study of a 23-week fetus whose cord was also wound about its neck (Gembruch & Baschat, 1996). Edematous cords occur in edematous as well as in immature infants, whereas thin cords often accompany growth-restricted infants. Angiomas are rare, but when present they are of great significance. Usually the cord is spiraled. When the twists are especially numerous, the cord is also usually excessively long. That such excessive spiraling can lead to fetal death is not in doubt. Indeed, the remarkable twisting on the fetus's abdominal surface in some abortuses testifies to this lethal effect of twists. More problematic is the chronic effect that may ensue from excessive cord twists. They are often associated with fetal surface vessel (venous) thrombi, and a reduced venous return (with oxygenated blood) from the placenta can be deduced. Future Doppler velocimetry and cordocentesis observations will have to clarify the hemodynamic aspects of cord twists. It is important, however, to be mindful of the correlation of fetal problems with excessively long umbilical

cords; thus, an accurate assessment of the complete length of the cord is essential in all placental studies.

## Placental Villous Color

Aside from the meconium staining of the fetal surface, the color of the villous tissue is an important notation at placental delivery, especially in problematical cases. The villous tissue is red because of its *fetal* hemoglobin content. Placentas of diabetic mothers are darker because of fetal plethora, and those of immature infants are lighter. Once a number of normal placentas have been examined with this fact in mind, the observer should be able to identify those placentas that are unusually light-colored. They may be from infants with hydrops or, more often, they are associated with infants that had a fetomaternal hemorrhage. In that case, immediate Kleihauer-Betke stains on maternal blood are mandatory. This test is important so that one may estimate the amount of fetal blood loss; it also provides information needed for the therapeutic transfusion that may have to be instituted. Although intervillous thrombi may be noted in these cases, they are not invariably present.

In hydropic infants, the cause of hydrops should be studied as best as possible. The protocol includes mandatory examination of the Rh status plus a search for nucleated red blood cells, for parvovirus inclusions in red blood cell precursors, and for the existence of other fetal infections, such as CMV. There are many other causes of fetal anemia and hydrops. For instance, cardiac arrhythmias often produce hydrops that the pathologist cannot detect at autopsy. These causes are detailed in Chapter 15. Here it is important to stress that the appreciation of an unusually light-colored placenta has relevance for legal purposes as well. Occasional hydropic infants are the result of high-output cardiac failure of the fetus that results from large placental chorioangiomas. They are readily apparent when the placenta is palpated and then sectioned. Neonatal anemia is obvious when a low hemoglobin value is found at neonatal examination. The adjustment of the fetal hematocrit may take some time after fetal blood loss but we have only the most superficial knowledge of how quickly the hematocrits adjust after fetal bleeding—information that would be useful in adjudicating the timing of fetal hemorrhage.

In patients with hepatitis and jaundice, the villous tissue may be a deep golden color, which is often difficult to visualize microscopically and is thus an important macroscopic descriptor. This discoloration also tends to bleach in the histologic slides from office lighting alone.

The maternal surface may be yellow and firmer than normal in a condition known as maternal floor infarction. This condition is strongly correlated with diffuse fibrinoid deposition throughout the placenta and with fetal growth

restriction. Some observers have suggested that an increased fibrinoid deposition confirms the diagnosis of prolonged placental perfusion problems, but the maternal floor infarction syndrome has an unknown etiology, although it is a frequent cause of stillbirth. Appropriate histologic study verifies the existence of this condition. Such excessive fibrinoid deposits are frequently a repetitive event in subsequent pregnancies. It has also been associated with adverse perinatal outcome (Adams-Chapman et al., 2002). Contrary to opinions expressed in the literature, this condition is not *caused* by fetal death.

Color changes on the maternal surface and behind the membranes may disclose an unrecognized abruptio placentae. Most cases of placental separation are clinically silent and can be observed only when the maternal surface is carefully scrutinized. A fresh retroplacental hematoma with indentation of the villous tissue is obvious, however, if the hematoma is formed within an hour or so of delivery; the placenta may then appear unaffected. The clot may have dried (in contrast to the “currant jelly” clot of normal retroplacental blood), and it may be stringy and compacted. When placental separation is focal and has occurred long before delivery, the clot may have largely disappeared, or it is replaced by a brown, filmy material. Still older clots leave a greenish (hemosiderin) residue.

Infarcts at the edge of the placenta are common and, when small, they are of little significance. Their age can be approximated from their initially red, then yellow, and eventually white color. Infarcts that are scattered throughout the placenta, however, signify maternal disease of some sort. This finding assumes particular importance in prematurely delivered infants in whom infarcts are generally rare. Most commonly, the cause of such infarcts is preeclampsia, but the lesions due to lupus anticoagulant have a similar appearance; and when infarcts are found in the absence of signs of pregnancy toxemia, their cause requires further study. Moreover, for the understanding of the fetal impact of infarcts, it is probably beneficial that a percentage estimate of the amount of infarcted villous tissue be recorded. Altshuler suggested that most infarcts are not associated with fetal CNS changes (Altshuler & Herman, 1989).

Chorangiomas, on the other hand, is correlated with prolonged fetal oxygen deprivation. Just how the placenta is able to adapt to changing oxygen supply was considered in detail by Kaufmann and his colleagues (1993) and in earlier chapters of this book. Vascular proliferation, mediated through a complex system, is one important feature. Chorangiomas, one such outcome, is a highly abnormal condition that must be recognized as being associated with many perinatal problems. Although minor forms of chorangiomas are reasonably common, its value for our understanding of the fetal/placental/maternal relations has so far been underestimated. Altshuler (1984, 1993a,b) found chorangiomas in about 5% of neonates admitted to

his intensive care unit—much more commonly than occurs in cases with “routine” placentas. Chorangiomas is never found in normal cases, and Altshuler made the point that chorangiomas is significantly different from congestion, and that it probably relates to chronic low-grade hypoxia. That suggestion is supported by the finding of chorangiomas in women gestating at very high altitude (Reshetnikova et al., 1996). Chorangiomas is also often seen with VUE, and we find it peripheral to atrophying villi when old vascular thrombi have occluded the fetal vascular bed. Other correlations exist to fetal death, diabetes, umbilical cord problems, etc. The recognition of chorangiomas is an important feature of placental study. Whether “grading” the degree of chorangiomas as promoted by Altshuler (1984) is truly helpful remains to be confirmed by new studies. From a legal perspective it must be emphasized that the development of chorangiomas takes time to develop. Scheffen et al. (1990) provided beautiful evidence of the capillary adaptation in the guinea pig placenta following long-standing hypoxia and indicated temporal aspects. Although this system may differ from the histology of human adaptation processes, the underlying mechanism is the same and confirms the clinical findings. Other adaptations to low oxygen saturation were discussed in the context of preeclampsia in Chapter 19. They included cytotrophoblast proliferation with syncytial excess, reduction of villous length, and the possible mediation of these processes through cytokines.

## Other Types of Pathology

The fetal circulation of the placenta normally contains very few nucleated red blood cells (NRBCs). When they are found in sections of the placenta, the pathologist must seek an explanation for their presence. It may be obvious from hematologic study that there is evidence of hemolytic disease, or that transplacental bleeding or chronic infection existed, but often the cause of an excessive number of NRBCs in the fetal vessels is not immediately evident. Fox (1967) suggested that NRBCs are often found in the fetal circulation because of acute hypoxia. Presumably, the human fetus reacts to oxygen deficiency, as it does to anemia, by secreting NRBCs from the hepatic or bone marrow stores. How acutely this reaction occurs and whether it reflects a quantitative response to certain levels of oxygen deprivation is unknown. But this relationship to fetal hypoxia has now been shown to have led to elevated NRBC counts in numerous studies of which only a few recent investigations will be cited here. Thus, Baschat et al. (1999, 2003, 2004) found that elevated NRBCs at birth, and especially the persistence of these cells into neonatal life, correlate well with major neonatal complication. Phelan et al. (1995) looked upon the presence of NRBCs in term neonates as evidence of prenatal

asphyxia. These investigators, as well as Minior et al. (2000a,b) also found it to accompany fetal growth restriction as the result of "placental insufficiency" (Baschat & Hecher, 2004). The finding of NRBCs in the fetal vessels merely signals to the pathologist that a careful review of the record is needed to explain this important observation that may otherwise be overlooked. As stated, how quickly such a response occurs is unknown, for which reason Shields et al. (1993) attempted to elucidate the blood replacement by experimental hemorrhage in ovine fetuses. Despite an initial increase in fetal erythropoietin (EPO) levels, a significant hemorrhage (40%) was not followed by a significant rise in the fetal reticulocyte count, nor were the former blood volume and hematocrit restored before birth. Thus, the ovine model may not be appropriate to settle this important question. Older studies have suggested that sheep fetuses marshal some response; the current understanding of all of these aspects is discussed in admirable detail in Altshuler's review (1993a). It cites the study by Ruth et al. (1988), which determined the EPO levels at birth in preeclamptic pregnancies and those of severe asphyxia. The EPO levels were elevated in most pregnancy-induced hypertension (PIH)-derived neonates, irrespective of CNS damage; the significant finding was the marked elevation of EPO levels in those infants who ultimately had CNS damage but not in others. Ferber et al. (2004) later clearly showed that the EPO levels correlate well with the neonatal NRBC counts. We can personally relate two experiences from our files that help in understanding the time course in human fetuses to some extent: One patient was at term and had a major gush of bright red blood (later identified as fetal blood from disrupted velamentous vessels) upon insertion of an intrauterine pressure catheter. She was delivered by cesarean section 48 minutes later; the infant was pale, the placenta otherwise entirely normal. The cord arterial pH was 7.05, hemoglobin 14.6g, hematocrit 44.8%, white blood count (WBC) 28,000, and platelets 120,000 and falling to 71,000. Three transfusions of packed red blood cells were given and the hemoglobin level was then only 10.3g, and hematocrit 29.9%. The first enumeration of NRBCs occurred 1½ hours after delivery and showed 19 NRBC/100 WBC; 6 hours later it was 32 NRBC/100 WBC. Thus, there was a continued hematologic response after the delivery of the anemic child, and some degree of an initial NRBC response was detectable within an hour. This is contrary to the rapid decline of NRBCs postnatally when the hypoxic event has been more remote; under those circumstances most NRBCs are gone on the second day. Another case that is relevant came as a consultation: the mother had a car accident with lap belt injury at 28 weeks' pregnancy. Approximately 12 hours later the fetus was born with a hematocrit of 25%. Kleihauer stains gave an estimated 40 to 50mL fetal blood in the maternal circulation; 45

NRBCs/100 WBC were found and there was villous edema. It is entirely possible that the acute blood loss as shown in these two cases initiated a stronger response than would gradual hypoxia. This is consistent with Altshuler's (1993b) comment that "acute fetal blood loss and congenital septic hemolysis reduce the time it takes fetal hypoxia to cause fetal erythropoiesis and increased nucleated red blood cells." In another child, the 102cm long umbilical cord had prolapsed and was hemorrhagic for half of its length. The neonate had 53 NRBCs/100 WBC, but the placenta showed chorangiosis and mural thrombi in large vessels. The latter observations indicate very long-standing fetal hypoxia, a more frequent finding in this complex situation that prevents adequate assessment of the temporal response of the fetal system. We do not know the complete answers to these questions at present, and encourage colleagues to collect case material in order to gain a better understanding of the time course of the NRBC response. It should also be cautioned that fetal growth restriction is known to be associated with an increased number of NRBCs in their circulation (Nicolini et al., 1990). These authors deduced from the blood studies by cordocentesis that the only reasonable explanation for intrauterine growth restriction with the presence of NRBCs is long-standing hypoxia. Korst et al. (1996) studied NRBCs in asphyxiated and normal neonates. They found that normal infants have  $3.4 (\pm 3.0)$  NRBCs/100 WBC, but that asphyxiated and neurologically damaged newborns had significantly elevated counts ( $30.3 \pm 77.5/100$  WBC). The most elevated NRBC counts were explicable only by assuming hypoxia to have occurred long before birth. More discussion of the control of NRBCs in the fetal circulation is to be found at the end of Chapter 8. It should also be related here that Korst et al. (1999) found that neonates with encephalopathy had statistically reduced platelet counts, yet another means of evaluating neonates with CNS problems.

During legal proceedings the pathologist is frequently asked to specify a time frame for the lesion under discussion (e.g., Naeye & Localio, 1995, who enumerated NRBCs and lymphocytes). He or she may be required to specify how quickly villi can become atrophic following thrombosis, or what is the exact temporal evolution of thrombi. How long has a significant phlebitis been present, and is it correlated with the length of time from rupture of membranes? These and other probing questions are often difficult to adjudicate, and the answers (with respect to best medical judgment) may present problems for a conscientious witness. It requires experience, and it may be better to state the lack of our knowledge than to express unwarranted opinions that are contradicted in the courtroom or by other experts. This uncertainty is also an indication for the pathologist to seek new information from appropriate cases in which clinical data corroborate a particular finding. It is the reason why the meticulous

FIGURE 26.2. Mural thrombus in a placental surface vein (“cushion”) of a child with unexplained cerebral palsy. Note that the vein wall is partially degenerated. The lesion was not recognized, macroscopically or microscopically, by the pathologist who signed off on the case. H&E  $\times 160$ .

study of twin placentas can be so useful as it often provides a “control,” a fetus who has shared the same intra-uterine environment as the case under litigation but who may be normal.

Another relevant feature found in the study of abnormal infants is villous dysmaturity, the discrepancy of villous maturation with the chronologic age. This is not to say that this placenta is merely an immature one, rather that the placenta shows abnormalities, often irregularly distributed, such as an increase in fibrin, villous size, and stromal cells; decreased syncytial knots; and frequently an increased vascularity. Irregularly matured villi are frequent in the placentas of a variety of chromosomal abnormalities, for instance. Similar villous changes are found in other placental disturbances, as shown in Figure 26.2, and they may be difficult to explain. In this case, they probably resulted

from partial venous thrombosis of surface vessels (Fig. 26.3) in a child whose outcome was cerebral palsy, and which involved litigation. The ultimate cause of these lesions was not apparent, but it is clear that they were long-standing prenatal deviations from normal. Similar thromboses and degenerative changes may have taken place in the organs of the surviving fetus. We will never know. Tenney-Parker changes of villi (increased syncytial knotting) signify deficient uteroplacental blood flow of some duration, and focal villous edema may all be associated with premature delivery and neonatal hypoxia. These notations are all microscopic findings, however, that cannot be anticipated macroscopically. Their frequent presence with abnormal fetal outcomes signifies the importance of placental examination by a competent pathologist and knowledge of the spectrum of what is “normal.”

FIGURE 26.3. Irregular villous maturation and adjacent chorangiosis of the placenta in a cerebral palsy case (see Fig. 26.3). The vascularity of the central group of villi is apparent. It is presumed that this focal villous vascular loss is due to the same abnormality that was responsible for the mural thrombus. H&E  $\times 60$ .

It may be pertinent to review the presence of villous edema in this context. Edema of villi has been associated with poor fetal outcome and has also played a role in the litigation process. Naeye et al. (1983) suggested that villous edema was frequent and severe in the immature placentas (more than 32 weeks) of pregnancy complications. It was believed to correlate with fetal hypoxia, and the authors postulated that the hypoxia was the result of compression of fetal villous capillaries by edema. We find villous edema exceedingly difficult to quantitate, especially when the placenta has been stored and has lost some of its fluid. Moreover, many mildly hydropic fetuses with marked villous edema have not had a hypoxic deficit from compression of villous vessels, making us uneasy to use this criterion in our evaluation of abnormal placentas. No additional studies of this topic were published until the report by Shen-Schwarz et al. (1989). These investigators found villous edema in 13% of singleton placentas during the second half of pregnancy. In 11% of term placentas, edema was associated with fetal and neonatal deaths. They also detected edema more often in prematurely delivered placentas but were unable to relate villous edema to chorioamnionitis. Altshuler (1993a,b) was also uncertain that villous edema was a *cause* of fetal hypoxia, as resulting from compressing the villous capillaries. Further studies are needed to clarify the importance of villous edema as a correlate of fetal well-being and to delineate its precise pathogenesis.

## Glossary

This glossary is intended to trace the roots of the often-confusing terms used in placental pathology and perinatal development. The accents are placed for pronunciation.

**Gk.** = Greek; **L.** = Latin; **Fr.** = French; **OE** = Old English; **ME** = Middle English.

**Abrúptio (placéntae):** detachment of placenta [L. *abrumpere* = to break away]

**Acárdius:** malformed twin without heart, invariably one of monozygotic twins [Gk. *a* = without, not + *kardia* = heart]

**Adventítia:** outer layer of vessel wall [L. *advenire* = to add]

**Allántoís (allantóic):** designation of one type of placenta, because of its roots in other mammals; thin membrane between amnion and chorion [Gk. *allantos* = sausage]

**Ámnion:** thin membrane surrounding the fetus; lamb's caul [Gk. *amnos* = lamb] **Note:** Because we use chorionic and not choriotic, it is here preferred to speak of amnionic, rather than amniotic. Hyrtl (1880) explored the various terminology used to describe placental structures. He concluded that amnios and amnion were both correct. It was first used by Galen, referring to skin. The reference to lamb comes from Vesalius.

**Androgénésis:** development of male gender [Gk. *andros* = man + *gennan* = produce]

**Anídian monster:** a hideous fetus with peculiar features; a form of acardiac twin [Gk. *an* = not + *idios* = peculiar + L. *monstrum*]

**Artiodáctyla:** order of mammals, the even-hoofed animals, e.g., cow, deer [Gk. *artios* = even + *daktylos* = toe]

**Báttledore (placenta):** marginal insertion of cord [OE = flat, wooden paddle used in the game of battledore to hit the shuttlecock]

**Blástocyst:** early germinative vesicle [Gk. *blaste* = germ + *kystis* = vesicle]

**Bosselátion:** surface granulation of placenta [Fr. *bosseler* = to ornament with bosses; from *bosse* = knob]

**Capillary:** hair-fine blood vessel [L. *capilla* = hair]

**Céllular:** belonging to the cell [L. *cellula* = small cabin, cell]

**Extracéllular:** outside the cell

**Interacéllular:** between cells

**Intracéllular:** within cells

**Transcélular:** across cells

**Chiméra (Chímerism):** the composite of several genotypes [Gk. *chimaira* = a monstrous beast. In Greek mythology a monster made of the head of a lion, body of a goat, and tail of a dragon.]

**Chiráility:** the quality of being chiral [Gk. *chiro* = the hand; a three-dimensional form, as a molecule, that cannot be superimposed on its mirror image; used in designating the twist of the umbilical cord; its first usage was discussed by McManus (2002)]

**Chorioangiópagus parasíticus:** a fetus, connected by blood vessels to another fetus [Gk. *chorion* = "little gut" = outer membranes around embryo + *angeios* = vessel + *pagos* = something set or fixed; *para* = next to + *sitos* = food]

**Chóríon:** outer membrane around embryo [Gk. *chorion* = "little gut"; according to Hyrtl (1880) the term was also used by Galen as the outer shell of the membranes]

**frondósum:** the placenta proper [L. *frondosus* = richly covered with leaves, as in tree]

**laéve:** the membranous portion of the chorionic sac [L. *levis* = smooth, without villi]

**Chorionepithelióma:** malignant tumor of trophoblast = chorio-epithelioma or choriocarcinoma [Gk. *chorion* = "little gut" (outer membrane enclosing an embryo) + *epi* = on + *thele* = nipple + *oma* = tumor]

**Circumvállate (placenta):** an abnormal form of placenta with circumferential, old hemorrhages [L. *circum* + *vallare* = to wall around]

**Cirsoíd:** aneurysmal dilatation of vessel [Gk. *kirsos* = enlarged vein]

**Cotylédón:** originally name for the single spots of placental tissue in the ruminants; lobe of the human placenta [Gk. *kotyle* = cup]

**Cytotrophoblast:** cellular type of the trophoblast [Gk. *kytos* = cell + *trephein* = to nourish + *blaste* = germ]

**Decídúa:** the endometrium at end of the luteal phase [L. *decidere* = fall, die]

**basális:** basal portion of placenta [Gk. *basis* = base]

- capsuláris:** outer portion of membranes [L. *capsula* = little box]
- parietális:** endometrium of pregnancy, covering wall portion of uterus [L. *paries* = wall; *parietalis* = pertaining to wall]
- véra:** uterine decidua, contrasting it to pseudodecidua, outside of uterus, as in endometriosis [L. *verus* = true]
- Désmosome:** intercellular junction [Gk. *desmos* = Ligament + *soma* = body]
- Dizygótic:** twins of two ova, “fraternal twins” [Gk. *dis* = twice, two + *zygon* = yoke]
- Eclámpsia:** coma and convulsive seizure in pregnancy [Gk. *eklampsis* = shining forth; or *ek* = out + *lampein* = to shine]
- Émbryoblast:** embryo-forming cells of the blastocyst [Gk. *embryon* = unborn child + *blaste* = germ]
- Endométrium:** innermost layer of the uterus [Gk. *endon* = inside + *metra* = uterus]
- Endoplásmic reticulum:** a net-like, membrane-lined cell organelle [Gk. *endon* = inside + *plasma* = juice; L. *reticulum* = small net]
- Endothélium:** innermost layer of blood vessels [Gk. *endon* = inside + *thele* = mamilla]
- Epígnathus:** tumorous mass in mouth, affixed to jaw and possibly a twin [Gk. *epi* = upon, at, over + *gnathos* = jaw]
- Epithelium:** superficial cellular layer [Gk. *epi* = upon + *thele* = mamilla]
- Fétus papyráceus:** paper-like, macerated, compressed (“compressed”) fetus [L. *papyrus* = plant from which paper is made]
- Fibrin:** blood clot product [L. *fibra* = fiber]
- Fibrinoid:** a substance similar to but not identical with fibrin [Gk. *...eides* = looking like]
- Fibroblast:** connective tissue cell [Gk. *blaste* = germ]
- Freemártin:** the female of fraternal cattle twins, sterilized in utero by the male co-twin with whose placental vessels she is joined; the term presumably comes from the St. Martin’s feast in England, when these animals were consumed
- Funiculópagous (twins):** twins joined at umbilical cord [L. *funis* = rope, cord + Gk. *pagos* = fixed]
- Fúnis (funiculus):** umbilical cord [L. *funis* = rope, cord]
- Funisítis:** inflammation of umbilical cord [L. *funis* = rope]
- Fúrcate (cord) (“insértio funiculi furcata”):** forked insertion of the little rope [L. *furca* = fork]
- Glycocálix:** superficial layer of polysaccharides, covering the cell surface [Gk. *glycos* = sweet + *kalyx* = goblet]
- Granulomatosis infantiséptica:** neonatal disseminated listeriosis [L. *granulum* = little grain + Gk. *oma* = tumor]
- Gynogénesis:** female development [Gk. *gyne* = woman + *gennan* = produce]
- Hemiacárdius:** acardiac monster in which remnants of heart may be found [L. *hemi* = a half]
- Holoacárdius:** completely heartless monster (twin) [Gk. *holos* = whole]
- Hydatídiform (mole):** severely hydropic placenta with bulbous, villous enlargement [Gk. *hydatis* = watery vesicle + L. *forma* = shape; L. *mola* = false conception; mass]
- Hydrámnios:** excessive amount of amnionic fluid [Gk. *hydor* = water (*hydros* = sweat; some early authors believed that amnionic fluid was fetal sweat) + *amnion* = lamb’s caul]
- Implantáció:** establishing of intimate fetomaternal contact in the uterus [L. *implantare* = to embed]
- Intervillous:** between the placental villi, i.e., in the maternal blood space [L. *inter* = between]
- Intravillous:** within a villus [L. *intra* = in]
- Lacúna:** [L. = hole, gap]
- Lithopédion:** stone-like fetus [Gk. *lithos* = stone + *paidion* = child]
- Lóchia** (pl.): uterine discharges after birth [Gk. *lochia*]
- Mácrophage:** phagocytotic and paracrine cell type [Gk. *macros* = large + *phagein* = to eat]
- Mágma reticuláre:** jelly-like fluid in original embryonic sac [Gk. *magma* = suspension of finely divided material in small amount of water + L. *reticulum* = little net (network)]
- Mármoset:** family of small South American primates that always produce fraternal twins [Old Fr. *marmouset* = grotesque figure]
- Mecónium:** fetal intestinal content [Gk. *mekonion* = poppy juice]
- Mésenchyme:** undifferentiated connective tissue [Gk. *mesos* = in the middle of + *chein* = to pour (something poured in between)]
- Mésoderm:** the middle germ layer [Gk. *derma* = skin]
- Mésóthelium:** connective tissue-derived epithelial layer [Gk. *thele* = mamilla]
- Microvillus:** finger-like extension of the cell surface
- Mitochondrion:** rod-shaped cell organelle [Gk. *mitos* = thread + *chondros* = grain]
- Mole (hydatídiform, Breus’, etc.):** vesicular mass of placenta [L. *mola* = false conception]
- Monozygótic:** single-egg-derived twins (“identical twins”) [Gk. *monos* = single + *zygotos* = yoked]
- Nódus spúrius vasculósus (gelatínus):** false knot in umbilical cord of vascular genesis [L. *nodus* = knot + *spurius* = not genuine + *gelatina* = gelatin]
- Núchal (cord):** umbilical cord entwined around neck [L. *nucha* = nape of the neck]
- Óctoploid:** having eight sets of chromosomes [Gk. *okto* = eight + *ploos* = fold + *eidós* = form]
- Oligohydrámnios:** too little, or no amnionic fluid [Gk. *oligos* = little + *hydor* = water (*hydros* = sweat) + *amnion* = lamb caul]
- Ómphalo-(mesentéric):** umbilicus [Gk. *omphalos* = Navel]
- Páraplacenta:** those parts of the chorionic sac, not belonging to the placenta, e.g., membranes [Gk. *para* = beside]
- Périvillous:** around the placental villi [Gk. *peri* = around]
- Placenta:** [L. flat cake] According to Hyrtl (1880) this term, with an originally Greek root, was introduced in 1559 by Realdus Columbus; others referred to it as “secundines”
- accréta:** unusually adherent placenta that fails to detach [L. *accrescere* = to grow together, adhere]

**incréta:** placenta that has grown into the myometrium [L. *increscere* = to grow into]

**membranácea:** very thin placental membrane, the entire outside of which is covered with villi [L. *membrana* = from parchment, membrane]

**percréta:** placenta that has grown through the uterine wall [L. *percrebescere* = to crowd everywhere]

**prévia:** placenta that is located in the lower uterus and is in the way before the fetus can be delivered [L. *praeuius* = in front of, before, leading the way]

**Plasmódium:** multinucleate mass of protoplasm [Gk. *plasma* = a thing formed (juice) + *eidos* = to form]

**Pólyploid:** having many sets of chromosomes [Gk. *polys* = much, many + *ploos* = fold + *eidos* = form]

**Pólypoid:** protrusion of tissue, polyp [Gk. *polys* = many + *pous* = foot + *oid* = like]

**Pycnósis (pyknosis):** degenerative condensation of cells or nuclei [Gk. *pyknos* = dense]

**Schístocytes:** broken red cells in disseminated intravascular coagulation [Gk. *schistos* = split]

**Secúndines:** synonymous with afterbirth [L. *secundus* = following]

**Sínusoid:** enlarged capillary [L. *sinus* = bight + Gk. *eides* = looking like]

**Siréniform (fétus):** malformed infant with fused legs [Gk. *seiren* = mermaid]

**Sirenoméla:** malformed infant with fused legs [Gk. *seiren* = mermaid + *melos* = limb]

**Stróma:** connective tissue core of an organ [L. *stroma* = cushion]

**Subchórial:** under the chorionic plate [L. *sub* = below + Gk. *chorion* = leather, embryonic membrane]

**Succentúriate (lobe):** accessory lobe of placenta [L. *succenturiare* = to substitute]

**Superfecundación:** fertilization of two or more ova at different times during the same menstrual period [L. *super* = beyond, excessively + *fecundus* = fertile]

**Superfetación:** pregnancy on top of already existing pregnancy [L. *superfetare* = to bring forth while already pregnant; L. *fetus* = fruit, offspring]

**Sympus:** fetus with fused legs [Gk. *syn* = together + *pous* = foot (same as siren)]

**Syncytiotrophoblast:** syncytial type of trophoblast

**Syncytium:** multinuclear mass, derived from cell fusion [Gk. *syn* = together + *kytos* = cell]

**Synéchia (pl. synéchiaie):** adhesion of parts, here in the uterus [Gk. *synecheia* = continuity]

**Tessellación:** irregular surface of placenta [L. *tessella* = little square stone (From Gk. *tessares* = four)]

**Tétraploid:** having four sets of chromosomes [Gk. *tettares* = four + *ploos* = fold]

**Thalassémias:** hemoglobin disorders [from Gk. *thalassa* = the sea; generally referring to the Mediterranean]

**Thixotrópic (Thyxo-) gel:** gel that liquefies when shaken, generally the extraembryonic fluid [Gk. *thixis* = touching + *tropé* = turn]

**Thoracópágus:** twins, conjoined at chest [Gk. *thorax* = chest + *pagos* = fix]

**Trabécula:** small septum [L. small beam]

**Tróphoblast:** the epithelium that covers the placenta [Gk. *trophe* = nourishment + *blastos* = germ]

**Trophótropism:** the “wandering” of the placenta to the site of best nourishment [Gk. *trophe* = nourishment + *tropé* = turn]

**Urachus:** connection of bladder to allantoic sac [Gk. *ourachos* (“that which has a tail”) = cord that extends from bladder to navel]

**Vas préviu (pl. Vása prévia):** blood vessels within membranes that present before fetal parts during delivery [L. *vas* = vessel(s) that is (are) ahead (“previous”) of fetal part]

**Vas vasórum (Vása vasórum):** blood vessels that nourish the vessels [L. *vas* = vessel]

**Velaméntous (cord insertion):** membranous insertion of umbilical cord [L. *velamen* = veil + *velamentum* = cover]

**Vérnix caseósa:** sebum, hair and other skin secretions from fetus [L. *vernix* = varnish + *caseus* = cheese]

**Víllus (pl. villi):** ramifications of placenta with fetal vessels that are the “business end” of the placenta, covered with trophoblast [L. *villus* = tuft of hair]

**Vitélline:** belonging to the yolk sac [L. *vitellus* = yolk of an egg]

Some quantitative structural and biochemical data concerning pregnancy, placental development, and composition of the term placenta are given in Tables 28.1 to 28.10.

When examining the tables on placental morphometry and comparing the results from different authors, it is important to note that quantitative structural data are heavily influenced by the mode of sampling and by the preparation of the material. Because of the high degree of maternal and fetal vascularization, the placenta reacts immediately to changes in intravascular pressure. Thus, the mode of birth, the time elapsing from cessation of maternal and fetal blood flows to tissue fixation (see Tables 28.6 to 28.10), and the nature of cord clamping (see Table 28.8) directly influence the volumetric relations of villi and intervillous space. In particular, parameters such as the width of fetal vessels, degree of fetal vascularization, maternal-fetal diffusion distance, and trophoblastic thickness are easily affected. Moreover, the composition of the fixative and its osmolarity (see Table 28.10), as well as the mode of fixation (immersion versus perfusion fixation) are of importance. Normally, immersion fixation of the entire placenta or of small pieces is used. The more advanced methods, such as perfusion fixation (Burton et al., 1987) or puncture biopsy of the still maternally perfused placenta during cesarean section (Schweikhart & Kaufmann, 1977; Voigt et al., 1978; Sen et al., 1979), are very time-consuming. When studying immersion fixed material, however, one should keep in mind that this material differs quantitatively and qualitatively from the *in vivo* conditions (see Tables 28.6 and 28.9). It is

impossible to include the results of numerous other valuable contributions to placental morphometry in these tables. For further information on special issues, we refer to the following publications: placental growth development in relation to birth weight (Bouw et al., 1978; Molteni et al., 1978); relationship of placental weight to body size at 7 years of age, and to abnormalities in children (Naeye, 1987); fetal and placental weights in relation to maternal weight (Auinger & Bauer, 1974); ultrasonographic measurements of volumetric growth of the placenta (Bleker et al., 1977); weight development of placenta and membranes in early pregnancy (Abramovich, 1969); ratio of gestational sac volume to crown-rump length in early pregnancy (Goldstein et al., 1986); villous surface area and villous volume densities in various placental regions and along different levels of the chorial basal axis (Teasdale, 1978; Boyd et al., 1980; Cabezon et al., 1985; Bacon et al., 1986); local variations of villous surface, fetal vascularization, and amount of vasculosyncytial membranes in the placentone (maternal-fetal circulatory unit) (Schuhmann et al., 1986); total villous surface in relation to fetal weight, in normal and various pathologic cases (Clavero-Nunez & Botella-Llusia, 1961, 1963); morphometric data affecting placental oxygen diffusion (Mayhew et al., 1984, 1986); computer measurement of the mass of syncytiotrophoblast (Boyd et al., 1983); ultrastructural morphometric analysis of the villous syncytiotrophoblast (Sala et al., 1983); microvillous surface enlargement of the villous surface (Teasdale & Jean-Jacques, 1985); comparison of villous structure following immersion and perfusion fixation (Burton et al., 1987).

TABLE 28.1. Length and weight data for placenta and fetus; pregnancies and deliveries at sea level. (1) Data extrapolated from Boyd & Hamilton (1970) and O'Rahilly (1973); (2) data from Johannigmann et al. (1972); (3) data from Winckel (1893), Branca (1922), Naeye & Tafari (1983), and Fujinaga et al. (1990); (4) data from Weissman et al. (1994). Placental weight data published by Molteni et al. (1978) are 5% to 10% lower because fetal blood was drained from chorionic vessels before weighing. Compare with data on influence of cord clamping given in Table 28.8. Umbilical cord length as measured by ultrasound throughout the first trimester (Hill et al., 1994) amounts to only about 50% of the length measured after abortion.

Pregnancy week (postconception)	Pregnancy week (postmenstruation)	Pregnancy month (postmenstruation)	Crown-rump length (mm) <sup>1</sup>	Embryonic/fetal weight (g) <sup>1</sup>	Diameter of the chorionic sac (mm) <sup>1</sup>	Placental diameter (mm) <sup>1</sup>	Placental weight (g) <sup>1</sup>	Placental thickness postpartum (mm) <sup>1</sup>	Placental thickness including uterine wall measured by ultrasound in vivo (mm) <sup>2</sup>	Length of the umbilical cord (mm) <sup>3</sup>	Diameter of the umbilical cord measured by ultrasound (mm) <sup>4</sup>	Diameter of the umbilical artery measured by ultrasound (mm) <sup>4</sup>	Diameter of the umbilical vein measured by ultrasound (mm) <sup>4</sup>

TABLE 28.2. Quantitative data of various placental tissues as related to fetal weight and stage of pregnancy. (1) Data calculated from Table 28.1; (2) Data from Kloos & Vogel (1974); (3) data from Kaufmann (1981); (4) data from Knopp (1960). Fetoplacental weight ratios calculated by Molteni et al. (1978) are generally higher because these authors had drained fetal blood from chorionic vessels before weighing.

Pregnancy week (postconception)	Pregnancy week (postmenstruation)	Pregnancy month (postmenstruation)	Fetal weight (g) per 1-g of placental weight <sup>1</sup>	Placental weight index: placental weight (g) per 1-g of fetal weight <sup>2</sup>	Villous weight (g) per placenta <sup>1</sup> (percentage of total placental weight) placental diameter (mm) <sup>1</sup>	Villous surface (cm <sup>2</sup> ) per placenta <sup>1</sup>	Fetal weight (g) per 10,000-cm <sup>2</sup> villous surface <sup>1</sup>	Villous surface (cm <sup>2</sup> ) per 1-g of placental villi <sup>1</sup>	Number of villous cross sections per mm <sup>2</sup> of paraffin sections <sup>3</sup>	Number of villous cross sections per mm <sup>2</sup> of paraffin sections <sup>4</sup>	Villous diameter (mean of all peripheral villous types) (μm) <sup>3</sup>

TABLE 28.4. Fetal and placental weights as related to the number of pregnancies.

Pregnancy no.	Male neonates				Female neonates			
	Mat. age (years)	Neo. length (cm)	Neo. wt. (g)	Plac. wt. (g)	Mat. age (years)	Neo. length (cm)	Neo. wt. (g)	Plac. wt. (g)
First ( <i>n</i> = 101)	22.37	51.04	3,141.3	548.7	22.42	50.96	2,974.0	560.7
Second ( <i>n</i> = 71)	25.24	51.95	3,442.8	607.9	25.15	51.29	3,133.6	565.5
Third ( <i>n</i> = 27)	30.21	50.29	3,495.0	603.2	26.69	50.29	3,228.1	553.9
Fourth ( <i>n</i> = 18)	30.00	53.83	3,677.5	599.6	29.00	50.83	3,095.0	568.3

Mat. = maternal; Neo. = neonatal; Plac. = placental.

All results are given as the mean value.

From Lips (1891).

TABLE 28.5. Qualitative data for the human placenta at term. The data were taken or calculated from (1) Knopp (1960); (2) Aherne &amp; Dunnill (1966); (3) Baur (1970); (4) Wördehoff (1971); (5) Laga et al. (1973); (6) Ehrhardt &amp; Gerl (1970); (7) Bacon et al. (1986); (8) Mayhew et al. (1986); (9) Bouw et al. (1976); (10) Feneley &amp; Burton (1991); (11) Voigt et al. (1978); (12) Burton &amp; Feneley (1992).

Mean placental volume (cm <sup>3</sup> ) (without cord and membranes)	448 (2)	448 (5)	540 (9)	408 (10)
Percentage of villous volume per placenta (%)	57.5 (1)	57.9 ± 5.7 (2)	45.6 (5)	62.9 ± 2.1 (7)
Mean villous volume per placenta (g)	273 (1)	214 (5)	224 (2)	239 (9)
Percentage of intervillous space per placenta (postpartum) (%)	35.8 ± 3.2 (2)	23.29 (5)	29.3 ± 2.0 (7)	37.9 (8)
Volume of intervillous space (cm <sup>3</sup> )	144 (2)	110 (5)	210 (9)	173 (8)
Percentage of intervillous fibrinoid per placenta (%)	4.3 ± 2.1 (2)	2.58 (5)		
Villous surface covered with fibrinoid (%)	0.364 (6)			
Percentage of villous tissues per placenta (chorionic plate, basal plate, septa, cell islands, infarctions) (%)	27.6 (5)			
Villous surface per placenta (m <sup>2</sup> )	13.3 ± 0.47 (4)	12.0 (3)	11.8 (6)	11.0 ± 1.3 (2)
Villous surface per 1 cm <sup>3</sup> of villous volume (cm <sup>2</sup> )	330 (1)	248 (3)	301.2 (4)	
Inner fetal capillary surface per placenta (m <sup>2</sup> )	12.2 ± 1.5 (2)	12.0 (5)		
Total length of all villi per placenta (km)	90 (1)			
Arithmetic mean thickness of villous membrane (mean maternofetal diffusion distance) (μm)	3.5 (2)	4.5 (10)	5.0 (11)	
Harmonic mean thickness of villous membrane (μm)	10.0 (5)	4.9 (8)		

TABLE 28.6. Quantitative composition of peripheral villous types of diameter of less than 80 μm following resin embedding.

Parameter	All villous types after spon. del.	After in situ puncture of placenta					
		All villous types	SV	IIV	MIV	TV, neck	TV, no neck
Villous surface showing cytotrophoblast below the syncytium (%)	27.5	22.8	21.4	23.4	24.6	20.0	23.5
Cytotrophoblastic volume as a percentage of total villous trophoblast (%)	13.3	14.0	11.7	14.3	13.8	11.6	15.7
Percent of total villous volume	Trophoblast	41.7	37.7	30.0	33.8	38.0	46.2
	Villous stroma	58.3	62.3	70.0	66.2	62.0	53.8
	Fetal vessel lumens	20.0	28.4	26.0	15.7	21.0	20.2
	Connective tissue including vessel walls	38.4	33.9	44.0	50.5	41.0	33.6
Mean trophoblastic thickness	4.7	4.1	4.7	5.2	4.4	4.0	3.3
Distribution of maternofetal diffusion distances in % of villous surface	-0-2 μm	10.4	21.0	9.2	10.9	13.1	21.8
	2.1-5 μm	29.9	40.2	27.3	27.3	37.5	41.4
	5.1-10 μm	40.3	32.4	50.5	37.7	37.8	32.6
	10.1-∞ μm	19.5	6.4	13.0	24.1	11.6	4.4
Mean maternofetal diffusion distance (μm)	7.1	5.0	6.8	7.5	6.0	4.8	3.7
Macrophages (no.)/mm <sup>2</sup> of histologic section			24	730	241	83	192
Mast cells (no.)/mm <sup>2</sup> of histologic section			18	10	5	<1	<1

Spon. del. = spontaneous delivery; SV = stem villi; IIV = immature intermediate villi; MIV = mature intermediate villi; TV, neck = neck regions of terminal villi; TV, no neck = terminal villi, excluding neck regions.

The data obtained from spontaneous deliveries (fixation about 10 minutes after cord clamping, ischemic period far above 10 minutes), are compared with such obtained by puncture aspiration out of the still maternally perfused in situ placenta (ischemic period: 0 minutes) (Voigt et al., 1978). In addition, data have been separately measured and calculated for different villous types (Sen et al., 1979).

TABLE 28.7. Number of villous cross sections (%), percentages of villous surface, and percentages of villous volume in different groups of villi.

Parameter	Villous cross sections (% of total no.)	Surface of villi (% of total)	Volume of villi (% of total)	Type of villus	Mean caliber (μm)	Mean length of cross sections (μm)
<b>Diameter of villi (μm)</b>						
>1,500	0.003	0.1	1.2	Trunci chorii		
1,201–1,500	0.002	0.1	0.8			
901–1,200	0.007	0.1	1.4			
601–900	0.02	0.5	2.4	Rami chorii		
301–600	0.2	1.9	9.0			
226–300	0.3	1.7	6.4	Ramuli chorii, mature and immature intermediate villi, terminal villi <sup>a</sup>		
151–225	0.6	3.2	7.7			
76–150	7.1	15.1	20.8			
0–75	91.8	77.2	50.4			
<b>Type of villus</b>						
Ramuli	5.1	12.4	22.7		120.5	340.1
Immature intermediate	5.1	8.4	10.1		76.6	233.5
Mature intermediate	29.1	31.0	27.8		60.6	153.5
Terminal	55.1	46.3	38.7		50.8	118.4
Neck regions	5.5	2.0	0.8		34.3	46.4

<sup>a</sup>The villi are classified according to diameter (using data from I. Hansen & V. König, personal communication, 1978) and compared according to structure.

Modified from Sen et al. (1979).

TABLE 28.8. Influence of cord clamping on placental structure.

Parameter	Early clamped ( $n = 9$ )	Late clamped ( $n = 7$ )
Placental weight (g)	567.4 $\pm$ 114.5	407.1 $\pm$ 74.0
Birth weight (g)	3,593.5 $\pm$ 380.0	3,404.3 $\pm$ 313.5
Placental weight index	0.156 $\pm$ 0.021	0.116 $\pm$ 0.088
Villous volume ( $\text{cm}^3$ )	239.1 $\pm$ 51.9	185.3 $\pm$ 39.5
Villous vessel volume ( $\text{cm}^3$ )	74.9 $\pm$ 28.2	33.4 $\pm$ 18.3
Villous vessel volume (%)	30.4 $\pm$ 5.8	17.4 $\pm$ 6.9
Villous vessel surface ( $\text{mm}^2$ ) per $\text{mm}^3$ of villous volume	66.9 $\pm$ 10.0	46.3 $\pm$ 10.5
Total villous surface ( $\text{m}^2$ )	13.3 $\pm$ 2.6	9.3 $\pm$ 2.1
Volume of intervillous space ( $\text{cm}^3$ )	210.3 $\pm$ 50.0	116.0 $\pm$ 21.7

Results are given as the mean  $\pm$  SD. A group of spontaneously delivered placentas of which the cord was clamped as early as possible as compared with a group of which the cord was clamped after cessation of the arterial pulsation.

Data from Bouw et al. (1976).

TABLE 28.9. Influence of total ischemia of varying length on the structure of terminal villi.

Parameter	Ischemic period				
	0 min	2 min	5 min	10 min	20 min
Fetal capillary volume (%)	45	32	19	13	17
Connective tissue volume (%)	25	42	49	54	47
Trophoblastic volume (%)	23	26	32	33	36
Mean maternofetal diffusion distance ( $\mu\text{m}$ )	3.2	3.7	5.2	7.1	7.4
Epithelial plates (percentage of villous surface) (%)	40.4	—	—	—	14.7
Mean mitochondrial diameter (syncytiotrophoblast) ( $\mu\text{m}$ )	0.30	0.34	0.51	0.63	0.61

Data from Kaufmann (1985).

TABLE 28.10. Influence of total osmolarity of the fixative (2.2% phosphate-buffered glutaraldehyde) on the volumes of syncytiotrophoblast and fetal capillary lumina in the guinea pig placenta.

Parameter	Osmolarity of the fixative				
	235	290	340	390	600
Trophoblastic volume (%)	39.5	39.3	33.3	32.7	24.6
Fetal capillary volume (%)	12.1	14.7	25.5	16.9	19.3
Extracellular space (%)	<1.0	<1.0	<1.0	2.3	11.7
Mean mitochondrial diameter (syncytiotrophoblast) ( $\mu\text{m}$ )	0.68	0.56	0.30	0.26	0.25

Data from Kaufmann (1980) can be transferred to the human.

## A

- Abdominal trauma, as transplacental hemorrhage cause, 552–557
- Ablatio placentae, 615
- ABO antigens  
in choriocarcinoma, 851–852  
in preeclampsia, 624
- ABO incompatibility, 519, 529
- Abortion  
criminal, 762, 772, 774  
definition of, 762  
embryonic *versus* fetal, 762  
frequency of, 763  
habitual, 762  
incomplete, 763  
methods of  
dilatation and curettage (D&C), 774, 776  
effect on abortion specimens, 774, 776–777  
missed, 762  
as premature rupture of the membranes cause, 675  
as selective fetal elimination  
of acardiac fetuses, 945–946  
as fetus papyraceus cause, 924  
in multiple pregnancies, 966  
in trisomy, 957  
septic, 669, 776–777, 779  
spontaneous, 762–764  
anatomic findings in, 764–768  
bacterial vaginosis-related, 690  
brucellosis-related, 682  
causes of, 763–764, 784  
*Chlamydia* infections-related, 690  
chorionic villous sampling-related, 778–779  
Coxsackie virus-related, 712  
factor V Leiden-related, 594  
herpes simplex virus-related, 708  
listeriosis-related, 684  
parvovirus B19-related, 536, 762–763  
recurrent or habitual, 784–787  
smallpox-related, 710, 711  
smoking-related, 588  
toxoplasmosis-related, 719–720  
of twins, 919  
*Ureaplasma urealyticum*-related, 688  
villitis-related, 725  
therapeutic (induced), 762, 772, 774  
as fetomaternal hemorrhage cause, 554  
in partial hydatidiform mole, 812–813  
RhoGAM prophylaxis during, 526  
threatened, 762  
in twins, 967, 968
- Abortion specimens  
anatomic examination of, 764–768  
chromosome studies of, 767–777
- Abruptio placentae, 6, 480  
alcohol abuse-related, 587  
automobile accidents-related, 555  
with bicornuate uterus, 616  
chorioamnionitis-related, 657, 659  
cocaine-related, 587  
decidual spiral arterioles in, 480  
definition of, 615  
fetal effects of, 620  
fetal survival in, 616  
frequency of, 616  
gender factors in, 619  
hydatidiform mole and, 806  
leiomyoma-related, 600  
major histopathologic findings in, 480  
neonate survival in, 619  
“painless,” 615  
preeclampsia-related, 55, 605, 616, 617–618, 620  
recurrence of, 619  
retroplacental hematoma associated with, 480, 615, 616  
retroplacental tumors associated with, 462  
smoking-related, 588, 589  
snake bite-related, 586  
systemic lupus erythematosus-related, 628  
Tenney-Parker changes in, 622  
as transplacental hemorrhage cause, 557  
trauma-related, 552–553, 616–617  
treatment of, 619  
in twins, 619  
unrecognized, 1010
- Abscess  
subchorionic, 665  
villous, 666  
intervillous, 665  
listeriosis-related, 684, 685  
syphilis-related, 693
- Acardia, 340–341, 941–950, 951  
anastomoses in, 940, 941, 943, 946, 949, 950  
in animals, 947, 948  
definition of, 941  
edema in, 950  
 $\alpha$ -fetoprotein in, 944  
as fetus compressus, 924, 925  
as fetus papyraceus, 925  
hydrops fetalis in, 532  
limb anomalies in, 942  
malnutrition in, 946  
omphalocele in, 941, 944  
pathogenesis and etiology of, 946–950  
single umbilical arteries in, 944  
treatment of, 945–946  
in triplets, 961  
in twins, 340–341, 941–950, 951  
anastomoses in, 941, 943, 946, 949, 950  
calcification in, 943

- stem, 21, 121, 136
- capillary regression in, 153
  - as chorangioma source, 864
  - development of, 138–140, 153
  - diameter of, 21
  - fibrinoid in, 482
  - for gestational age determination, 497
  - histologic characteristics of, 21, 22
  - maturation of, 498
  - myofibroblasts of, 84–86
  - paravascular capillary net of, 141, 142, 143
  - stromal differentiation in, 85
  - in term placenta, 504–505
  - vascularization of, 140–142, 143, 483–484
- stroma of, 17, 82–93
- connective tissue cells of, 82–87
  - matrix components of, 86–87
- in syphilis, 692–693
- tangential sectioning in, 494–497, 504, 505, 510
- terminal, 21, 23, 121, 126, 129, 131–132, 140, 497
- capillarization in, 482
  - deficiency of, 511, 512
  - development of, 140
  - effect of ischemia on, 1024
  - function of, 129, 133
  - hypermaternity, 507
  - knots of, 21, 482
  - in premature placenta, 476
  - sinusoids of, 145
  - structure of, 57
  - in term placenta, 504
  - vascularization of, 140–141, 143–145, 149, 150, 482
- tertiary, 46, 48
- during third trimester, 20, 22
- total weight of, 135
- in toxoplasmosis, 718, 719
- in trisomic placenta, 781–782, 783
- trophoblastic basement membrane of, 82
- trophoblastic surface of, 17
- use in structural and genetic studies, 781
- vasculogenesis in, 46, 147–162
- Villitis
- acute, 486
  - alcohol abuse-related, 587
  - Chagas’ disease-related, 721
  - chlamydial, 690, 691
  - Coxsackie virus infection-related, 712
  - cytomegalovirus infection-related, 701, 702–705, 706, 1006

- Villitis (*Continued*)  
 necrotizing, listeriosis-related, 684  
 of unknown etiology (VUE), 486, 700, 707, 710, 711, 712, 724–732, 785, 1006–1007  
 chorangiosis-related, 1010  
 definition of, 724
- Villous blood vessels, thrombosis of, 431, 432
- Villous tissue  
 color of, 7, 1009–1010  
 examination of, legal aspects of, 1003  
 premature aging of, 621
- Villous trees, 40. *See also* Cotyledons  
 central stems of, 17  
 connective tissue of, 82–87  
 development of, 46  
 expansion of, 46  
 inhomogeneity of, 163–164  
 in placental vessel thrombosis, 430–431  
 relationship to intervillous space, 160–164
- Vimentin, 136, 326, 329
- Vinblastine, 589
- Vinci, da, Leonardo, 394
- Viral infections, 700–716. *See also specific viral infections*  
 diagnosis of, 1006
- Vitamin A deficiency, 852
- Vitamin C, 339
- Vitelline (omphalomesenteric) duct, remnants of, 342, 343, 389–391
- W**
- Warfarin, 590
- Weinberg formula, for zygosity of twins, 877–878, 955, 960
- West Nile virus, 716
- Wharton's jelly, 381  
 compression of, 418  
 cysts within, 411  
 decrease in, 412, 419–420, 422  
 green discoloration of, 1009  
 leukocyte infiltration of, 666, 667  
 meconium-related dissolution of, 347, 349
- Wharton's jelly-like material, in chorangioma, 864
- White blood cell count, in premature fetuses, 662
- Whole-body chimerism, 950
- Willebrand's disease, 594
- Wilson's disease, 590
- Windei, 764, 768
- Wolman's disease, 541
- X**
- X-cell cysts, 337
- X cells, 6. *See also* Trophoblast, extravillous  
 in choriocarcinoma, 838  
 in chorionepitheliosis, 850  
 in I-cell disease, 579  
 in mucopolipidoses, 577  
 in placental site trophoblastic tumors (PSTT), 846, 847, 848, 849
